**FIGURE 18-28** Patent ductus arteriosus. Blood flow through the duct is usually from the aorta to the pulmonary artery and produces an acyanotic shunt.

functionally, and within a few weeks it closes permanently. The ductus arteriosus allows blood to flow from the pulmonary artery into the aorta, thus bypassing the lungs. Low oxygen tension and local production of prostaglandins appear to be important in maintaining patency of the channel during fetal life. After birth, flow through the ductus arteriosus switches to left to right because of the higher pressure in the aorta. This change in flow direction brings oxygenated blood through the ductus arteriosus and stimulates it to close. A reduction in prostaglandin E production after birth appears to contribute to constriction and closure. In many cases the reason for abnormal continued patency of the ductus arteriosus after birth is not well understood. Conditions that cause low blood oxygen tension may contribute to continued patency.

Most often a patent ductus arteriosus has no clinical significance early in life because the shunt is left to right and no cyanosis is evident. Surgical management is usually delayed because these defects tend to close spontaneously. Prostaglandin inhibitors may be given to induce closure of the defect. Continued patency of the ductus arteriosus is usually obvious because of a harsh, grinding systolic murmur and often a systolic thrill (vibration). Surgical closure of the patent ductus arteriosus is done as soon as it becomes evident that spontaneous closure is unlikely. As with other left-to-right shunt disorders, uncorrected patent ductus arteriosus results in pulmonary hypertension complicated by respiratory and right-sided heart failure. Eventual reversal of the shunt to a right-to-left pattern results in cyanosis. Because the ductus is usually located distal to the origin of the subclavian artery, the lower extremities may show cyanosis whereas the upper extremities remain pink.

### Coarctation of the Aorta

*Coarctation* refers to a narrowing or stricture that may impede blood flow. Coarctation of the aorta is a common heart defect that affects males three to four times more frequently than females. Narrowing of the aorta may occur anywhere along its length; however, in most cases the coarctation is located just before or just after the ductus arteriosus (Figure 18-29). Preductal coarctation (proximal to the ductus arteriosus) is usually more severe and often associated with other anomalies. In some instances, the aortic stricture is so severe that blood flow to the lower part of the body must be maintained solely by flow through

**FIGURE 18-29** Coarctation of the aorta. The arterial narrowing can produce a weaker pulse in the lower extremities.

the ductus arteriosus. This situation results in a very high workload for the right side of the heart and may lead to heart failure in the early neonatal period. Blood supply to the arms and head is unaffected because these arteries arise proximal to the stricture. Postductal coarctation is generally less severe and may remain unrecognized until adulthood.

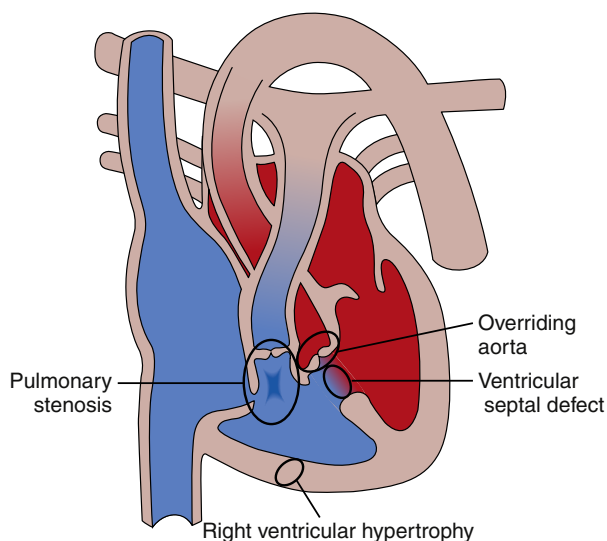

The upper extremities typically have an elevated blood pressure, whereas the lower extremities have weak pulses and low blood pressure. An important part of assessment of the newborn is comparison of pulses in the upper and lower extremities to assess for symmetry. All types of coarctation are usually accompanied by systolic murmurs and ventricular hypertrophy. The stricture can be repaired surgically by resection of the narrowed region. If left untreated, significant coarctation may lead to congestive heart failure, intracranial hemorrhage, or aortic rupture.

### Pulmonary Stenosis or Atresia

Isolated pulmonary stenosis and atresia are included in the category of acyanotic defects because they do not themselves result in cyanosis. However, they often occur in conjunction with other anomalies that allow survival into the neonatal period. The other defects may allow shunting of blood and result in cyanosis. In pulmonary atresia, no communication is found between the right ventricle and the lungs, so that blood must enter the lungs by first traveling through a septal opening and then through a patent ductus arteriosus. The right ventricle is typically underdeveloped (hypoplasia), and the atrial septal defect is large. Pulmonary stenosis can be mild to severe, depending on the extent of narrowing of the pulmonic valve. Pulmonary stenosis is usually due to abnormal fusion of the valvular cusps. Right ventricular hypertrophy occurs secondary to the high ventricular afterload caused by the narrowed outflow opening. Isolated pulmonary stenosis is easily corrected by surgery; however, the prognosis depends in large part on the health of the right ventricle.

### Aortic Stenosis or Atresia

Congenital aortic atresia is rare and not compatible with survival. Depending on its severity, aortic stenosis is correctable and associated with a good prognosis. Aortic stenosis may involve the valvular cusps or the subvalvular fibrous ring just below the cusps. The narrowed aortic outflow tract results in a high left ventricular afterload, which causes

**FIGURE 18-30** Tetralogy of Fallot showing the four characteristic abnormalities: pulmonary stenosis, ventricular septal defect, overriding aorta, and right ventricular hypertrophy. Tetralogy of Fallot is a cyanotic defect.

the left ventricle to enlarge. A prominent systolic murmur is usually apparent. Surgical replacement is the definitive treatment if the stenosis is severe, progresses, or becomes symptomatic.

### Cyanotic Congenital Defects

#### Tetralogy of Fallot

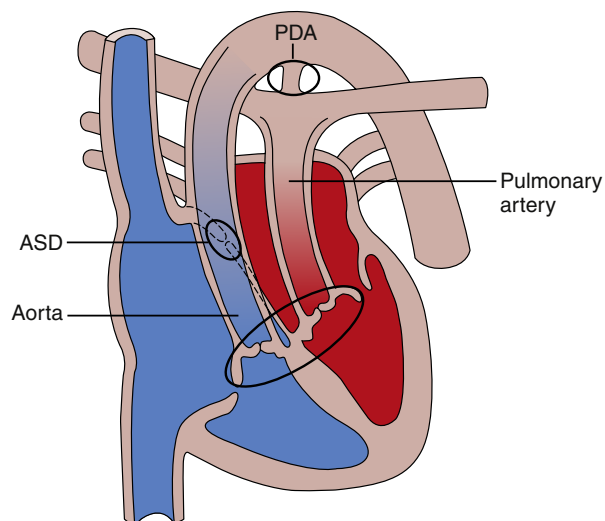

The four defining features of tetralogy of Fallot are: (1) a ventricular septal defect; (2) an aorta positioned above the ventricular septal opening (overriding aorta); (3) pulmonary stenosis that obstructs right ventricular outflow; and (4) right ventricular hypertrophy (Figure 18-30).

The severity of the symptoms is related primarily to the degree of pulmonary stenosis. The heart is generally enlarged because of the extensive right ventricular hypertrophy. Even if the condition is untreated, individuals with tetralogy of Fallot may live into adulthood. The defect often results in cyanosis because the overriding aorta receives unoxygenated blood from the right side of the heart as well as oxygenated blood from the left side. The degree of cyanosis depends on the amount of blood received from the right side, which in turn depends on the degree of pulmonary obstruction. Surgical correction of the defects is usually recommended because prolonged noncorrective management carries the risk of infective endocarditis and secondary polycythemia.

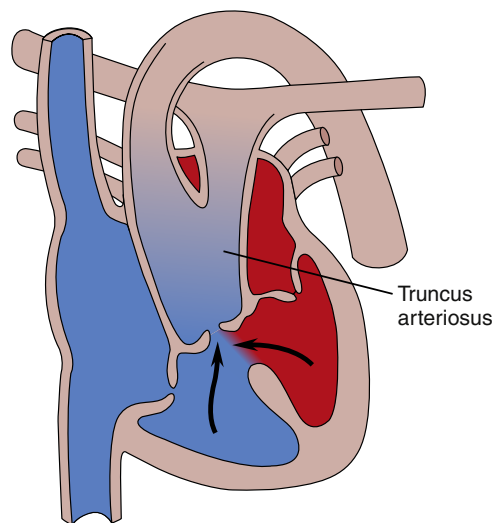

#### Transposition of the Great Arteries

In the most common form of transposition of the great arteries, the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle (Figure 18-31). This anomaly results in the formation of two separate, noncommunicating circulations. The right side of the heart receives blood from the systemic circulation and recirculates it through the body by way of the aorta. Blood reaching the body has not passed through the lungs and is therefore not oxygenated. The left side of the heart receives oxygenated blood from the lungs and then recirculates it through the lungs by way of the pulmonary artery. Unless some mixing of these separate circulations takes place through other heart defects, such as septal defects, transposition is not compatible with life.

Nearly all infants who survive the neonatal period have an interatrial opening, and most also have a patent ductus arteriosus. A good

**FIGURE 18-31** Transposition of the great arteries. Two separate circulations are formed, which is incompatible with life unless mixing of blood occurs through other defects. ASD, Atrial septal defect; PDA, patent ductus arteriosus.

**FIGURE 18-32** Truncus arteriosus is a cyanotic defect. Failure of septation results in a common outflow tract from the ventricles. A ventricular septal defect is also present.

deal of mixing must be maintained after birth for the infant to survive. Surgery may be directed at improving the mixing of systemic and pulmonary blood by enlarging or creating openings in the heart. Corrective surgery in which the aorta and pulmonary arteries are excised from the heart and sutured to the opposite ventricular outflow tract is the treatment of choice. The coronary arteries must also be reimplemented into the new left ventricular outflow tract in this procedure.

#### Truncus Arteriosus

Truncus arteriosus is a congenital malformation in which failure of the pulmonary artery and aorta to separate results in formation of one large vessel that receives blood from both the right and left ventricles (Figure 18-32). A large ventricular septal defect and a single valvular structure are present and lead to the single large artery. Mixing of blood from the right and left sides of the heart results in systemic cyanosis.

The amount of blood entering the systemic versus the pulmonary circulation depends on the degree of vascular resistance in the two systems. Abnormally high pulmonary blood flow may progress to pulmonary hypertension and right ventricular hypertrophy. Increased pulmonary resistance causes the cyanosis to become more severe as more venous blood enters the systemic circulation. Surgical correction is required for survival.

### Tricuspid Atresia

Absence of the tricuspid valve is almost always associated with underdevelopment of the right ventricle and an atrial septal defect. Circulation is maintained by the defect, which allows blood to bypass the right ventricle. A patent ductus arteriosus is required to perfuse the lungs. In some cases, a concomitant ventricular septal defect is present and may allow some blood to pass into the right ventricle and enter the pulmonary circulation. Cyanosis is present from birth, and the mortality rate is high. Surgical correction is required for survival.

### KEY POINTS

- Different congenital heart anomalies result in two primary pathologic processes: (1) shunting of blood through abnormal pathways in the heart or great vessels and (2) obstruction to blood flow because of abnormal narrowing.
- Disorders that result in left-to-right shunting of blood or obstruction to flow are generally acyanotic. These disorders include atrial septal defect, ventricular septal defect, patent ductus arteriosus, coarctation of the aorta, and pulmonary and aortic stenosis or atresia.
- Disorders that result in right-to-left shunting of blood result in cyanosis. These disorders include tetralogy of Fallot, transposition of the great arteries, truncus arteriosus, and tricuspid atresia.

## SUMMARY

A variety of disease processes may interfere with the heart's ability to provide the body with oxygenated blood. Among these processes are coronary heart disease, valvular and endocardial diseases, myocardial diseases, pericardial diseases, and congenital heart defects. Coronary heart disease includes several clinical forms: angina pectoris, acute coronary syndrome (unstable angina, MI), chronic ischemic heart disease, and sudden cardiac arrest. Stenotic coronary lesions obstruct blood flow to the myocardium and result in these ischemic clinical syndromes. Distinction between unstable angina and MI relies on the presence of serum markers of myocardial damage. Unstable angina is ischemia without cellular death and therefore does not result in biomarker elevation. MI, on the other hand, is associated with the death of myocardial cells and subsequent release of intracellular components. MI may be complicated by dysrhythmias and failure of the heart to pump efficiently.

Valvular disorders are of two types: those that impede flow because of stenosis and those that allow regurgitation because of failure to close completely. The general consequence of valvular disorders is increased myocardial workload secondary to high afterload (stenosis) or high preload (regurgitation). The heart may eventually decompensate and proceed to heart failure. The endocardial diseases rheumatic heart disease and infective endocarditis also primarily affect the heart valves and create stenosis and regurgitation.

Disorders of the myocardium include myocarditis, which is an inflammatory process, and cardiomyopathy, which is a noninflammatory process, usually of unknown cause. Most cases of myocarditis are viral; however, it is the immune system's response to the virus that appears to cause myocardial damage. Myocarditis results in a dilated, flabby heart with decreased pumping efficiency. The cardiomyopathies are a diverse group of disorders that may be classified as primary (having unknown cause) and specific (caused by a known disease process). Cardiomyopathies include a dilated form, a hypertrophic form, and a restrictive form. The primary problem in the dilated form is poor

contractility of all heart chambers. The hypertrophic form may cause left ventricular outflow obstruction that interferes with cardiac output and increases left ventricular strain. Dysfunction in the restrictive form is caused by poor diastolic filling as a result of a stiff, fibrosed ventricular chamber.

Pericardial disorders include accumulations of fluid in the pericardial sac and acute and chronic forms of pericarditis. Pericardial fluid may be serous, serosanguineous, chylous, or frank blood. Pericardial accumulations are usually of little consequence except as indicators of underlying pathophysiologic processes. However, if the accumulation is large or rapid, it may compress the heart and interfere with diastolic filling—a process called *cardiac tamponade*. Pericarditis refers to inflammation of the pericardium. It is usually secondary to other disease processes. Pericardial inflammation generally causes pain and may be associated with a friction rub. Chronic pericarditis can cause erosion of the pericardial sac such that the epicardial layer of the heart may become fused to other mediastinal structures. Alternatively, chronic pericarditis may cause the pericardial sac to become fibrotic and noncompliant such that it restricts expansion of the heart during diastolic filling.

A number of heart disorders may be present at birth and can be categorized as obstructions or shunts and as cyanotic or acyanotic. In general, disorders that allow unoxygenated blood from the right heart to enter the systemic circulation (right-to-left shunt) cause cyanosis. Examples of cyanotic defects include tetralogy of Fallot, transposition of the great arteries, truncus arteriosus, and tricuspid atresia. Examples of acyanotic defects are coarctation of the aorta, atrial and ventricular septal defects, and patent ductus arteriosus.

All heart diseases discussed in this chapter may be complicated by heart failure. Heart failure occurs when the pumping efficiency of the heart is decreased such that cardiac output is subnormal. It is often accompanied by congestion of the lungs or the systemic venous system. Heart failure is discussed in Chapter 19.

## CHAPTER 19 Heart Failure and Dysrhythmias: Common Sequelae of Cardiac Diseases

Heart failure (HF) and cardiac dysrhythmias (arrhythmias) may occur in association with cardiac diseases from a number of different causes. *Heart failure* refers to the inability of the heart to maintain sufficient cardiac output to optimally meet metabolic demands of tissues and organs, and is the end stage of most cardiac diseases. Heart failure involves multiple organ systems and is a progressive syndrome. If the contracting ability of the heart is impaired, then blood flow to the systemic circulation will be reduced, and congestion of blood can occur in the pulmonary venous circulation. In patients with HF, these symptoms of fluid overload are described as *congestive heart failure* (CHF), a term used as a diagnosis in some cases. The term CHF may also be used to differentiate chronic heart failure from acute heart failure. This chapter includes the chronic forms of heart failure; acute heart failure is discussed in Chapter 20 because it commonly results in cardiogenic shock. Disturbances in electrical activity of the heart may signify underlying pathophysiologic processes and may also lead to insufficient cardiac output. Neither heart failure nor dysrhythmia is a primary cardiac disease; therefore, underlying pathophysiologic processes must be investigated.

Heart failure is the fastest-growing cardiac disorder; it affects about 5.7 million Americans. More than 550,000 new cases are diagnosed in the United States each year, with an incidence of 10 per 1000 population after age 65.<sup>1</sup> Heart failure is the most common reason for hospitalization in patients older than 65 years.<sup>2</sup> The increasing incidence and hospitalization rates of HF reflect aging of the U.S. population, as well as better treatment and an improved survival rate after myocardial infarction (MI).<sup>1,3</sup>

### HEART FAILURE

#### Pathogenesis and Diagnosis

A large number of cardiac disorders, including most of those discussed in Chapter 18, can lead to the development of heart failure. Coronary artery disease (CAD) is responsible for 60% to 75% of HF cases, and hypertension (HTN) contributes to nearly 75% of HF cases. CAD contributes to HF progression through mechanisms that include endothelial dysfunction, ischemia, and infarction. CAD and HTN interact to increase the risk of HF.<sup>1</sup> In recent years, the impact of obesity and type 2 diabetes mellitus (T2DM) has become important. T2DM is known to accelerate atherosclerosis, and is frequently associated with HTN. Less common causes of HF include dilated cardiomyopathy, congenital heart defects, valvular disorders, respiratory diseases, anemia, and hyperthyroidism. The diagnosis of heart failure is based on the presence of a constellation of signs and symptoms that are characteristic of the syndrome. However, different sets of criteria are in use, including the Framingham Criteria and Minnesota Heart Failure Criteria.<sup>4</sup> Commonly used criteria for identifying heart failure include the presence of dyspnea, pulmonary rales, cardiomegaly, pulmonary edema, S<sub>3</sub> heart sound, and tachycardia (greater than 120 beats/min), although many other criteria may be applied. No single diagnostic test is available for HF. The diagnosis should be based on a thorough medical history and physical examination.<sup>1</sup>

CHF is generally classified as systolic or diastolic heart failure.<sup>5,6,7</sup> Regardless of specific cause, the pathophysiologic state of heart failure results from the impaired ability of myocardial fibers to contract (systolic failure), relax (diastolic failure), or both.<sup>7</sup> Until the late 1980s, systolic dysfunction was thought to be the primary problem in all forms of HF. However, epidemiologic studies have shown that about half of patients with chronic HF have preserved systolic function, but impaired diastolic function.<sup>8,9</sup> The severity and differentiation of heart failure patients with systolic failure or preserved systolic function is based primarily on the left ventricular ejection fraction (EF). Ejection

fraction is calculated by dividing stroke volume by end-diastolic volume. A normal EF is 60% to 80%. Patients with systolic failure have characteristically low ejection fractions (<40%). Patients with EF greater than 50% do not have significant systolic dysfunction and are categorized as HF with normal EF (HFnlEF). The majority of patients diagnosed with heart failure who have an EF greater than 50% have diastolic dysfunction.<sup>8,9</sup> Many patients with low EF also have impaired diastolic function. In general, patients with low EF but no congestive symptoms have a survival rate about the same as those with preserved EF who have congestive symptoms. The highest mortality occurs in patients with both low EF and congestive symptoms.

The overall mortality for heart failure is high with about 50% (42% to 65% in various studies) of patients dying within 5 years of diagnosis.<sup>2,5,6</sup> Survival rates vary significantly between genders, with men having a 35% survival rate at 5 years and women having a 53% survival rate. The median survival time after diagnosis is 1.7 years in men and 3.2 years in women.<sup>6</sup>

#### Systolic Dysfunction

Patients with systolic dysfunction have reduced myocardial contractility evidenced by a low EF and a reduced  $dP/dt$  during ventricular systole. The  $dP/dt$  is a measure of **inotropy**—how quickly the ventricle can develop a forceful contraction. The nature of the impaired contractility is only partially understood; however, myocyte loss, mechanical derangements of myocardial cells, and dysregulation of neurohormones are believed to be critical elements.<sup>10</sup>

Impaired contractility attributable to myocardial infarction (MI) is a common cause of heart failure.<sup>11</sup> MI, with cell death and loss of contractile elements, reduces the heart's contractile force. The degree of pump failure is related to the amount of heart muscle lost. In patients with heart failure, myocardial cells are also subject to high rates of apoptosis or programmed cell death. Apoptosis can be triggered by excessive stimulation by certain neurohormones and by ischemia. Over time, the loss of myocardial cells contributes to reduced contractility. In severe systolic HF, the EF may fall below 15% or 20%. In general, the prognosis worsens as EF decreases. Symptomatic patients with systolic heart failure often have impaired diastolic function, which is associated with a higher mortality rate.<sup>7</sup>

Inadequate supplies of oxygen to the contracting cells may impair contractility because each myosin cross-bridge cycle requires a molecule of adenosine triphosphate (ATP). When ATP production is low, fewer cross-bridge cycles are completed with each contraction, which results in a reduced EF.

$\beta_1$ -Receptor down-regulation is thought to be an important mechanism of impaired systolic function. Chronic overexcitation of cardiac  $\beta_1$  receptors by sympathetic neurotransmitters (e.g., norepinephrine) leads to a reduction in the number of  $\beta_1$  receptors, and results in a myocardium that is less responsive to sympathetic stimulation and adrenergic drug therapy.  $\beta_1$ -Receptor blocking agents have been shown to improve EF and also to reduce mortality, which lend support to the view that chronic excessive sympathetic nervous system (SNS) activation is detrimental to cardiac function.<sup>12-14</sup>

#### Diastolic Dysfunction

Coronary artery disease and hypertension are the two main causes of diastolic dysfunction, just as they are the primary causes of systolic failure. Why the same disease processes result in different cardiac dynamics in different individuals is not known. Some patients have isolated systolic failure, whereas others have isolated diastolic failure. Some patients exhibit both abnormal systolic and diastolic function. HF with normal EF is more common in women, the elderly, and those with no history of MI.<sup>7</sup> Diastolic failure is a disorder of myocardial relaxation.

**FIGURE 19-1** Comparison of the left ventricular pressure-volume loop in normal heart (A), systolic dysfunction (B), and diastolic dysfunction (C). Note that end-diastolic pressure is higher than normal in both systolic and diastolic failure, but end-diastolic volume is lower in diastolic dysfunction. EDV, End-diastolic volume; EF, ejection fraction; ESV, end-systolic volume.

In this condition, the left ventricle is excessively noncompliant and does not fill effectively. Two separate functional processes occur during the diastolic relaxation phase: The first is an energy-requiring process (**lusitropy**) that removes free calcium ions from the cytoplasm by pumping them back into the sarcoplasmic reticulum and across the cell membrane into the extracellular fluid. Removal of calcium ions inhibits cross-bridge formation and allows the thick and thin filaments of the sarcomere to passively slide apart. Ischemia, with subsequent ATP deficiency, interferes with the efficiency of calcium ion removal and can impair the active phase of diastolic relaxation.

The second process is passive stretch of the ventricular myocardium to accommodate filling. Passive compliance of the ventricle can be decreased by deposition of fibrin and collagen during scar formation or by hypertrophic thickening of the ventricular wall. Both active and passive processes may be impaired together and are difficult to distinguish clinically.

The hallmark of HF with normal EF is that the patient exhibits clinical manifestations of HF, including low cardiac output, pulmonary congestion, and edema formation, but has a normal EF (usually defined as greater than 50%), indicating absence of significant systolic impairment.<sup>8,9</sup> Because prognosis and treatment recommendations may differ, an echocardiogram to measure EF is recommended in all patients with HF to determine the presence of isolated diastolic dysfunction from systolic failure.<sup>11,13</sup> A comparison of the left ventricular pressure-volume loop in systolic and diastolic dysfunction is shown in Figure 19-1. Systolic failure is characterized by higher than normal diastolic volume and low EF, whereas the pressure-volume loop in diastolic failure indicates poor compliance with a lower diastolic volume at a higher than normal pressure.

#### KEY POINTS

- HF is the end stage of most cardiac disorders. HF occurs when the heart is unable to provide sufficient cardiac output to meet normal metabolic functions of the body.
- The most common cause of HF is myocardial ischemia from coronary artery disease, followed by hypertension and dilated cardiomyopathy.
- Impaired contractility resulting in systolic failure is frequently associated with HF. The biochemical basis of impaired contractility involves loss of cardiac muscle cells,  $\beta_1$ -receptor down-regulation, and reduced ATP production.

- In about half of HF patients, systolic function is preserved and diastolic dysfunction predominates. HF with normal EF is particularly likely to develop in the elderly, in women, and in those without a history of MI.
- Left ventricular pressure-volume loops characterize the differences in systolic and diastolic dysfunction. High diastolic volume and reduced EF indicate systolic failure, whereas diastolic failure is characterized by higher diastolic pressure and low volume.

### Compensatory Mechanisms and Remodeling

When the heart fails to provide adequate cardiac output to meet tissue demands, a number of compensatory mechanisms are triggered. In the short term, these mechanisms are helpful in restoring cardiac output toward normal levels, but in the long term, they are detrimental to cardiac structure and function. Much of the current management of HF is aimed at attenuating the harmful consequences of these compensatory responses.<sup>7</sup> Three main compensatory mechanisms are activated in heart failure: SNS activation, increased preload, and myocardial hypertrophy (Figure 19-2).

#### Sympathetic Nervous System Activation

Sympathetic activation of the heart is primarily a result of baroreceptor reflex stimulation. The baroreceptors (pressoreceptors), located in the aorta and carotid arteries, detect a fall in pressure because of diminished stroke volume and transmit this information to the central nervous system (CNS). The CNS increases activity in the sympathetic nerves to the heart, resulting in increased heart rate and contractility. However, because of impaired contractile ability, the failing heart may have reduced responsiveness to sympathetic activation. Sympathetic activation also causes venoconstriction, which redistributes blood and increases cardiac preload. Sympathetic constriction of arterioles helps to maintain blood pressure when cardiac output is reduced. Specialized cells in the kidney called *juxtaglomerular cells* also receive SNS stimulation when cardiac output falls. The juxtaglomerular cells release renin and initiate the renin-angiotensin-aldosterone cascade, leading to salt and water retention by the kidney. Sympathetic activation is an early and immediate compensatory response to insufficient cardiac output.

Sympathetic activation is a very effective means for increasing cardiac output in an acute process, such as volume depletion. However, in heart failure, sympathetic activation becomes a chronic process that is ultimately deleterious. A major problem with excessive sympathetic

**FIGURE 19-2** Major compensatory mechanisms in heart failure that act to restore cardiac output. *GFR*, Glomerular filtration rate; *RAAS*, renin-angiotensin-aldosterone system; *SNS*, sympathetic nervous system.

activation is that afterload on the left ventricle can be increased significantly. A high afterload increases cardiac workload and may decrease stroke volume. Therefore, treatment of high blood pressure is important to improve cardiac function in patients with HF.<sup>8</sup>

Drugs that block  $\beta_1$  receptors have been advocated in the management of HF to inhibit the cardiac effects of sympathetic activation. Many clinicians had been reluctant to use  $\beta$ -blockers in patients with HF because these drugs are negative inotropes and have the potential to reduce cardiac output. In HF, where cardiac output is already low, the use of a negative inotrope would seem to be contraindicated. However, several randomized clinical trials have reported an improved mortality rate in patients receiving certain  $\beta_1$ -blockers, and they are now recommended as standard therapy in most HF guidelines.<sup>6,13</sup> Long-term SNS stimulation of the heart may contribute to heart failure progression and remodeling of the cardiac tissue. Remodeling is a process of myocyte loss, hypertrophy of remaining cells, and interstitial fibrosis (Figure 19-3). The remodeled tissue is less functional and may predispose to worsening failure and cardiac dysrhythmias.

### Increased Preload

Increased **preload** in the cardiac chambers is initially a consequence of reduced EF with a resultant increase in residual end-systolic volume. Subsequently, decreased cardiac output to the kidney reduces glomerular filtration, resulting in fluid conservation. In addition, the renin-angiotensin-aldosterone system (RAAS) is activated because of reduced blood flow to the kidney and SNS activation of the juxtaglomerular cells. Angiotensin II (AII) and aldosterone enhance sodium and water reabsorption by the kidney, contributing to an elevated blood volume. Increased preload is a compensatory mechanism that enhances the ability of the myocardium to contract forcefully. An enlarged chamber volume causes the myocardial fibers to lengthen during diastole, which results in greater fiber shortening during contraction (Frank-Starling mechanism).<sup>12</sup> The diastolic length of the

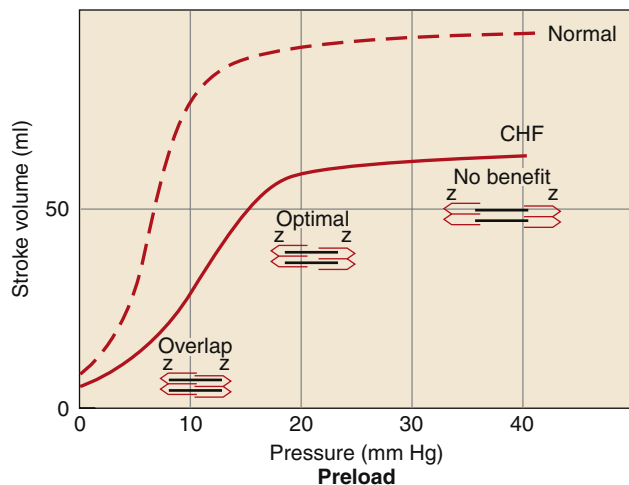

muscle fibers is thought to determine the number of effective cross-bridge cycles that can be accomplished during systole.<sup>10</sup> Thus, up to a point, an increase in the volume or preload of the heart will result in a greater force of contraction (Figure 19-4). The cardiac function curve flattens out at a certain point, and minimal benefit is obtained despite increasing preload. Patients with systolic failure have a cardiac function curve that is flat and shifted to the right of normal. Thus, they require a higher preload to achieve a given stroke volume. However, patients with HF often retain so much volume that their hearts are functioning on the flat part of the curve. These patients benefit from preload reduction, which will decrease systemic and pulmonary congestive symptoms and cardiac workload with little or no reduction in cardiac output. Diuretics are commonly used to achieve moderate preload reduction.

### Myocardial Hypertrophy and Remodeling

**Hypertrophy** of cardiac muscle cells is the third mechanism of compensation and generally takes much longer to occur than preload enhancement or sympathetic activation. Hypertrophy appears to result, in part, from a chronic elevation of myocardial wall tension.<sup>10</sup> Wall tension may be high as a result of increased diastolic blood volume (high preload) or as a consequence of high systolic pressures generated in the chamber (to overcome high afterload). The relationship between myocardial wall tension and intrachamber pressure and diameter is described by the law of Laplace: tension = (transmural pressure  $\times$  radius)/wall thickness. When the ventricular chamber enlarges and pressures increase, more tension is created in the ventricular muscle wall (Figure 19-5). The development of high systolic pressures in the ventricle may be necessary to overcome a high afterload, such as occurs with arterial hypertension and aortic valve stenosis. The hypertrophy of contractile elements in the myocardium increases the heart's pumping force and helps to reduce the wall tension of the heart toward normal levels. In general, an increase in chamber diameter because of excessive preload is thought to contribute

**FIGURE 19-3** Mechanisms of ventricular remodeling in heart failure. Activation of  $\beta_1$  receptors and Ang II receptors along with stretch of the cell membrane trigger signaling cascades. Under some conditions these triggers lead to effective hypertrophy and an increase in size and function, and in others they trigger apoptotic cell death. Ang II, Angiotensin II; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol;  $IP_3$ , 1,4,5-inositol trisphosphate; NE, norepinephrine; RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

**FIGURE 19-4** Effect of increased preload on sarcomere length and stroke volume. Systolic failure results in a shift of the curve to the right and a dampening of maximal stroke volume. A greater preload is required to achieve a given stroke volume compared with the normal ventricle. CHF, Congestive heart failure.

to eccentric hypertrophy in which the muscle fibers elongate.<sup>7,10</sup> High afterload results in concentric hypertrophy in which the muscle fibers grow in diameter and thicken the ventricular wall (Figure 19-6).

Neurohormones, which include norepinephrine (NE) and angiotensin (Ang II), also have hypertrophic effects on the heart. Circulating

Ang II levels are higher than normal in HF because of poor kidney perfusion, which triggers production of Ang II through the RAAS. In heart failure, Ang II is also produced locally in the heart. Ang II binds to the angiotensin type 1 (AT1) receptor on cardiac myocytes to activate genes in various growth pathways. Initially, hypertrophy may help the heart compensate for acute loss of myocardial tissue from MI or help maintain cardiac function during chronic hypertension. But over time, the signals that promote hypertrophy are thought to trigger a type of ventricular remodeling that contributes to progression of heart failure. Pathologic remodeling includes loss of myocardial cells through apoptosis and production of fibrous changes in the heart that stiffen the ventricles and contribute to diastolic failure (Figure 19-7). In addition to NE and Ang II, a number of immune cytokines have been implicated in cardiac remodeling.<sup>7,11,12</sup>

Evidence for a role of Ang II in remodeling comes from drug studies in which Ang II production is inhibited or the actions of Ang II are blocked at the AT1 receptor. An important enzyme in the pathway of Ang II production is angiotensin-converting enzyme (ACE). Drugs called ACE inhibitors (ACEIs) have been developed to inhibit the activity of this enzyme and prevent formation of Ang II. Another drug class, angiotensin type 1 receptor blockers (ARBs), binds to this Ang II receptor and blocks the intracellular actions of Ang II. ARBs were developed as a more selective means of RAAS inhibition, and to improve the safety and tolerability profile of ACE inhibitors. Both ACE inhibitors and ARBs have been shown to significantly reduce HF mortality, and both drug classes are used as standard therapy in HF.<sup>1,4,6</sup> In general, ARBs are prescribed if a patient is intolerant of ACE inhibitors.

**FIGURE 19-5** Mechanism of myocardial hypertrophy attributable to increased ventricular wall tension. According to the law of Laplace, an increase in chamber radius or pressure will increase wall tension. The hypertrophic response increases wall thickness and helps to relieve wall tension. **A**, Heart with normal radius ( $r$ ) and intraventricular pressure. **B**, Heart with enlarged chamber and high intraventricular pressure.  $P_T$ , Transmural pressure.

In summary, enhanced preload and cardiac hypertrophy may allow a heart to compensate for reduced ventricular function for an extended period. Unfortunately, these compensatory mechanisms, which serve to restore cardiac output to the tissues, also result in an increase in myocardial work and oxygen requirements and appear to cause pathologic remodeling. Progression and decompensation may occur when the primary disease plus the superimposed burdens of compensation overwhelm the heart's ability to generate adequate contractile force. The focus of therapy for HF is to maintain a state of compensation by minimizing cardiac work while optimizing cardiac output and preventing or delaying ventricular remodeling.

**KEY POINTS**

- Compensatory mechanisms are activated in heart failure in an attempt to improve cardiac output. Unfortunately, these responses also increase myocardial workload and may perpetuate the heart failure. Treatment for HF is aimed at attenuating the harmful effects of the compensatory responses.
- Sympathetic activation is an early response to reduced cardiac output. Sympathetic nervous system activation increases heart rate, contractility, arterial vasoconstriction, and renin release. The failing heart generally has reduced responsiveness to SNS neurotransmitters because of  $\beta_1$ -receptor down-regulation.

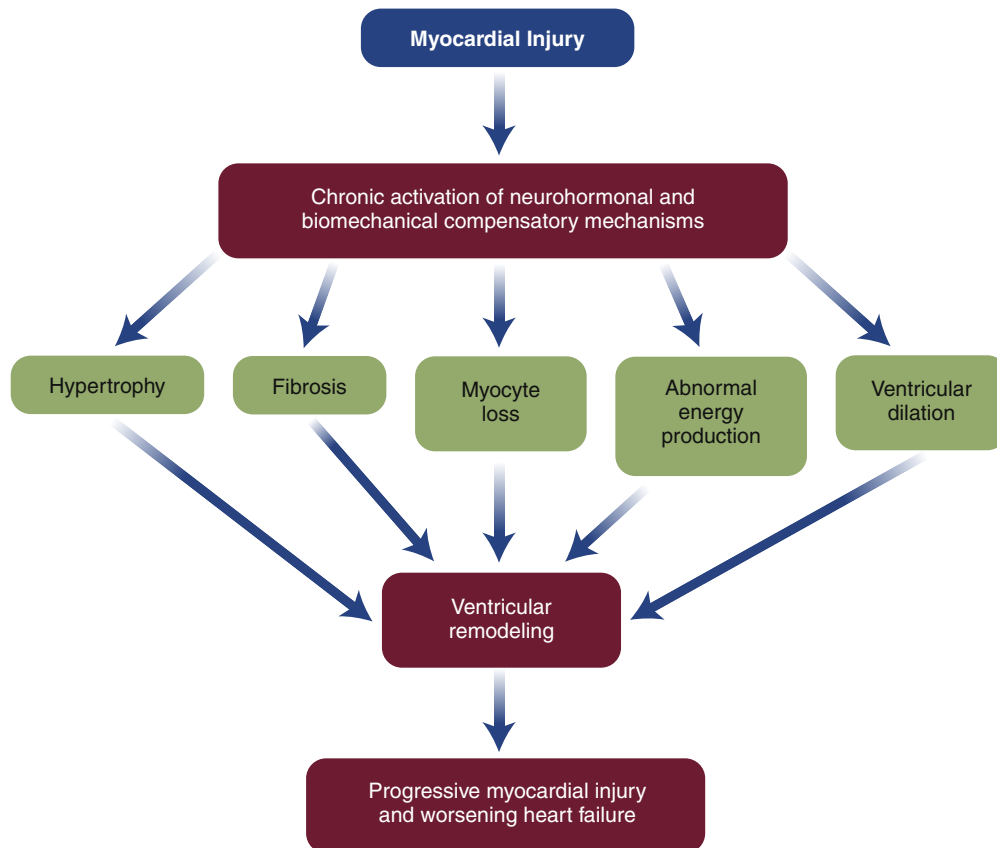

**FIGURE 19-6** Forms of ventricular hypertrophy. **A**, Eccentric, in which muscle fibers grow in length and the chamber diameter increases. **B**, Concentric, in which muscle fibers grow in diameter and the ventricular wall becomes thicker. *LV*, Left ventricle; *RV*, right ventricle.

- Decreased cardiac output reduces kidney perfusion and leads to activation of the renin-angiotensin-aldosterone system and volume retention. Extra blood volume increases cardiac preload. Higher preload results in more forceful ejection of blood from the heart (Frank-Starling law) and improves cardiac output.
- Cardiac hypertrophy is stimulated by elevated myocardial wall tension and the growth-promoting actions of neurohormones, such as NE and Ang II. Hypertrophy adds contractile filaments and improves contractile force.
- The mechanisms that enable the heart to compensate for reduced stroke volume are detrimental in the long term. Excessive neurohormones, volume overload, and high wall tension contribute to abnormal ventricular remodeling. Gradually, the ventricle loses myocytes and accumulates fibrotic tissue. The remaining myocytes are usually hypertrophied and less efficient. These processes lead to progression of HF over time.

**Clinical Manifestations**

The clinical presentation of HF differs depending on which ventricle (left, right, or both) is failing to pump blood adequately. Left ventricular failure is the most common presentation of HF. Because of circulatory dynamics, left ventricular failure often leads to right ventricular failure—a condition termed *biventricular failure*. The etiologic process, clinical manifestations, and management of isolated right ventricular failure differ substantially from those for left ventricular and biventricular failure. Recall that the right side of the heart receives blood from the systemic venous circulation and pumps blood into the pulmonary system, whereas the left side of the heart receives blood from the pulmonary circulation and delivers it to the systemic arterial system (Figure 19-8). Insufficient cardiac pumping is manifested by poor cardiac output, called *forward failure*, and by congestion of blood behind the pumping chamber, called *backward failure*. The clinical manifestations of left and right ventricular failure differ as a result of the anatomic location of the “backward” or congestive processes, but the forward effects of low cardiac output are the same.

**FIGURE 19-7** Mechanisms of cardiac remodeling that contribute to heart failure progression.

The *forward* effects of HF are due to insufficient cardiac output with diminished delivery of oxygen and nutrients to peripheral tissues and organs. Inadequate perfusion of the brain may lead to restlessness, mental fatigue, confusion, anxiety, and impaired memory. Generalized fatigue, activity intolerance, and lethargy may be present.

Reduced perfusion of the kidney results in a decline in urine output (oliguria) with subsequent fluid retention. Activation of the RAAS contributes to conservation of sodium and water by the kidney, and may also cause blood vessel constriction. Constriction of blood vessels serves to maintain blood pressure and redistribute reduced cardiac output to vital organs. However, this vasoconstriction also increases afterload, so the damaged left ventricle must generate more force to pump the same volume of blood. Depending on how much the afterload increases, the damaged left ventricle may not be able to pump sufficient quantities of blood into the circulation. If renal blood flow becomes severely limited, the patient with left ventricular failure may develop kidney failure. Forward failure also results in activation of the SNS because of the baroreceptor reflex. Sympathetic activation contributes to blood vessel constriction and helps maintain blood pressure in the face of reduced cardiac output; however, as with Ang II, SNS activation increases left ventricular afterload. SNS activation results in a compensatory increase in heart rate that may augment cardiac output to some extent, but also raises myocardial ATP consumption.

### Left-Sided Heart Failure

Left-sided heart failure is most often associated with left ventricular infarction and systemic hypertension.<sup>7,8</sup> The *backward effects* of left-sided heart failure may produce dramatic clinical symptoms attributable to pulmonary dysfunction (Figure 19-9). Ineffective pumping of

the left ventricle results in an accumulation of blood within the pulmonary circulation. As hydrostatic pressure builds within the pulmonary veins and capillaries, fluid is forced from the capillaries into interstitial and alveolar spaces, causing edema. Pulmonary congestion and edema are associated with a number of clinical findings (Figure 19-10). **Dyspnea**, or breathlessness, occurs early in the progression of left-sided heart failure and may be considered the cardinal symptom. Difficulty breathing may be exacerbated by activity (dyspnea on exertion), lying down (**orthopnea** and **paroxysmal nocturnal dyspnea**), and blood volume expansion from excessive salt or fluid intake. Orthopnea and paroxysmal nocturnal dyspnea are due in part to a redistribution of blood volume from the periphery to the heart when the individual lies down. The failing left ventricle is unable to effectively pump extra volume, and pulmonary congestion is worsened. The severity of orthopnea may be quantified by the degree of head elevation (e.g., number of pillows) used to relieve dyspnea. Paroxysmal nocturnal dyspnea refers to intermittent attacks of severe dyspnea during the night and is a most distressing form of orthopnea. The individual experiences a feeling of suffocation and panic at not being able to overcome the dyspnea. Sitting or standing helps to relieve the dyspnea because blood pools in the extremities, reducing pulmonary hydrostatic pressure and congestion.

Clinical signs of pulmonary congestion include cough, respiratory crackles (rales), hypoxemia, and high left atrial pressure (LAP). Cough results from bronchial irritation associated with congestion. In severe cases, sputum may be blood tinged, from breakage of fragile capillaries, and frothy, from fluid buildup in the alveoli. The severity of pulmonary edema can be estimated from the location of crackles within the lung fields. Crackles are abnormal sounds caused by the movement of air through partially fluid-filled alveoli. Edema fluid collects in dependent lung fields because of gravity and progressively moves up the lung as

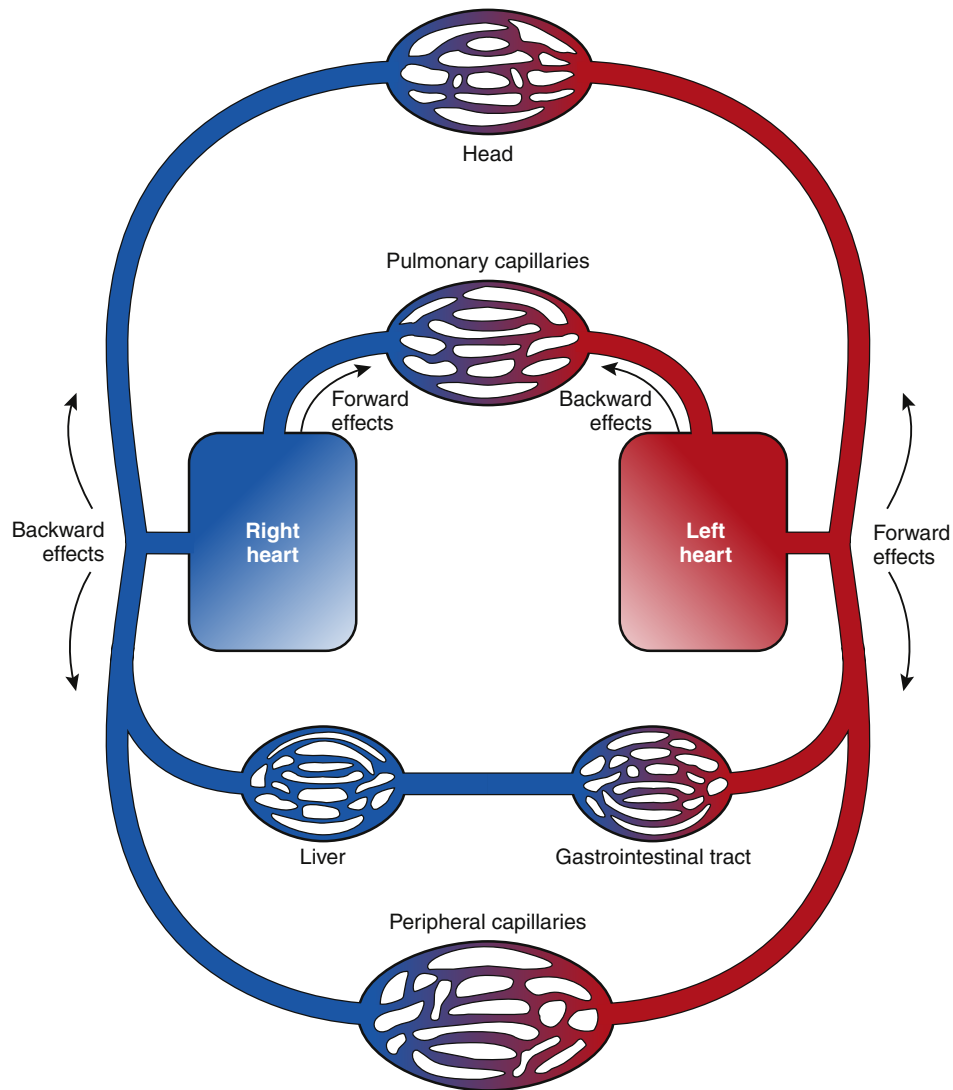

FIGURE 19-8 Systemic and pulmonary circulations viewed as separate but interdependent systems.

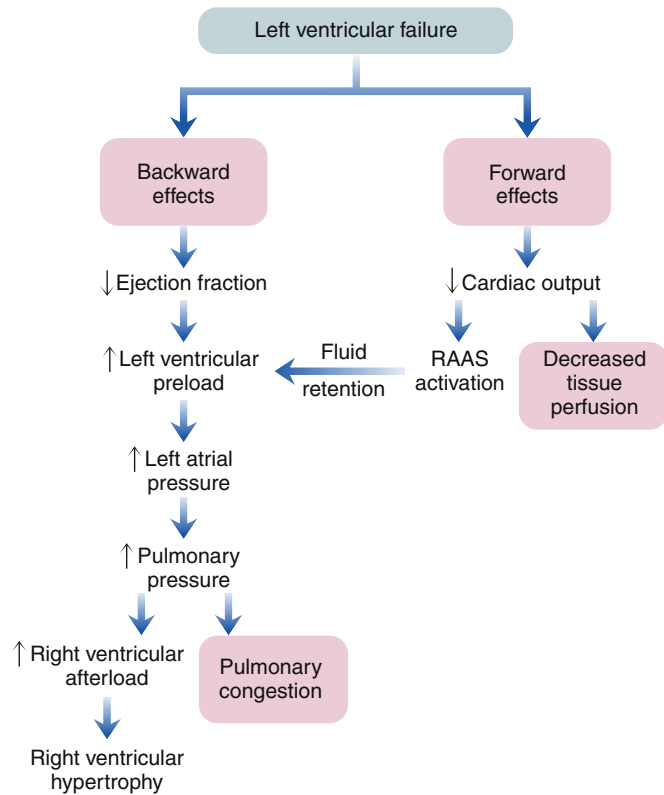

more edema fluid accumulates. For example, in mild pulmonary edema, crackles might be heard with a stethoscope only at the base of the upright lung, but with increasing severity they become apparent in the lower third to half of the lung. Fluid in the alveoli and interstitial spaces also interferes with alveolar-capillary gas exchange and results in some degree of hypoxemia. Hypoxemia may be detected by arterial blood gas analysis or pulse oximetry and may be apparent clinically as cyanosis. **Cyanosis** refers to a blue coloration of the skin typically seen around the mouth (circumoral cyanosis) and results from the presence of significant amounts of desaturated hemoglobin in the blood. Cyanosis is a late sign, and is clinically evident only when a large amount (about 5 g/dl) of hemoglobin is deoxygenated (less than or equal to 75% saturated).

Elevated LAP is a common finding in left-sided heart failure because of excessive blood volume and the compensatory responses of atrial dilation and hypertrophy. Atrial pressure can be estimated by inserting a balloon-tipped catheter (Swan-Ganz) into the pulmonary artery. If LAP acutely increases to 25 mm Hg (normal is 4 to 12 mm Hg), increased capillary filtration leads to pulmonary edema. Patients with chronic elevations in LAP associated with chronic HF are more resistant to developing acute pulmonary edema, and may not experience symptoms until pressures approach 40 mm Hg.<sup>7</sup> On x-ray, findings of fluid overload include an enlarged heart and engorged pulmonary capillaries and lymphatic vessels.

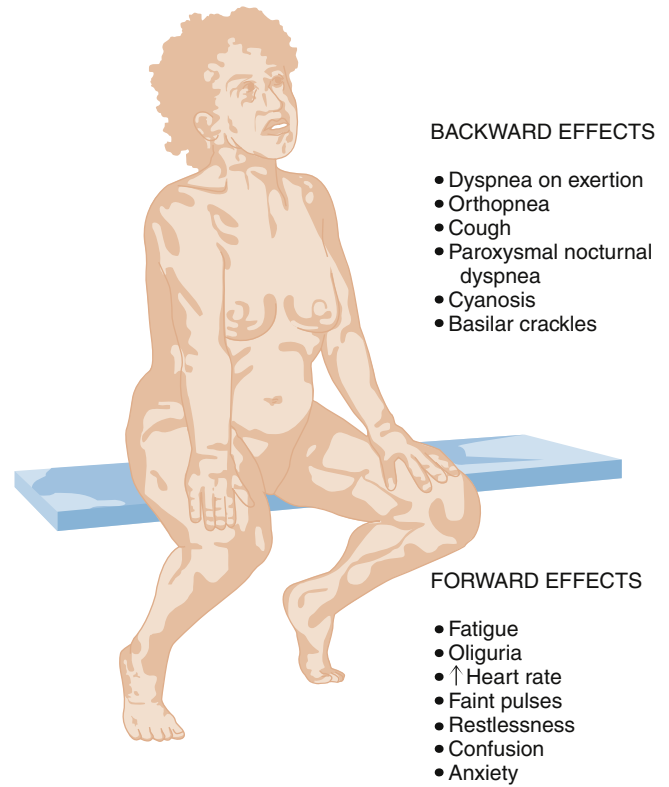

*Acute cardiogenic pulmonary edema* is a life-threatening condition associated with left ventricular failure that severely impairs gas exchange, producing dramatic signs and symptoms. The patient exhibits severe dyspnea and anxiety, and a bolt-upright posture is usually assumed in order to maximize respiratory effort. Bubbly crackles may be heard all the way up the lung from the bases to the apices, and pink frothy sputum may be expectorated or well up from the trachea into the nose and mouth. Anxiety and hypoxemia contribute to tachycardia, which may worsen the pumping efficiency of the failing heart. Cyanosis and symptoms of tissue hypoxia are usually apparent. The immediate treatment is aimed at reducing the fluid volume in the lungs and supporting oxygenation.

### Right-Sided Heart Failure

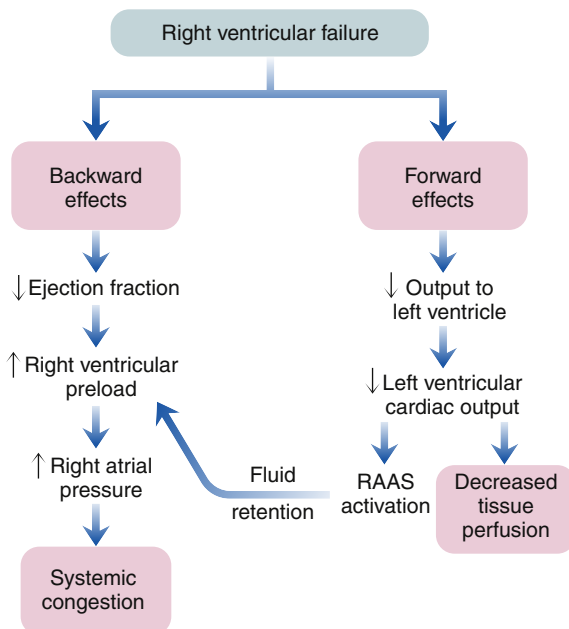

Because the right and left ventricles function in series, left ventricular failure eventually increases the workload on the right ventricle. Consequently, the right ventricle may fail. The etiology of right ventricular failure must include all the causes of left ventricular failure. Isolated right ventricular failure is rare and is usually a consequence of right ventricular infarction or pulmonary disease. Only 3% of MIs occur in the right ventricle; however, right ventricular infarctions are often poorly tolerated and difficult to manage.<sup>7</sup> Pulmonary disorders that result in increased pulmonary vascular resistance impose a high

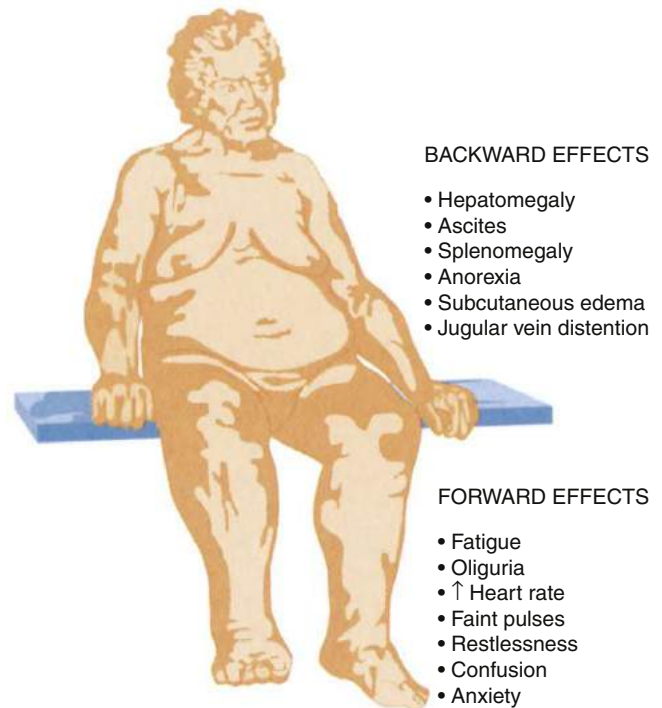

**FIGURE 19-9** Pathophysiologic process of isolated left-sided heart failure, showing backward and forward effects. RAAS, Renin-angiotensin-aldosterone system.

**FIGURE 19-10** Clinical manifestations of isolated left-sided heart failure.

**FIGURE 19-11** Pathophysiologic process of isolated right-sided heart failure, showing backward and forward effects. RAAS, Renin-angiotensin-aldosterone system.

**FIGURE 19-12** Clinical manifestations of isolated right-sided heart failure.

afterload on the right ventricle. The resultant right ventricular hypertrophy, called **cor pulmonale**, may progress to right ventricular failure as the lung disease worsens.

Any lung disorder that decreases the total cross-sectional area of the lung vasculature can increase pulmonary vascular resistance and produce right ventricular strain. Hypoxemia, for example, causes the pulmonary arterioles to constrict, which increases pulmonary resistance. Constriction or blockage of the vascular bed, such as occurs with pulmonary hypertension or pulmonary embolus, similarly reduces the cross-sectional area of the pulmonary vasculature and leads to increased pulmonary resistance. If the increase in pulmonary resistance and right ventricular workload occurs gradually, the right ventricle can compensate by increasing preload and hypertrophy. However, the thin musculature of the right ventricle has limited ability to adjust to acute changes in workload, as would occur with a right ventricular infarction or large pulmonary embolus.

As with left-sided heart failure, congestion of blood occurs behind the failing right ventricle because of inefficiency of the pump. The *backward effects* of right-sided heart failure are due to congestion in the systemic venous system (Figure 19-11). Systemic venous congestion results in impaired function of the liver, portal system, spleen, kidneys, peripheral subcutaneous tissues, and brain (Figure 19-12).

The liver is usually somewhat increased in size and weight, but individual hepatocytes may show signs of atrophy and necrosis attributable to chronic passive congestion.<sup>7</sup> Impedance to blood flow through the liver may cause hydrostatic pressure to build in the portal system, leading to edema formation in the peritoneal cavity (ascites). Increased pressure in the portal system is reflected back to the spleen and gastrointestinal tract. The spleen is generally enlarged (congestive splenomegaly), and gastrointestinal symptoms such as anorexia and abdominal discomfort may be present.

Increased systemic venous pressure causes congestion of the kidneys, which contributes to the decreased glomerular filtration and fluid retention. Fluid retention may be perpetuated by the congested liver, which is unable to metabolize plasma aldosterone normally.<sup>7</sup> Excess fluid volume and venous congestion caused by right-sided heart failure result in subcutaneous edema. Edema is usually particularly apparent in the lower extremities or sacral area if the patient is supine.

Drainage of venous blood from the head and neck by way of the superior vena cava is also impeded by right-sided heart failure. The jugular veins may be abnormally distended, and mental functioning

may be impaired. The hepatjugular reflux test can be done to assess the severity of right-sided heart failure. The liver is manually compressed, causing a sudden increase in venous blood returning to the right heart, while jugular neck veins are observed for sudden distention. In the absence of right-sided heart failure, the sudden increase in venous return would enter the heart unimpeded and no neck vein distention would be apparent.

**Biventricular Heart Failure**

In many cases, heart failure is not isolated to one side of the heart. Biventricular failure is most often a result of primary left ventricular failure that has progressed to right-sided heart failure. With biventricular failure, cardiac output is reduced and pulmonary congestion exists as a result of left-sided heart failure, as well as systemic venous congestion attributable to right-sided heart failure.

**Class and Stage of Heart Failure**

A variety of clinical criteria have been used to aid in the diagnosis of HF, but to date, no diagnostic test has been universally accepted. A commonly suggested tool for detecting heart failure in previously undiagnosed individuals is called **FACES** of heart failure: *fatigue, activity limitation, congestion, edema, shortness of breath*. These are classic findings in HF and, if present, indicate a need for further diagnostic assessment. Traditionally, a patient with suspected HF would be diagnosed by x-ray and echocardiography. Echocardiography is the gold standard for evaluation of HF, and is able to measure chamber size, volume, and dynamics during diastole and systole, as well as determine ejection fraction. A blood test for B-type natriuretic peptide (BNP) may also be used to help identify patients with HF. BNP is synthesized by left ventricular myocytes under conditions of increased left ventricular wall stress. A significant correlation between the amount of plasma BNP or the BNP precursor, N-terminal pro-BNP (NT-proBNP), and the severity of HF has been documented.<sup>15</sup>

The severity of symptoms can be used to assign a heart failure class (New York Heart Association classes [NYHA] I to IV).<sup>15</sup> Another classification scheme has been proposed by the American Heart Association (AHA) to allow inclusion of patients at high risk for heart failure but whose disease is not yet symptomatic. By including this pre-heart failure group, efforts aimed at prevention may be instituted in more patients. Class and stage are used to determine prognosis, therapy, and monitoring in HF. These two classification schemes are compared in Table 19-1.

**TABLE 19-1 COMPARISON OF ACC/AHA STAGES OF HEART FAILURE AND NEW YORK HEART ASSOCIATION CLASSES**

ACC/AHA STAGE	DESCRIPTION	CLINICAL CLUES	NYHA CLASS
A	Patients at high risk of developing HF	Coronary artery disease, hypertension, diabetes, dyslipidemia, family history of cardiomyopathy	Not applicable
B	Patients who have structural heart disease but have never manifested signs or symptoms of HF	Left ventricular hypertrophy (by ECG or echo), valvular disease, past myocardial infarction	I
C	Patients who have current or previous symptoms of HF	Dyspnea, fatigue, exercise intolerance, prior HF hospitalization	II-III
D	Patients with advanced structural heart disease and marked symptoms of HF at rest	End-stage, awaiting transplant, receiving palliative care	IV

Adapted from Hunt SA et al: American College of Cardiology; American Heart Association: 2009 focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: summary article, *J Am Coll Cardiol* 53(15):e3-e62, 2009. HF, Heart failure.

**KEY POINTS**

- The clinical manifestations of HF are characterized by the effects of forward failure (reduced cardiac output) and backward failure (congestion behind the pumping chamber).
- Insufficient cardiac output may be manifested as confusion, fatigue, tachycardia, reduced urine output, and poor peripheral circulation.
- Left-sided heart failure is characterized by pulmonary congestion, which may manifest with dyspnea, orthopnea, crackles, cough, pulmonary edema, and hypoxemia.
- Right-sided heart failure is characterized by systemic venous congestion, which may manifest with jugular vein distention, hepatomegaly, splenomegaly, and peripheral edema.
- Left-sided heart failure frequently leads to development of right-sided heart failure. With biventricular failure, congestive signs and symptoms are found in both the pulmonary and the systemic venous circulation.
- Heart failure is diagnosed by signs and symptoms, x-ray findings, and echocardiographic findings. A plasma BNP or NT-proBNP level may be used to diagnose HF in patients with shortness of breath.
- The severity of signs and symptoms is used to assign a heart failure class or stage.

**Treatment**

Therapy for HF is aimed at improving cardiac output while minimizing congestive symptoms and cardiac workload. These objectives are obtained by manipulating preload, afterload, and contractility. When possible, specific treatment is undertaken to correct the underlying cause of the heart failure.

Despite the large number of pharmacologic agents being used in the management of HF, only a few have been associated with significant improvement in mortality risk, particularly ACE inhibitors, ARBs, aldosterone antagonists, and certain  $\beta_1$ -blockers (Table 19-2).<sup>16</sup> A classification system has been developed by the AHA and American College of Cardiology (ACC), and suggests therapy goals and treatments for the four stages of heart failure (Figure 19-13).

A better understanding of the underlying molecular mechanisms of HF is needed to improve pharmacologic management. Little research has been conducted to determine the best treatment for patients with primarily diastolic failure, and treatment recommendations are similar.<sup>3</sup> Many patients with HF have signs and symptoms of elevated preload attributable to an expanded intravascular volume and a reduced EF. According to the Frank-Starling law, an elevated preload is desirable to enhance systolic shortening and improve cardiac output. Unfortunately, high preload exacerbates congestive symptoms and adds to the workload of an already damaged heart. Thus, the aim of therapy is to optimize preload, so that congestive symptoms are minimized, but cardiac output is not compromised. The right ventricle is particularly sensitive to reductions in preload, and care must be taken to avoid a significant drop in right ventricular output when intravascular volume is decreased. Drugs, such as diuretics, may be administered to reduce intravascular volume. Diuretics promote the excretion of fluid by increasing renal blood flow, blocking sodium and chloride reabsorption, or both. Patients may also be instructed to modify salt and fluid intake.

With the exception of digitalis, positive inotropic agents are avoided in chronic heart failure because they are associated with higher mortality. However, when improving cardiac output is necessary to avoid shock, positive inotropic agents may be used. Positive inotropes work by increasing the availability of intracellular calcium ions during systole. Drugs that mimic SNS effects, such as norepinephrine, isoproterenol, dobutamine, and dopamine, may be used to improve cardiac output, but have a potential for dramatically increasing myocardial oxygen consumption.

Digitalis or a related cardiac glycoside may be used for symptom management of heart failure. Cardiac glycosides directly inhibit the sodium-potassium pump present in the cell membrane of all cells. This results in an increase in intracellular sodium accumulation and a decrease in the gradient for sodium entry into the cell. A diminished sodium gradient slows the sodium-dependent calcium pump that normally removes intracellular calcium. This allows more calcium to remain in the cell, thus strengthening myocardial contraction. Digitalis also slows the heart rate through parasympathetic system activation and promotes sodium and water excretion through improved cardiac output to the kidney. Depletion of serum potassium (hypokalemia) may potentiate digitalis toxicity. Unlike the other positive inotropic agents, digitalis does not appear to increase mortality.<sup>17</sup> Digitalis also does not improve mortality and is not recommended as routine therapy.<sup>1,6,13,17</sup>

Patients with enlarged hearts and conduction delays may benefit from pacemakers, which help to synchronize ventricular contraction. A wide QRS complex is the usual indication for resynchronization therapy in the HF patient. Pacing electrodes are placed in the atrium and both ventricles to allow coordinated depolarization of the heart muscle. Many patients experience significant improvement in congestive symptoms and activity tolerance with resynchronization.

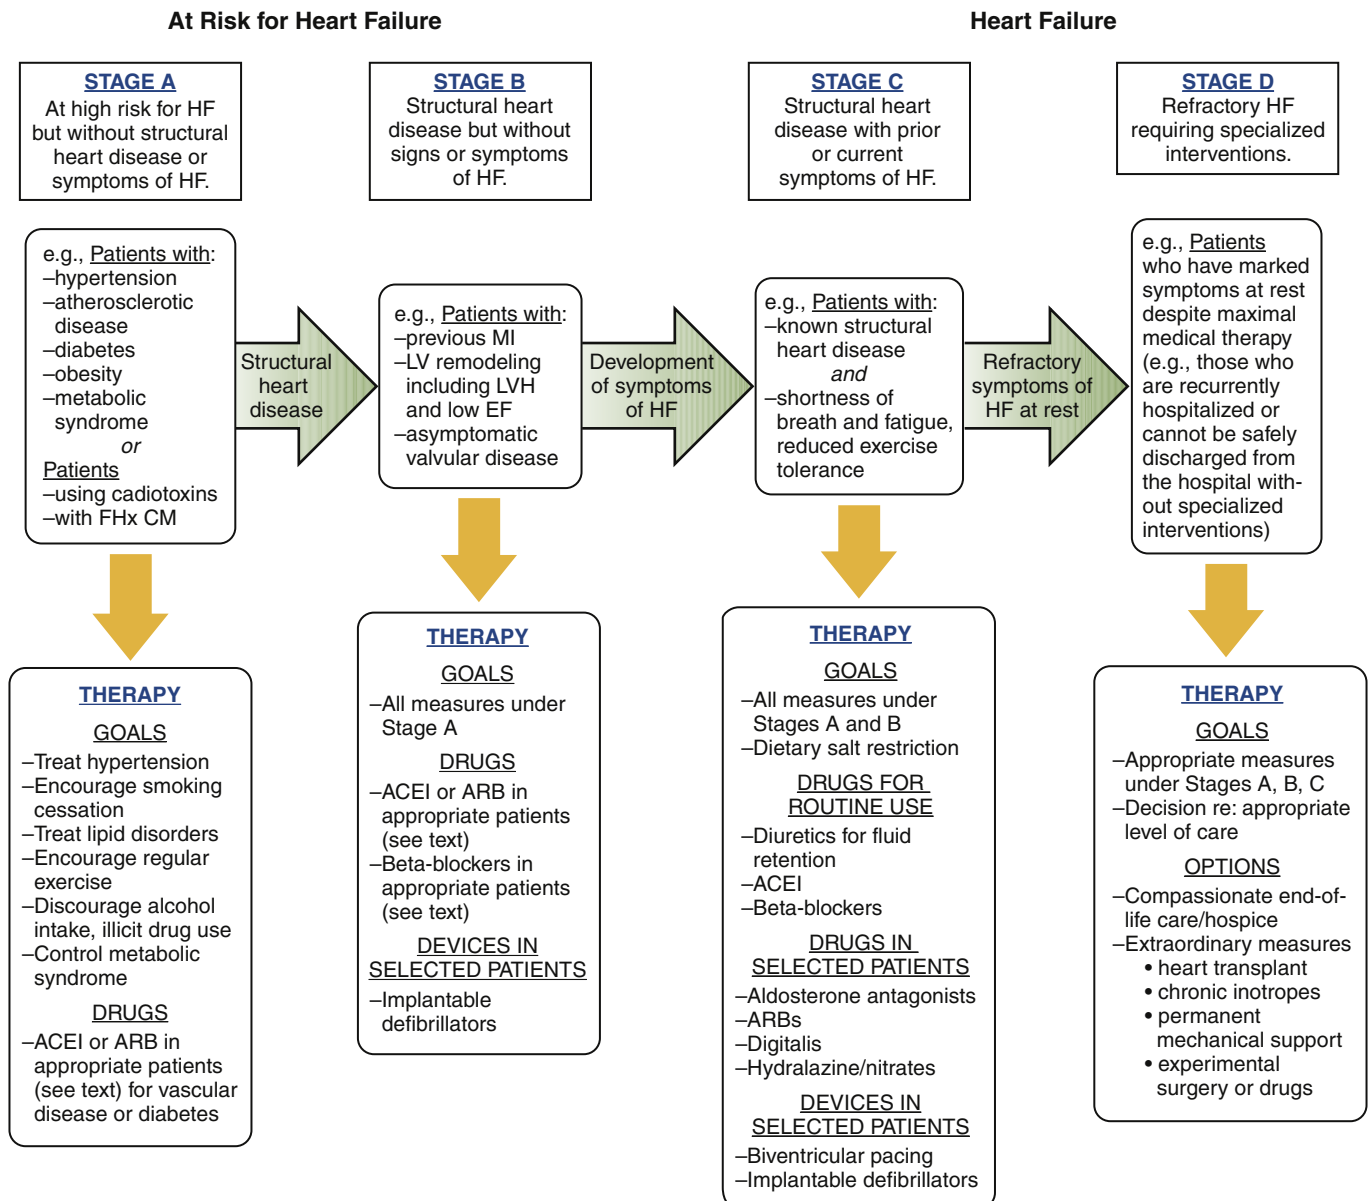

**TABLE 19-2 INHIBITORS OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM AND  $\beta$ -BLOCKERS COMMONLY USED FOR THE TREATMENT OF PATIENTS WITH HEART FAILURE WITH LOW EJECTION FRACTION**

DRUG	INITIAL DAILY DOSE(S)	TARGET DAILY DOSE
<b>ACE Inhibitors</b>		
Captopril	6.25 mg 3 times	50 mg 3 times
Enalapril	2.5 mg twice	10 mg twice
Fosinopril	5-10 mg once	80 mg once
Lisinopril	2.5-5 mg once	20 mg once

## CHAPTER 19 Heart Failure and Dysrhythmias: Common Sequelae of Cardiac Diseases

**FIGURE 19-13** Stages of heart failure and recommended therapy according to stage. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; FHx CM, family history of cardiomyopathy. (From Hunt SA et al: American College of Cardiology; American Heart Association: 2009 focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: summary article, *J Am Coll Cardiol* 53[15]:e3-e62, 2009.)

Little research has been conducted to determine the best treatment for patients with HF and normal EF who have primarily diastolic failure. The effectiveness of renin-angiotensin-aldosterone system blocking agents,  $\beta_1$ -blockers, and digitalis in this population is not well established. Treatment goals are aimed at controlling etiologic factors, such as hypertension and rhythm abnormalities, as well as managing symptoms (Box 19-1).

### KEY POINTS

- The primary aims of treatment are to improve cardiac output, minimize congestive symptoms, and prevent progression.
- ACE inhibitors, ARBs, and some  $\beta_1$ -blocking agents have been shown to improve mortality risk in patients with HF characterized by low EF.

- Diuretics alleviate congestive symptoms and reduce cardiac workload by reducing preload.
- Myocardial contractility may be improved acutely by positive inotropic drugs, such as  $\beta$  agonists; however, long-term use is associated with higher mortality. An exception is digitalis, which has positive inotropic effects, does not appear to alter mortality, and may improve symptoms in some patients.
- Resynchronization of ventricular depolarization with pacemakers may improve contraction in patients with wide QRS complexes.
- Few studies are available to guide therapy in patients with HF characterized by normal EF. Efforts to improve etiologic factors, such as atherosclerosis, hypertension, type 2 diabetes, and atrial dysrhythmias, are recommended.

### BOX 19-1 RECOMMENDATIONS FOR TREATMENT OF PATIENTS WITH HEART FAILURE WITH NORMAL EJECTION FRACTION

- Physicians should control systolic and diastolic hypertension, in accordance with published guidelines.
- Physicians should control ventricular rate in patients with atrial fibrillation.
- Physicians should use diuretics to control pulmonary congestion and peripheral edema.
- Coronary revascularization is reasonable in patients with coronary artery disease in whom symptomatic or demonstrable myocardial ischemia is judged to be having an adverse effect on cardiac function.
- Restoration and maintenance of sinus rhythm in patients with atrial fibrillation might be useful to improve symptoms.
- The use of  $\beta$ -adrenergic blocking agents, angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, or calcium antagonists in patients with controlled hypertension might be effective to minimize symptoms of heart failure.

The use of digitalis to minimize symptoms of heart failure is not well established.

Adapted from Hunt SA et al: American College of Cardiology; American Heart Association: 2009 focused update incorporated into the ACC/AHA 2005 guidelines for the diagnosis and management of heart failure in adults: summary article, *J Am Coll Cardiol* 53(15):e3-e62, 2009.

## CARDIAC DYSRHYTHMIAS

**Dysrhythmia** or arrhythmia refers to a cardiac rhythm abnormality affecting impulse generation or conduction. A normal heartbeat is initiated at an appropriate rate in the sinoatrial (SA) node and follows a consistent pathway of depolarization through the atria, atrioventricular (AV) node, His-Purkinje system, and, finally, the ventricular myocardium (see Chapter 17). Electrical depolarization

of the heart is normally followed by atrial and then ventricular muscular contraction. A number of factors may lead to disturbances in heartbeat, including hypoxia, electrolyte imbalance, trauma, inflammation, and drugs. Dysrhythmias are significant for two reasons: (1) they indicate an underlying pathophysiologic disorder and (2) they can impair normal cardiac output. Dysrhythmias can be categorized into three major types: abnormal rates of sinus rhythm, abnormal sites (ectopic) of impulse initiation, or disturbances in conduction pathways.

### Dysrhythmia Mechanisms

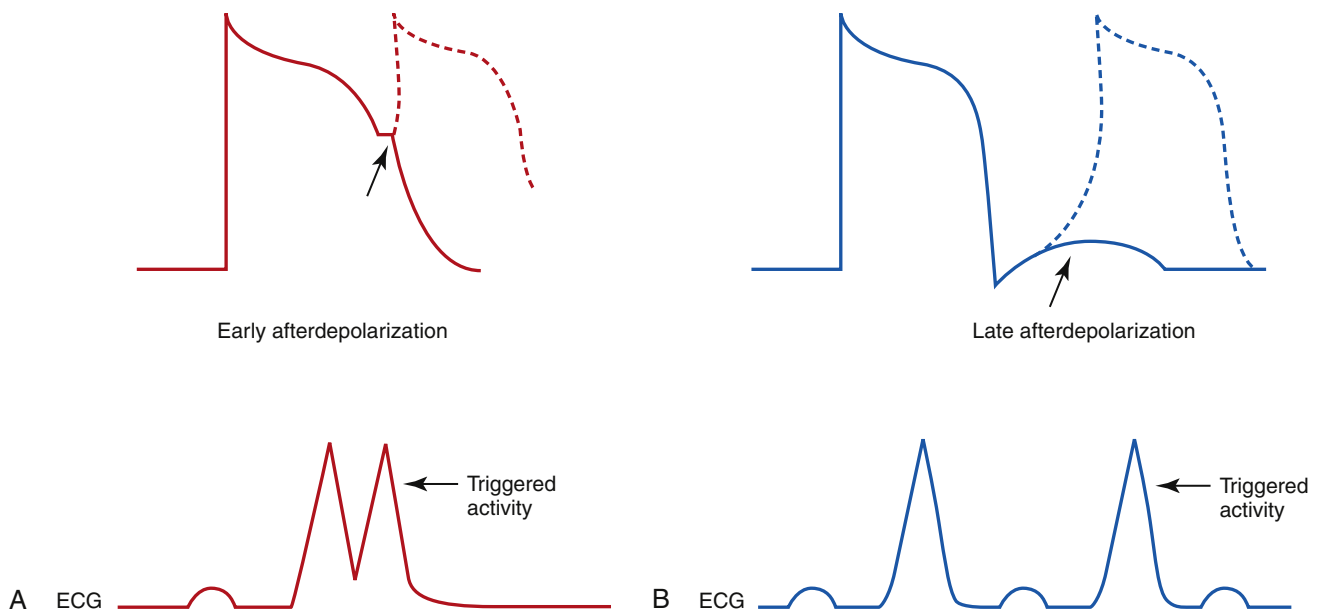

Disorders of impulse generation result from abnormalities in the *rate* of impulse generation from a normal pacemaker or from impulse generation from an abnormal (*ectopic*) site. Abnormal automaticity and triggered activity are the two mechanisms most commonly cited for dysrhythmias of impulse generation. Abnormalities of impulse conduction are attributed to reentry phenomena.

#### Automaticity

Failure to repolarize to normal resting membrane potential or plasma membrane leakiness to sodium or calcium ions at rest (phase 4) is thought to cause a shift in the resting membrane potential toward threshold, generating an action potential. Ischemia and subsequent ATP deficiency reduce the cell's ability to control electrolyte flux across the cell membrane. Electrolyte imbalance, particularly hypokalemia, contributes to abnormal automaticity. Alterations in spontaneous calcium ion flux from the sarcoplasmic reticulum and the subsequent triggering of calcium influx across the plasma membrane may also contribute to abnormal automaticity (see Chapter 17).

#### Triggered Activity

Triggered activity occurs when an impulse is generated during or just after repolarization because of a depolarizing oscillation of the membrane potential (Figure 19-14). Early afterdepolarizations occur during the relative refractory period of phase 3 in patients with abnormally

**FIGURE 19-14** Mechanisms of triggered activity. **A**, Early afterdepolarization in ventricular cell showing triggered action potential during the repolarization phase. The electrocardiogram (ECG) shows an R wave occurring on top of the T wave (R-on-T phenomenon). **B**, Late or delayed afterdepolarization occurs after the repolarization phase has been completed and results in an early beat after the T wave. If the late afterdepolarization does not reach threshold, no triggered beat will occur.

long repolarization times (prolonged QT syndrome). The prolonged action potential is thought to allow some of the voltage-gated calcium channels to reopen during phase 3 and trigger another impulse<sup>18</sup> (see Figure 19-14, A). Delayed or late afterdepolarizations occur after the repolarization phase is complete and are seen as oscillating depolarizing waves on the ECG (see Figure 19-14, B). If the delayed afterdepolarization reaches threshold, it will trigger an action potential. Digitalis toxicity and excessive catecholamine stimulation may contribute to this mechanism. Delayed afterdepolarizations are thought to occur because calcium ions are spontaneously released from the sarcoplasmic reticulum after repolarization. An increase in intracellular free Ca<sup>2+</sup> concentration during phase 4 can trigger Ca<sup>2+</sup> influx across the plasma membrane and release more Ca<sup>2+</sup> from the sarcoplasmic reticulum, resulting in an action potential.<sup>18</sup> A number of genetic abnormalities in intracellular calcium handling have been associated with triggered activity mechanisms.

### Reentry

Reentry is thought to be the culprit in most tachydysrhythmias, including atrial and ventricular tachycardia, flutter, and fibrillation. Reentry is a complex process in which a cardiac impulse continues to depolarize in a part of the heart after the main impulse has finished its path and the majority of the fibers have repolarized. If the errant impulse proceeds slowly enough, it may eventually meet with nonrefractory cells and initiate an extra, ectopic cardiac depolarization. Reentry processes are produced when electrical conduction in a portion of the heart is abnormally slowed (functional) or has an unusually long pathway (anatomic). A number of theories have been proposed to describe the generation and conduction of reentry depolarizations including specific subsets of cells that continue to produce waves of activation or more general involvement of the myocardial tissue in propagating waves of conduction. The rate of conduction is controlled in part by the density and structure of gap junctions that connect the cardiac cells together. Recall that a wave of depolarization moves from cell to cell through these gap junctions; however, different regions of the heart may have different gap junction properties that predispose to different conduction rates. Mutations in the genes that code for gap junction proteins (connexins) may increase the predisposition to dysrhythmias.<sup>19</sup> Reentry depolarizations may

occur as complex spiral waves in which the activating wavefront follows or “chases” its repolarizing tail (Figure 19-15). If the wavefront encounters only refractory tissue, the reentrant process suddenly terminates.<sup>19</sup> Myocardial ischemia and electrolyte abnormalities predispose to reentry mechanisms.

### Dysrhythmia Analysis

ECG recording paper is specifically designed to allow easy measurement of waveform amplitude and duration (Figure 19-16). Each small box on the ECG paper represents an amplitude of 0.1 mV and a duration of 0.04 second (paper speed at 25 mm/sec).<sup>20</sup> Larger boxes are also marked on the paper and correspond to 0.5 mV in amplitude (five small boxes) and 0.2 second in duration (five small boxes). These markings allow measurement of waveform amplitude, duration, and heart rate. Rhythm strips presented in this chapter are from a single lead only (usually lead II), but it should be emphasized that thorough ECG interpretation often requires several leads to provide different views of electrical conduction through the heart. (Lead placement is discussed in Chapter 17.)

### Normal Sinus Rhythm

Before one proceeds to the interpretation of dysrhythmias, the features of normal sinus rhythm must be understood. Normal sinus rhythm is generally defined as an impulse rate between 60 and 100 per minute that begins in the sinus node and follows the normal conduction pathway. Characteristics of normal sinus rhythm are listed in Table 19-3. The rhythm shown in Figure 19-17 is regular; there is a P wave for every QRS complex; the PR, QRS, and QT intervals are of normal duration; and there are no “funny-looking” beats.

There are several methods for determining heart rate using the rhythm strip. The easiest but least accurate method is to count the number of QRS complexes within 6 seconds and multiply by 10. Electrocardiogram (ECG) paper has 3-second marks along the top that can be used to determine a 6-second interval. A more accurate method for determining heart rate is to count the number of small boxes between complexes. The number of boxes is divided by 1500 to determine heart rate because there are 1500 small boxes per minute ( $1500 \times 0.04 \text{ second} = 60 \text{ seconds}$ ). Neither of these methods is accurate with irregular rhythms,

**FIGURE 19-15** Mechanism of reentry. **A**, A wave of depolarization that travels slowly or by an abnormal pathway may encounter myocardium that has had time to recover and can restimulate it. **B**, This may result in an extra beat, or the depolarization may continuously “chase its tail” in a circuit, causing defibrillation. The circuit can be relatively fixed or can wander into various “wavelets.”

so heart rate must be calculated for a longer interval, usually 1 minute. With this understanding of rate calculation and methods to measure the duration and amplitude of waveforms, one can analyze dysrhythmias.

### KEY POINTS

- Dysrhythmias are initiated by three types of depolarizing mechanisms: abnormal automaticity, triggered activity from afterdepolarizations, and reentrant circuits.
- Measurement of ECG waveform amplitude, duration, and frequency is necessary to analyze cardiac rhythms. ECG paper is marked in small boxes representing 0.1 mV of amplitude and 0.04 second of duration.
- Normal sinus rhythm is characterized by regular PP and RR intervals, a rate of 60 to 100 beats/min, and normal PR (0.12 to 0.20 second) and QRS (0.04 to 0.10 second) intervals.

## Abnormal Rates of Sinus Rhythm

### Sinus Tachycardia

Sinus tachycardia is an abnormally fast heart rate of greater than 100 beats/min (Figure 19-18). A number of factors, including sympathetic activation, decreased parasympathetic activity, fever, hyperthyroidism, pain, increased metabolism, low blood pressure, and hypoxia, can lead to sinus tachycardia, making it a very common dysrhythmia. Sinus tachycardia often is a compensatory response to increased demand for cardiac output or reduced stroke volume. Treatment is aimed at correcting the underlying cause. In some instances, however, the rate can become so high that ventricular filling is impaired and cardiac output is compromised. The heart rate at which this occurs will

vary depending on age and cardiac function. Sympatholytic agents or calcium channel–blocking agents may then be indicated.

### Sinus Bradycardia

Traditionally a heart rate of less than 60 beats/min is called *bradycardia*; however, lower rates are commonly encountered in physically trained individuals. Sinus bradycardia results from slowed impulse generation by the sinus node in response to increased parasympathetic activity, sleep, drugs, increased stroke volume, or acute hypertension (baroreceptor reflex). Important features of sinus bradycardia are shown in Figure 19-19. Sinus bradycardia may be a normal finding in well-conditioned individuals who have large resting stroke volumes. Abnormal parasympathetic activation can result from pain (vasovagal response), carotid sinus massage, endotracheal suctioning, and the Valsalva maneuver (bearing down). Slow heart rates may be well tolerated by some individuals and not require treatment. If the slow heart rate precipitates low cardiac output, it is usually treated with sympathomimetic or parasympatholytic drugs.

### Sinus Arrhythmia

A degree of variability in the heart rate, or sinus arrhythmia, is a normal finding associated with fluctuations in autonomic influences and respiratory dynamics. Sinus arrhythmia can be particularly pronounced in children. Sinus arrhythmia must be differentiated from a sinus node irregularity called *sick sinus syndrome*, in which alternating periods of sinus bradycardia and tachycardia occur (Figure 19-20). Sick sinus syndrome may necessitate implantation of a permanent pacemaker. Sinus arrhythmia is a normal finding and thus requires no treatment.

**FIGURE 19-16** Electrocardiographic strip showing the markings for measuring amplitude and duration of waveforms, using a standard recording speed of 25 mm/sec.

**TABLE 19-3 ELECTROCARDIOGRAPHIC CHARACTERISTICS OF NORMAL SINUS RHYTHM**

#### CHARACTERISTIC FINDINGS

Rhythm	Regular, PP intervals and RR intervals may vary as much as 3 mm and still be considered regular
Rate	60-100 beats/min
P waves	One P wave preceding each QRS
PR interval	0.12-0.20 sec, constant
QRS duration	0.04-0.10 sec, constant
QT interval	0.40 sec (varies with rate)

**FIGURE 19-17** Normal sinus rhythm (rate, 64/min).

**Sinus Arrest**

The absence of impulse initiation in the heart results in electrical *asystole*. It is characterized by a flat ECG lacking recognizable waveforms (Figure 19-21). Electrical asystole results in mechanical asystole and zero cardiac output. An escape rhythm from a slower pacemaker will generally begin to fire after several seconds of sinus arrest. Sinus arrest may result from MI, electrical shock, electrolyte disturbances, acidosis, and extreme parasympathetic activity. Prolonged complete electrical asystole is unlikely, and fine ventricular fibrillation may be the underlying rhythm. Sinus arrest may be treatable with a cardiac pacemaker.

**Escape Rhythms**

Escape beats can originate in the AV nodal region or in the ventricular Purkinje fibers. A junctional escape rhythm originates in the AV node, has a rate of 40 to 60 per minute, and has a normal QRS configuration (Figure 19-22). A ventricular escape rhythm originates in the Purkinje fibers, has a rate of 15 to 40 per minute, and is characterized by an abnormally wide QRS complex on the ECG (Figure 19-23). An important clue to identifying escape rhythms is the absence of normal P waves and PR intervals. After the impulse is generated in the Purkinje or nodal cell, it can be conducted backward to the atria (retrograde P wave). Thus, a P wave, if present, may be inverted and located before,

**KEY POINTS**

- Sinus tachycardia (more than 100 beats/min) usually occurs from sympathetic activation of the heart. SNS activation may be compensatory (e.g., occurring in the setting of low blood pressure, low cardiac output, or hypoxemia) or may be due to pain and anxiety.
- Sinus bradycardia (less than 60 beats/min) usually occurs in response to parasympathetic activity. Bradycardia is treated if the slow heart rate precipitates inadequate cardiac output.
- Sinus arrhythmia is usually normal and more pronounced in young persons than in older adults.
- Sinus arrest may lead to prolonged intervals of electrical asystole and zero stroke volume until another pacemaker begins to fire. An artificial pacemaker may be required.

**Abnormal Site of Impulse Initiation**

Initiation of a cardiac impulse at a site other than the SA node occurs primarily for two reasons. First, SA node failure may allow a slower pacemaker to take over. Takeover by a slower pacemaker is called an *escape rhythm*. Second, enhanced excitability, triggered activity, or reentrant circuits may cause a premature depolarization and override the SA node.

FIGURE 19-18 Sinus tachycardia (rate, 150/min).

FIGURE 19-19 Sinus bradycardia (rate, 35/min).

FIGURE 19-20 A, Sinus arrhythmia is a normal finding that may be particularly pronounced in children. B, Sick sinus syndrome. The strip shows alternating periods of tachycardia and bradycardia.

during, or after the QRS complex. Escape rhythms are usually poorly tolerated because they are slow and associated with decreased cardiac output. Failure of the sinus node can be managed with a pacemaker.

### Atrial Dysrhythmias

**Premature atrial complexes and tachycardia.** Premature atrial complexes (PACs) originate in the atria but not at the SA node. The PAC occurs earlier than normal, is preceded by a P wave, and has a normal QRS configuration (Figure 19-24). P waves preceding the PAC usually have a different shape (morphology) than the sinus beats. Sometimes the PAC is not conducted through the AV node to the ventricle and is not followed by a QRS complex (nonconducted P wave). Isolated or rare PACs are not clinically significant. However, frequent PACs may indicate an underlying pathophysiologic process and may be precursors to more serious dysrhythmias. Paroxysmal focal atrial tachycardia is a burst of atrial complexes resembling several PACs in a row (Figure 19-25). The rhythm is regular at a usual rate of 130 to 240 beats/min. It may be difficult to distinguish this rhythm from sinus tachycardia; however, differences in P-wave configuration are usually apparent. The period of atrial tachycardia may last for minutes, hours, or days and can result in ischemia. Patients may perceive atrial tachycardia as palpitations and may experience chest pain. Focal atrial tachycardia can occur in persons with no underlying heart disease in response to emotional stress or drugs. An episode may start as a PAC that has an abnormally

FIGURE 19-21 Electrical asystole.

FIGURE 19-22 Junctional escape rhythm (rate, 59/min).

FIGURE 19-23 Ventricular escape rhythm (rate, 33/min).

slow conduction time through the atria and AV node. This is thought to allow the wave of depolarization to reexcite previously depolarized cells, resulting in reentry and perpetuation of the abnormal rhythm.

**Atrial flutter and fibrillation.** Atrial flutter is typically manifested by a rapid atrial rate of 240 to 350 beats/min and a characteristic sawtooth pattern of atrial depolarizations (Figure 19-26). There is overlap in the mechanism of atrial tachycardia and atrial flutter, and several types of flutter have been described. These are commonly categorized according to atrial rate; type I (typical) has rates of 240 to 350 beats per minute, and type II has rates in excess of 350 beats per minute. The QRS configuration is normal; however, some of the atrial depolarizations do not conduct through the AV node, resulting in a slower ventricular rate. The ventricular rate may be irregular if there is a variable block or may be regular if there is a uniform block, such as 2:1 or 3:1. Reentry is the probable mechanism for typical atrial flutter. Persons exhibiting atrial flutter usually have underlying heart disease, fluid overload, or atrial ischemia.

Atrial fibrillation is a completely disorganized and irregular atrial rhythm accompanied by an irregular ventricular rhythm of variable rate (Figure 19-27). The atrial impulses appear as small, squiggly waves of

FIGURE 19-24 Premature atrial complex (arrow). Note early P wave and different P wave morphology.

FIGURE 19-25 Paroxysmal focal atrial tachycardia (PFAT) followed by transition to normal sinus rhythm (NSR).

**FIGURE 19-29** Premature ventricular complex.

**FIGURE 19-28** Junctional tachycardia (rate, 108/min). Note that P waves follow the QRS waves because of retrograde depolarization spreading from the atrioventricular node to the atria. This rhythm may also be called supraventricular tachycardia.

**FIGURE 19-30** Ventricular tachycardia (rate, 178/min).

various sizes and shapes. Atrial fibrillation is sustained by multiple reentrant “wavelets” that continually change in size and direction. The majority of atrial depolarizations are blocked at the AV node, with few reaching the ventricles and initiating ventricular contraction. Atrial fibrillation causes the atria to quiver rather than to contract forcefully. This allows blood to become stagnant in the atria and may lead to formation of thrombi. Atrial fibrillation may occur intermittently or be sustained in the long term. Patients with chronic atrial fibrillation often are treated with anticoagulant medications to prevent atrial clot formation. Atrial fibrillation is a significant risk factor for cerebrovascular stroke. Patients with heart failure may experience more symptoms when they are in atrial fibrillation because the usual “atrial kick” that normally adds 15% to 20% more blood to the ventricle before systole is lost and therefore cardiac output may be reduced. Cardioversion with an electrical shock to the chest is commonly used to manage atrial fibrillation. Numerous antidysrhythmic agents can be used to convert atrial fibrillation to sinus rhythm or control the ventricular response rate, including calcium channel blockers,  $\beta$ -blockers, digitalis, and amiodarone.

### Junctional Dysrhythmias

Premature junctional complexes can be initiated in two junctional zones: in the area just proximal to the AV node, where atrial fibers enter; or in the area just distal to the AV node, where nodal fibers enter the bundle of His. The impulse spreads upward into the atrium, causing a P wave, and downward into the ventricle, causing a normally configured QRS complex. The P wave may precede, follow, or be buried in the QRS complex. Premature junctional beats have the same clinical significance as PACs and are generally well tolerated.

Junctional tachycardia is a rapid junctional discharge in the range of 70 to 140 beats/min (Figure 19-28). The rhythm resembles a series of junctional premature beats, with P waves preceding, following, or buried in the QRS complexes. Differentiation of the electrocardiographic pattern produced by junctional tachycardia from that

produced by atrial tachycardia is often difficult, and the term *supraventricular tachycardia* may be used for both.

### Ventricular Dysrhythmias

**Premature ventricular complexes.** Premature ventricular complexes (PVCs) arise from the ventricular myocardium. The impulse depolarizes the ventricles but does not activate the atria or depolarize the sinus node. Thus, the normal rhythm of sinus discharge is not disturbed. The normal sinus impulse is generally buried in the bizarre-looking QRS complex from the premature ventricular beat. The sinus impulse does not result in a QRS complex because the ventricles are refractory from the premature depolarization. The next sinus beat occurs just when it would have occurred normally if there had been no premature beat. Thus, the interval between the sinus beat preceding the premature beat and the sinus beat following the premature beat is twice the regular interval (Figure 19-29). This is known as a *compensatory pause* and helps confirm the diagnosis of PVCs. The QRS of the premature complex is prolonged (more than 0.10 second) and bizarre in appearance. The T wave is usually in a direction opposite to the main QRS deflection. Premature ventricular beats are commonly associated with coronary artery disease, drug overdose, and electrolyte disturbances—particularly hypokalemia and hypomagnesemia. The clinical significance depends in part on the frequency of the premature beats. The PVCs may occur at regular intervals, such as bigeminy (every other beat) or trigeminy (every third beat). With high frequency, cardiac output may be compromised. Frequent PVCs may be managed with antidysrhythmic drugs, such as amiodarone. However, prophylactic use of antidysrhythmic drugs in patients with asymptomatic disease is not recommended. In some groups (e.g., after MI), certain antidysrhythmics have been linked to higher mortality.<sup>19</sup>

**Ventricular tachycardia.** Ventricular tachycardia consists of 3 or more consecutive ventricular complexes at a rate greater than 100 beats/min (Figure 19-30). The rhythm is fairly regular, and the complexes generally have the same configuration (monomorphic). With rapid rates, it may be difficult to distinguish the QRS complexes from the ST segments and T waves, and the ECG depicts a series of large, wide, undulating waves. The sinus node usually continues to discharge independently of the ventricular rhythm, and P waves, if seen, are not associated with the QRS complexes.

FIGURE 19-31 Ventricular fibrillation.

Reentry is the probable mechanism of ventricular tachycardia in most cases, although automaticity and triggered activity have also been implicated. Ventricular tachycardia is often associated with myocardial ischemia and infarction. Damage to the myocardium alters conduction times and conduction pathways, which sets the stage for reentry loops. High catecholamine levels and an abnormal electrolyte balance may contribute to the dysrhythmogenesis.

Ventricular tachycardia is a serious dysrhythmia that is nearly always indicative of significant heart disease. It may be fatal unless it is successfully and rapidly managed. Ventricular tachycardia may compromise cardiac output, resulting in loss of consciousness. Treatment consists of administration of antidysrhythmic drugs and, if necessary, cardiopulmonary resuscitation and electrical cardioversion.

**Ventricular fibrillation.** Ventricular fibrillation is a rapid, uncoordinated cardiac rhythm that results in ventricular quivering and lack of effective contraction. The rhythm is generally easily identified, particularly when assessment of the patient indicates absence of pulse and loss of consciousness. The ECG is rapid and erratic, with no identifiable QRS complexes (Figure 19-31). Ventricular fibrillation results in death if not reversed within minutes.

The same conditions that result in ventricular tachycardia may cause ventricular fibrillation. A critically timed premature beat or accelerating ventricular tachycardia may be the precursor to ventricular fibrillation. The ventricular depolarization is thought to be fractionated into a number of localized reentrant currents within the myocardial mass. The uncoordinated depolarizations are sustained because of variability in conduction velocities and refractory periods.

Ventricular fibrillation must be rapidly identified and managed with cardiopulmonary resuscitation and defibrillation with electrical current. Defibrillation differs from cardioversion in that the administration of current is not synchronized with the R wave and the amount of energy delivered is greater (200 to 350 J). The earlier the defibrillation is performed, the better is the chance for successful resuscitation. In some instances, the ventricular fibrillation pattern is very fine and is similar to the tracing seen in atrial arrest. Defibrillation is still indicated. Defibrillation and cardiopulmonary resuscitation are usually followed by administration of antidysrhythmic drugs.

#### KEY POINTS

- Failure of the SA node to generate impulses may result in a junctional or ventricular escape rhythm. These rhythms are slow and may be poorly tolerated. Absence of P waves is important in determination of escape rhythms.
- In most cases, premature beats and ectopic rhythms are attributed to reentry mechanisms. Reentry circuits may be established when portions of the heart have abnormal conduction rates or pathways. Enhanced automaticity and triggered activity are alternative mechanisms for generation of ectopic complexes.

- Atrial dysrhythmias include premature atrial complexes, tachycardia, flutter, and fibrillation. Atrial dysrhythmias are usually well tolerated unless the ventricular response rate is significantly altered.
- Junctional tachycardias are difficult to distinguish from atrial tachycardias and they are often regarded together as supraventricular tachycardias.
- Frequent PVCs, ventricular tachycardia, and ventricular fibrillation are associated with a significant fall in cardiac output and must be rapidly diagnosed and managed.

FIGURE 19-32 First-degree atrioventricular block. PR interval, 0.32 second.

### Conduction Pathway Disturbances

Disorders of cardiac impulse conduction include delays, blocks, and abnormal pathways. Cardiac ischemia and infarction commonly are associated with conduction blocks and delays, whereas abnormal pathways are usually congenital.

#### Disturbances of Atrioventricular Conduction

A disturbance in conduction between the sinus impulse and its associated ventricular response has been called *atrioventricular block*. The conduction may be abnormally slowed or completely blocked. The AV block results from a functional or pathologic defect in the AV node, bundle of His, or bundle branches. Three categories of AV block have traditionally been described: first-degree block, second-degree block (which includes types I and II), and third-degree (complete) block. These AV conduction disorders are associated with different pathologic processes and clinical implications.

*First-degree block* is generally identified by a prolonged PR interval (more than 0.20 second) on the ECG (Figure 19-32). The rhythm remains regular, and each P wave is associated with a QRS complex. First-degree block is a common finding and may occur in the absence of organic heart disease. Drugs and organic heart disorders, such as myocardial ischemia and congenital heart defects, may cause first-degree block. First-degree block is generally monitored but is not actively managed except to alleviate the underlying cause if possible.

*Second-degree block* is diagnosed when some of the atrial impulses are not conducted to the ventricles. Two types of second-degree block are identified by the pattern of nonconducted impulses. Type I (Mobitz type I, Wenckebach) is associated with progressively lengthening PR intervals until one P wave is not conducted (dropped beat). The pattern repeats, causing the QRS complexes to occur in groups. The PP intervals are constant, whereas the RR intervals vary (Figure 19-33). Type I second-degree block is usually due to reversible ischemia of the AV node, often associated with acute MI. The ischemic node is slow to recover after each depolarization, resulting in a longer and longer nodal delay until one impulse is not conducted. This gives the AV node time to recover, and the next atrial impulse is conducted more quickly, with a nearly normal PR interval, beginning the cycle again. Treatment

**FIGURE 19-33** Second-degree atrioventricular block, type I (Wenckebach, Mobitz type I). Note the progressive lengthening of the PR interval until one P wave is not conducted (dropped).

**FIGURE 19-34** Second-degree atrioventricular (AV) block, type II (Mobitz type II). Every third P wave is followed by a QRS complex. The other P waves are not conducted through the AV node. The PR interval on conducted impulses is constant.

**FIGURE 19-35** Complete third-degree atrioventricular block. Note that there is no relationship between P waves and QRS complexes because the atria and ventricles are depolarizing independently.

is rarely required. If the block progresses to a type II block, a pacemaker may be required.

Type II second-degree block is identified by the presence of non-conducted P waves (dropped beats) with a consistent PR interval (Figure 19-34). The QRS complex is usually, but not always, wide (0.12 second or greater). Type II block is generally associated with pathologic lesion of the bundle of His, the right bundle branch, or both. It is the bundle branch block that causes the QRS complexes to be abnormally wide. Type II second-degree block is less common than type I but is more serious. It is usually associated with anterior septal MI or fibrosis of the conduction system. Type II block may progress to complete heart block with slow ventricular escape rhythm and poor cardiac output. Type II block may also result in severe bradycardia because of the number of dropped beats. Symptomatic type II block may require implantation of a pacemaker.

*Third-degree block* may occur as a result of a pathologic lesion of the AV node, bundle of His, or bundle branches. No impulses are conducted from the atria to the ventricles, and a junctional or ventricular escape rhythm is evident. The ECG shows regularly occurring P waves

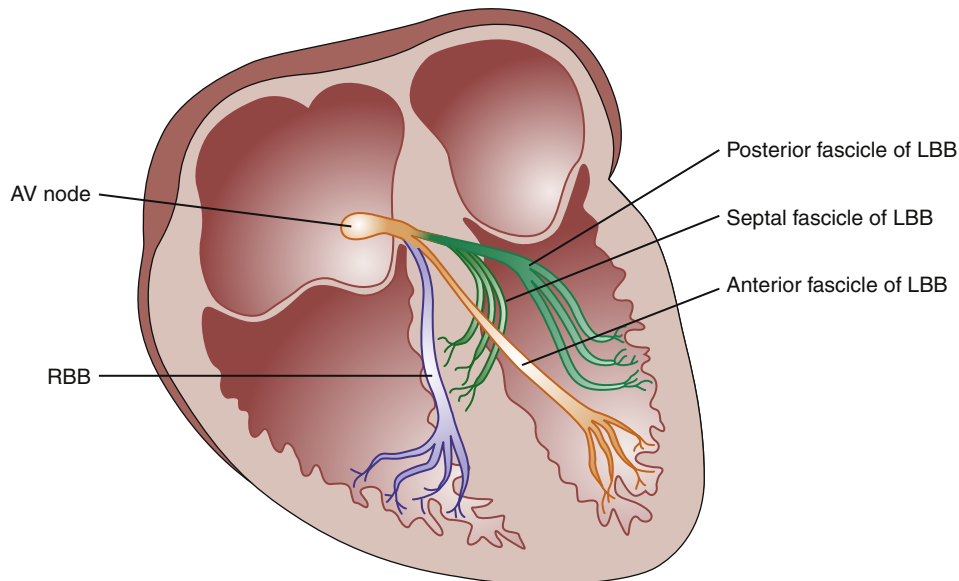

that are totally independent of the ventricular rhythm (Figure 19-35). If the QRS complex is narrow, the block is most likely in the AV node, proximal to the bundle of His. A prolonged QRS interval (more than 0.12 second) indicates pathology distal to the bundle of His, within the bundle branches. The severity of symptoms is determined primarily by the heart rate, with slower rhythms being more serious. A pacemaker is generally required.

### Abnormal Conduction Pathways

Some individuals have congenital abnormalities of the cardiac conduction system called *accessory pathways*. These extra conduction tracts provide alternative pathways for depolarization of the heart, resulting in abnormally early ventricular depolarizations following atrial depolarizations. The best known of these preexcitation syndromes is Wolff-Parkinson-White syndrome. This syndrome is caused by accessory pathways that originate in the atria, bypass the AV node, and enter a site in the ventricular myocardium. This results in more rapid activation of the ventricle, a short PR interval, initial slurring of the QRS ( $\delta$  wave), and a wide QRS complex (Figure 19-36). The accessory

**FIGURE 19-36** Electrocardiogram in lead II from a patient with Wolff-Parkinson-White syndrome. Note the slurred upstroke of the R wave (delta wave). (From Conover MB: *Understanding electrocardiography*, ed 8, St Louis, 2003, Mosby, p 288.)

**FIGURE 19-37** The right bundle branch (RBB) innervates the right ventricle. The left bundle branch (LBB) has three divisions: the posterior, septal, and anterior fascicles. AV, Atrioventricular.

pathway may provide a mechanism for reentry and the development of supraventricular tachycardia. Identification and treatment of individuals with preexcitation syndromes is desirable to prevent symptoms of supraventricular tachycardia and to reduce the possibility of deterioration of the rhythm to atrial or ventricular fibrillation. Antidysrhythmic agents and measures to interrupt the pathway, such as vagal stimulation or ablation, may be used.

### Intraventricular Conduction Defects

Abnormal conduction of impulses through the intraventricular bundle branches is called *bundle branch block*. The two primary bundles are the right bundle branch, which supplies the right ventricle, and the left bundle branch, which supplies the left ventricle. The left bundle branch is further divided into three fascicles: anterior, posterior, and septal (Figure 19-37). These supply the anterior, posterior, and septal portions of the left ventricle, respectively. Slowed or obstructed conduction occurring in one or more of these bundles results in abnormal ventricular depolarization and wide, bizarre-appearing QRS complexes. Bundle branch blocks are best detected with ECG leads  $V_1$  and  $V_6$ .

Right bundle branch block may be present in almost any form of heart disease. It is occasionally found in individuals having no clinical evidence of heart disease. Right bundle branch block can progress to complete heart block in some cases. The electrocardiographic pattern is indicative of blocked conduction to the right ventricle such that the left ventricle depolarizes first, then spreads to the right ventricle. Right bundle branch block is classically associated with a late R wave in lead  $V_1$  and an S wave in  $V_6$ . These changes are compared with the normal  $V_1$  and  $V_6$  in Figure 19-38.

**FIGURE 19-38** Right bundle branch block pattern. Note late R wave in  $V_1$  and abnormal S wave in  $V_6$ .

Left bundle branch block causes a delay in left ventricular depolarization. The right ventricle is activated first through the right bundle branch, followed by right-to-left activation of the septum and, finally, left ventricular activation. The QRS complex is abnormally wide (more than 0.12 second) but has a nearly normal deflection pattern in  $V_1$  and  $V_6$ . In  $V_1$ , the small R wave normally associated with septal depolarization is absent, and  $V_6$  consists of a wide R wave (Figure 19-39).

**FIGURE 19-39** Left bundle branch block pattern. Note wide S wave in  $V_1$  and wide R wave in  $V_6$ .

Left anterior fascicular block is also called *anterior hemiblock*. Impaired conduction in the anterior fascicle causes the posterior aspect of the left ventricle to be activated first, followed by spread through the left ventricular myocardium in an upward and leftward direction. The electrocardiographic pattern shows small initial R waves followed by large S waves in leads II and III. The duration of the QRS complex is within normal limits.

Left posterior fascicular block (hemiblock) is due to a block in the posterior fascicle of the left bundle, which causes the anterior left ventricle to be activated first, followed by spread in a downward and rightward direction. The electrocardiographic findings include Q wave in leads II, III, and  $aV_F$  and R wave in leads I and  $aV_L$ . These electrocardiographic findings may mimic ventricular hypertrophy or inferolateral MI, making recognition difficult.

Slowed or obstructed conduction may occur simultaneously in more than one bundle or fascicle, leading to the terms *bifascicular block* and *trifascicular block*. For example, a right bundle branch block occurring in conjunction with a left posterior hemiblock is called a *bilateral* or *bifascicular block*. Trifascicular block refers to a bifascicular bundle block (most commonly right bundle branch block with left anterior hemiblock) in addition to a first-degree block (prolonged PR interval). The prolonged PR interval is usually due to incomplete block in the left posterior fascicle. Complete trifascicular block would make it impossible for a supraventricular depolarization to activate the ventricles and would be a third-degree or complete heart block.

### KEY POINTS

- Disturbances of AV conduction are generally referred to as AV blocks. First-degree block is characterized by a prolonged PR interval and usually requires no treatment.
- Two types of second-degree block have been identified. Type I (Wenckebach) is characterized by progressive prolongation of the PR interval until one P wave is not conducted. Type I block is associated with AV nodal ischemia. Type II second-degree block is identified by a rhythm showing a consistent PR interval with some nonconducted P waves. This block is more serious because it has a tendency to progress to complete AV (third-degree) block.
- Third-degree or complete heart block is diagnosed when there is no apparent association between atrial and ventricular conduction. This rhythm is serious, because it is typically associated with slow ventricular rhythm and poor cardiac output.
- Accessory conduction pathways are suspected in persons exhibiting preexcitation syndromes such as Wolff-Parkinson-White syndrome. Severe tachycardias and other reentrant rhythms may occur.
- Disturbances of intraventricular conduction (bundle branch blocks) are characterized by wide, bizarre-looking QRS complexes. Any of the three ventricular fascicles may be affected (right bundle, left anterior fascicle, or left posterior fascicle).

### Treatment

Dysrhythmias are generally treated if they produce significant symptoms or are expected to progress to a more serious level. A number of antidysrhythmic drugs have proved effective in managing many dysrhythmias; however, most have also been shown to cause dysrhythmias (prodysrhythmic).<sup>19</sup> These drugs alter the properties of ion movement across cardiac membranes and affect automaticity as well as the rate and duration of depolarization and repolarization. The major electrophysiologic classes of antidysrhythmic (antiarrhythmic) compounds are summarized in Table 19-4. Treatment may also include measures to improve cardiac output, including pacemakers and drugs to improve contractility and blood pressure. Dysrhythmias causing severely reduced cardiac output, such as severe bradycardia, asystole, ventricular tachycardia, and ventricular fibrillation, require cardiopulmonary resuscitation until an effective cardiac rhythm is established.

Ablation procedures may be effective in eliminating a focus of dysrhythmia generation if one can be identified. An electrophysiologic study is done to evoke and analyze the dysrhythmia, followed by interruption (ablation) of the area generating it. Ablation is accomplished with high-frequency radio waves (radioablation) or by surgical excision. The electrophysiologic study requires insertion of electrodes directly into the heart by way of a venous or arterial catheter. The electrodes are used to record activity in specific locations and to deliver electric shocks to initiate or terminate an abnormal rhythm.<sup>21</sup> This test is useful in assessing responses to drug therapy and in identifying risk for sudden cardiac arrest. Those at high risk may benefit from insertion of implantable defibrillators that detect lethal rhythms and apply an electric shock to convert the rhythm.

**TABLE 19-4 CLASSIFICATION OF DRUG ACTIONS BASED ON MODIFICATION OF VULNERABLE PARAMETER**

MECHANISM	DYSRHYTHMIA	VULNERABLE PARAMETER (EFFECT)	DRUGS (EFFECT)
<b>Automaticity</b>			
Enhanced normal	Inappropriate sinus tachycardia Some idiopathic ventricular tachycardias	Phase 4 depolarization (decrease)	$\beta$ -Adrenergic blocking agents Na <sup>+</sup> channel blocking agents
Abnormal	Atrial tachycardia	Maximum diastolic potential (hyperpolarization) Phase 4 depolarization (decrease)	Muscarinic receptor subtype 2 (M <sub>2</sub> ) agonists Ca <sup>2+</sup> or Na <sup>+</sup> channel blocking agents; M <sub>2</sub> agonists
	Accelerated idioventricular rhythms	Phase 4 depolarization (decrease)	Ca <sup>2+</sup> or Na <sup>+</sup> channel blocking agents
<b>Triggered Activity</b>			
Early afterdepolarization (EAD)	Torsades de pointes	Action potential duration (shorten)	$\beta$ -Adrenergic agonists, vagolytic agents (increase rate)
		EAD (suppress)	Ca <sup>2+</sup> channel blocking agents; Mg <sup>2+</sup> ; $\beta$ -adrenergic blocking agents
Delayed afterdepolarization (DAD)	Digitalis-induced dysrhythmias	Calcium overload (unload)	Ca <sup>2+</sup> channel blocking agents
		DAD (suppress)	Na <sup>+</sup> channel blocking agents $\beta$ -Adrenergic blocking agents
	Right ventricular outflow tract ventricular tachycardia	Calcium overload (unload) DAD (suppress)	Ca <sup>2+</sup> channel blocking agents; adenosine
<b>Na<sup>+</sup> Channel-Dependent Reentry</b>			
Long excitable gap	Typical atrial flutter	Conduction and excitability (depress)	Types IA, IC Na <sup>+</sup> channel blocking agents
	Circus movement tachycardia in Wolff-Parkinson-White syndrome (WPW)	Conduction and excitability (depress)	Types IA, IC Na <sup>+</sup> channel blocking agents
Short excitable gap	Sustained uniform ventricular tachycardia	Conduction and excitability (depress)	Na <sup>+</sup> channel blocking agents
	Atypical atrial flutter	Refractory period (prolong)	K <sup>+</sup> channel blocking agents
	Atrial fibrillation	Refractory period (prolong)	K <sup>+</sup> channel blocking agents
	Circus movement tachycardia in WPW	Refractory period (prolong)	Amiodarone, sotalol
	Polymorphic and uniform ventricular tachycardia	Refractory period (prolong)	Type IA Na <sup>+</sup> channel blocking agents
	Bundle branch reentry	Refractory period (prolong)	Type IA Na <sup>+</sup> channel blocking agents; amiodarone
	Ventricular fibrillation	Refractory period (prolong)	K <sup>+</sup> channel blocking agents
<b>Ca<sup>2+</sup> Channel-Dependent Reentry</b>			
	Atrioventricular nodal reentrant tachycardia	Conduction and excitability (depress)	Ca <sup>2+</sup> channel blocking agents
	Circus movement tachycardia in WPW	Conduction and excitability (depress)	Ca <sup>2+</sup> channel blocking agents
	Verapamil-sensitive ventricular tachycardia	Conduction and excitability (depress)	Ca <sup>2+</sup> channel blocking agents

## SUMMARY

Heart failure may result from a number of cardiac and noncardiac disorders that diminish myocardial contractility or impose an excessive workload on the heart. Heart failure is a clinical diagnosis based on characteristic signs and symptoms. Decreased cardiac output to the tissues results in decreased renal blood flow, fluid retention, activity intolerance, and mental fatigue. Backward effects are due to congestion of blood behind the ineffectively pumping ventricle. With left-sided heart failure, the congestion is located in the lungs and produces a number of signs and symptoms, including dyspnea, orthopnea, hypoxemia, crackles, and frank pulmonary edema. Isolated right-sided heart failure causes congestion in the systemic venous system leading to congestion and dysfunction of the liver, spleen, and kidney, as well as peripheral subcutaneous edema and distended neck veins. In the early stages HF may be asymptomatic, and attention to risk factors and early structural abnormalities of the heart may allow early intervention. Two types of HF have been described based on EF. Those with low ejection fraction are commonly described as having systolic failure. Those with normal EF, usually defined as greater than 50%, usually have diastolic failure. Many patients with low EF have both systolic and diastolic dysfunction.

Three major compensatory mechanisms operate to maintain cardiac output in the failing heart: (1) sympathetic activation,

(2) increased preload, and (3) cardiac muscle cell hypertrophy. Unfortunately, these mechanisms also increase myocardial workload and oxygen requirements and may trigger neurohormonal dysregulation and ventricular remodeling associated with HF progression and decompensation. Progression of HF is related to myocardial remodeling characterized by myocyte loss and myocardial fibrosis. Therapies that slow the remodeling process may slow the progression of heart failure. The primary aims of therapy are to improve cardiac output, minimize congestive symptoms and cardiac workload, and slow the detrimental remodeling process.

*Dysrhythmia* refers to an abnormality of electrical impulse generation or conduction. Dysrhythmias may occur in association with a number of cardiac and noncardiac disorders. Disturbances in electrical activity of the heart can indicate underlying pathophysiologic processes but are not themselves primary medical diseases. Dysrhythmias are significant because they can signal underlying pathophysiologic disorders and can disrupt normal cardiac output. Dysrhythmias can be categorized into three major types: (1) abnormal rates of sinus rhythm, (2) abnormal sites of impulse initiation, and (3) disturbances in conduction pathways. Treatment for dysrhythmias centers on maintaining adequate cardiac output, providing antidysrhythmic drugs as needed, and diagnosing and managing the underlying pathologic process.

Shock is a life-threatening condition characterized by insufficient delivery of oxygenated blood to the microcirculation, resulting in tissue hypoxia and cellular dysfunction. In 1895, John Collins Warren described shock as a momentary pause in the act of death.<sup>1</sup> In spite of advances in the understanding and management of shock, it still has a high rate of mortality. This chapter presents an overview of circulatory shock, including the major causes, cellular and systemic pathogenesis, clinical manifestations, and general therapeutic management.

### PATHOGENESIS OF SHOCK

Shock is characterized by an imbalance between oxygen supply and oxygen requirements at the cellular level.<sup>2</sup> When the cell does not have adequate amounts of oxygen and nutrients, it is unable to meet its metabolic demands. Cellular hypoxia results in impaired cellular function and may progress to irreversible organ damage and death. The causes of circulatory shock classically are divided into four general types: cardiogenic, obstructive, hypovolemic, and distributive.<sup>3</sup>

### BOX 20-1 ETIOLOGY OF CIRCULATORY SHOCK

#### Cardiogenic Shock

Myocardial infarction  
 Cardiomyopathy  
 Valvular heart disease  
 Ventricular rupture  
 Congenital heart defects  
 Papillary muscle rupture

#### Obstructive Shock

Pulmonary embolism  
 Cardiac tamponade  
 Tension pneumothorax  
 Dissecting aortic aneurysm

#### Hypovolemic Shock

Acute hemorrhage  
 Dehydration from vomiting, diarrhea  
 Overuse of diuretics  
 Burns  
 Pancreatitis

#### Distributive Shock

Anaphylaxis  
 Neurotrauma  
 Spinal cord trauma  
 Spinal anesthesia  
 Sepsis

Each of these types is associated with a number of primary causes (Box 20-1). Cardiogenic shock results from heart disorders that cause inadequate cardiac output despite sufficient vascular volume. Obstructive shock develops when circulatory blockage disrupts cardiac output, such as a large pulmonary embolus or cardiac tamponade. Because the causes of obstructive shock are associated with failure of the heart to pump sufficiently, some sources include obstructive shock within the category of cardiogenic shock. Hypovolemic shock is associated with loss of blood volume as a result of hemorrhage or excessive loss of extracellular fluids, such as through vomiting, diarrhea, or excessive diuresis. Distributive shock is characterized by a greatly expanded vascular space because of inappropriate vasodilation. Vasodilation leads to hypotension and altered perfusion of tissues. Anaphylactic, neurogenic, and septic are forms of distributive shock. Each type of shock has certain unique features (Table 20-1), but all are associated with impaired tissue oxygenation that can progress to refractory shock and organ failure.

### Impaired Tissue Oxygenation

The common denominator of all forms of shock is impaired oxygen utilization by cells, which disrupts function and, if ongoing or severe, may lead to cell death, organ dysfunction, and stimulation of inflammatory reactions. Recent discoveries about the contribution of inflammatory reactions in the pathogenesis of shock have provided new insight into this complicated syndrome.

The reason for impaired oxygen utilization by cells differs with the various types of shock, but the outcomes are similar. A continuous supply of oxygen is needed by cells to allow sufficient production of energy in the form of adenosine triphosphate (ATP). Inadequate oxygen availability at the cellular level quickly impairs aerobic metabolism of

### TABLE 20-1 COMPARISON OF CLINICAL FINDINGS IN DIFFERENT TYPES OF SHOCK

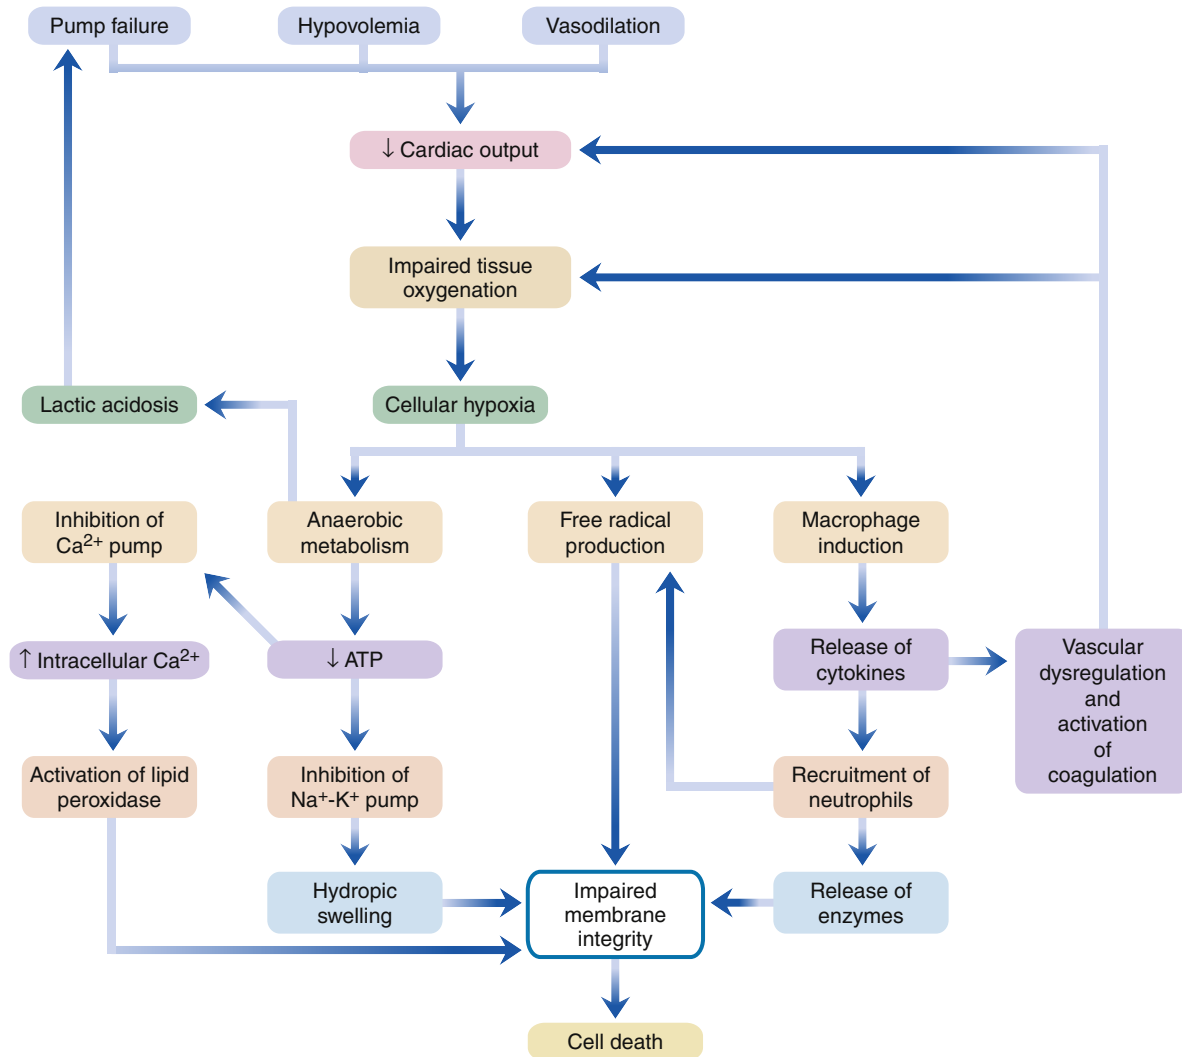

PARAMETER	CARDIOGENIC	HYPOVOLEMIC	SEPTIC
Hypotension	Yes	Yes	Yes
Systemic vascular resistance	High	High	Low
Cardiac output	Low	Low	High
Cardiac preload	High	Low	Low
Venous oxygen saturation	Low	Low	High
Urine output	Low	Low	Low
Skin temperature	Cool	Cool	Warm

glucose, fatty acids, and amino acids and causes the cells to rely on the relatively inefficient processes of glycolysis to produce cellular ATP. (A review of ATP synthesis can be found in Chapter 3.) Glycolysis is the enzymatic process of converting glucose to pyruvate, with the net production of two ATP molecules per glucose molecule. If oxygen were available, pyruvate would normally enter the mitochondria and proceed through the citric acid cycle. In the absence of cellular oxygen, the citric acid cycle is inhibited and pyruvate accumulates in the cytoplasm. Pyruvate accumulation would quickly inhibit further glycolysis and shut down ATP production entirely if not for the conversion of pyruvate to *lactate*. Lactate diffuses from the cell and into the extracellular fluid, and accumulation of lactate in the bloodstream (more than 5 to 6 mmol/L) is considered a sign of significant tissue hypoxia.<sup>4,5</sup>

An inadequate supply of cellular ATP inhibits energy-requiring cellular functions, including maintenance of ion concentrations across the plasma membrane. Because of their steep electrochemical gradients, extracellular sodium and calcium ions tend to leak into the cell. ATP-dependent pumps in the cell membrane are needed to continuously pump these ions back out. Failure of ion pumps leads to sodium and water accumulation in the cell (hydropic swelling) and an excess of intracellular free calcium. Intracellular calcium ions trigger a cascade of cellular events that further impair energy production and plasma membrane integrity. Cell death from oxygen deprivation takes from minutes to several hours, depending on the rate of cellular metabolic activity. However, even a short period of oxygen deprivation often sets in motion a complex cascade of events that lead to further cell damage (Figure 20-1). Two important aspects of this cascade are (1) formation of oxygen free radicals, and (2) induction of inflammatory cytokines.

Ischemic cells may produce oxygen free radicals when oxygen supplies are restored. This process has been called *reperfusion injury*. Reactive oxygen molecules include superoxide ( $O_2^-$ ), peroxide ( $H_2O_2$ ), hydroxyl radicals ( $OH^-$ ), and singlet oxygen ( $O$ ). These molecules are unstable and will attack membrane structures, denature proteins, and damage DNA. Another source of oxygen free radicals is immune cells, particularly neutrophils, which are recruited to the area of tissue injury. Thus, cellular injury may continue and progress long after the initial hypoxic insult has been resolved.

The role that immune cytokines play in shock has been studied extensively in septic shock. The roles of these cytokines are thought to be similar in the late stages of other types of shock as well. Macrophages and tissue cells are stimulated to release inflammatory cytokines in response to hypoxic tissue injury and, in the case of septic shock, in response to endotoxin or other microorganism antigens.<sup>6</sup> The levels of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-1 (IL-1) cytokines in particular have been shown to increase in the bloodstream

**FIGURE 20-1** Shock is a complex process involving cellular hypoxia, free radical formation, and systemic inflammation. All forms of shock are associated with impaired tissue oxygenation, which triggers a cascade of events leading to tissue injury and death. *ATP*, Adenosine triphosphate.

of patients with septic shock, and these cytokines are thought to be important mediators of vascular failure and progressive organ damage.<sup>6</sup> Numerous other immune cytokines and neurohormonal mediators have been implicated in the pathogenesis of shock (Table 20-2). These mediators represent potential therapeutic targets for a disorder that is notoriously difficult to manage effectively.

A hallmark of shock is failure of the microcirculation to appropriately autoregulate blood flow. Normal tissues are able to match blood flow with metabolic needs across a wide range of blood pressures. This property ensures that blood flow is evenly distributed to tissues according to metabolic needs. In shock, autoregulation fails, leading to an abnormal distribution of blood flow.<sup>7</sup> Some capillary beds receive inadequate flow and become progressively more hypoxic, whereas other vascular routes are excessively dilated and receive too much flow. Advances in technology have allowed direct visualization of capillary flow through tissue beds and confirmed the presence of perfusion abnormalities in the microcirculation. These abnormalities differ depending on the primary cause of shock.<sup>7</sup> In cases of reduced cardiac output resulting from hypovolemic or cardiogenic shock, there is a homogeneous reduction in blood flow through a given tissue's arterioles, capillaries, and venules that is directly related to the severity of cardiac output reduction. In

distributive shock states, such as septic shock, the degree of microcirculatory flow is heterogeneous within a tissue, with some capillaries being closed and others open. Often there is high flow rate through some of the venules and the degree of microcirculatory dysfunction is poorly correlated with systemic hemodynamics. Overall, this imbalance leads to a so-called *oxygen debt* in the tissues. It has been suggested that the overall oxygen debt can be estimated clinically by the serum lactate level and degree of metabolic acidosis, both of which imply a switch to anaerobic metabolism by oxygen-deprived tissues.<sup>5</sup>

In septic shock, immune cytokines are believed to be at the root of the microcirculatory maldistribution problem. TNF- $\alpha$ , IL-1, and other inflammatory mediators induce vascular cells to produce excessive amounts of the vasodilator nitric oxide.<sup>6</sup> Nitric oxide in normal quantity is thought to be protective for tissues during shock, whereas excessive production is detrimental. Nitric oxide is produced in endothelial cells and vascular smooth muscle by two enzymes: nitric oxide synthase (NOS) and inducible nitric oxide synthase (iNOS). TNF- $\alpha$  and IL-1 increase the activity of iNOS and thereby cause excessive production of nitric oxide (Figure 20-2). Efforts to minimize the microcirculatory oxygen debt in early shock and to quickly restore adequate microcirculatory blood flow distribution, as evidenced by normalized

**TABLE 20-2 IMMUNE CYTOKINES AND NEUROHORMONES ASSOCIATED WITH CIRCULATORY SHOCK**

MEDIATOR	ASSOCIATED DYSFUNCTION
IL-1 $\alpha$	Inflammation, vasodilation, vascular leakiness
IL-1 $\beta$	Inflammation, vasodilation, vascular leakiness
IL-6	Fever, increased acute phase protein
TNF- $\alpha$	Inflammation, neutrophil activation
IL-10	Antiinflammatory, may suppress shock
TGF- $\beta$	Fibrosis, pulmonary edema
PAF	Platelet activation, chemotaxis
PAI-1	Increased clotting, thrombosis
Substance P	Proinflammatory
Chemokines	Neutrophil recruitment and binding to vessel endothelium
Nitric oxide	Vasodilator
C5a	Chemotactic
Protein C	Inhibits thrombus formation
Vasopressin	Improves vascular tone and responsiveness to NE/E
Cortisol	Antiinflammatory, improves vascular response to NE/E
Endothelin	Vasoconstriction
Adrenomedullin	Vasodilation
Norepinephrine	Vasoconstriction
Epinephrine	Inotropic, bronchodilation
Leukotrienes	Inflammation, bronchospasm
Histamine	Increased vascular permeability, edema
Heparin	Inhibits action of histamine
Angiotensin II	Vasoconstriction
Heat-shock proteins	Protect protein structure and function, inhibit apoptosis

serum lactate concentration and acid-base balance, are an important focus of therapy for all types of shock.

### Compensatory Mechanisms and Stages of Shock

A number of compensatory responses are set in motion to restore tissue perfusion and oxygenation in the early stage of shock. Historically, these responses to shock have been divided into three clinical stages: compensated shock, progressive shock, and refractory shock. Although these stages may be useful for determining prognosis and the likelihood of the patient's recovering, shock is viewed as a continuum in which compensatory mechanisms become progressively less effective as function of the microcirculation becomes increasingly impaired.

Insufficient cardiac output and decreased effective tissue perfusion are early defects in all types of shock. Insufficient cardiac output may be a consequence of an ineffective cardiac pump (cardiogenic, obstructive) or insufficient blood volume to fill the vascular space (hypovolemic, distributive). A number of compensatory mechanisms are triggered in response to inadequate cardiac output in an attempt to restore adequate perfusion pressure (Figure 20-3). Baroreceptors located in the aorta and carotid arteries quickly sense the decrease in pressure and transmit signals to the vasomotor center in the brainstem medulla. Stimulation of the sympathetic nervous system (SNS) results in increased cardiac output and vascular resistance. Because blood pressure is determined by the

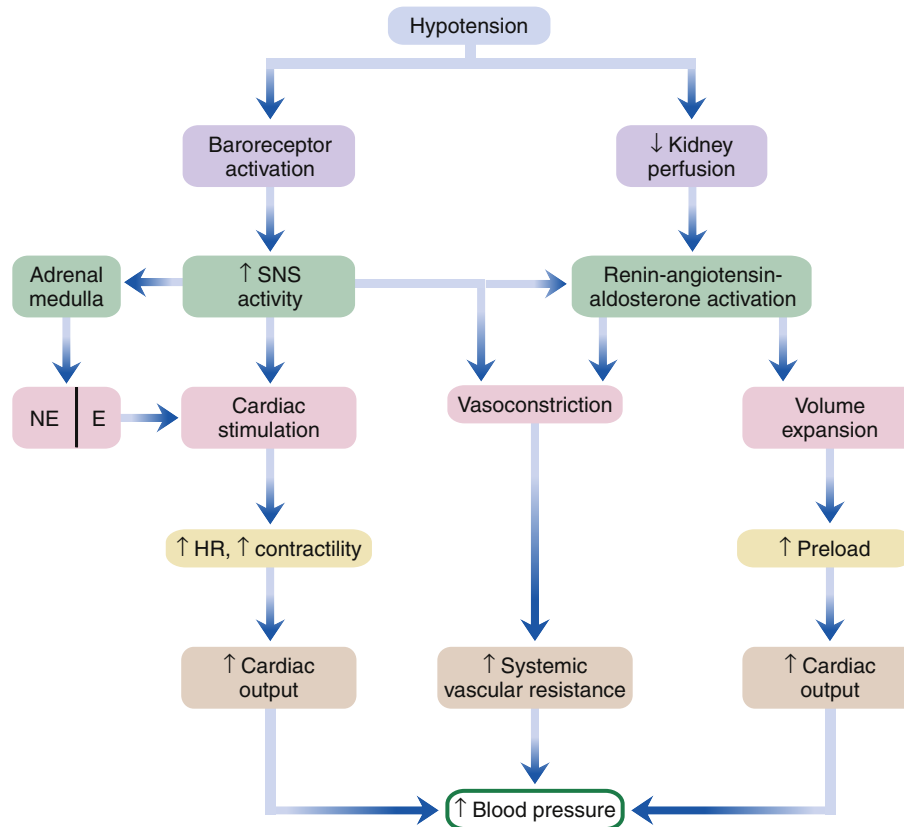

**FIGURE 20-2** Excess production of nitric oxide is an important mechanism of vascular failure in shock. The tumor necrosis factor- $\alpha$  and interleukin-1 cytokines are promoters of inducible nitric oxide synthase. These cytokines are released from macrophages that have been activated by tissue injury or toxins. *IL-1*, Interleukin-1; *TNF- $\alpha$* , tumor necrosis factor- $\alpha$ .

product of cardiac output and vascular resistance, an increase in one or both of these factors will help restore blood pressure. The SNS increases cardiac output through several mechanisms. The adrenal medulla is stimulated to release increased amounts of the catecholamines epinephrine and norepinephrine (NE), which circulate to the heart and stimulate  $\beta_1$  receptors. The  $\beta_1$  receptors respond by increasing the heart rate and force of contraction in an attempt to increase cardiac output. The SNS also enhances venous return to the heart by constricting systemic arterioles and venules. Arterial vasoconstriction reduces flow through the capillary bed, which causes hydrostatic pressure in the capillaries to fall. Fluid reabsorption from interstitial spaces helps increase blood volume and improve preload. Blood vessels in the skin, kidneys, and gastrointestinal tract constrict and shunt blood to the heart and brain.

The SNS stimulates cells in the kidney to release renin, which triggers the renin-angiotensin-aldosterone system (RAAS). Renin is also secreted from the kidneys in response to decreased blood flow and pressure in the afferent arterioles. Renin triggers the formation of angiotensin II, which is a potent vasoconstrictor and also stimulates kidney nephrons to conserve sodium and water. Conservation of volume by the kidney is further enhanced by aldosterone, which is secreted from the adrenal cortex in response to angiotensin II (Ang II). Reabsorption of fluid from the kidney helps increase blood volume and enhances venous return to the heart. Another hormone, antidiuretic hormone (vasopressin), is secreted from the posterior pituitary in response to reduced blood volume. Antidiuretic hormone stimulates the kidney tubules to reabsorb water and improves the vascular response to catecholamines. In shock, urine output may fall to zero as the kidneys attempt to conserve fluid to maintain blood volume and cardiac output. Unfortunately, the kidney tubules often sustain damage because of the low-flow state, which may result in the complication of acute renal failure.

These compensatory mechanisms work well in the early stage of hypovolemic shock and may maintain blood pressure within the normal range until the volume of blood loss becomes too great (Figure 20-4). In other forms of shock, compensatory mechanisms are less effective in restoring cardiac output. In cardiogenic shock, the compensatory responses may

**FIGURE 20-3** Compensatory mechanisms are triggered in shock to help maintain arterial blood pressure despite a fall in cardiac output. *E*, Epinephrine; *HR*, heart rate; *NE*, norepinephrine; *SNS*, sympathetic nervous system.

**FIGURE 20-4** In early stages of hypovolemia, blood pressure is stable even though cardiac output is falling. When volume losses equal about 25% of the total blood volume, blood pressure falls precipitously. (Redrawn from Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 274.)

worsen the already high preload and impose a greater workload on the failing heart. In distributive shock, the vasculature is not responsive to SNS signals to constrict. Blood pools in the peripheral tissues, which makes it difficult for the heart to maintain cardiac output despite sympathetic stimulation to increase the heart rate and contractility.

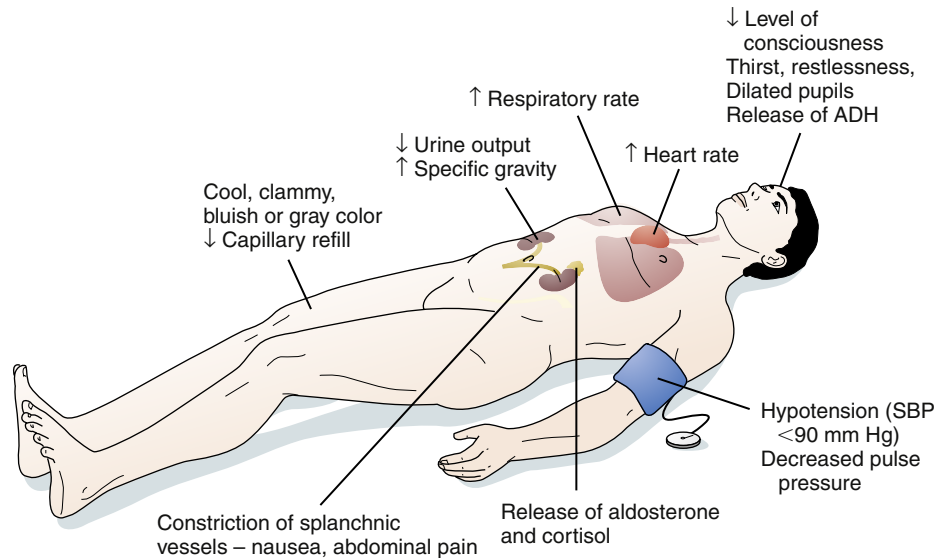

The early, compensated stage of shock may be difficult to detect clinically (Figure 20-5). A high index of suspicion is needed in patients with heart failure, trauma, blood loss, and severe infection. In addition, the following clinical findings may be present:

- A narrow pulse pressure with or without hypotension
- Tachycardia greater than 100 beats/min

- Fast and deep respirations
- Decreased urinary output
- Increased urine specific gravity
- Cool, clammy skin
- Altered mentation
- Dilated pupils

At some point, which is highly variable and differs among individuals depending on age, comorbidities, and specific etiology, the compensatory mechanisms can no longer sustain adequate perfusion to tissues and cells begin to suffer significant hypoxic injury. This condition is sometimes called the *progressive stage of shock*. Active therapeutic intervention is required at this stage or the patient will probably not survive. As previously described, reduced delivery of oxygen to tissues results in hypoxic injury, free radical damage, and stimulation of the inflammatory response. Lactic acidosis may occur during the progressive stage of shock. In addition to being a marker of anaerobic metabolism, lactate can alter the acid-base balance of the blood and create metabolic acidosis. Metabolic acidosis places a greater burden on the respiratory and renal systems and may contribute to further dysfunction. Metabolic acidosis can affect electrolyte balance and contribute to cardiac dysrhythmias and conduction disturbances. In addition, myocardial depressant factors are released that impair myocardial contractility.<sup>8</sup> These factors contribute to reduced cardiac output and a progressive cycle of worsening tissue hypoxia.

As shock continues to progress, the vascular system begins to fail. Arterioles become unresponsive to catecholamines and previously constricted vascular beds begin to dilate. Widespread dilation and low cardiac output combine to produce severe hypotension. The low blood pressure is not sufficient for organ perfusion. At this stage the effects of shock produce more shock processes. Tissue

**FIGURE 20-5** Classical manifestations of shock. *ADH*, Antidiuretic hormone; *SBP*, systolic blood pressure.

damage often activates the clotting cascade, which contributes to sluggish blood flow, vascular thrombosis, and more severe tissue ischemia. Release of inflammatory mediators, along with vascular occlusion, may precipitate organ failure. The kidney, liver, and lung are particularly susceptible. At some point, the stage of refractory shock occurs and the patient becomes unresponsive to therapeutic interventions.

The progressive stage of shock is characterized by the following clinical manifestations:

- Low blood pressure, usually lower than 90 mm Hg
- Narrow pulse pressure
- Tachycardia
- Acute renal failure (e.g., oliguria, increased levels of blood urea nitrogen and serum creatinine)
- Decreased level of consciousness
- Increased respiratory rates
- Metabolic and respiratory acidosis with hypoxemia

#### KEY POINTS

- Shock represents a diverse group of life-threatening circulatory conditions. The common factor among all types of shock is hypoperfusion and impaired cellular oxygen utilization. Inadequate cellular oxygenation may result from decreased cardiac output, maldistribution of blood flow, or reduced blood oxygen content.
- During the compensatory stage of shock, homeostatic mechanisms are sufficient to maintain adequate tissue perfusion despite a reduction in cardiac output. Manifestations of SNS activation are an elevated heart rate, increased myocardial stimulation, bronchodilation, vasoconstriction, cool clammy skin, dilated pupils, and decreased urine output. Blood pressure is maintained even though cardiac output has fallen.
- During the progressive stage of shock, compensatory mechanisms begin to fail and hypotension and progressive tissue hypoxia result. Shift of cells to anaerobic metabolism results in lactate production and metabolic acidosis. A lack of cellular ATP production leads to cellular swelling, dysfunction, and death. Generation of oxygen free radicals, release of inflammatory cytokines, and activation of the clotting cascade lead to further cellular and organ dysfunction.

## TYPES OF SHOCK

In addition to the general pathophysiology of shock just described, each type of shock has special features that affect prevention, diagnosis, and treatment. These features are briefly reviewed here, and the reader is referred to the specific chapters that describe the primary disorders that predispose to shock, including cardiogenic (Chapters 18 and 19), hypovolemic (Chapter 24), anaphylactic (Chapter 10), neurogenic (Chapter 44), and septic (Chapter 8).

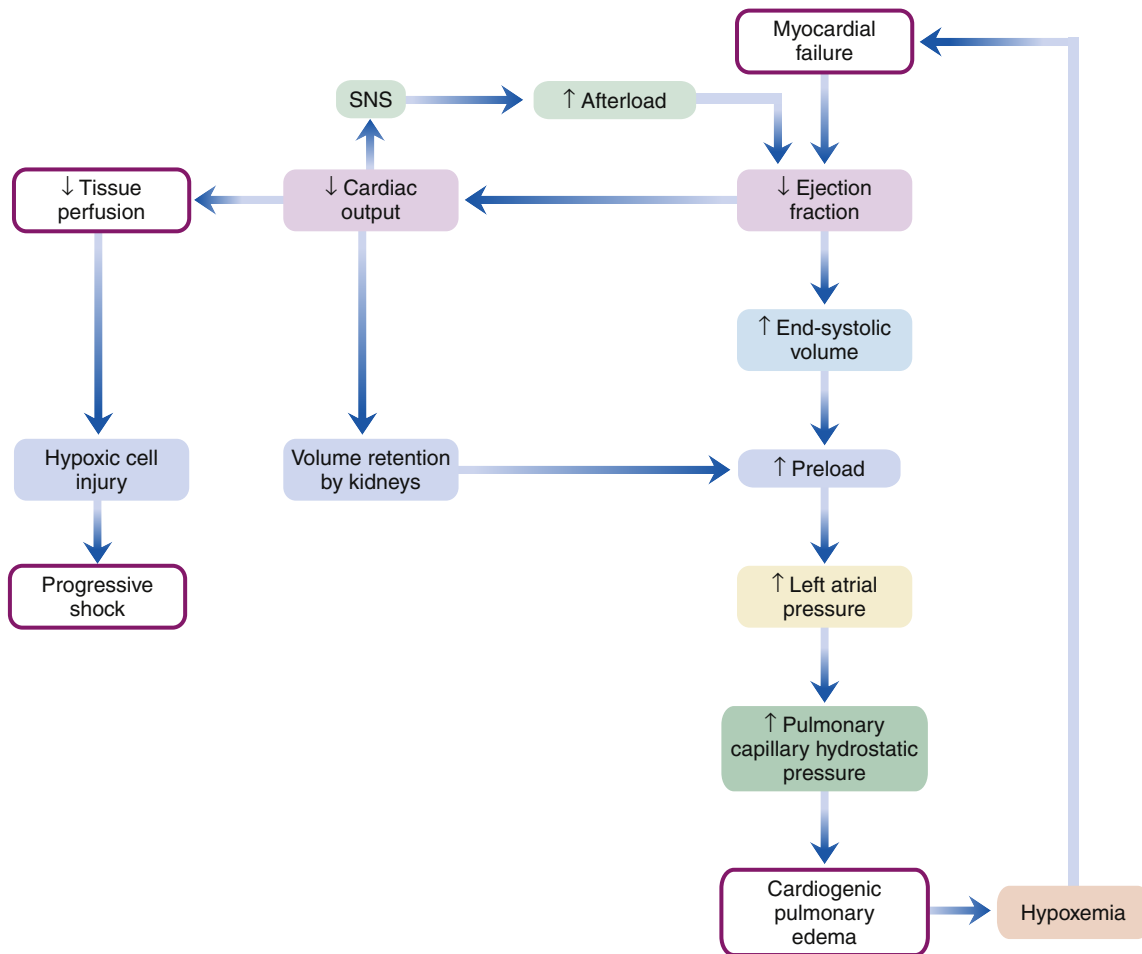

### Cardiogenic Shock

**Etiology and pathogenesis.** Cardiogenic shock occurs primarily as a result of severe dysfunction of the left, right, or both ventricles that results in inadequate cardiac pumping. The most common cause of cardiogenic shock is myocardial infarction resulting in a significant dysfunction or loss (greater than 40%) of left ventricular myocardium.<sup>9</sup> Other causes of cardiogenic shock include right ventricular myocardial infarction, end-stage cardiomyopathy, papillary muscle dysfunction, free wall rupture, and congenital heart defects.

The low cardiac output state is associated with a high left ventricular diastolic filling pressure (preload), a finding that differentiates cardiogenic from hypovolemic forms of shock (Figure 20-6). High left ventricular preload leads to movement of fluid from the pulmonary vascular beds into the pulmonary interstitial space, which initially results in interstitial pulmonary edema and later in alveolar pulmonary edema.

The SNS is stimulated as a compensatory mechanism to increase cardiac output. The result is an increase in heart rate and systemic vascular resistance. High systemic vascular resistance increases the workload on the heart. Activation of the RAAS results in further increases in resistance and preload. The net effect of the activation of compensatory mechanisms is to increase myocardial workload and oxygen demand. Consequently, the compensatory responses can precipitate further cardiac damage and cause a progressive decline in cardiac output.

**Clinical manifestations.** Sympathetic nervous stimulation increases the heart rate and vascular resistance, which maintain blood pressure even though cardiac output has decreased. As compensatory mechanisms fail, systolic blood pressure falls and diastolic pressure increases

**FIGURE 20-6** Cardiogenic shock results in decreased tissue perfusion and cardiogenic pulmonary edema because of reduced myocardial function, usually associated with left ventricular failure. SNS, Sympathetic nervous system.

(as a result of the sympathetic stimulation), thus narrowing the pulse pressure. Heart rates exceed 100 beats/min. Peripheral vasoconstriction occurs and produces cool, clammy skin. Auscultation of the lungs reveals coarse crackles resulting from pulmonary edema. An  $S_3$  summation gallop may be audible over the left apex as a result of increased preload in the left ventricle.

Frequent assessments of cardiac output and cardiac index are helpful in the clinical treatment of a patient in cardiogenic shock. A pulmonary artery catheter may be inserted to measure cardiac index and left heart filling pressures (e.g., pulmonary capillary occlusion pressure). Pulmonary artery pressures are increased, with the pulmonary capillary occlusion pressure typically being greater than 15 mm Hg (normal, less than 12 mm Hg).<sup>9</sup> When pulmonary capillary occlusion pressure acutely increases, pulmonary congestion may develop because fluid shifts from the capillary into the interstitial and alveolar spaces. Patients with chronic congestive heart failure may not develop pulmonary edema until pulmonary occlusion pressures exceed 20 to 40 mm Hg. Arterial blood gas values initially demonstrate a respiratory alkalosis secondary to hyperventilation. As pulmonary edema progresses, respiratory acidosis with hypoxemia may occur. Hypoxemia further impairs myocardial function.

Determination of mixed venous oxygen levels in blood samples obtained from the pulmonary artery catheter is helpful in assessing the adequacy of cardiac output. Decreased tissue oxygen delivery because of low cardiac output increases the degree of oxygen extraction. Mixed

venous blood samples show decreased venous oxygen saturation ( $SvO_2$ ) with a decreased cardiac output. An increase in mixed venous oxygenation would be expected with improved cardiac output.

**Treatment.** Cardiogenic shock is difficult to manage because the underlying myocardial damage is often not reversible. Prevention of cardiogenic shock through measures to limit infarct size during acute myocardial ischemia is desirable. Early efforts to restore coronary perfusion are associated with a decrease in the incidence of cardiogenic shock after myocardial infarction.<sup>9,10</sup> (A discussion of reperfusion therapy can be found in Chapter 18.)

The goal of treatment for cardiogenic shock is to decrease myocardial oxygen demands, increase myocardial oxygen delivery, and increase cardiac output. It is difficult to achieve these goals because interventions to increase cardiac output tend to increase myocardial oxygen demands.

**Pharmacotherapy.** Positive inotropic drugs are frequently used in the management of cardiogenic shock to increase contractility. Positive inotropes include  $\beta$ -adrenergic agonists such as NE, dobutamine, and dopamine and phosphodiesterase inhibitors that prevent the degradation of cyclic adenosine monophosphate (cAMP). These drugs have the ability to increase contractility, increase cardiac output, and increase tissue perfusion; however, these drugs increase myocardial oxygen demand. NE is the natural neurotransmitter of the sympathetic nerves and mimics SNS activation by increasing heart rate, contractility, and vascular resistance. Dobutamine increases contractility by

stimulating  $\beta$  receptors. However, unlike NE or dopamine, dobutamine has minimal  $\alpha$ -receptor activity. The major effect of dobutamine is on contractility rather than heart rate. Dobutamine may contribute to a decrease in vascular resistance and must be used with caution in hypotensive patients.<sup>11</sup> Vasodilators may be used to decrease the workload of the heart by decreasing left ventricular afterload. Examples of commonly used vasodilators include nitroprusside and nitroglycerin.

**Mechanical assist devices.** Cardiogenic shock is sometimes managed by mechanical assist devices. For temporary management, **intraaortic** balloon counterpulsation may be indicated.<sup>12</sup> A catheter with a balloon at the distal segment is inserted through the femoral artery and positioned in the aorta just distal to the left subclavian artery. The balloon is connected to a console that triggers the balloon to inflate in diastole and deflate in systole. The effect of balloon inflation during diastole is to increase perfusion pressure of the coronary arteries. Sudden deflation of the balloon just before ventricular systole creates a vacuum effect in the aorta that reduces left ventricular afterload. A reduction in afterload decreases left ventricular workload and increases stroke volume. Balloon counterpulsation restricts mobility and is associated with a number of vascular complications. Long-term management of patients with low cardiac output can be achieved with mechanical pumps that take over the function of the ventricle or ventricles (ventricular assist devices). Ventricular assist devices (VADs) are commonly used in patients waiting for a heart transplant. In some cases, the temporary decrease in cardiac workload afforded by the VAD is associated with significant improvement in cardiac structure and function, and the device can be removed.

#### KEY POINTS

- Cardiogenic shock is usually a result of severe ventricular dysfunction associated with myocardial infarction. Other causes include cardiomyopathy, ventricular rupture, and congenital heart defects.
- Diagnostic features of cardiogenic shock include decreased cardiac output as a result of left ventricular dysfunction, along with elevated left ventricular end-diastolic pressure,  $S_3$  heart sounds, and pulmonary edema. Sympathetic activation leads to an increased heart rate, vasoconstriction, and a narrow pulse pressure.
- Low cardiac output leads to reduced oxygen delivery to tissues. Tissues extract a greater percentage of oxygen from the delivered blood, which leads to reduced  $SvO_2$ .
- Therapy is aimed at improving cardiac output and myocardial oxygen delivery while reducing cardiac workload. Pharmacologic treatment often includes the use of inotropic agents, afterload-reducing agents (e.g., vasodilators), and preload-reducing agents, such as venodilators and diuretics. Intraaortic balloon counterpulsation may be used to reduce afterload and improve coronary artery perfusion. Ventricular assist devices may be used for longer-term circulatory support, whereas heart transplantation provides definitive treatment.

### Obstructive Shock

**Etiology.** Obstructive shock develops when the heart is prevented from pumping because of a mechanical obstruction to blood flow. Impaired ventricular filling leads to reduced cardiac output and signs and symptoms similar to cardiogenic shock, and is considered by many to be a form of cardiogenic shock. Causes of mechanical obstruction include pulmonary embolism, cardiac tamponade, and tension pneumothorax. Prompt relief of the obstruction is necessary to restore cardiac output and prevent cardiovascular collapse.

**Clinical manifestations.** Obstructive shock is usually characterized by manifestations of right-sided heart failure. Depending on the

location of the obstruction, elevated pressures in the cardiac chambers may be evident.

Pulmonary embolism results in elevated right-sided heart pressures, but left-sided pressures remain normal to low. Pulmonary emboli are usually generated in the veins of the lower extremities in patients with immobility, trauma, or hypercoagulable states. Pulmonary embolism is manifested as sudden, severe dyspnea and deteriorating arterial blood gas values. A perfusion scan of the lung may demonstrate an area of reduced blood flow. Pulmonary emboli are not generally detectable by chest radiographs.

Cardiac tamponade, which results from an accumulation of fluid in the pericardial sac, causes elevation of pressures on both the right side and the left side of the heart. Despite the elevated pressure, preload in the heart chambers is low, as is stroke volume. The elevated pressure is due to external compression of the heart chambers. Risks for the development of cardiac tamponade include pericarditis, blunt trauma to the chest, and cardiac surgical procedures. In pericarditis, a pericardial friction rub can sometimes be heard and may help with the diagnosis.

Tension pneumothorax results in shifting and compression of mediastinal structures, including the heart, which compromises left ventricular filling. Accumulation of air in the pleural space may occur because of trauma or spontaneous rupture of lung parenchyma. A tension pneumothorax develops when the air in the pleural space begins to exert a positive pressure on lung and mediastinal structures. A deviated trachea and decreased or absent breath sounds may occur. Arterial blood gas values can deteriorate rapidly. Tension pneumothorax is detectable by chest radiography.

**Treatment.** Management of obstructive shock is aimed at identifying and removing the offending obstruction. Compensatory mechanisms are generally ineffective in obstructive shock, and the patient's condition may deteriorate rapidly.

#### KEY POINTS

- Obstructive shock results from mechanical obstructions that prevent effective cardiac filling and stroke volume.
- Pulmonary embolism, cardiac tamponade, and tension pneumothorax are common causes of obstructive shock.
- Prompt management of the underlying obstruction is necessary to prevent cardiovascular collapse.

### Hypovolemic Shock

**Etiology and classification.** Hypovolemic shock results when circulating blood volume is inadequate to perfuse tissues.<sup>13</sup> The pathogenesis of early stage hypovolemic shock is straightforward: decreased intravascular volume leads to a decrease in venous return, which causes a decrease in cardiac output (Figure 20-7). The decrease in cardiac output results in decreased tissue perfusion and decreased oxygen delivery.

Circulatory volume deficits may be the result of internal or external losses. Internal losses can result from internal hemorrhage, fracture of long bones, or leakage of fluid into the interstitial spaces. External losses can result from external hemorrhage, burns, severe vomiting and diarrhea, or diuresis. External hemorrhage is the most common cause of hypovolemic shock.

The American College of Surgeons stratifies hemorrhagic shock into four classes according to the degree of blood volume lost (Table 20-3).<sup>3</sup> These values are based on a 70-kg adult and are guidelines that may not apply to all patients with hemorrhage, depending on etiology, rate of blood loss, and comorbidities.

The initial stage hemorrhage (Class I) occurs with blood loss up to 750 ml or 15% of total blood volume. Compensatory mechanisms

maintain cardiac output, and the patient's vital signs remain within the normal range. Class II compensated hemorrhage is categorized as blood loss between 750 and 1500 ml (15% to 30% of total blood volume). The patient becomes anxious and restless. Blood pressure remains normal when the patient is supine but decreases upon standing (orthostatic hypotension). The heart rate is between 100 and 120 beats/min. The respiratory rate is normal to mildly increased. Urine output is between 20 and 30 ml/hr. The capillary refill time may be prolonged. (The capillary blanch test is performed by depressing a patient's fingernail and observing how long after release the skin color takes to return to normal. Normal capillary refill times are less than 2 seconds.)

Class III hemorrhage (progressive stage) is blood loss between 30% and 40% of total blood volume (1500 to 2000 ml). The patient is anxious and confused. Blood pressure is decreased with a narrow pulse pressure. The heart rate is greater than 120 beats/min. Respiratory rates are between 30 and 40 respirations/min. Urine output is 5 to 20 ml/hr. The capillary refill test is prolonged.

Severe Class IV hemorrhage (refractory stage) occurs when more than 40% of total blood volume is lost (2000 ml or more). The patient

is lethargic and has severe hypotension with a narrow pulse pressure. The heart rate usually exceeds 140 beats/min, and the respiratory rate is markedly increased. Urine output is negligible. The capillary refill test is prolonged.

The clinical features of other forms of hypovolemic shock are similar to those of hemorrhagic shock, although the volume loss has usually occurred more gradually.

**Clinical manifestations.** The cardiac output and cardiac index are found to be decreased. Pulmonary artery pressures and pulmonary capillary wedge pressures are decreased because of the decreased preload. The finding of a low preload distinguishes hypovolemic shock from cardiogenic shock. In cardiogenic shock, preload is high and cardiac output is low. In hypovolemic shock, preload and cardiac output are both low.

Systemic vascular resistance is increased as a result of sympathetic activation. This increase is a compensatory mechanism in hypovolemia to maintain perfusion pressure. SvO<sub>2</sub> may be decreased because of decreased oxygen delivery and increased oxygen extraction.

**Treatment.** The first intervention for hemorrhagic shock is to control the source of blood loss. Second, volume losses are replaced with appropriate fluids to normalize blood pressure, cardiac output, and perfusion of the microvasculature. In severe, uncontrolled hemorrhage, efforts to increase blood pressure should be postponed until the hemorrhage is under control.<sup>13</sup> Otherwise, the increased blood pressure may worsen the hemorrhage. In all types of hypovolemic shock, fluid replacement is the primary therapy. The three main types of fluid therapy agents are colloids, crystalloids, and blood products. There continues to be controversy about which type of fluid is the most appropriate for resuscitation of hypovolemic shock.

**Colloids** are solutions that increase the serum colloid osmotic pressure within the vascular compartment. Increased colloid pressure pulls fluid from the interstitium into the vascular space. Examples of colloid solutions are normal human serum albumin, dextran, and hetastarch. Colloids generally are not recommended for hypovolemic shock unless the patient has significant interstitial edema.

**Crystalloids** are solutions that contain electrolytes. Isotonic solutions such as lactated Ringer solution or normal saline solution are commonly used crystalloid solutions. Isotonic fluids are preferred over hypotonic solutions because isotonic solutions remain in the extracellular space and are more effective in increasing blood volume. Isotonic crystalloid fluids are preferred for volume resuscitation in hypovolemic shock that is not associated with severe anemia.<sup>14</sup>

When significant anemia accompanies hypovolemia, *blood products* may be the treatment of choice. In hemorrhagic shock, whole blood or packed red blood cells (RBCs) with saline may be given to replace blood volume loss. Significant anemia may contribute to tissue hypoxia simply because of reduced oxygen-carrying capacity; however, recent research suggests that RBCs may also regulate capillary blood flow by

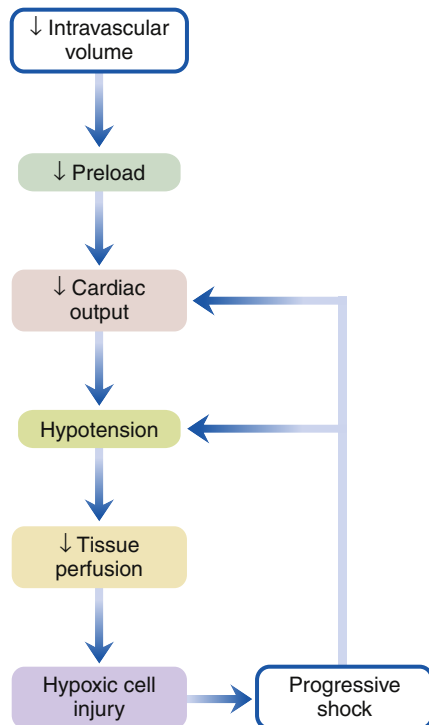

FIGURE 20-7 Pathogenesis of Hypovolemic Shock.

TABLE 20-3 CLASSIFICATION OF HEMORRHAGIC SHOCK

	CLASS I (INITIAL STAGE)	CLASS II (COMPENSATED STAGE)	CLASS III (PROGRESSIVE STAGE)	CLASS IV (REFRACTORY STAGE)
<b>Blood loss (ml)</b>	≤750 (15%)	750-1500 (15-30%)	1500-2000 (30-40%)	>2000 (>40%)
<b>Clinical features</b>	Minimal tachycardia Normal or increased pulse pressure	Tachycardia Tachypnea Decreased pulse pressure Cool, clammy skin Delayed capillary refill Slight anxiety	Tachycardia Tachypnea Decreased systolic blood pressure Oliguria Changes in mental status such as confusion and agitation	Marked tachycardia Decreased systolic blood pressure Narrowed pulse pressure Markedly decreased urinary output Loss of consciousness Cold, pale skin

releasing vasodilating substances, including ATP, into the microcirculation under conditions of hypoxia. Significant reduction in RBC flow through capillaries has been suggested as a mechanism for further impairing microcirculatory function.<sup>2</sup>

In general, pharmacologic agents are not indicated for hypovolemia. Restoration of blood volume is essential. However, in some cases of shock, blood pressure remains low despite large amounts of fluid replacement, so vasoconstrictor agents must be used to support blood pressure.

#### KEY POINTS

- Hypovolemic shock results from inadequate circulating blood volume precipitated by hemorrhage, burns, dehydration, or leakage of fluid into interstitial spaces.
- The classic features of hypovolemic shock are the result of low cardiac output and low intracardiac pressures. Manifestations are due primarily to SNS activation: elevated heart rate, vasoconstriction, and increased myocardial contractility.
- The severity of symptoms of hemorrhagic shock correlates with the amount of blood loss; however, there is significant variation in the clinical presentation of hypovolemic and hemorrhagic shock and careful assessment is required to diagnose it in the early stages.
- Therapy for hypovolemic shock is aimed at fluid replacement and control of the source of volume loss. Colloids, isotonic crystalloids, and blood products may be used as replacement fluids.

### Distributive Shock

Distributive shock is characterized by an abnormally expanded vascular space caused by excessive vasodilation. Vasodilation results in peripheral pooling of blood in the venous capacitance vessels and creates a relative hypovolemia. Preload and stroke volume are insufficient to maintain perfusion of the brain and tissues. Anaphylactic, neurogenic, and septic are the types of distributive shock. All are characterized by vasodilation and profound hypotension, but the cause and pathogenesis of each type differ significantly.

#### Anaphylactic Shock

**Etiology and pathogenesis.** Type I anaphylactic reactions involve an antigen/immunoglobulin E (IgE) antibody reaction on the surface of mast cells and basophils. IgE antibodies attach to receptor sites on these cells, where they await activation by specific antigens. Exposure to that antigen causes receptors on mast cells and basophils to cross-link and become activated. A host of vasoactive chemicals are released, including histamines, leukotrienes, bradykinins, and prostaglandins.<sup>15</sup> These substances result in bronchoconstriction, peripheral vasodilation, and increased capillary permeability. (A detailed discussion of type I anaphylaxis can be found in Chapter 10.) In some cases, mast cell degranulation is triggered by a mechanism that does not involve IgE. These reactions may be called *anaphylactoid* (Box 20-2).

Most type I anaphylactic reactions are mild and do not result in shock. Even in more severe anaphylaxis, prompt treatment can prevent the shock syndrome.<sup>16</sup> Shock occurs when peripheral dilation is massive, and a type of hypovolemic shock is precipitated. In this case, blood volume may be normal but the sudden enlargement of the vascular space causes blood to pool in the periphery. In some cases, there is also significant leakage of fluid from the bloodstream into the interstitial spaces.<sup>15</sup> Both of these conditions cause cardiac preload to drop, followed by a decrease in cardiac output.

**Clinical manifestations.** The onset of symptoms is usually within 2 to 30 minutes of exposure to the antigen; however, symptoms may

not develop for several hours.<sup>15</sup> The clinical presentation can vary widely in severity depending on the stimulus and rapidity of therapy. Initially the patient appears very anxious, with an increased heart rate and respiratory rate. Hypotension, urticaria (hives), pruritus (itching), and angioedema then develop. Often the patient has a sense of impending doom. Bronchoconstriction causes wheezing and cyanosis, and laryngeal edema results in hoarseness and stridor.

**Prevention and treatment.** Prevention of anaphylactic shock is achieved by avoidance of precipitating allergens. Anaphylactic shock is most frequently associated with antibiotic therapy, in particular  $\beta$ -lactams.<sup>15</sup> Other common causes include other types of drugs, peanuts and tree nuts, insect stings, and snake bites (see Box 20-2). More than one third of cases are of unknown cause. Anaphylaxis is not a reportable disease, and the incidence is unknown; however, the estimated risk of occurrence is 1% to 3% per person in the United States.<sup>15</sup>

Initial therapy for anaphylactic shock is directed to removing the inciting antigen if possible. Airway management and circulatory support are critical. Tracheal intubation and assisted ventilation may be needed. Bronchodilators can be used to manage bronchospasm. Epinephrine is helpful in stabilizing mast cells to prevent further release of inflammatory mediators and increasing blood pressure.<sup>15</sup> Intravenous fluid therapy is used to increase intravascular volume and fill the enlarged vascular space. Increased preload will enhance cardiac output. A vasopressor may be given in an attempt to constrict the arterioles and raise blood pressure. Steroids may be given for their antiinflammatory effects, but their onset of action tends to be slow. Antihistamines may be administered to block histamine receptors, although their effectiveness is reduced once

### BOX 20-2 COMMON TRIGGERS OF ANAPHYLAXIS

#### Anaphylactic (IgE-Dependent)

##### Foods

- Peanuts
- Tree nuts
- Crustaceans (crab, shrimp)

##### Medications

- $\beta$ -Lactam antibiotics
- Other antibiotics
- Aspirin and other nonsteroidal antiinflammatory drugs

##### Venoms

- Bee sting
- Snake bite

##### Animal proteins

- Cat
- Dog

symptoms are present and the inflammatory mediators have been released.<sup>15</sup> New therapeutics are being developed to target endotoxin and proinflammatory cytokines.<sup>16</sup> Response to therapy for anaphylactic shock is usually rapid with a good outcome if instituted early; however, approximately 1% of anaphylactic episodes are fatal, and the majority of these are associated with antibiotics and nut allergies.<sup>15</sup>

### Neurogenic Shock

Neurogenic shock is often transitory. It may result from depression of the vasomotor center in the medulla or from interruption of sympathetic nerve fibers in the spinal cord. Causes of neurogenic shock include brain trauma that results in depression of the vasomotor center, spinal cord injury, high spinal anesthesia, and drug overdose.

Interruption of the neural pathway for the baroreceptor reflex results in loss of sympathetic tone in the vasculature. Profound peripheral vasodilation of both arterioles and veins occurs and leads to peripheral pooling of blood and hypotension. Decreased venous return to the heart results in decreased cardiac output and hypotension. Body position greatly influences the development of neurogenic shock. When the body is horizontal, venous return may be adequate and cardiac output and blood pressure are sufficient. However, when an upright position is assumed, peripheral pooling from gravitational effects causes a severe drop in cardiac output and blood pressure. Syncope and fainting will follow unless measures are taken to redistribute the blood. Elevation of the legs, slow position changes, and the use of pressure stockings on the legs may help prevent peripheral pooling. Vasoconstricting drugs and fluid expansion may sometimes be used to increase blood pressure if mechanical measures are ineffective. The outcome of neurogenic shock depends in large part on the severity of neurologic injury. Shock resulting from head trauma has a poor prognosis, whereas acute neurogenic shock associated with spinal cord injuries may resolve as spinal cord reflexes return in the weeks following the injury.

### Septic Shock

Septic shock is a common cause of death in intensive care units in the United States, and the incidence continues to increase. Large numbers of immunocompromised individuals in the population and extensive

use of invasive technology contribute to the high rates of septic shock. The mortality associated with septic shock averages between 30% and 50% in various clinical trial registries.<sup>17,18</sup> High mortality is in part because of the underlying diseases that often accompany sepsis, such as trauma, peritonitis, cancer, and immunodeficiency diseases.

**Etiology.** Sepsis results from the presence of microorganisms in the bloodstream (bacteremia). However, most cases of bacteremia do not result in shock. Normally, the body's defense systems effectively destroy the bacteria and prevent widespread dissemination of the infection. Immunocompromised individuals are prone to disseminated infections called *bacteremia* (the term *septicemia* is still in clinical use, but is discouraged because of imprecise meaning). When the body's response to infection or other insults results in systemic signs and symptoms of widespread inflammation, the term *systemic inflammatory response syndrome* (SIRS) is applied. Septic shock is a severe systemic inflammatory reaction to infection that results in abnormal vasodilation, hypotension, and tissue hypoxia attributable to the maldistribution of blood flow. Confusion about the meaning of the terms bacteremia, sepsis, septic shock, and SIRS prompted the planning of a consensus conference to provide definitions for clinical and research purposes (Table 20-4).<sup>19</sup>

Patients at high risk for septic shock include the very young and the elderly. Patients in these age groups are less likely to be able to destroy invading microorganisms. Patients who are debilitated, malnourished, or immunocompromised by acquired immunodeficiency syndrome or chemotherapy or have chronic health problems are also at increased risk. Medical interventions that predispose a patient to septic shock include the use of invasive lines, catheters, and procedures; surgery; and immunosuppressive therapy.

**Pathogenesis.** Septic shock commonly is associated with gram-negative infections. Gram-negative bacteria include *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter aerogenes*, *Serratia marcescens*, *Pseudomonas aeruginosa*, and *Proteus* species.<sup>20</sup> Gram-positive organisms (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*) and fungi (*Candida* species) are also important causes of septic shock. A frequent portal of entry is the genitourinary tract. Other entry sites include the gastrointestinal tract, the respiratory tract, and the skin.

TABLE 20-4 DEFINITIONS RELATED TO SEPSIS

CONDITION	DEFINITION
Bacteremia (fungemia)	Presence of viable bacteria (fungi) in bloodstream
Infection	Inflammatory response to invasion of normally sterile host tissue by microorganisms
Systemic inflammatory response syndrome (SIRS)	Systemic inflammatory response to a variety of clinical insults that can be infectious or noninfectious; response is manifested by two or more of the following conditions: $T > 38^{\circ}\text{C}$ ( $100.4^{\circ}\text{F}$ ) or $< 36^{\circ}\text{C}$ ( $96.8^{\circ}\text{F}$ ); $\text{HR} > 90$ beats/min; $\text{RR} > 20$ breaths/min or $\text{Paco}_2 < 32$ torr; $\text{WBC} > 12,000$ cells/ $\text{mm}^3$ , $< 4000$ cells/ $\text{mm}^3$ , or $> 10\%$ immature (band) forms; positive fluid balance ( $> 20$ ml/kg over 24 hr); hyperglycemia; plasma C-reactive protein/procalcitonin $> 2$ SD above normal value; arterial hypotension; cardiac index $> 3.5$ L/min; arterial hypoxemia; acute oliguria; creatinine increase $> 0.5$ mg/dl; coagulation abnormalities; ileus; platelets $< 100,000/\mu\text{L}$ ; bilirubin $> 4$ mg/dl; hyperlactatemia; decreased capillary refill
Sepsis	SIRS secondary to infection
Severe sepsis	Sepsis associated with one or more organ dysfunctions, hypoperfusion, or hypotension; hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or acute alteration in mental status
Septic shock	Sepsis with persistent hypotension despite fluid resuscitation, along with presence of perfusion abnormalities; patients taking inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured
Refractory septic shock	Persistent septic shock requiring dopamine $> 15$ mcg/kg/min to maintain mean arterial blood pressure
Multiple organ dysfunction syndrome (MODS)	Presence of altered organ function requiring intervention to maintain homeostasis

HR, Heart rate;  $\text{Paco}_2$ , arterial carbon dioxide tension; RR, respiratory rate; SD, standard deviation; T, temperature; torr, mm Hg; WBC, white blood cell count.

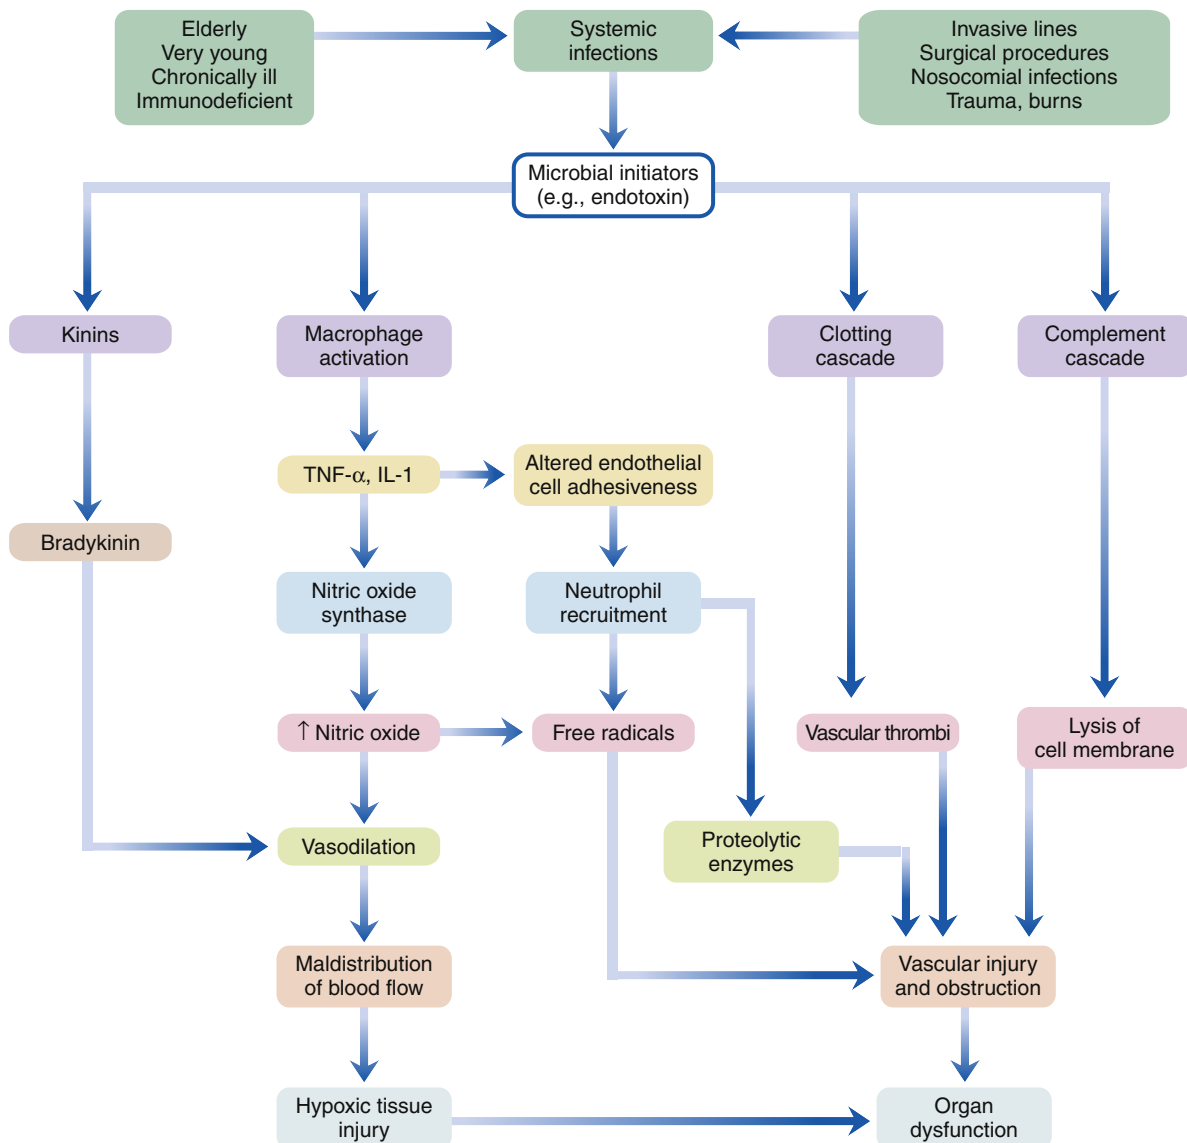

Adapted from Dipiro JT et al, editors: *Pharmacotherapy: a pathophysiologic approach*, ed 8, New York, 2011, McGraw-Hill, p 2042.

Gram-negative bacteria have within their cell walls a lipopolysaccharide or **endotoxin**. The cell wall is composed of an O antigen side chain, an R core, and an inner lipid A, the toxic component of the endotoxin.<sup>20</sup> Endotoxins are released into the blood during bacterial cell lysis and initiate a chain of pathophysiologic events. Macrophages are stimulated by endotoxin to release inflammatory cytokines, including TNF- $\alpha$  and IL-1.<sup>6</sup> As previously described, TNF- $\alpha$  and IL-1 are thought to be major factors in the pathogenesis of septic shock because they stimulate release of more immune cytokines and the overproduction of nitric oxide.

Macrophage cytokines activate neutrophils and platelets, which release many toxic mediators such as platelet-activating factor, oxygen free radicals, and proteolytic enzymes.<sup>6</sup> Activation of the arachidonic acid cascade in neutrophils and platelets results in prostaglandin, leukotriene, thromboxane, and prostacyclin release, all of which have profound effects on vascular smooth muscle. Increased levels of thromboxanes A<sub>2</sub> and B<sub>2</sub> produce pulmonary vasoconstriction, mediate bronchoconstriction, and act as potent platelet aggregators. Prostacyclin is a potent vasodilator and may contribute to the development of hypotension.

A number of other inflammatory cascades are activated in septic shock. The complement system is activated with release of C5a and C3a, and can produce microemboli and endothelial cell destruction. Histamine, a potent vasodilator, is released by mast cells. Histamine also increases capillary permeability, which enhances edema formation. The coagulation system is activated and may enhance the development of thrombi. The kinin system is activated and bradykinin is released, which results in vasodilation and increased capillary permeability. All these immune responses are normal reactions to microbial invasion and are necessary for eradicating infections. In overabundance, however, these mechanisms constitute a systemic inflammatory response that can result in shock. The major components of the complex pathophysiologic processes of septic shock are illustrated in Figure 20-8.

Septic shock is associated with profound peripheral vasodilation. Systemic vascular resistance is decreased, and despite the increased cardiac output, blood pressure falls. The veins also dilate, and intravascular pooling occurs in the venous capacitance system. Because of maldistribution of blood flow, some portions of the

**FIGURE 20-8** Pathophysiologic process of septic shock. Septic shock is characterized by immune-mediated mechanisms of cellular injury and organ dysfunction. *IL-1*, Interleukin-1; *TNF- $\alpha$* , tumor necrosis factor- $\alpha$ .

tissue are underperfused and some are overperfused. Excessive flow to areas of lower metabolic demand limits oxygen extraction, which contributes to a common finding of lower overall oxygen consumption. In the initial stage of septic shock, a relative hypovolemia is present because of the increased size of the vascular compartment. Fluid administration to increase preload to a central venous pressure between 8 and 12 mm Hg is advocated at this stage, even though cardiac output may already be quite high.<sup>21</sup> Cardiac output between 8 and 12 L/min is common in early septic shock. Even this level of cardiac output may be inadequate to perfuse the expanded vascular bed.

The generalized inflammatory response triggered in septic shock affects capillary permeability. Increased capillary permeability results in fluid movement out of the vascular beds into the interstitial space. Generalized soft-tissue edema occurs and can interfere with tissue oxygenation and organ function.

**Clinical manifestations.** In contrast to other forms of shock, the clinical manifestation of early septic shock is a hyperdynamic state characterized by high cardiac output and warm extremities (see Table 20-1).

In the hyperdynamic stage of septic shock, blood pressure falls because of the decreased systemic vascular resistance and decreased venous return. Diastolic pressure declines because of a lack of sympathetic tone, and a widened pulse pressure results. The heart rate and stroke volume increase and cardiac output is higher than normal, but the patient remains hypotensive. The patient is usually febrile and may have associated chills. In contrast to cardiogenic and hypovolemic shock in which the peripheral circulation is reduced and extremities are cool and constricted, the skin is pink and warm to the touch in sepsis as a result of peripheral vasodilation. The patient's level of consciousness may be altered as a result of cerebral ischemia. In septic shock,  $SvO_2$  levels may be higher than normal because of the maldistribution of blood flow. Abnormal vasodilation causes greater flow through areas with low metabolic activity. Oxygen consumption by tissues is decreased because metabolically active tissues do not receive enough flow. Lactic acidosis may be present because of tissue hypoxemia.

In the progressive stage of septic shock, some patients deteriorate to a hypodynamic phase. The hypodynamic phase is characterized by decreased cardiac output and the development of organ ischemia. The pulse pressure narrows and the skin becomes cool and clammy. Profound hypotension unresponsive to catecholamines generally occurs. Arterial blood gas analysis reveals a metabolic and respiratory acidosis with hypoxemia. Myocardial depression either from ischemia or from toxins acting as myocardial depressants contributes to a decreasing cardiac output, deteriorating tissue perfusion, and refractory shock.

**Treatment.** The primary treatment in early septic shock is isotonic fluid administration to restore adequate ventricular preload.<sup>21</sup> If fluid administration does not restore hemodynamic stability, inotropic treatment may be indicated to increase cardiac output and oxygen delivery to tissues.<sup>21</sup> Vascular unresponsiveness to these agents may improve with administration of glucocorticoids. In some cases the normal adrenal production of cortisol may be insufficient and glucocorticoid replacement is helpful. High-dose and high-potency glucocorticoids are not recommended because of their immunosuppressive activity.<sup>21</sup>

Appropriate broad-spectrum antibiotic therapy is started as soon as septic shock is suspected and after quickly obtaining appropriate cultures. Positive blood cultures can be used to narrow the antibiotic regimen to cover the specific microbes; however, blood cultures are negative in about 50% of cases despite the probable presence of

systemic microorganisms.<sup>21</sup> Eradication of the inciting organism reduces the stimulus perpetuating SIRS. Shock itself may propagate sepsis by impairing circulation to the intestinal wall and allowing resident microorganisms to traverse from the colon to the bloodstream. Antibiotic selection for septic shock must be modified as new infective organisms are detected.

Because the inflammatory response is believed to be a critical aspect of septic shock, numerous agents designed to inhibit various components of SIRS have been investigated. Unfortunately, nearly all of these agents have failed to provide significant benefit. Some subgroups of septic patients may be helped by these agents, but overall the trials have been disappointing. Activated protein C is currently recommended for those with severe sepsis and a high-risk score for mortality.<sup>21</sup> Protein C has both antiinflammatory and antithrombotic actions, which may be helpful in sepsis, but the complication of bleeding is common. Therapy for septic shock is complicated and requires intensive monitoring and treatment of complications. These aspects are discussed in the next sections of this chapter.

#### KEY POINTS

- Anaphylactic, neurogenic, and septic shock are types of distributive shock characterized by excessive vasodilation and peripheral pooling of blood. Cardiac output is inadequate because of reduced preload.
- Anaphylactic shock is a result of excessive mast cell degranulation in response to antigen. Mast cell degranulation usually is mediated by IgE antibodies. Release of vasodilatory mediators such as histamine into the circulation by mast cells results in severe hypotension. Urticaria, bronchoconstriction, stridor, wheezing, and itching are usually present. Treatment includes maintenance of airway patency and the use of epinephrine, antihistamines, vasopressors, and fluids to restore blood pressure.
- Neurogenic shock results from loss of sympathetic activation of arteriolar smooth muscle. Medullary depression from brain injury, drug overdose, or lesions of sympathetic nerve fibers, such as spinal cord injury, are the usual causes.
- Septic shock results from a severe systemic inflammatory response to infection. Gram-negative bacteria, gram-positive bacteria, and fungal infections are common causes of septic shock. In gram-negative shock, endotoxins in bacterial cell walls stimulate massive immune system activation. Septic shock from any organism is characterized by release of large numbers of immune mediators (e.g., cytokines) resulting in widespread inflammation. The clotting cascade, complement system, and kinin system are activated as part of the immune response.
- Widespread inflammation leads to profound peripheral vasodilation with hypotension, maldistribution of blood flow with cellular hypoxia, and increased capillary permeability with edema formation.
- Initially, septic shock is characterized by abnormally high cardiac output resulting from immune-mediated vasodilation and sympathetic activation of the heart. The patient is usually febrile, pink, and warm. Even though cardiac output is high, cellular hypoxia is present because of maldistribution of blood flow. Reduced cellular oxygen utilization is manifested as a high  $SvO_2$ .
- Therapy for septic shock is aimed at improving the distribution of blood flow and managing infection with antibiotics. Administration of fluid and drugs to increase cardiac and vascular performance is done to improve the distribution of blood flow.

#### ASSESSMENT AND HEMODYNAMIC MONITORING

Astute assessment and appropriate hemodynamic monitoring are essential for the prevention, detection, and management of shock.

Although new methods of direct visualization of capillary flow are in development, it is not clinically feasible to directly measure the adequacy of cellular oxygenation in all of the body tissues. A number of indirect measures and clinical signs and symptoms are used to help indicate when tissue hypoxia is probably occurring. These same parameters are used to tailor therapy and assess outcomes of that therapy.

Most hospitalized patients experiencing shock will have monitoring devices in place to facilitate assessment of cardiac output, blood pressure, preload, vascular resistance, arterial oxygen content, and venous oxygen content. In addition, frequent measurement of serum lactate concentration, acid-base status, and urine output can be used to indirectly assess the severity of tissue hypoperfusion and hypoxemia.

An understanding of hemodynamic principles and monitoring techniques is helpful to the discussion of shock states. A more thorough discussion can be found in Chapters 15 and 17, and only the main points are reviewed here. The most important factors determining adequate tissue oxygenation are cardiac output, arterial oxygen content, and distribution of blood flow.

### Cardiac Output

When the cardiac index falls below 2.2 L/min/m<sup>2</sup>, the potential for inadequate tissue perfusion is high.<sup>9</sup> The cardiac index is the cardiac output divided by the body surface area. Cardiac output is the product of heart rate and stroke volume. Stroke volume is the amount of blood ejected by the ventricle with each heartbeat. Stroke volume is influenced by three major factors: preload, contractility, and afterload. *Preload* is the amount of blood in the ventricle at the end of diastole. In patients with low preload, a significant improvement in cardiac output often can be achieved by administering blood or intravenous fluids.

*Afterload* is the aortic impedance that the left ventricle must overcome to eject blood during systole. The major factors determining aortic impedance are the patency of the aortic valve and the resistance in the systemic vascular system. As resistance to left ventricular ejection increases, stroke volume decreases. Conversely, as resistance falls, stroke volume increases. In patients with high afterload, vasodilating agents may be useful in reducing the workload on the left ventricle. Care must be taken not to lower arterial blood pressure excessively, which would reduce perfusion.

*Contractility* is the inherent state of activation of cardiac muscle fibers. Contractility depends on the amount of free calcium ions available in the cardiac muscle cells after each electrical impulse. Contractility is influenced by sympathetic and parasympathetic nervous system neurotransmitters and other hormones and drugs. Contractility also depends on the amount of muscle mass and is influenced by myocardial ischemia and necrosis, and myocardial depressant factors that may be released by tissues in shock. Contractility can be increased by measures that increase myocardial perfusion and oxygenation, as well as by use of positive inotropic agents.

Most of the therapeutic interventions aimed at increasing cardiac output also increase myocardial workload and myocardial oxygen consumption. Especially in cardiogenic shock, these parameters must be carefully monitored and manipulated to avoid further cardiac compromise.

### Arterial Oxygen Content

**Oxygen delivery** ( $\dot{D}_{O_2}$ ) can be determined by multiplying cardiac output and arterial oxygen content ( $Ca_{O_2}$ ).  $Ca_{O_2}$  is the sum of dissolved oxygen and oxygen bound to hemoglobin. Adequate gas exchange in the pulmonary capillaries is necessary to fully saturate hemoglobin with oxygen. Impaired ventilation may result in reduced  $Ca_{O_2}$  and impair  $\dot{D}_{O_2}$ . Mechanical ventilation and supplemental oxygen administration may be used to improve arterial oxygen saturation. For patients with low levels of hemoglobin, blood transfusion may significantly improve  $\dot{D}_{O_2}$ .

A concept closely related to  $\dot{D}_{O_2}$  is **oxygen consumption** ( $\dot{V}_{O_2}$ ). Whereas  $\dot{D}_{O_2}$  is a measure of the oxygen delivered to the tissues each minute,  $\dot{V}_{O_2}$  is the amount of oxygen actually used by the tissues per minute. In a normal physiologic state, only about 25% of the oxygen delivered is taken up by tissues, which leaves about 75% of the oxygen to return to the heart in venous blood. When  $\dot{D}_{O_2}$  falls because of low cardiac output, tissues extract a greater percentage of the oxygen delivered such that the amount returning in venous blood is lower. When distribution of blood flow and tissue extraction of oxygen are impaired, as in septic shock, oxygen consumption falls and the amount of oxygen returning in venous blood will be higher than it should be. The amount of oxygen returning to the heart in venous blood can be measured by a special catheter in the pulmonary artery that detects venous oxygen saturation ( $Sv_{O_2}$ ). Outcomes of therapy to improve  $\dot{D}_{O_2}$  can be assessed by monitoring  $Sv_{O_2}$ . In cardiogenic shock, for example, one would expect to see  $Sv_{O_2}$  increase from a low value back toward 75% as cardiac output improves. In septic shock, one would expect to see  $Sv_{O_2}$  decrease from a high value back toward 75% as distribution of blood flow to metabolically active tissues improves.

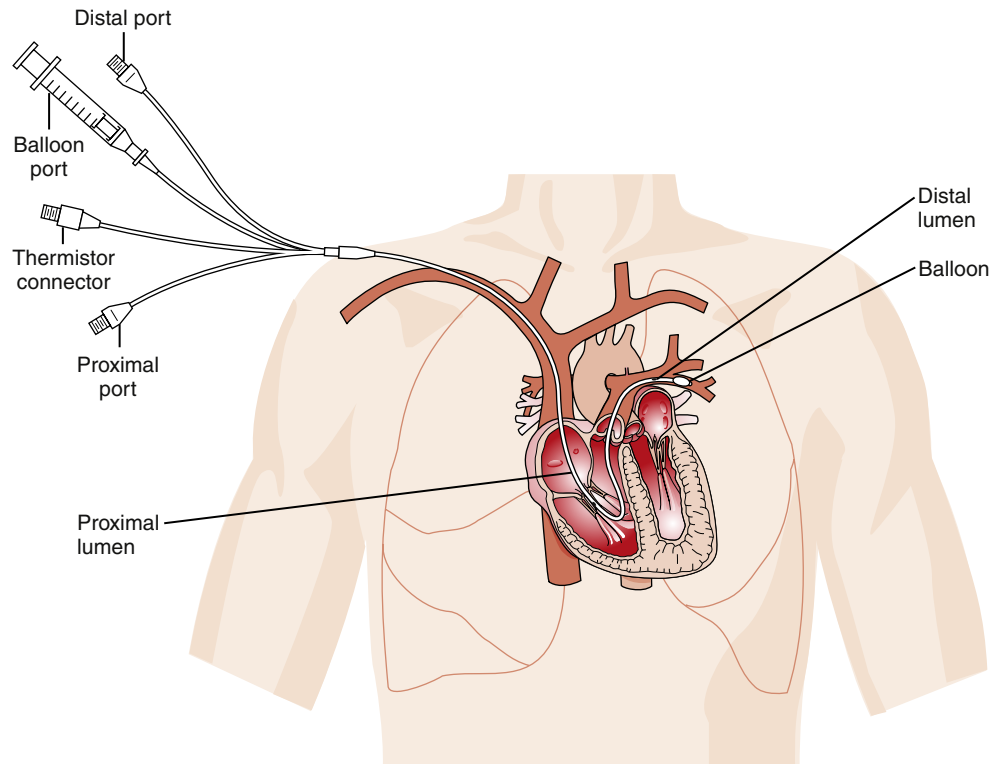

### Hemodynamic Monitoring

Sophisticated monitoring equipment is available to assess the hemodynamic status of patients in shock. A flow-directed, pulmonary artery catheter can be inserted through the jugular or subclavian vein to allow measurement of intracardiac pressures, cardiac output, and  $Sv_{O_2}$  (Figure 20-9). A catheter lumen in the right atrium allows measurement of right atrial pressure. Right atrial pressure is used to indicate right ventricular end-diastolic volume or preload. The primary value of monitoring right atrial pressure is in the management of blood volume. A low right atrial pressure is associated with a low preload and may indicate a need for extracellular volume replacement to enhance cardiac output. Conversely, a high right atrial pressure may indicate a need for extracellular volume reduction to decrease cardiac workload and congestive symptoms.

Another catheter lumen located in the pulmonary artery allows measurement of pulmonary artery pressure. Measurement of pulmonary artery pressure is helpful in assessing pulmonary complications of shock. An increase in pulmonary artery pressure may occur in progressive shock as the lungs react to inflammatory mediators and become edematous. In the absence of lung disease, pulmonary artery diastolic pressure reflects left atrial pressure. Assessment of left atrial pressure is important because it indicates left ventricular preload—an important determinant of cardiac output. A more accurate assessment of left atrial pressure can be obtained by using a small balloon at the tip of the catheter to obtain a pulmonary capillary occlusion pressure. When the balloon is inflated, the catheter tip floats into a small pulmonary artery and wedges itself there. The balloon blocks the arterial pressure events behind it and allows measurement of pressure in the capillary. Pulmonary capillary occlusion pressure is a direct reflection of left atrial pressure. Low left atrial pressure indicates reduced left ventricular preload and may signify the need for extracellular volume replacement.

#### KEY POINTS

- Hemodynamic monitoring during shock states is helpful for assessing cardiac output, volume status, oxygen delivery, and oxygen consumption. The pressures usually monitored include right atrial pressure, pulmonary artery pressure, and left atrial pressure.
- Hemodynamic monitoring is used to guide management of cardiac preload, afterload, and contractility to optimize cardiac output, while minimizing cardiac workload.

**FIGURE 20-9** Properly positioned pulmonary artery catheter showing the proximal port in the right atrium and the distal port in the pulmonary artery. Cardiac output determinations can be made by injecting hypothermic solution into the proximal port and measuring the degree of warm-up near the distal port. A balloon at the end of the catheter can be intermittently inflated to measure pulmonary capillary occlusion pressure. When the balloon is inflated, it will float into a small artery and wedge there. Then the distal port measures the pressure in the capillary, which is a direct reflection of left atrial pressure.

- Normally, about 25% of the oxygen in arterial blood is extracted by the tissues, so the mixed venous oxygen saturation ( $SvO_2$ ) is approximately 75%. Low cardiac output may result in greater oxygen extraction and lower  $SvO_2$ ; maldistribution of flow, as occurs in septic shock, may result in less oxygen extraction and higher  $SvO_2$ .

## COMPLICATIONS OF SHOCK

The pathologic process of the shock state and the effects on other organs may precipitate life-threatening complications. In severe shock of any cause, particularly in septic shock, a generalized inflammatory reaction may occur and is thought to contribute to the organ damage associated with shock states. Complications associated with shock include acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), acute renal failure, and multiple organ dysfunction syndrome (MODS). Damage to organ systems may be ongoing even after the initial precipitating event has been addressed. Inflammatory cytokines are thought to mediate this organ damage by altering metabolism, recruiting neutrophils, initiating the coagulation cascade, and altering capillary permeability. The complexities of this syndrome are being slowly unraveled as the mechanisms of immune signaling are better understood.

### ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS, a form of respiratory failure, is most commonly associated with septic shock. ARDS is characterized by the development of refractory hypoxemia, decreased pulmonary compliance, and radiologic evidence of pulmonary edema associated with normal cardiac

preload (noncardiogenic pulmonary edema). The mortality in patients with shock that is complicated by ARDS ranges from 34% to 64%.<sup>22</sup> The primary cause of death in ARDS patients is multiple organ failure, not severe hypoxemia.

The lungs are a common target of immune-mediated damage in all types of shock. Tissue ischemia, even in areas distant from the lungs, leads to neutrophil migration to pulmonary capillaries.<sup>4</sup> Neutrophils release destructive proteolytic enzymes, produce oxygen free radicals, and secrete inflammatory chemicals that make pulmonary capillaries leaky. A protein-rich inflammatory exudate leaks into the interstitial spaces and alveoli of the lung, where it interferes with pulmonary gas exchange. Inflammation may also damage type II pneumocytes, which normally produce surfactant. Surfactant deficiency alters alveolar surface tension and causes smaller alveoli to collapse. The effort to breathe is very great in patients with ARDS because of pulmonary edema and alveolar collapse (atelectasis). Further discussion of ARDS and its clinical manifestations can be found in Chapter 23.

### DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a serious complication of septic shock characterized by abnormal clot formation in the microvasculature throughout the body. DIC is thought to result from immune activation of the clotting cascade. Obstruction of blood flow by small clots in the microcirculation leads to ischemic tissue damage. In addition, widespread clot formation consumes platelets and clotting factors, which leaves the patient at risk for serious bleeding. Laboratory assessment of the platelet count and clotting function is helpful in detecting and monitoring DIC. The platelet count and fibrinogen levels are typically low, whereas levels of fibrin degradation products (e.g., D-dimer) are elevated. Measures of

the intrinsic and extrinsic clotting cascades demonstrate an elevated partial thromboplastin time and prothrombin time.

The clinical features of DIC are variable, depending on the location and severity of vascular thrombi. Vascular obstruction may be manifested as acute ischemia of the fingers and toes, with pain, pallor, and poor capillary refill. Obstruction of the kidney, liver, spleen, and lung by clots may result in signs and symptoms of organ failure. Patients may demonstrate various degrees of bleeding. Intravenous lines and catheters may begin to ooze around insertion sites. Previously stable incision lines may begin to bleed, and hematuria and hemoptysis may be present. Spontaneous intracranial hemorrhage is a particularly disastrous complication of DIC. Further discussion of DIC can be found in Chapter 14.

## ACUTE RENAL FAILURE

In shock, the kidneys undergo prolonged periods of hypoperfusion. Vasoconstriction of the afferent arterioles causes decreased glomerular blood flow, decreased glomerular hydrostatic pressure, and decreased glomerular filtration rates. Hypoxic cellular damage occurs after 15 to 20 minutes of acute ischemia and results in necrosis of tubular epithelial cells. Acute tubular necrosis (ATN) is associated with decreased urinary excretion of waste products such as creatinine and urea. Rapidly increasing blood urea nitrogen and serum creatinine concentrations are indicative of ATN.

Urine output quickly falls toward zero, and the kidneys do not respond to fluids or diuretics. Renal tubular epithelial cell casts in the urine indicate sloughing of tubular cells. ATN is potentially reversible, although renal function must generally be supported for a time with dialysis. Recovery of tubular function begins 1 to 2 weeks after the initial injury and may take up to 1 year to be completed. Further discussion of ATN can be found in Chapter 28.

## MULTIPLE ORGAN DYSFUNCTION SYNDROME

When organ dysfunction develops in two or more systems, the term *MODS* may be applied. When the patient sustains multiple organ

injury from a primary insult such as trauma, the term *primary MODS* is used. *Secondary MODS* is associated with SIRS and usually develops days to weeks after the primary insult. Sepsis and septic shock are the most common causes of secondary MODS. Mortality from MODS differs depending on the number of organs affected; involvement of two organ systems carries a 54% mortality, and involvement of five organs carries a 100% mortality.<sup>21</sup> In MODS, the body is unable to maintain homeostasis, and intensive intervention is necessary to maintain life.

As with other manifestations of septic shock, MODS is thought to be initiated by immune mechanisms that are overactive and destructive. Immune cytokines affect endothelium throughout the body and cause recruitment of neutrophils and activation of inflammation in vascular beds. Ongoing inflammation leads to tissue destruction and organ dysfunction. Inflammatory cytokines and stress hormones stimulate an increased body metabolism, which places a greater demand on already dysfunctional organs.

### KEY POINTS

- Shock states result in reduced or inadequate cellular oxygen consumption and may affect all organs and systems in the body. Complications of shock can be viewed as inflammatory in nature. Inflammation is triggered by hypoxic injury to cells, by antigen, or by endotoxin. Excessive or inappropriate immune system responses lead to leaking capillaries, damage from proteolytic enzymes, and systemic activation of the clotting, complement, and kinin systems.
- Respiratory failure and kidney failure are commonly associated with shock. Inappropriate activation of the clotting cascade may result in DIC. MODS may occur with widespread cellular hypoxia and necrosis.

## SUMMARY

Shock is a life-threatening syndrome associated with high mortality. Early identification of patients at risk and initiation of therapeutic measures may decrease the development of shock syndrome. Four major categories of circulatory shock have been described: cardiogenic, obstructive, hypovolemic, and distributive. Although each type of shock has specific characteristics, all are associated with a deficiency of cellular oxygen consumption. Tissue ischemia leads to hypoxic cellular

dysfunction and death, generation of oxygen free radicals, and stimulation of a systemic inflammatory response. In late-stage shock and in septic shock, ongoing systemic inflammation leads to progressive organ dysfunction and can precipitate a number of shock complications, including ARDS, DIC, ATN, and MODS. Ongoing research into effective ways to improve microcirculatory function and intervene in the inflammatory cascade is needed to improve outcomes.

**FIGURE 21-1** Four primary types of tracheoesophageal fistulas. **A**, The most common type, with complete atresia (blind pouch) of the esophagus. **B**, A common opening between the trachea and esophagus. **C**, An opening from an esophageal pouch into the trachea. **D**, A double opening from two unconnected ends of the esophagus. Arrows indicate flow of fluid from the esophagus to the trachea.

The primary function of the lungs is gas exchange. Oxygen is transported to the body tissues, and carbon dioxide, a waste product, is transported out of the body. The exchange of these gases takes place at the alveolar-capillary membrane. For effective gas exchange to occur, the processes of ventilation, perfusion, and diffusion must occur simultaneously at the alveolar-capillary interface. Problems with any of these three processes can result in hypoxemia (low arterial oxygen concentration) or hypercarbia (high arterial carbon dioxide concentration). An understanding of the anatomy and physiology of pulmonary gas exchange is necessary for learning about the pathophysiologic processes that follow.

## FUNCTIONAL ANATOMY

### Development of the Pulmonary System

Initially, the laryngotracheal diverticulum includes the esophagus and the trachea as a single tube. Then longitudinal ridges begin to develop along the tube and form a septum (wall), which separates the esophagus from the trachea. Failure of this septum to develop leads to a tracheoesophageal fistula (abnormal opening), leaving a communication between the esophagus and the trachea. This abnormality occurs about once in every 2500 births. Approximately 90% of the cases of esophageal atresia (blind pouch) are of the type seen in Figure 21-1, A. Parts B through D show variations of tracheoesophageal fistulas.<sup>1</sup>

As the laryngotracheal tube continues to elongate, the lung bud divides into two bronchial buds, which become the bronchi and the right and left lungs. The right bronchus becomes larger than the left. The right mainstem bronchus is normally more vertical than the left because it is the main continuation of the laryngotracheal tube and branches off the trachea at a 20-degree angle. The left bronchus branches off the trachea at an angle of 40 to 60 degrees. This normal anatomic development increases the chances that an inhaled foreign body will lodge in the right mainstem bronchus rather than the left.

Fetal lung development can be divided into the following four periods:

1. During the pseudoglandular period (5 to 17 weeks) the bronchial divisions are differentiated, and the major elements of lung tissue are present except for those involved in gas exchange: the respiratory bronchioles and alveoli.
2. During the canalicular period (16 to 25 weeks) the bronchi and bronchioles enlarge and vascularization of lung tissue takes place. At the end of this period, respiration is possible because of the development of respiratory bronchioles and primitive alveoli. Alveoli are grapelike sacs in which gas exchange occurs. Type II pneumocytes (epithelial cells that are on the internal surface of alveoli) begin to secrete surfactant at the end of this period. Surfactant is a phospholipid essential for maintaining alveolar patency.
3. During the terminal sac period (24 weeks to birth), terminal air sacs become thinner, preparing the lung tissue for gas exchange. Proliferation of pulmonary capillaries is also prominent during this period. Infants born prematurely in the early weeks of this period (25 to 28 weeks) are susceptible to the development of respiratory distress syndrome (RDS) because of the immaturity of the pulmonary structures.
4. The alveolar period (late fetal life to 8 years) is the final period of lung development when alveolar ducts form from terminal sacs and alveoli mature by increasing in size and number. Approximately one eighth to one sixth of the adult number of alveoli are present at birth.<sup>1</sup> During this growth period, there is a lack of structural collateral pathways necessary for maintaining open airways. This may make the individual more susceptible to atelectasis (incomplete expansion) and obstruction. Lung damage during this period may cause permanent defects in lung development.<sup>1</sup>

### Upper Airway Structures

The respiratory system can be divided into two major anatomic areas: the upper airway and the lower airway. The upper airway consists of

## CHAPTER 21 Respiratory Function and Alterations in Gas Exchange

**FIGURE 21-2** Sagittal view diagram of the nasopharyngeal cavity (nasal cavity, nasopharynx, oropharynx, and laryngopharynx) and the respiratory passages beginning at the trachea and ending at the alveoli.

the nasopharyngeal cavity (nasopharynx, oropharynx, laryngopharynx) (Figure 21-2). The lower airway contains the larynx, trachea, bronchi, bronchopulmonary segments, terminal bronchioles, and the acinus (the alveolar region supplied by one terminal bronchiole, which includes numerous alveoli) (see Figure 21-2).

The nasal cavity conducts gases to and from the lungs, and filters, warms, and humidifies the air. It is a rigid box composed of two-thirds cartilage and one-third bone, which prevents collapse during movement of air. The convoluted turbinates (cone-shaped bones) of the nasal cavity are highly vascular, and their blood flow forms an efficient heat exchanger. Evaporation of water from the turbinate surface and from the mucus secreted by mucosal glands raises the water vapor of the inspired air to normal saturation. Therefore, air is warmed to body temperature and humidified.

Air is filtered by the large hairs (vibrissae) of the nasal cavity and cilia that line the nasal cavity. The cilia sweep foreign particles trapped by mucus into the nasopharynx, where they are swallowed or expectorated. An electron micrograph of the tracheobronchial lining is shown in Figure 21-3. Pseudostratified ciliated columnar epithelium lines the trachea and bronchi. Goblet cells and mucus-producing glands are contained in this area and are responsible for synthesizing approximately 100 ml/day in the adult, more with disease. The composition of mucus is 95% water with the remaining 5% consisting of mucopolysaccharides, mucoproteins, and lipids. Maintenance of water content and fluid balance is important to the mobilization of secretions. A child has more mucus-producing glands and therefore produces more mucus than an adult. Consequently, in an ill child the overproduction of mucus in combination with small airway size may precipitate tracheobronchial obstruction.<sup>2,3</sup>

**FIGURE 21-3** Cells composing the bronchial epithelium are ciliated epithelial cells (CE), goblet cells (G), and basal cells (B). Goblet cells have abundant mucus granules in the cytoplasm, and their apical surface is devoid of cilia. Basal cells, as their name indicates, are located along the abluminal portion of the lining epithelium, adjacent to the basal lamina. The arrows at the apical surface of the airway cells indicate the location of junctional complexes between contiguous epithelial cells. (Human lung surgical specimen, transmission electron microscopy.) (From Murray JF, Nadel JA: *Textbook of respiratory medicine*, ed 4, Philadelphia, 2005, Elsevier.)

**FIGURE 21-4** **A**, Electron micrograph shows the ultrastructural characteristics of cilia (*Ci*) on airway epithelial cells (*E*). Each cilium has a long slender shaft that ends with a conical tip. The base of the cilium is anchored in the cell's apical cytoplasm by a curved and tapered basal foot (modified centriole; *arrowhead*). Also extending from the apical surface of ciliated airway epithelial cells are microvilli (*Mv*). The two horizontal arrows in panel **A** represent the cross-sectional planes illustrated in panels **B** and **C**. **B** and **C**, Airway cilia have the classic microtubular arrangement of motile cilia, namely, nine peripheral doublets and two central singlets. Microvilli are randomly distributed among the cilia. (Human lung surgical specimen, transmission electron microscopy.) (From Murray JF, Nadel JA: *Textbook of respiratory medicine*, ed 4, Philadelphia, 2005, Elsevier.)

Cilia (Figure 21-4) beat in a sweeping motion like oars rowing a boat at approximately 1000 to 1500 strokes per minute.<sup>2,3</sup> Mucociliary transport (movement of mucus upward) is a primary defense mechanism of the tracheobronchial tree. Inhaled particles, bacteria, and macrophages are removed from the respiratory tract by ciliary clearance and the cough reflex. Ciliary function is impaired by smoking, alcohol ingestion, hypothermia, hyperthermia, cold air, low humidity, starvation, anesthetics, corticosteroids, noxious gases, the common cold, and increased mucus production.<sup>2,3</sup>

The four paranasal sinuses are air-containing spaces adjacent to the nasal passages that provide speech resonance and increase the surface area for heat and water vapor exchange. The sinuses are swept clean by mucociliary action when the communicating passages that connect them with the nasal passages remain open.

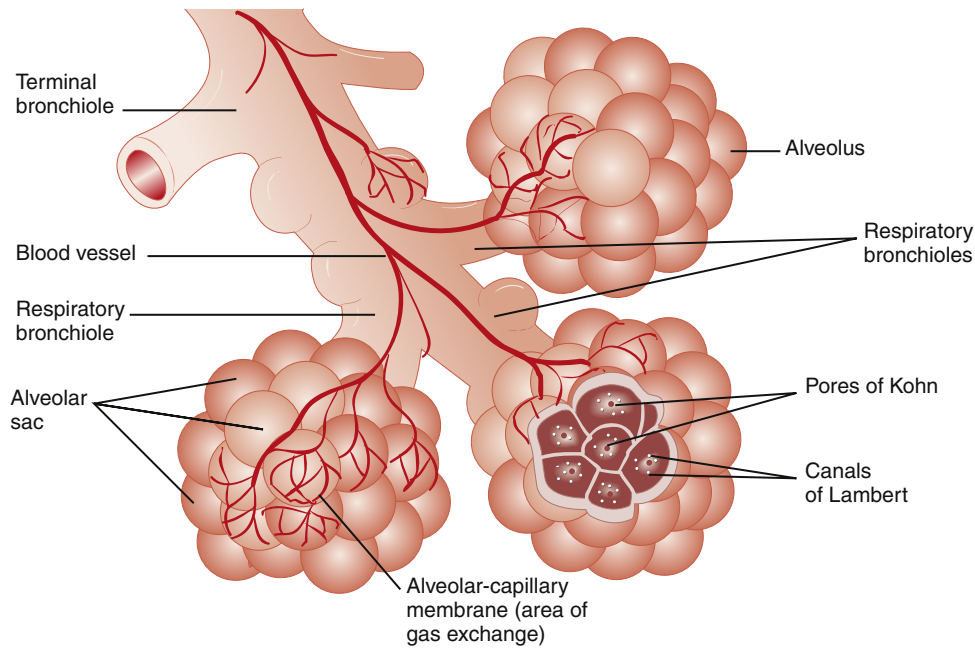

The eustachian tube between the middle ear and the posterior nasopharynx maintains the air in the middle ear at atmospheric pressure. To prevent secretions or food from entering the middle ear during swallowing, the pharyngeal muscles close the eustachian tube briefly. The nasal end of the eustachian tube is surrounded by flexible cartilage arranged in a spiral configuration. The muscles surrounding the

eustachian cartilage close the opening by pulling the cartilage tighter. Because the tube is shorter in children, the potential for otitis media (infection of the middle ear) is increased.<sup>2,3</sup>

### Lower Airway Structures

After air passes through the nasal cavity or oral cavity into the pharynx, it moves into the larynx and finally into the tracheobronchial tree. The acinus (Figure 21-5) is located at the end of the tracheobronchial tree and is composed of bronchioles, alveolar ducts, and alveoli.

The larynx is the transition area between the upper and lower airways. Anatomically it is considered part of the lower airway, but functionally it is similar to the upper airway. The larynx contains the epiglottis, vocal cords, and cartilages. The anatomic arrangement of the larynx functions to prevent aspiration during swallowing and to assist in phonation and coughing. Each vocal cord is attached anteriorly to the thyroid cartilage and posteriorly to the arytenoid cartilage. Vibration of the cords leads to phonation. Food is prevented from entering the trachea during swallowing by closure of the epiglottis. If food or fluid should bypass the epiglottis and enter the tracheobronchial tree, the cough reflex is initiated. The majority of cough receptors lie at the

**FIGURE 21-5** A portion of the lower respiratory tract, including a terminal bronchiole, respiratory bronchioles, and alveoli, where interchange of  $O_2$  and  $CO_2$  occurs between the thin walls of the alveoli and the capillary membrane.

carina. A cough reflex is produced when the epiglottis and vocal cords close tightly against air entrapped in the lungs. Occasionally, individuals cough hard enough to break a rib. When the expiratory muscles contract forcefully against the closed epiglottis and vocal cords, a pressure of approximately 100 mm Hg is created. When the cords and epiglottis suddenly open, the high-pressure buildup is allowed to escape. This reflex rapidly removes foreign matter from the tracheobronchial tree.<sup>2,3</sup>

The major cartilages of the larynx are the thyroid, cricoid, and arytenoid. The thyroid cartilage is a large shield-shaped cartilage often referred to as the *Adam's apple*. Immediately below the thyroid cartilage is the site for emergency opening (cricothyroidotomy) of the tracheal passageway. The cricoid cartilage lies below the thyroid cartilage and is the narrowest point in the airway of a child. It is the only complete tracheal ring, and because of its narrowness in the small child's airway, an endotracheal tube cuff is not necessary for required intubation of the airway.

The trachea, bronchi, and bronchioles make up the conducting airways that allow passage of gases to and from the gas exchange units (alveoli). These conducting airways comprise a proportionately larger amount of the total airway system in the infant and child than in the adult. The trachea (Figure 21-6) contains incomplete cartilaginous rings; it is approximately 11 to 13 cm long and lies between the cricoid cartilage and the carina (ridge located at the lower end of the trachea). Individual variations in tracheal shape include U, circular, D, C, triangular, and elliptical (Figure 21-7). Of 111 adult tracheas studied, the incidence of shapes in order of frequency was 48.6% C, 27% U, 12.6% D, 8.2% elliptical, 1.8% circular, and 1.8% triangular.<sup>4</sup> These tracheal variations may affect ventilation of patients who have endotracheal tubes in their airways and require mechanical ventilation.

The trachea divides into two mainstem (primary) bronchi, which contain cartilage and smooth muscle. Viewing the body anteriorly, the carina is located at the angle of Louis, between the sternum and manubrium at the second intercostal space.

The small size of the conducting airway in the infant and child makes even a small decrease in the size of the lumen from an obstruction

critical to airway conduction.<sup>5</sup> Primary bronchi further divide into five (secondary) lobar branches, three to the right lung and two to the left lung. Each lobar branch enters a lobe of the lung and further divides into bronchopulmonary segments (10 segments in the right lung, 9 segments in the left lung) (Figure 21-8).<sup>2,3</sup> Each bronchopulmonary segment is composed of 50 or more terminal bronchioles (conducting airways), which branch into respiratory bronchioles, where gas exchange begins.

Terminal bronchioles, which include the conducting airways, further subdivide into two or more respiratory bronchioles in which gas exchange begins. The respiratory bronchioles divide into two or more alveolar ducts, which in turn supply several alveoli.

Nervous system control of the bronchi and bronchioles is mediated by the autonomic nervous system. Stimulation of the parasympathetic nervous system via the vagus nerve leads to constriction (by means of acetylcholine receptors) of bronchial smooth muscle. Stimulation of the sympathetic nervous system leads to relaxation of bronchial smooth muscle. Sympathetic stimulation is mediated by  $\beta_2$ -adrenergic receptors, which are under the control of circulating catecholamines.<sup>5</sup> (See the discussion in the Neurologic Control of Ventilation section later in this chapter for additional information.)

The lung is fully developed by the eighth year of life.<sup>1,2</sup> The large alveolar surface area in conjunction with pulmonary surfactant, a phospholipid produced by type II alveolar cells, lowers surface tension and facilitates gas exchange. Two other types of cells are found: type I alveolar cells (type I pneumocytes), which are the epithelial structural cells of the alveoli, and alveolar macrophages, which act as a defense mechanism by phagocytizing particles in the alveoli. Alveolar macrophages can be damaged by cigarette smoking and by inhalation of silica ( $SiO_2$ ).

Adult lungs contain approximately 300 million alveoli, and the newborn lung contains one eighth to one sixth the adult number.<sup>1-3</sup> An elderly person may also have a reduction in the number of alveoli as part of the normal aging process, but many elderly people retain the same number of alveoli they had as a younger adult.

## CHAPTER 21 Respiratory Function and Alterations in Gas Exchange

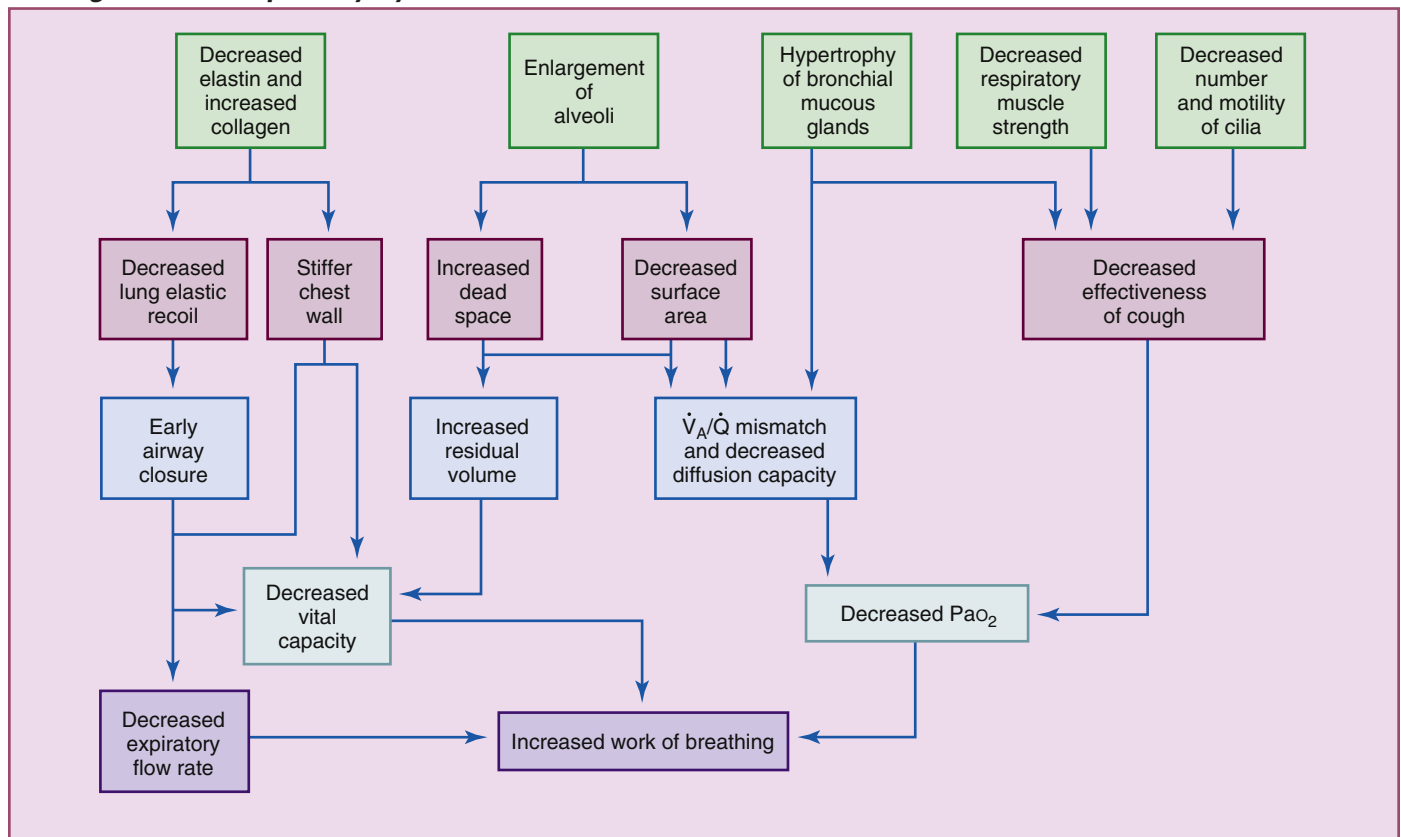

Gas exchange occurs in the alveolar units (see Figure 21-5) where oxygen ( $O_2$ ) and carbon dioxide ( $CO_2$ ) transfer across the alveolar-capillary membrane. The partial pressures of gases in the alveoli are termed  $PAO_2$  for oxygen and  $PACO_2$  for carbon dioxide. The partial pressures of gases in the blood are termed  $PaO_2$  for oxygen and  $Paco_2$  for carbon dioxide. Collateral alveolar ventilation can also occur through holes in the alveolar walls, called the pores of Kohn or canals of Lambert. A small child has less collateral ventilation, because of fewer pores of Kohn.<sup>6</sup> The alveolar membrane is thicker in the neonate and reaches the adult thinness of 0.5 mm by the age of 8 years. This thinner membrane may allow increased transfer of  $O_2$ . The healthy older adult has very thin-walled, enlarged air sacs and fewer capillaries than a younger adult.<sup>2,7</sup> Respiratory system changes associated with normal aging are described in Geriatric Considerations: Changes in the Respiratory System.

### Pulmonary Circulation

Blood supply to the lungs comes from two sources: the bronchial artery system, which supplies a small amount of oxygenated blood to the pleura and lung tissues, and the pulmonary artery system, which provides a vast capillary network for  $O_2$  and  $CO_2$  exchange. The capillary networks of the neonate, young child, and elderly person are less than those in the average healthy adult. Oxygen-depleted (unoxygenated) blood leaves the right ventricle by way of the pulmonary artery trunk, which branches into the right and left pulmonary arteries. The pulmonary arteries further divide into smaller arteries and arterioles that feed into the capillary network where gas exchange occurs from the alveolar-capillary membrane. Pulmonary artery blood is unoxygenated, and blood in the pulmonary veins is oxygenated. The opposite is true in the rest of the body, where the arterial blood is oxygenated and the venous blood is unoxygenated.

### GERIATRIC CONSIDERATIONS

#### Changes in the Respiratory System

With aging, the result of all pulmonary changes is an increase in the work of breathing. The lungs show a reduction in the amount of elastin and an increase in collagen concentration, leading to decreased elastic recoil and increased compliance. These changes lead to increased residual volume and early airway closure. The chest wall becomes stiffer or more rigid as a result of rib and cartilaginous calcification. The strength of the diaphragm, intercostal muscles, and accessory muscles declines. The stiff chest wall and diminished respiratory muscle strength cause other functional changes, including an increase in dead space and decreased expiratory flow rates and vital capacity.

There is a reduction in the number and motility of cilia, resulting in a decrease in respiratory clearance. There is an increase in and hypertrophy of bronchial mucous glands. The decreased respiratory muscle strength, increased mucus production, increased chest wall stiffness, and loss of cilia together reduce cough effectiveness.

Within the lungs, there is enlargement of alveoli and respiratory bronchioles with subsequent decreased surface area. The arterial blood flow through the pulmonary vessels decreases proportionally to changes in cardiac output. The loss of elastic recoil causes the enlarged respiratory bronchioles to collapse or close before the alveoli empty. Alveolar enlargement, along with reduced pulmonary artery blood flow and early airway closure, lowers diffusion capacity and the amount of gas exchange. It also increases air trapping and residual volume.

Because of chest wall stiffness and lung rigidity, apical ventilation increases in the elderly, whereas basilar ventilation decreases. Ventilation-perfusion mismatch occurs as a result of increasing apical ventilation with poor apical capillary blood flow. The result of these changes leads to reduced arterial oxygen pressure ( $PaO_2$ ). Because of increased ventilation-perfusion mismatch, the  $PaO_2$  may decrease when the elderly individual reclines.

The capillary network is a low-pressure system that can expand two to three times the normal size before a significant increase in pulmonary capillary pressures is detectable. The normal pulmonary arterial pressure in a healthy adult is about 22/8 to 25/8 mm Hg. The mean pulmonary arterial pressure is approximately 15 mm Hg. This compares with the high pressure of the systemic circulation, which is normally considered to be 120/80 mm Hg, with a mean arterial pressure of 96 mm Hg.

Under normal resting conditions, some pulmonary capillaries are closed and not perfused (filled with blood). The pulmonary circulation has two mechanisms for lowering pulmonary vascular resistance, when vascular pressures are increased because of increased blood flow (Figure 21-9).<sup>2,3,5</sup> The first mechanism is recruitment, which allows opening of previously closed capillary vessels. The second mechanism is distention, which allows for widening of capillary vessels.

Another factor influencing pulmonary circulation is the fluid balance of the lung tissues. Fluid balance is regulated by the hydrostatic pressure, colloid osmotic pressure, and capillary permeability. When

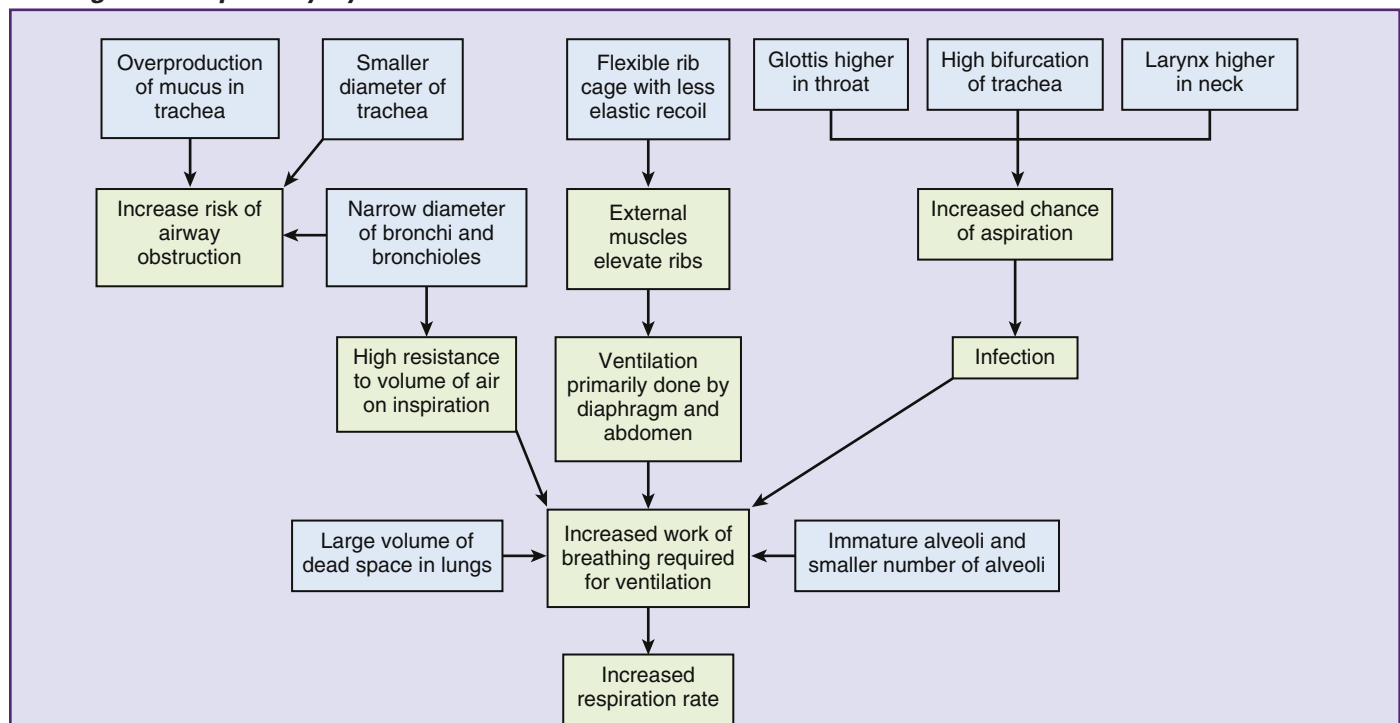

capillary hydrostatic pressure exceeds colloid osmotic pressure, fluid moves from the capillary to the interstitium. If the fluid shift is not controlled, the fluid volume will continue to increase until fluid is moved into the alveoli. Alveolar edema is more serious than interstitial edema (fluid in the interstitial space), because of its negative effects on gas exchange. Pulmonary interstitial and alveolar edema is common in disease processes such as congestive heart failure and infectious diseases of the lung. Other disease processes that also increase capillary permeability are acute respiratory distress syndrome (ARDS) and infant respiratory distress syndrome. (See Chapter 23 for further discussion.)

### Age-Related Variations

Structural and physiologic variations occur at each end of the age continuum. A summary of anatomic and physiologic respiratory variations by age group is presented in Table 21-1.<sup>8</sup> Pediatric considerations are shown in the box below.

## PEDIATRIC CONSIDERATIONS

### Changes in Respiratory System in Children

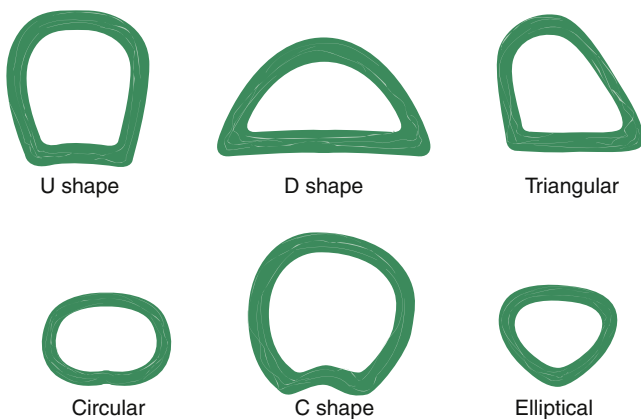

The respiratory system in children is very different than that of the adult, which makes the child susceptible to airway obstruction, aspiration, and infection. The trachea in the infant has more mucus-producing glands, which can create an overproduction of mucus in the infant. The trachea lumen, bronchi, and bronchioles are also smaller with a more narrow diameter. The excess mucus and more narrow respiratory structures increase the risk of airway obstruction in the child. The positioning of respiratory structures in the infant increases the chance of aspiration. The glottis is higher in the throat of an infant compared to a 5-year-old child (MacGregor, 2008). The trachea bifurcates at the third thoracic vertebra compared to the sixth in adults (MacGregor, 2008) and the larynx is located higher in the neck of the infant. Aspiration can lead to infection in the child and increase the work of breathing.

The infant has to work harder for ventilation of the lungs because of several factors. The more narrow diameter of bronchi and bronchioles creates a higher resistance to

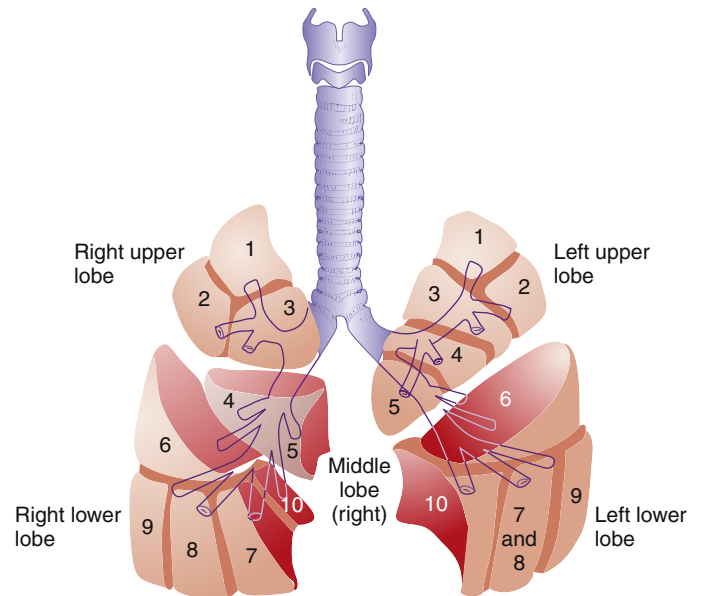

volume of air on inspiration. The large volume of dead space in the lungs requires the infant to breathe faster to meet oxygen demands. Compared to an adult, the alveoli are smaller and immature, which decreases the area for gas exchange to occur in the lungs. The number of alveoli and the size increase as the child ages. The flexible ribcage is unable to support the lungs adequately because it has less elastic recoil. The intercostal muscles of the ribcage also work inefficiently. The external intercostal muscles elevate the ribs for inspiration, whereas the internal intercostal muscles cannot lift the chest wall and do not help with inspiration. The infant depends on the diaphragm and abdomen for ventilation to compensate for the lack of intercostal muscle strength. All of these factors increase the work of breathing required for ventilation and the infant compensates by increasing his or her respiratory rate. By age 8 years the lungs are fully developed and the child's respiratory system begins to resemble the adult's respiratory system (MacGregor, 2008).

**KEY POINTS**

- Respiratory system development begins at about day 26 of gestation. Abnormal development of the septum during this time can lead to tracheoesophageal fistula. At 25 weeks' gestation, the fetal lungs have developed sufficiently to allow respiration, although alveolar development and surfactant production are just beginning.
- The upper airway includes the nasopharynx, oropharynx, and laryngopharynx. The primary functions of the upper airway are to warm, filter, and humidify inspired air.
- The lower airway includes structures below the larynx—the trachea, bronchi, bronchioles, and alveoli. The larynx functions to prevent aspiration during swallowing and is the location of the vocal cords.
- The trachea, bronchi, and bronchioles serve as conducting passageways for air. They do not engage in gas exchange. Sympathetic influence on these airways causes relaxation (by means of  $\beta_2$ -adrenergic receptors), and parasympathetic influence causes constriction (by means of acetylcholine receptors).
- Exchange of respiratory gases occurs in the alveoli. The epithelial cells that comprise the alveoli are called *type I cells* (type I pneumocytes). Type II pneumocytes produce surfactant in the alveoli. The grapelike structure of the alveoli provides a huge surface area for gas exchange.
- The upper and lower airways are lined with cilia, which move rhythmically to transport mucus and trapped debris out of the respiratory tree. Ciliary function is impaired by a number of factors, including smoking, alcohol consumption, low humidity, and anesthesia.
- The lungs are perfused by two sources: bronchial arteries bring a small amount of oxygenated blood to nourish lung tissues; pulmonary arteries transport the entire cardiac output of the right ventricle to the alveoli for gas exchange.
- The lung has a large reserve capacity for gas exchange. At rest, some of the pulmonary capillaries are not perfused. During periods of high lung blood flow (such as high cardiac output during exercise), previously unperfused capillaries are recruited, and already perfused capillaries become distended.
- Filtration of fluid through pulmonary capillaries is influenced by hydrostatic pressure and colloid osmotic pressure in the same way as other capillaries. Excessive filtration can lead to pulmonary edema, which interferes with normal gas exchange.

**TABLE 21-1 VARIATIONS IN ANATOMY AND PHYSIOLOGY OF THE RESPIRATORY SYSTEM BY AGE GROUP**

	YOUNG NEWBORNS	CHILDREN	ADULTS	ELDERLY (OVER 60 YEARS OLD)
Pao <sub>2</sub> (mm Hg)	60-70	90-100	90-100	70-80
Paco <sub>2</sub> (mm Hg)	45-50	35-45	35-45	35-45
pH	7.3-7.4 (depends on Apgar score)	7.35-7.45	7.35-7.45	7.30-7.45
Bicarbonate (mEq/L)	20-26	22-28	24-30	24-30
Anatomic dead space	Proportional to size	Proportional to size	≈150 ml	≈150-200 ml
Number of alveoli	12.5-16.5% of adult number	Adult number by 8 years old	300,000/lung	≤300,000/lung
Thickness of alveolar membrane	Thicker than adult	Adult by 8 years old	<0.5 μm	Thinner than adult
Number of capillaries	Less than adult	Adult by 8 years old	Adult	Less than adult
Vital capacity	Proportionately less than adult	Proportional to size	4.7 L	Less than adult
Tidal volume	Proportional to size	Proportional to size	500 ml	Less than adult (30% less by age 80 years)
Compliance	More compliant than adult	Similar to adult	Static compliance (90-100 ml/cm H <sub>2</sub> O)	Less compliant
Airway resistance	Greater than adult	Greater than adult	1.0-1.5 cm H <sub>2</sub> O/L/sec	Adult level or less

## VENTILATION

### Lung Volumes and Capacities

Ventilation is the process of moving air into the lungs and distributing air within the lungs to gas exchange units (alveoli) for maintenance of oxygenation and removal of carbon dioxide (CO<sub>2</sub>).<sup>5</sup> Measures of ventilation (amount of air moved) include four lung volumes and four lung capacities. Figure 21-10 schematically presents the various lung volumes and capacities; Table 21-2 defines each term and provides further details.

Lung volumes and capacities vary according to the individual's body size, age (decreased in the neonate, young child, and the elderly),<sup>7-9</sup> and body position (supine versus upright). Testing of pulmonary function to measure these volumes and capacities is covered under the Diagnostic Tests section in Chapter 22. Other measures important to ventilation are dead space, minute ventilation, and alveolar ventilation.

### Dead Space

Dead space includes three dimensions: anatomic dead space, alveolar dead space, and physiologic dead space. Anatomic dead space includes the volume of gas (not used in gas exchange) in the conducting airways from the nose to the respiratory bronchioles.<sup>5,10,11</sup> Generally, in adults this area is equal to 1 ml per pound of *ideal* body weight, or approximately 150 ml. In newborns and young children, the anatomic dead space is proportionately larger for their size.<sup>6</sup> The anatomic dead space of elderly persons may increase slightly over that of healthy young adults because of the loss of alveolar sacs. Alveolar dead space is composed of ventilated, but unperfused areas of the lung, and is often referred to as *wasted ventilation*.<sup>5</sup> Physiologic dead space (functional dead space) is the sum of the anatomic dead space and alveolar dead space.<sup>7,11</sup> Approximately one third of each breath occupies dead space.

**TABLE 21-2 LUNG VOLUMES AND CAPACITIES**

TERM	DEFINITION (TYPICAL VOLUME)
<b>Lung Volumes</b>	
Tidal volume	A normal breath (≈500 ml) or amount of gas entering or leaving lung during normal breathing
Inspiratory reserve volume	Amount of gas a person is able to inspire above a normal breath (e.g., maximal deep breath, ≈3 L)
Expiratory reserve volume	Amount of gas expired beyond tidal volume (≈1.2 L)
Residual volume	Volume of gas left in lungs at end of a maximal expiration (≈1.2 L)
<b>Lung Capacities</b>	
Vital capacity	Total volume of gas that can be exhaled during maximal expiration (≈4.8 L)
Inspiratory capacity	Amount of gas that can be inspired from a resting expiration (≈3.5 L)
Functional residual capacity	Amount of gas left in lungs at end of a normal expiration (≈2.4 L)
Total lung capacity	Amount of gas contained in lungs at maximal inspiration (≈6.0 L)

**Minute Ventilation**

Minute ventilation is the product of tidal volume (milliliters of air inhaled with each breath) times respiratory rate per minute. For example, a person with a tidal volume of 500 ml who is breathing at a rate of 15 breaths/minute has a minute ventilation of 7500 ml (see Table 21-2 for typical volumes).

**Alveolar Ventilation/Oxygenation**

By comparison, alveolar ventilation ( $\dot{V}_A$ ) equals the difference between tidal volume ( $V_T$ ) and anatomic dead space volume ( $V_D$ ) multiplied by the respiratory rate (RR) per minute.<sup>10</sup>

$$\text{Alveolar ventilation } (\dot{V}_A) = (V_T - V_D) \times \text{RR}$$

Because alveolar ventilation is affected by both the anatomic dead space and the respiratory rate, slow deep breathing yields greater alveolar ventilation than rapid shallow respiration. The patient breathing 25 times/minute at a  $V_T$  of 200 ml would have alveolar ventilation as follows:

$$(200 \text{ ml} - 150 \text{ ml [anatomic dead space]}) \times 25 \text{ breaths/minute} = 1250 \text{ ml}$$

A patient breathing 10 times/minute at a  $V_T$  of 600 ml would have an alveolar ventilation of

$$(600 \text{ ml} - 150 \text{ ml}) \times 10 = 4500 \text{ ml}$$

The partial pressure of oxygen in the alveoli ( $P_{AO_2}$ ) is the driving force to move  $O_2$  into the blood and is estimated with the following equation:

$$P_{AO_2} = F_{IO_2}(P_B - 47) - (P_{ACO_2} \div 0.8)$$

where  $F_{IO_2}$  is the fraction of inspired oxygen,  $P_B$  is the barometric pressure, 47 is the constant for water vapor pressure (mm Hg), 0.8 is the respiratory quotient, and  $P_{ACO_2}$  is the laboratory measurement of arterial  $CO_2$  pressure (mm Hg).

The value for  $P_{AO_2}$  is normally very close to that for  $P_{aO_2}$ . The difference between alveolar and arterial oxygen tensions is called the Alveolar-arterial Difference in oxygen ( $A - aDO_2$ ). A large  $A - aDO_2$  value indicates poor matching of alveolar ventilation with alveolar blood flow ( $\dot{V}_A/Q$  matching)

For example, the calculation of  $A - aDO_2$  for a person at sea level ( $P_B = 760$  mm Hg) breathing room air ( $F_{IO_2} = 0.21$ ) with  $P_{aO_2} = 75$  mm Hg and  $P_{aCO_2} = 40$  mm Hg is

$$P_{AO_2} = 0.21(760 - 47) - (40/0.8) = 150 - 50 = 100$$

Therefore, using the arterial blood gas value obtained for the  $P_{aO_2}$  and the calculated  $P_{AO_2}$  of 100, a difference of 25 mm Hg is determined:

$$A - aDO_2 = 100 - 75 = 25 \text{ mm Hg}$$

This large of a difference indicates a significant problem with gas exchange.

In critical care settings, it is useful to calculate the  $A - aDO_2$  value to monitor the efficacy of oxygen exchange across the lung. The normal  $A - aDO_2$  gradient in a normal, healthy young adult is less than 10 mm Hg at room air, but it increases with age and increasing  $F_{IO_2}$ . A rising  $A - aDO_2$  value indicates worsening lung function, even though hypoxemia ( $P_{aO_2}$  lower than 80 mm Hg at sea level) may not necessarily be present.

Hypoxemia that is primarily caused by hypoventilation suggests that the lung is normal, and treatment that increases ventilation will remedy the problem. This type of hypoxemia is characterized by a normal  $A - aDO_2$  value.

A simple method of calculating expected  $P_{AO_2}$  is the “law of 5’s.” By multiplying the  $F_{IO_2}$  (%) by 5, the care provider has an estimate of what the oxygen level should be under normal, healthy conditions (e.g.,  $5 \times 21\%$  room air = 105).

**Mechanics of Breathing**

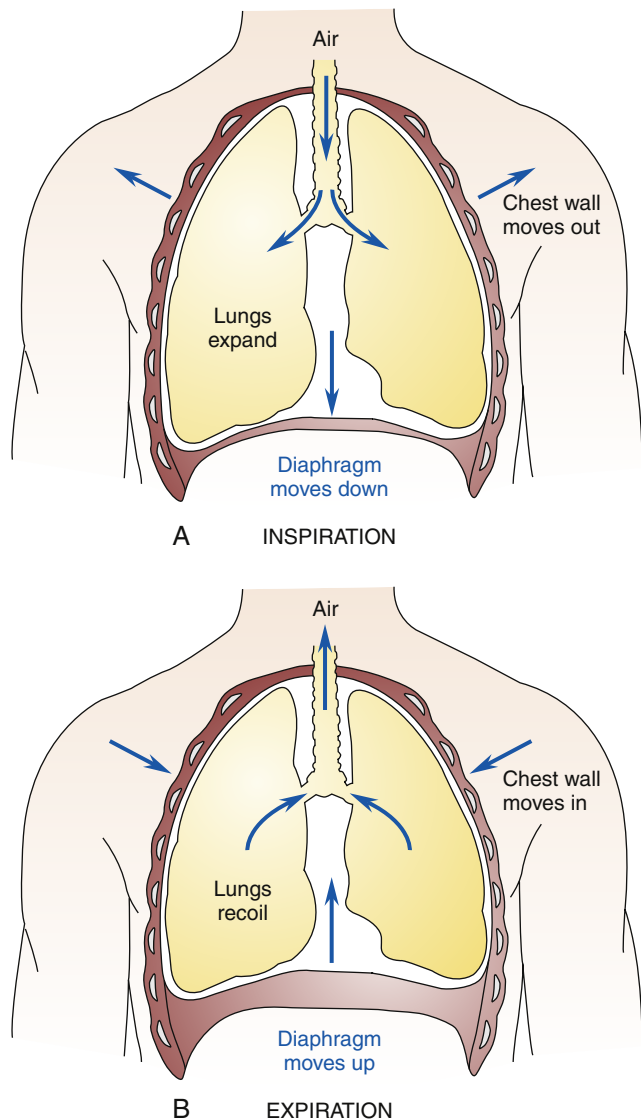

The mechanics of breathing include the concepts of airway resistance, lung compliance, and opposing lung forces (elastic recoil versus chest wall expansion) of the lung. These factors affect the overall performance of gas exchange and the work of breathing.

The lungs have a natural recoil tendency, whereas the chest wall favors the expanded state. During inspiration, the chest wall muscles (external intercostals) contract, elevating the ribs as the diaphragm moves downward. These two actions create a negative intrapleural pressure that causes the lung to expand. During expiration, the lung deflates passively because of the elastic recoil (elastic fibers in the lung tissue) and relaxation of the diaphragm. During heavy breathing, as seen with exercise, the elastic forces are not strong enough to cause the necessary rapid expiration, so abdominal muscles contract, pushing the abdominal contents upward, compressing the lungs.<sup>3</sup> Figure 21-11 shows the interaction of lung forces during inspiration and expiration. In the normal, healthy resting individual, expiration is accomplished almost entirely by relaxation of the diaphragm.<sup>5</sup> At the end of a normal expiration, the alveoli still contain some air volume, known as the *functional residual capacity*. If the alveoli were allowed to empty completely, the high surface tension in the alveoli would make it more difficult to reinflate them and add significantly to the work of breathing. In the absence of surfactant, which reduces alveolar surface tension, the alveoli tend to collapse—a condition called *atelectasis*. Excessive surface tension can increase the work of breathing so much that mechanical ventilation may be required. This is often the case in ARDS and in infant respiratory distress syndrome (see Chapter 23).

**Airway Resistance**

Airway resistance is determined by the relationship between driving pressure and flow. It is influenced by airway radius and the pattern of gas flow. Resistance increases as the radius of the airway tube decreases. Resistance is calculated by the following formula:

$$\text{Resistance} = \text{driving pressure} \div \text{rate of airflow}$$

**FIGURE 21-11** Lung forces during inspiration and expiration. **A**, During inspiration, the respiratory muscles contract, the chest wall expands, and air flows into the lungs. **B**, During expiration, the respiratory muscles relax, the lungs recoil, and air flows passively out of the lungs.

The radius of the airway decreases from the trachea to the terminal bronchioles. As mucus builds up in the airway, the passage is narrowed, and resistance to airflow increases. Other factors affecting airway resistance include stress, pulmonary conditioning, and age.

The trachea and bronchi contain cartilage and small amounts of muscle. The cartilage assists in maintaining airway passage stability, thus preventing airway collapse. The bronchioles and terminal bronchioles do not contain cartilage, but have increased amounts of smooth muscle that are innervated by the autonomic nervous system. Stimulation of cholinergic fibers leads to bronchoconstriction. Stimulation of the  $\beta_2$ -adrenergic receptors leads to bronchodilation. The bronchial muscles function to maintain an even distribution of ventilation. A circadian rhythm is associated with bronchial tone, with maximal bronchodilation occurring at about 6 pm and maximal bronchoconstriction occurring at 6 AM.<sup>2</sup>

**FIGURE 21-12** Patterns of gas flow.

Airway resistance is also affected by the pattern of gas flow (Figure 21-12). Air movement from the nasal cavity through the large bronchi occurs by turbulent flow, which creates friction and increases resistance. Bronchospasm in the smaller airways and high gas flow also create turbulent flow. Laminar flow occurs in the small airways of the lung and creates minimal resistance to airflow. Transitional flow (mixed pattern of flow) occurs in the larger airways, especially at bifurcations. The highest airway resistance is at the nose, because of turbulent flow with high velocities of airflow. Airway resistance is even higher in the newborn than the adult and continues to be greater than that of the adult up to the age of 5 years. Resistance changes very little in the elderly lung.<sup>6,12,13</sup>

### Lung Compliance

Lung compliance is another factor that influences the work of breathing. Compliance represents lung expandability and the ease of lung inflation. It is best illustrated by the effort required to blow up a new balloon as compared to blowing up a balloon that has been inflated many times before. It is a measure of the relationship between pressure and volume. It is represented by the formula:

$$\text{Compliance} = \text{change in volume} \div \text{change in pressure}$$

Two factors associated with compliance are chest wall expandability and lung expandability. Lung compliance can be measured in the static (motionless) or dynamic state. Effective static compliance is determined by dividing the pressure required to deliver a volume of gas by the tidal volume as delivered by a ventilator. A more accurate measurement of compliance requires the insertion of an esophageal balloon. Normal static compliance in a healthy young adult would be 90 to 100 ml/cm H<sub>2</sub>O.

Compliance provides an estimate of airway resistance and elasticity. Lung compliance is increased in neonates and children younger than 3.5 years because of their chest wall flexibility.<sup>6</sup> Lung compliance may decrease in the elderly because of increasing chest wall rigidity from calcification of costal cartilages, reduced mobility of ribs, and partial contraction of inspiratory muscles.<sup>11,12</sup> Changes in the thoracic vertebrae and intervertebral disks also lead to decreased expansion of the chest wall in the elderly.<sup>7,8,12</sup> Disease processes that make the lung stiffer and decrease respiratory function include pneumonia, pulmonary edema, atelectasis, ARDS, and pulmonary fibrosis. Other factors that decrease compliance by decreasing chest wall distensibility are obesity, abdominal distention, pregnancy, kyphoscoliosis, and abdominal surgery (attributable to decreased respiratory effort from surgical pain). Lung compliance may be increased by loss of the lung's elastic fibers that occurs with age and obstructive lung diseases.<sup>11,12</sup> An abnormally high lung compliance, with loss of elastic recoil increases the work of breathing by requiring greater effort to expel air from the lungs during exhalation (see Chapter 22).

**FIGURE 21-13** Sections of lung from the apex (*upper panel*) and 20 cm below the apex (*lower panel*) obtained from a greyhound dog lung (specimens frozen in a vertical position). The upper panel illustrates alveoli in the apex (*zone 1*) of the lung in the upright position: the air sacs are large, and blood flow is diminished. The lower panel represents the base of the lung zone with optimal ventilation and perfusion ( $\times 188$ ). (From Murray JF: *The normal lung*, ed 2, Philadelphia, Saunders, p. 110. Courtesy Jon B. Glazier, MD.)

### Distribution of Ventilation

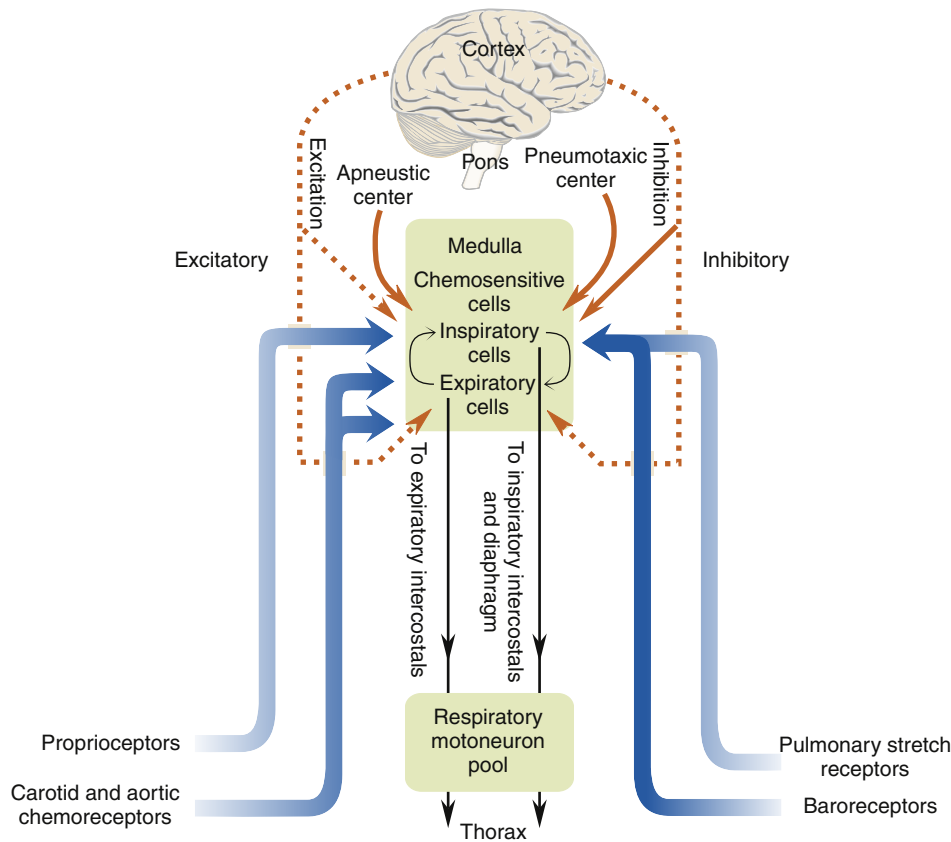

Distribution of ventilation is affected by body position. In the upright individual, the alveoli at the apices (top) of the lung are much larger than those at the base. **Figure 21-13** shows the variation in structural size of alveoli at the apex compared with that at the base. In the healthy upright individual, ventilation is greatest near the bottom of the lung and decreases toward the apices.<sup>5</sup> These regional differences are less in a supine person. The greater lung expansion at the bases results from a greater compliance of the alveoli at the bases and the downward displacement of the diaphragm, which expands the lower lobes more than the upper lobes. When an individual is in the supine lateral position, ventilation is best in the dependent part

of the lung fields, but the difference is not as great as that seen in the upright lung.

### Neurologic Control of Ventilation

Respiration is influenced by a number of factors. These include neural control centers, chemoreceptors, lung receptors, proprioceptors, and pressure receptors. The factors that regulate respiration are reviewed in this section.

Neural control of the respiratory system is located in the medulla oblongata and the pons, which is commonly referred to as the *respiratory center*. Efferent nerve impulses travel from the brainstem by way of the phrenic nerve to the diaphragm to stimulate muscular contractions for inspiration.

**FIGURE 21-14** Interactive mechanisms influencing control of respiration.

The medullary respiratory center within the brainstem consists of two groups of widely dispersed neurons that function as a unit to regulate breathing. The dorsal respiratory group of neurons transmits impulses that stimulate inspiratory muscles (in the intercostals and diaphragm). The impulses are generated in increasing fashion, termed a *ramp signal*. Impulses begin slowly and increase steadily for about 2 seconds. Abrupt cessation of signals for 3 seconds allows for expiration, and then the cycle begins again.<sup>2,3,5</sup> This system establishes the basic respiratory rhythm. Figure 21-14 provides a schematic diagram of these interactive mechanisms on respiratory control.

The pneumotaxic center of the upper pons (see Figure 21-14) appears to influence the rate of respiration and ends inspiration by inhibition of the inspiratory ramp. In addition, input from the spinal cord, cortex, and midbrain contributes to the normal smooth pattern of respiration. The apneustic center of the lower pons (demonstrated to exist in dogs) influences the pattern of respiration and may function to provide an extra driving force for the inspiratory neurons, thus prolonging inspiration.

Sensory inputs to the respiratory control center include central chemoreceptors, peripheral chemoreceptors, Hering-Breuer stretch receptors, proprioceptors, baroreceptors, and environmental sensations.

The central chemoreceptors within the medullary center respond to changes in  $\text{CO}_2$  level and pH. A stimulus to breathe occurs when a small increase in arterial carbon dioxide tension ( $\text{Paco}_2$ ) leads to stimulation of respiration. Alveolar ventilation can increase 10-fold with an acute rise in  $\text{Paco}_2$ .

The peripheral chemoreceptors located in the aortic arch and carotid bodies respond primarily to decreases in arterial  $\text{O}_2$  concentration.

Increases in the hydrogen ion concentration (decreased pH) or the  $\text{Paco}_2$  also stimulate peripheral chemoreceptors, however the response of peripheral chemoreceptors to a change in  $\text{Paco}_2$  is minor compared with central chemoreceptors.

The Hering-Breuer reflex involves stretch receptors located in the alveolar septa, bronchi, and bronchioles. Inflation of the lung initiates the response that sends neuronal impulses up the vagus nerve to the medulla to cause inhibition of inspiration. Therefore, the rate and duration of inspiration are affected. This reflex is primarily seen in neonates (less so in adults) and at high tidal volumes (greater than 1500 ml) and prevents overinflation of the lung.<sup>2,3,5</sup>

Proprioceptors located in the muscles and tendons of movable joints respond to body movement (exercise). Body movement, such as with exercise, leads to stimulation of respiration (rate and depth) to maintain oxygen levels.<sup>3</sup>

Baroreceptors located in the aortic arch and carotid arteries respond to changes in blood pressure. The aortic arch transmits impulses through the vagus nerve, and the carotid bodies transmit impulses through the glossopharyngeal nerve. An increase in arterial blood pressure leads to inhibition of respiration. A decrease in mean arterial blood pressure below 80 mm Hg leads to stimulation of respiration.

Environmental factors also influence respiration. Individuals demonstrate changes in respiration related to such factors as a cold shower, a pin prick, stress, or airway irritation from air pollution and smoking. Infection and fever also increase the respiratory rate. During normal breathing, energy expenditure is only 3% to 5% of total energy expenditure. During exercise and in patients with high airway resistance energy, expenditure can increase to 50%.

**KEY POINTS**

- Approximately one third of each breath occupies areas of the lung that do not engage in gas exchange. Total (physiologic) dead space includes the anatomic dead space of the bronchial tree and the dead space of unperfused alveoli.
- Alveolar ventilation may be severely compromised in persons with small tidal volumes or increased dead space. When tidal volume is not significantly greater than dead space, increased respiratory rate is not effective in restoring alveolar minute ventilation.
- To move air into the lungs, the respiratory muscles generate a negative intrapleural pressure that causes air inflow, owing to the pressure gradient between the atmospheric pressure at the mouth (zero pressure) and the alveolar pressure (negative pressure).
- Airways and tissues of the lung resist inflation. Resistance is provided by the airways, elastic fibers in the lung, and surface tension in the alveoli. The degree of resistance can be estimated by measuring overall lung compliance. A compliant lung requires minimal pressure to accomplish a large increase in volume; a noncompliant (stiff) lung requires the generation of high pressure to inflate the lung.
- Airway resistance is primarily determined by the diameter of the airways. Airway constriction greatly increases airway resistance. Parasympathetic stimulation of the airways results in constriction; sympathetic ( $\beta_2$ ) stimulation results in dilation.
- Elastic fibers in the lung are stretched during inspiration, then recoil passively to achieve expiration. Destruction of elastic fibers increases lung compliance; excessive fiber production (fibrosis) decreases lung compliance.
- High surface tension in the alveoli causes the surfaces to adhere, making inflation more difficult. Surfactant functions to reduce surface tension. A lack of surfactant makes the lungs more difficult to inflate (decreased compliance).
- The medulla oblongata and pons contain the neurons that integrate information regarding the ventilatory status of the body from chemoreceptors, proprioceptors, and stretch receptors. Respiratory neurons in the medulla initiate inspiration and establish the basic inspiratory-expiratory pattern. Pneumotactic center neurons in the pons primarily influence the rate and depth of respiration.
- Central chemoreceptors located within the medulla detect changes in pH and  $P_{CO_2}$ . Peripheral chemoreceptors are located in the aorta and carotid arteries and detect changes in arterial pH,  $P_{CO_2}$ , and  $P_{O_2}$ . An increase in  $P_{CO_2}$  or a decrease in pH or  $P_{O_2}$  stimulates ventilation.

**PULMONARY BLOOD FLOW****Pulmonary Vasculature**

Perfusion (blood flow) is the second process of respiration, the first being alveolar ventilation. The pulmonary circulation is a low-pressure system (25/8 mm Hg). The volume of blood in the lungs is about 450 ml or 9% of the total amount of blood in the body. This volume can vary from one half normal to twice normal.<sup>3</sup> Unoxygenated blood from the right ventricle is pumped into the main pulmonary artery and then into its branches, which divide into capillary beds throughout lung tissue. The capillary beds surround the alveoli and allow for diffusion of  $O_2$  and  $CO_2$ .

**Distribution of Blood Flow**

Distribution of blood flow (perfusion) is uneven and is affected by body position and exercise. When a person is upright, blood flow is decreased in the upper regions of the lungs (apices), when compared to the lower regions (bases). When a person assumes the supine position, blood flow to the posterior dependent portion of the lung is higher than to the anterior lung, although the redistribution of blood flow is less dramatic than that seen in the upright lung.

The effect of gravity on the lung has led to the concept of lung zones.<sup>5</sup> Figure 21-15 depicts three lung zones. Zone 1 reflects blood flow in the apices of the lung. Blood flow is minimal at the apices because the enlarged alveolar sacs create an alveolar pressure that is higher than capillary pressure, leading to pulmonary capillary collapse. Zone 2, the middle region of the lung, has a pulmonary arterial pressure greater than the pressure inside the alveoli during ventricular systole, but this may fall below alveolar pressure during diastole. Thus, zone 2 is characterized by intermittent perfusion.

Zone 3 is continuously perfused throughout the entire cardiac cycle. Pulmonary arterial pressure is greater than pulmonary venous pressure, which in turn is greater than alveolar pressure. In this zone, capillary vessels are distended and vascular resistance is low.<sup>5,6</sup>

Normally, 1% to 2% of the cardiac output bypasses (right-to-left shunt) alveolar ventilation, creating a decrease in arterial oxygen pressure by 3 to 5 mm Hg.<sup>3,10</sup> In bronchial anastomotic diseases, the amount of shunting may rise to 10% to 20%.<sup>10</sup>

**Ventilation-Perfusion Ratios**

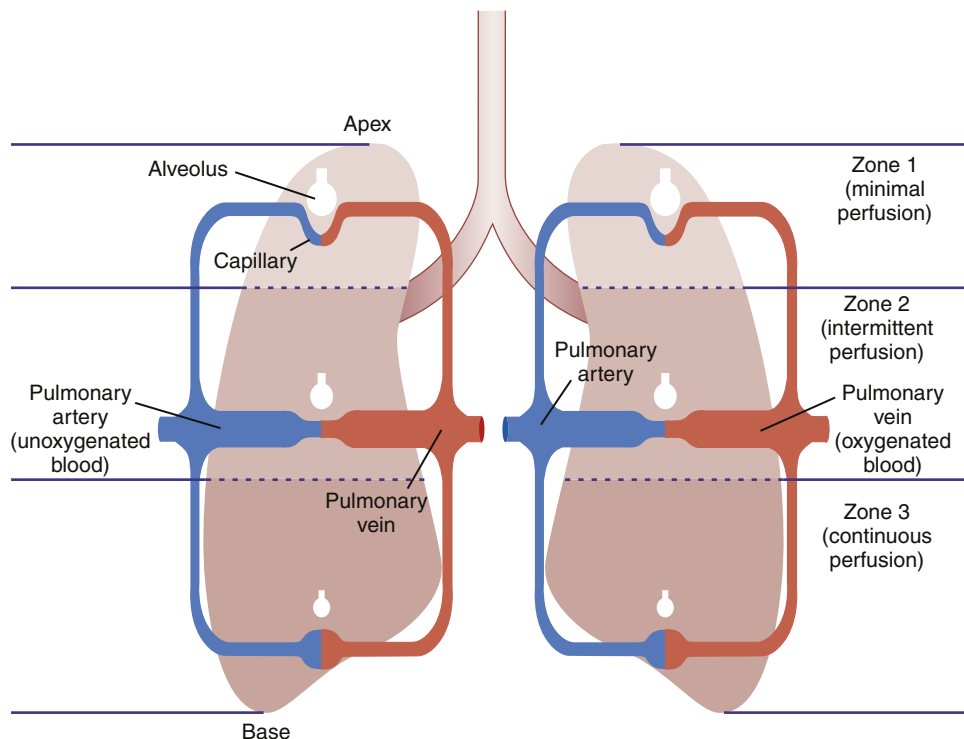

The discussion about distribution of ventilation and perfusion indicates that the best overall ventilation and perfusion occurs in the dependent lung fields. A factor important to the concepts of ventilation and perfusion is the matching of an adequate volume of air in the alveoli to adequate pulmonary blood flow. In the ideal state, 4 L/min of alveolar ventilation is matched to 5 L/min of capillary blood flow in the lungs, creating a normal alveolar ventilation-to-perfusion ratio ( $\dot{V}_A/\dot{Q}$ ) of 0.8 (Box 21-1). Two major factors that affect this normal  $\dot{V}_A/\dot{Q}$  ratio are right-to-left shunt and regional ventilation and perfusion changes. Other factors influencing the ratio are position changes, exercise, bed rest, and lung disease.

To review, in a normal person in the upright position, ventilation and perfusion are lower in the upper lung (apex) than the lower lung (base). In the apex, alveoli are large and receive limited blood flow, whereas in the base, alveoli are smaller and allow for greater expansion of capillaries and thus more blood flow. In the apex,  $\dot{V}_A/\dot{Q}$  is as much as 2.5 times the ideal value, causing a moderate degree of physiologic dead space. In the base,  $\dot{V}_A/\dot{Q}$  is as low as 0.6 times the ideal value, representing lower volumes of air where the blood flow exceeds ventilation. During exercise, blood flow to the upper lung region increases dramatically, thus decreasing physiologic dead space. With bed rest, the dependent area of the lungs becomes the back region in the supine position, so that blood flow is increased to that region and alveoli are smaller.

The three types of ventilation-perfusion imbalances are: (1) high  $\dot{V}_A/\dot{Q}$ , (2) low  $\dot{V}_A/\dot{Q}$ , and (3) true shunt. High  $\dot{V}_A/\dot{Q}$  is conceptually related to physiologic dead space and zone 1, in which the alveolar unit is ventilated but not perfused. High  $\dot{V}_A/\dot{Q}$  units have a low  $P_{CO_2}$  and normal  $P_{AO_2}$  and can be viewed as a respiratory reserve, which can be used if perfusion is restored.

Low  $\dot{V}_A/\dot{Q}$  is conceptually related to lower  $P_{aO_2}$  (hypoxemia). Low  $\dot{V}_A/\dot{Q}$  occurs regionally in areas where the airways are partially obstructed and airflow rates are low. Although an increase in total ventilation results in a decrease in alveolar  $CO_2$  concentration, the increment in  $P_{AO_2}$  and  $O_2$  content in end-capillary blood is minimal.<sup>5,13,14</sup> Low  $\dot{V}_A/\dot{Q}$  is responsive to treatment with oxygen, because the airways are only partially obstructed, so it is possible for oxygen to enter the alveoli by diffusion.

True shunt, which is a right-to-left shunting of unoxygenated blood through the pulmonary circulation, contributes to lowering of  $P_{aO_2}$ . Normally, in a healthy person, there is a small physiologic shunt of less than 5% of cardiac output because of bronchial, thebesian and other veins that bypass the alveoli. In patients with acute respiratory failure

**FIGURE 21-15** Schematic representation of the three lung zones in which different hemodynamic conditions govern blood flow (see text for discussion).

### BOX 21-1 VENTILATION-PERFUSION ( $\dot{V}_A/\dot{Q}$ )<sup>\*</sup> EQUATIONS

#### Low $\dot{V}_A/\dot{Q}$ (underventilated):

$$\frac{2\text{L/min alveolar ventilation}}{5\text{L/min blood flow}}$$

#### Normal $\dot{V}_A/\dot{Q}$ :

$$\frac{4\text{L min alveolar ventilation}}{5\text{L/min blood flow}}$$

#### High $\dot{V}_A/\dot{Q}$ (overperfused):

$$\frac{4\text{L min alveolar ventilation}}{2\text{L/min blood flow}}$$

<sup>\*</sup> $\dot{V}_A/\dot{Q}$ , where  $\dot{V}_A$  = alveolar ventilation and  $\dot{Q}$  = blood flow.

(ARF), physiologic shunt may rise to more than 50%.<sup>14</sup> Although pulmonary shunt is similar to low  $\dot{V}_A/\dot{Q}$  in affecting low arterial oxygen levels, true shunt is not responsive to oxygen therapy because the alveoli are collapsed or consolidated and oxygen cannot gain entry into them. See the Acute Respiratory Failure section for details.

### Hypoxic Vasoconstriction

Alveolar hypoxia leads to a normal compensatory hypoxic vasoconstriction of the pulmonary vessels passing through poorly ventilated portions of the lungs. Blood is diverted from areas of low alveolar oxygen concentration to areas of higher oxygen concentration as a means of compensatory adaptation. By diverting blood flow to areas of higher oxygen concentration, the negative effects on gas exchange

are reduced. Low alveolar oxygen concentration leads to contraction of smooth muscle in the walls of the small pulmonary arterioles.<sup>5</sup>

### KEY POINTS

- Distribution of blood flow is affected by gravity such that perfusion is greatest in dependent lung fields.
- Zones of the lung describe regional differences in perfusion. Zone 1 has no perfusion and is equivalent to dead space; zone 2 is intermittently perfused; zone 3 is continuously perfused throughout the cardiac cycle.
- Optimal alveolar-capillary gas exchange depends on matching of ventilation and perfusion at the alveolus. Abnormalities in  $\dot{V}_A/\dot{Q}$  matching can result in inadequate oxygenation of the blood and insufficient  $\text{CO}_2$  removal. Three types of regional  $\dot{V}_A/\dot{Q}$  imbalance have been described: high  $\dot{V}_A/\dot{Q}$  (dead space), low  $\dot{V}_A/\dot{Q}$  (poor ventilation), and intrapulmonary true shunt (no ventilation).
- Vessels in lung areas that are poorly ventilated, and therefore hypoxic, will constrict to minimize imbalances by diverting blood to better ventilated areas. This is termed *hypoxic vasoconstriction*.

## DIFFUSION AND TRANSPORT OF RESPIRATORY GASES

### Barriers to Diffusion

Diffusion is the passive movement of gas from a high-concentration area to a low-concentration area. Diffusion occurs because of the random, kinetic motion of molecules through the respiratory membranes and fluids.<sup>3</sup> The alveolar-capillary membrane, also known as the respiratory membrane, through which  $\text{O}_2$  and  $\text{CO}_2$  must diffuse consists of six barriers (Figure 21-16). The membrane averages

**FIGURE 21-16** Schematic representing the six barriers through which  $O_2$  and  $CO_2$  must diffuse for gas exchange to occur.

about 0.6 micrometer in thickness.<sup>3</sup> For  $O_2$  to reach the hemoglobin molecule, it must pass through surfactant, the alveolar membrane, interstitial fluid, the capillary membrane, plasma, and the red blood cell (RBC) membrane. The rate of diffusion of a gas is proportional to the tissue area and the difference in gas partial pressure between the two sides of alveoli, and inversely proportional to the tissue thickness through which the gas must move. Oxygen diffuses into the blood from the alveoli, and  $CO_2$  diffuses out of the blood into the alveoli. Under normal conditions,  $O_2$  and  $CO_2$  move across the alveolar-capillary membrane in only 0.25 second. The RBC spends about 0.75 second within the pulmonary capillary system surrounding the alveoli, thus allowing an extra 0.50 second of exchange time. Even with mild disease processes,  $O_2$  and  $CO_2$  have adequate time for transfer. Oxygen concentration in the alveoli, as well as its partial pressure, is controlled by (1) the rate of absorption in the blood and (2) the rate of entry of new oxygen into the lungs by the ventilation process.<sup>3</sup>

Under abnormal conditions, such as thickening of the alveolar-capillary membrane (pneumonia, pulmonary edema, and interstitial lung disease) and decreased available surface area (emphysema), the diffusion capacity of the lung tissue is impaired. Diffusion capacity may be further impaired by increased physical activity, because of the decreased time spent by the RBCs in the pulmonary capillary system. Thickening of the alveolar-capillary membrane also occurs with aging. However, barriers to diffusion are rarely a primary cause of abnormal  $Pao_2$  or  $Paco_2$ ; abnormal diffusion of gases is usually secondary to  $\dot{V}_A/\dot{Q}$  mismatch.

$CO_2$  is more diffusible than  $O_2$ , because of its greater solubility.<sup>5</sup> Factors that determine the ability and the speed of a gas to diffuse include the available surface area of alveoli and capillaries, the integrity of the capillary and alveolar membranes, the availability of hemoglobin to transport oxygen, the solubility of the gas, the diffusion coefficient of the gas, and the differences in partial pressure of the gases on each

side of the alveolar membrane. For example, because  $CO_2$  is 24 times more soluble than  $O_2$ , it diffuses 20 times more rapidly and requires a lower partial pressure for exchange.

The decreased diffusing capacity seen in the aged person is further compromised by a decrease in the number of pulmonary capillaries and decreased lung volume and capacities. The end result is a decreased  $Pao_2$  and increased  $\dot{V}_A/\dot{Q}$  mismatch. The  $Pao_2$  value drops about 3 to 5 mm Hg for each decade after age 30 years.<sup>5</sup> Therefore, an 80-year-old individual could be expected to have a  $Pao_2$  of 75 mm Hg. Diffusion is also decreased in the newborn because of the thickness of the alveolar membrane.<sup>6</sup> In a healthy adult, the  $Pao_2$  value would be 90 to 100 mm Hg (see Table 21-1 for variations in respiratory anatomy and physiology by age grouping).

### Oxygen Transport

Oxygen is transported to the tissues by two mechanisms: (1) dissolved in plasma and (2) bound to the hemoglobin molecule. Only about 0.3 ml of  $O_2$  per 100 ml is carried dissolved in the plasma.<sup>5</sup> The remaining  $O_2$  is transported on the hemoglobin molecule. A high concentration (partial pressure) of  $O_2$  in the pulmonary capillaries causes  $O_2$  to bind to the hemoglobin molecule. Heme is an iron-porphyrin compound that joins with the four polypeptide chains of the protein globin. Oxygen binds to iron in each of the four heme sites to form oxyhemoglobin. At the tissue level where the partial pressure of  $O_2$  is low,  $O_2$  is released from the hemoglobin molecule. Depending on tissue needs, 25% of the oxygen is normally unloaded at the tissues in a resting individual, which results in venous blood being 75% saturated with oxygen.

When hemoglobin is fully bound to  $O_2$  it is nearly 100% saturated and yields a  $Pao_2$  of 95 to 100 mm Hg. Increasing alveolar  $O_2$  concentration above this level will have no further effect on increasing the amount of  $O_2$  carried on the hemoglobin molecule (Figure 21-17). Oxygen binds when there is a high affinity of hemoglobin for oxygen (at the lungs) and releases when the affinity is decreased at the tissue level to maintain adequate metabolic processes. When  $Pao_2$  is less than 60 mm Hg, saturation of hemoglobin with oxygen ( $Sao_2$ ) falls steeply (see Figure 21-17). The oxyhemoglobin dissociation curve diagram shows the effects of increases and decreases in  $O_2$  affinity at any  $Pao_2$  level. Decreased  $O_2$  affinity, also termed a *shift to the right*, aids in the release of  $O_2$  from the hemoglobin molecule, thus facilitating movement of  $O_2$  from the blood to the tissues. Factors that shift the curve to the right include acidosis, hyperthermia, increased  $Paco_2$  value, and increased 2,3-bisphosphoglycerate (2,3-BPG) concentration, which is an end product of RBC metabolism. The availability of  $O_2$  is also decreased by reduced cardiac output and anemia.<sup>3</sup>

Increased  $O_2$  affinity, termed a *shift to the left*, represents a tighter binding of  $O_2$  to the hemoglobin molecule that helps loading of oxygen in the lungs, however it may impair delivery to the tissues. Although an increased affinity for  $O_2$  reflects a higher percentage of saturated hemoglobin, its ineffective release in the tissues may be profound. Factors that affect hemoglobin affinity and shift the curve to the left (increased affinity) include alkalosis, hypothermia, decreased  $Paco_2$  value, and decreased 2,3-BPG concentration.

$CaO_2$  is the sum of dissolved oxygen in the plasma plus the oxygen carried on the hemoglobin (Hb) molecule. (See Chapter 13 for a more detailed discussion of oxygen carriage and transport.) Normal arterial blood oxygen content ( $CaO_2$ ) is 20 ml of  $O_2$  per 100 ml of blood (vol%) and can be calculated by the following formula:

$$CaO_2 \text{ (vol \%)} = [\text{Hb (g/dl)} \times 1.34 \text{ (ml of } O_2 \text{ / g of Hb)} \times SaO_2] + (PaO_2 \times 0.003)$$

**FIGURE 21-17** Oxyhemoglobin dissociation curve showing factors affecting hemoglobin's affinity for oxygen. Curve *B* is the standard curve under normal conditions. Curve *A* shows a shift to the left, which represents an increased affinity of hemoglobin for oxygen. Curve *C* demonstrates a shift to the right, which represents a decreased affinity. (From Gottlieb JE: *Breathing and gas exchange*. In Kinney MR, Packa DR, Dunbar SB, editors: *AACN's clinical reference for critical care nursing*, ed 4, New York, 1998, McGraw-Hill, p 672.)

## Carbon Dioxide Transport

Carbon dioxide, a byproduct of cellular metabolism, is transported in the blood in three ways: dissolved in plasma (5% to 10% of the total  $\text{CO}_2$  transport); as bicarbonate (60% to 70%); and as carbamino compounds on the hemoglobin molecule (20% to 30%). The greatest bulk of  $\text{CO}_2$  transport is in the bicarbonate form. In the presence of the RBC enzyme carbonic anhydrase,  $\text{CO}_2$  combines with water to form carbonic acid, which in turn almost instantaneously breaks down into bicarbonate ions and hydrogen ions. The released hydrogen ions attach to the hemoglobin molecule, while the bicarbonate ion diffuses into the plasma. Chloride ions in the surrounding plasma shift into the RBC (chloride shift). This chemical process is reversed when the venous blood reaches the lungs, so that  $\text{CO}_2$  can diffuse across the alveolar membrane to be exhaled.

### KEY POINTS

- Oxygen and  $\text{CO}_2$  diffuse quickly across alveolar-capillary membranes. Complete equilibration of gases occurs in the first third of the capillary under normal conditions. Diffusion may be incomplete when the alveolar-capillary membrane is abnormally thickened or capillary blood flow is extremely rapid.
- Carbon dioxide is more soluble and diffuses more quickly than  $\text{O}_2$ . Disorders of diffusion often affect  $\text{O}_2$  transfer earlier and more significantly than  $\text{CO}_2$  transfer.

- Oxygen is carried in the blood in two forms: dissolved in solution ( $\text{PaO}_2 \times 0.003$ ) and bound to hemoglobin ( $\text{Hb} \times \text{Sao}_2 \times 1.34$ ). Significantly more  $\text{O}_2$  is bound than dissolved. Low hemoglobin level and low hemoglobin saturation profoundly affect the  $\text{O}_2$  content in the blood.
- The oxyhemoglobin saturation curve describes the relationship between  $\text{PaO}_2$  and hemoglobin saturation. At a  $\text{PaO}_2$  of 90 to 100 mm Hg, hemoglobin is fully saturated. An increase in  $\text{PaO}_2$  above this level does not significantly improve  $\text{O}_2$  content.
- The affinity of hemoglobin for  $\text{O}_2$  is affected by temperature, acid-base status, 2,3-BPG levels, and  $\text{CO}_2$  concentration. Affinity decreases at the tissue level because of increased concentrations of  $\text{H}^+$  ions, 2,3-BPG, and  $\text{CO}_2$ . This "shift to the right" enhances the unloading of  $\text{O}_2$  at the tissue. A "shift to the left" occurs at the lung, where the blood is more alkalotic and  $\text{CO}_2$  levels are lower. Increased affinity of hemoglobin in the lung enhances oxygen binding.
- Carbon dioxide is transported in the blood in three major forms: dissolved, as carbaminohemoglobin, and as bicarbonate ion. The most important of these is bicarbonate ion, which is formed from the combination of  $\text{CO}_2$  and  $\text{H}_2\text{O}$ , producing carbonic acid ( $\text{H}_2\text{CO}_3$ ). Carbonic acid dissociates into  $\text{HCO}_3^-$  and  $\text{H}^+$ . At the lung, the reaction proceeds in the reverse direction to form  $\text{CO}_2$ , which diffuses into the alveoli.

## ALTERATIONS IN PULMONARY FUNCTION

Partial pressures of arterial  $O_2$  in the newborn (60 to 70 mm Hg) and elderly (70 to 80 mm Hg) are less than those in the adult. The lower  $O_2$  pressure is well tolerated in the newborn, because of the presence of fetal hemoglobin, which has decreased binding of 2,3-BPG, thus facilitating oxygen transfer by shifting the oxygen dissociation curve to the left. The newborn also has a higher hemoglobin concentration (20 to 21 g/dl) for the first few weeks after birth. Therefore, oxygenation is not normally a problem. The lower  $P_{aO_2}$  of the newborn is also associated with an increased  $P_{aCO_2}$ . Other blood gas values (see Table 21-1) show little difference from those of adults unless an oxygenation problem is present, such as infant respiratory distress syndrome or congenital heart disease.

### Hypoventilation and Hyperventilation

*Hypoventilation* occurs when delivery of air to the alveoli is insufficient to meet the need to provide oxygen and remove carbon dioxide. It is influenced by decreased rate and depth of respiration. Hypoventilation results in increased  $P_{aCO_2}$  (>45 mm Hg) and resultant hypoxemia due to increased alveolar carbon dioxide, which displaces oxygen.<sup>12</sup> Causes may be drugs, such as morphine or barbiturates (which depress the central respiratory drive), or disorders such as obesity (pickwickian syndrome), myasthenia gravis, obstructive sleep apnea, chest wall damage, or paralysis of respiratory muscles (especially the diaphragm).<sup>5</sup> Pain related to surgery of the thorax or abdomen often results in hypoventilation secondary to decreased inspiration.

*Hyperventilation* is an increase in the amount of air entering the alveoli, leading to hypocapnia ( $P_{aCO_2}$  <35 mm Hg).<sup>5,13</sup> A physiologic cause of hyperventilation is hypoxic stimulation of peripheral chemoreceptors. Pain, fever, and anxiety are common causes of hyperventilation. Less common causes include obstructive and restrictive lung diseases, sepsis, and brainstem injury (central neurogenic hyperventilation). Hyperventilation is a normal physiologic response to high altitude as a compensatory mechanism to decrease  $P_{aCO_2}$ . Low  $P_{aCO_2}$  leads to a greater ability to bind oxygen to hemoglobin (shift to the left) despite low oxygen pressure in the inspired air at high altitude.

Ineffective gas exchange from ventilatory failure occurs when an adequate volume of gas is maldistributed, minute ventilation is decreased, and/or alveolar hypoventilation occurs. Maldistribution of gas occurs in patients with emphysema, in which gas exchange occurs only in some alveolar units.<sup>5</sup> In the healthy lung, some maldistribution of gas occurs because of gravitational forces on the lung, as previously discussed. In addition to the gravitational forces, airway resistance affects distribution of gases. In obstructive pulmonary diseases, increased airway resistance develops in localized regions because of (1) obstruction of airways from increased sputum production, (2) mucosal hypertrophy and edema, (3) loss of structural integrity of the airway, and (4) narrowing of the airway from bronchial smooth muscle contraction, when there is hyperactivity of the airways.<sup>5</sup> During expiration, air leaves the areas of least resistance first, thus creating areas of maldistribution of gas.

### Hypoxemia and Hypoxia

Two terms frequently used in discussing decreased  $P_{aO_2}$  are *hypoxemia* and *hypoxia*. Hypoxemia refers to deficient levels of blood oxygen as measured by low arterial  $O_2$  concentration and low hemoglobin saturation as measured by arterial blood gases or pulse oximetry ( $O_2$  saturation). Hypoxia refers to a decrease in tissue oxygenation. Tissue hypoxia is difficult to measure, but may be assumed when either blood

flow or  $P_{aO_2}$  is abnormally low. A decrease in blood flow leads to a decrease in oxygen delivery.

Resultant types of hypoxia can be classified into four categories: hypoxic hypoxia, anemic hypoxia, circulatory hypoxia, and histotoxic hypoxia. Hypoxic hypoxia occurs when the  $P_{aO_2}$  is decreased despite normal  $O_2$ -carrying capacity.<sup>6</sup> Causes include high altitude, hypoventilation, and airway obstruction. Oxygen therapy usually provides adequate treatment.

Anemic hypoxia results from a decrease in  $O_2$ -carrying capacity. Any disorder resulting in low hemoglobin concentration can cause anemic hypoxia.

Circulatory hypoxia results from a low cardiac output state in which the  $O_2$ -carrying capacity is normal, but blood flow is reduced. Examples of circulatory hypoxia include shock, cardiac arrest, severe blood loss, thyrotoxicosis, and congestive heart failure.

The final classification is histotoxic hypoxia, which occurs when interference of a toxic substance leads to the inability of tissues to utilize available oxygen. Cyanide poisoning is an example of histotoxic hypoxia.

Ineffective gas exchange when ventilation and perfusion are mismatched, when diffusion abnormalities exist, and when right-to-left shunt exists. During periods of normal perfusion not all capillaries are open; however, the capillary system has the ability to recruit (open up) more capillaries and to distend (expand) capillaries already in use (see Figure 21-9) to increase alveolar blood flow when it is needed as a compensatory mechanism. In addition, 1% to 3% of the total blood flow in the lung is not oxygenated because the thebesian, pleural, and bronchial veins drain unoxygenated blood into the left side of the heart and into the pulmonary veins.

Areas of low ventilation-perfusion (see Box 21-1) may have normal perfusion, but receive inadequate alveolar ventilation (Figure 21-18, A). These areas are similar to shunting of unoxygenated pulmonary arterial blood through totally unventilated units except that they are responsive to oxygen therapy. Areas of high ventilation-perfusion (see Figure 21-18, B) may have adequate ventilation (high oxygen level in the alveoli), but have areas of decreased perfusion. This effect is similar to having increased dead space, clinically represented by areas of ventilation without blood flow. Although it is difficult clinically to differentiate diffusion defects from shunt effect, abnormalities occur in patients who have thickening of the alveolar-capillary membrane. Examples of diseases with thickened membranes include Goodpasture syndrome, systemic lupus erythematosus, sarcoidosis, diffuse interstitial fibrosis, and alveolar cell carcinoma.<sup>3</sup>

Ineffective gas exchange is also seen in patients with true pulmonary shunt (see Figure 21-18, C). A shunt effect results from blood flowing from the right side to the left side of the heart without passing through ventilated areas of the lung. Anatomic shunts may occur in patients with ventricular septal defects, atrial septal defects, and patent ductus arteriosus. Localized pneumonia and adult respiratory distress syndrome (ARDS) result in intrapulmonary shunts because of  $\dot{V}_A/\dot{Q}$  mismatch, in which alveoli are perfused but not ventilated.

### Acute Respiratory Failure (ARF)

Acute respiratory failure (ARF) is defined as a state of disturbed gas exchange resulting in abnormal arterial blood gas values: a  $P_{aO_2}$  value less than 60 mm Hg (hypoxemia), and a  $P_{aCO_2}$  value greater than 50 mm Hg (hypercapnia) with a pH less than 7.30 when the patient is breathing room air.<sup>1,13-15</sup> Patients with respiratory failure can be divided into three categories: (1) those with failure of respiration or oxygenation leading to hypoxemia and normal or low carbon dioxide levels; (2) those with failure of ventilation leading to hypercapnia; and (3) those with a combination of respiratory and ventilatory failure.

**FIGURE 21-18** Ventilation-perfusion abnormalities. **A**, Low  $\dot{V}_A/\dot{Q}$  areas that are well perfused but underventilated. **B**, High  $\dot{V}_A/\dot{Q}$  areas that are well ventilated but underperfused. **C**, Shunt areas that have no ventilation but are perfused (blood flow passes unventilated alveoli).

**Etiology.** The precise pathophysiologic mechanism of ARF depends on the cause or causes of the disease process. A number of conditions may cause respiratory failure (Box 21-2), including disorders of the neuromuscular chest apparatus (poliomyelitis, Guillain-Barré syndrome, quadriplegia, hemiplegia), disorders affecting the chest skeletal system (kyphoscoliosis), and chest trauma (rib and sternal fractures). Shock (e.g., septic, hypovolemic), pulmonary emboli (PE), and pulmonary edema may also lead to respiratory failure. Extreme obesity may lead to alveolar hypoventilation, resulting in respiratory failure. The most common lung diseases causing ARF are advanced emphysema, pneumonia, asthma, and ARDS.

In general, the development of hypoxemia is related to poorly matched ventilation and perfusion. The development of hypercapnia is related to inadequate alveolar ventilation in relation to production of carbon dioxide.

**Clinical manifestations.** Clinical features of ARF vary with the cause. General features of hypoxia and hypercapnia include headache, dyspnea, confusion, decreased level of consciousness, restlessness, agitation, dizziness, tremors, and initial hypertension, followed by hypotension and tachycardia.<sup>13</sup> Early signs include rapid, shallow breathing with increased inspiratory muscle movement. Late findings include cyanosis, nasal flaring, and sternal and intercostal retractions.<sup>1,5,7,12</sup> The increased work of breathing may lead to cool, clammy skin, dysrhythmias, and decreased capillary refill time.

**Diagnosis.** Diagnostic tests include measurement of arterial blood gases and chest radiography. A  $P_{aO_2}$  of less than 60 mm Hg and a  $P_{aCO_2}$  of greater than 50 mm Hg on room air are common findings.<sup>12,13</sup> Chest radiographic findings depend on the disease process. Other supporting tests include an electrolyte panel with evidence of electrolyte imbalance such as low potassium and low sodium concentrations, and a complete blood cell count with evidence of increased numbers of white blood cells associated with infection or decreased levels of red blood cells and hemoglobin attributable to anemia.

**Treatment.** Maintaining ventilatory support by maintaining airway patency and ensuring adequate alveolar ventilation is the primary goal of therapy. Mechanical ventilation may be the initial treatment, followed by management of the underlying cause. If a neuromuscular problem or skeletal weakness is present, assisted ventilation with a positive-pressure volume ventilator is indicated to maintain airway patency and ensure adequate alveolar ventilation.

The primary goal of therapy is to provide adequate oxygenation at the cellular level by maintaining a  $P_{aO_2}$  greater than 60 mm Hg (oxygen saturation, 90%). Specific interventions depend on the cause. If acute respiratory failure is caused by chronic obstructive pulmonary disease, then vigorous management of bronchospasm and possible infection is required using a combination of methylxanthines,  $\beta_2$  agonists, corticosteroids (controversial), and antibiotics. Heart failure or hypotension may require drug therapy. Diuretics may be given for volume reduction depending on the fluid volume status of the patient. Hypotension should be managed promptly with volume replacement and/or vasopressors. The use of corticosteroids in high doses for the first 24 to 48 hours of the disease process is controversial, because no conclusive evidence of efficacy is available.<sup>12-14</sup>

General supportive care consists of providing adequate nutrition to maintain fluid and electrolyte balance, offering pain management and emotional support, and preventing complications of gastrointestinal stress and bed rest. Developing a method of communication with ventilated patients is also very important. High-calorie, high-protein, low-carbohydrate nutritional support is recommended. A diet high in carbohydrates should be avoided because of its tendency to increase carbon dioxide production.<sup>13</sup> (See Chapter 23 for specific treatments for ARDS and infant respiratory distress syndrome.)

#### KEY POINTS

- Ventilatory failure occurs when alveolar ventilation is insufficient to accomplish adequate gas exchange. Ventilatory failure may result from decreased respiratory rate, decreased tidal volume, or increased dead space. Arterial blood gas analyses demonstrate hypercarbia and hypoxemia.
- A general deficiency of  $O_2$  in the blood (hypoxemia) results from poor diffusion at the alveoli (hypoxic hypoxia) or anemia (anemic hypoxia). Tissue hypoxia may be due to general hypoxemia or poor perfusion (circulatory hypoxia) or result from poor uptake of  $O_2$  by the tissue (histotoxic hypoxia).
- Oxygenation failure occurs when diffusion of gases across the alveolar-capillary interface is impaired. Oxygenation failure may be due to mismatching, right-to-left shunt, or excessive barriers to diffusion. Arterial blood gas values demonstrate hypoxemia but not necessarily hypercarbia.
- Acute respiratory failure is generally diagnosed from arterial blood gas disturbances. The usual defining values are a  $P_{aO_2}$  less than 60 mm Hg and a  $P_{aCO_2}$  greater than 50 mm Hg when the subject is breathing room air.
- Conditions that predispose an individual to hypoventilation, ventilation-perfusion mismatch, or right-to-left shunt may lead to respiratory failure

**BOX 21-2 CAUSES OF ACUTE RESPIRATORY FAILURE**

**Central Nervous System**

Drug overdose (sedative, hypnotic, opioid, anesthetic)  
 Cerebral vascular accident (stroke)  
 Hypothyroidism  
 Central nervous system infections  
 Brain trauma  
 Brain tumor

 Cardiac and noncardiac pulmonary edema  
 Shock  
 Increased CO<sub>2</sub> production
 

- Fever
- Infection
- Hyperthyroidism
- Drugs

(e.g., drugs, neuromuscular weakness, chest wall deformities or trauma, and parenchymal lung diseases).

- Manifestations of respiratory failure are due to tissue hypoxia and compensatory responses and include confusion, tremors, hypotension, depressed consciousness, tachypnea, and tachycardia.
- The goal of therapy is to reduce tissue hypoxia by maintaining Pao<sub>2</sub> above 60 mm Hg. Depending on the underlying disease process, this may require mechanical ventilation, supplemental oxygen administration, nutritional supplementation, and utilization of bronchodilators and antibiotics.

**ALTERATIONS IN PULMONARY VASCULATURE**

**Pulmonary Hypertension**

**Etiology.** Normally the pulmonary circulation is a high-flow, low-pressure system. Pulmonary hypertension is defined as a sustained increase in pulmonary artery pressure above 25 mm Hg systolic resting and above 30 mm Hg systolic with exercise. In some cases of pulmonary hypertension, systolic pressures may be as high as 60 to 110 mm Hg. Two broad types of pulmonary hypertension exist: primary (idiopathic) and secondary. Primary pulmonary hypertension (PPH) is relatively rare (1300 per 1 million people), rapidly progressive, and more common in women than men (1.7:1 ratio). PPH usually presents in the third to fourth decade of life.<sup>16</sup> The cause is unknown, but can be associated with portal hypertension of cirrhosis, use of appetite-suppressant drugs, and human immunodeficiency virus infection. Most cases are sporadic and may be familial<sup>14</sup> (6% to 12% of cases); however, mutations in the genes that code for members of the tumor growth factor-β family of receptors

on chromosome 2q33 have been found in some cases.<sup>16</sup> The long-term prognosis is poor, and medical management is usually ineffective.

Secondary pulmonary hypertension results from a known disease process or pathophysiologic condition. Increased pulmonary blood flow, increased resistance to blood flow, and increased left atrial pressure are the three major mechanisms resulting in pulmonary hypertension. Of these, increased resistance to blood flow is the most common cause and is attributable to hypoxic vasoconstriction as seen in chronic bronchitis and advanced emphysema.<sup>15,16</sup> Box 21-3 lists the major causes of secondary pulmonary hypertension.

**Pathogenesis.** Chronic exposure to the mechanisms listed in Box 21-3 (except PPH) results in morphologic changes within the arterial lumen. Initially, the walls of the small pulmonary vessels thicken because of an increase in the muscle. This initial response is thought to occur as a result of local tissue hypoxia, acidosis, or both.

As the underlying pathologic process intensifies, the internal layer of the pulmonary artery wall becomes fibrotic, with further muscle thickening. In addition, muscle development occurs in vessels that are normally nonmuscular. Pulmonary atherosclerosis is present in major pulmonary vessels as well.

Sustained pulmonary hypertension (mean pulmonary arterial pressure of 27 to 60 mm Hg) results in the formation of plexiform (network of blood vessels) lesions. These nodular lesions are composed of irregular, interconnecting blood channels that further impede an already compromised pulmonary vasculature. Tissue necrosis and hemorrhage often result.

**Clinical manifestations.** The clinical manifestations of pulmonary hypertension vary according to the severity and duration of the underlying pathologic process. Because of the normal distensibility of

## BOX 21-3 MECHANISMS OF SECONDARY PULMONARY HYPERTENSION

### Increased Pulmonary Vascular Resistance

#### Vasoconstrictive

- Alveolar hypoxia attributable to bronchitis or emphysema
- Acidosis
- High altitude
- Thromboembolic causes from obstruction or release of histamine, serotonin, or catecholamines
- Hypoxia attributable to neuromuscular disease, obesity, obstructive sleep apnea, or kyphoscoliosis

#### Obstructive

- Embolism (blood clots, fat emboli, amniotic emboli, tumor cells, or foreign body)

#### Obliterative (loss of capillary bed)

- Emphysema
- Lung resection
- Pulmonary fibrosis
- Collagen vascular disease
- Vasculitis

### Increased Left Atrial Pressure

Mitral stenosis, mitral regurgitation

Left ventricular failure

Constrictive pericarditis

### Increased Pulmonary Blood Flow/Viscosity

Atrial septal defects

Ventricular septal defects

Polycythemia

Sickle cell disease

Patent ductus arteriosus

Congenital heart disease

### Other

Portal hypertension/liver cirrhosis

Appetite-suppressant drugs

HIV

Schistosomiasis

Sarcoidosis

pulmonary capillaries and the ability of the lung to recruit additional reserve capillary beds with increased pressure or flow, the condition often remains asymptomatic until significant damage to pulmonary vasculature has occurred. Exercise intolerance (because of progressive loss of pulmonary capillary distention and recruitment capabilities) is often one of the earliest clinical symptoms. Patients may also experience syncope, increasing dyspnea, chest pain on exertion, fatigue, hemoptysis, and pulmonary edema. Eventually, cor pulmonale (right-sided heart enlargement secondary to primary lung disease) and right ventricular failure will develop if persistent, severe pulmonary hypertension continues, because of persistent backpressure to the right-sided heart chambers. (See the discussion of cor pulmonale and heart failure in Chapter 19.) Common signs and symptoms of pulmonary hypertension are dyspnea (60% of cases),<sup>16</sup> syncope, chest pain, jugular venous distention, a systolic ejection click, narrowing or a splitting of  $S_2$  and  $S_4$ , and accentuation of the pulmonary component of the second heart sound ( $P_2$ ).<sup>11,14,16,17</sup> In advanced cases, tricuspid and pulmonary valve insufficiency are present.<sup>14,16</sup> Development of a hoarse voice attributable to compression of the recurrent laryngeal

nerve by an engorged pulmonary artery (Ortner syndrome) may occur.

**Diagnosis.** Pulmonary artery catheters are used to obtain accurate pulmonary arterial pressure measurements in patients at rest and during exercise. Unfortunately, even if mild pulmonary hypertension is present, pulmonary arterial pressure values are usually normal at rest. Pulmonary arterial pressures measured in the exercising subject would be the optimal diagnostic tool. However, the feasibility of exercising a patient with invasive central line monitoring is problematic. The pulmonary artery catheter could become wedged and necrosis could occur, or the catheter could slip back into the ventricle and irritate the myocardium, causing ventricular dysrhythmias. Stress testing without exercise may be done in the cardiac catheterization laboratory by using medications to increase cardiac output.

A chest radiograph, although usually normal in cases of mild pulmonary hypertension, is one of the earliest diagnostic tools to suggest the presence of moderate to severe hypertension. Enlargement of the pulmonary arteries and right ventricle, as well as abnormal vessel contours, is indicative of hypertensive disease. The 12-lead electrocardiogram (ECG) shows evidence of right ventricular hypertrophy. The two-dimensional echocardiogram (a noninvasive technique) can also provide evidence of pulmonary hypertension. Echocardiography may reveal mitral stenosis, left atrial myxoma, and right heart enlargement. Further diagnostic tests should be done to exclude causes of secondary pulmonary hypertension.

**Treatment.** The major treatment for pulmonary hypertension is early identification and control of the underlying disease process. In the case of left-to-right shunts, surgical closure of an atrial septal defect or patent ductus arteriosus may be indicated. Because the most common cause of pulmonary hypertension is related to increased pulmonary vascular resistance, treatment is often directed at reversing vasoconstriction by administering supplemental oxygen and avoiding vigorous exercise and pregnancy. Depending on the stage of hypertension, vasodilators and diuretics are commonly used in an attempt to control the symptoms. These medical regimens have produced inconsistent results.<sup>15,16</sup>

Advanced stages of primary pulmonary hypertension are irreversible. The only feasible intervention is lung or heart-lung transplantation. Continuous long-term infusion of prostacyclin (epoprostenol, treprostinil) is being used for its potent vasodilatory effect on the pulmonary vessels. It improves exercise capacity, quality of life, and long-term survival.<sup>16</sup>

## Pulmonary Venous Thromboembolism

**Etiology.** A pulmonary embolus (PE) is undissolved detached material that occludes blood vessels of the pulmonary vasculature. As a result, circulation distal to the obstructed area is impaired. Approximately 650,000 patients are affected annually, with an estimated mortality of 50,000 annually. Of those who experience fatal PE, 8% to 10% die within 1 hour of the onset of initial symptoms.<sup>18-20</sup>

More than 90% of pulmonary thromboemboli originate in the deep veins of the lower extremities.<sup>17,18</sup> Other sources of PE include fat, air, and amniotic fluid. The types of emboli and their causes are summarized in Table 21-3.

Virchow, a pathologist of the 1800s, discovered three physiologic factors that predispose patients to thrombus formation, increasing the risk of PE. The three factors, commonly referred to as *Virchow's triad*, are venous stasis (sluggish blood flow), hypercoagulability, and damage to the venous wall (intimal injury). Several predisposing factors enhance the probability of thrombus development and the subsequent risk for PE. Using Virchow's triad, predisposing factors have been categorized under each of the three components (Box 21-4). The most common

**TABLE 21-3 EMBOLISM TYPES AND CAUSES**

EMBOLISM TYPE	CAUSE
Thrombotic	Blood clots develop in venous system, predominantly in thighs and legs
Fat	Globules of fat secondary to fractures of pelvis or long bones
Amniotic fluid	Collections of fluid, hair, or other debris related to complicated labor, especially in older, multiparous women
Air	Venous access through IV catheters
Tumor	Fragments from malignant tissue
Foreign material	Foreign bodies (bullets, sutures, catheter tips, orally prepared medications injected IV)
Septic	Infected tissue or related substances (fungal/bacterial)
Parasitic	Parasites present in lung vasculature

**BOX 21-4 FACTORS PREDISPOSING TO PULMONARY EMBOLISM OF VIRCHOW'S TRIAD**

**Venous Stasis**

- Extended bed rest (delayed venous removal of activated clotting factors)
- Postoperative state
- Immobility (activated clotting factors)
- Vascular disorders (thrombophlebitis of lower extremities and pelvic area)
- Congestive heart failure (venous backflow/stasis)
- Cardiac dysrhythmias (atrial fibrillation)
- Dehydration
- Prolonged air travel
- Obesity

**Hypercoagulability**

- Oral contraceptives (estrogen therapy), hormone replacement therapy
- Pregnancy, early puerperium
- Polycythemia (chronic high altitude; chronic pulmonary disease with decreased Pao<sub>2</sub> and increased Paco<sub>2</sub>)
- Malignant pathologic processes, visceral cancer
- Cigarette smoking
- Inherited resistance to activated protein C
- Deficiency of protein S
- Deficiency of antithrombin III
- Prothrombin gene mutation
- Presence of antiphospholipid antibodies (lupus), anticoagulant and anticardiolipin antibodies

**Damage to Vessel Wall (Intimal Injury)**

- Blunt trauma
- Penetrating wounds
- Bone fractures with soft-tissue injury
- Surgical procedures (hip, pelvic, abdominal, cardiovascular)
- Obstetric manipulations during labor and delivery
- Burns
- Central venous catheter

action, and changes in blood flow. Regardless of whether the emboli are blood clots or an alternative type of material (see Table 21-3), once they are released into the venous system, the undissolved material travels to the pulmonary vasculature.<sup>13</sup> The lower lobes are frequently involved because of high blood flow.<sup>14</sup> The impact of pulmonary emboli on the cardiopulmonary circulation depends on the size and cross-sectional area of circulatory impairment. If the embolus occludes less than 25% of the pulmonary vessels in a healthy individual, no physiologic changes may be seen. When the occlusive area approaches 25% to 30%, pulmonary arterial pressures may begin to rise, with potential right-sided heart failure.<sup>16,17</sup> In the patient without any underlying pulmonary pathology, 50% of the cross-sectional pulmonary circulation must be impaired before dangerously high pulmonary arterial pressures are generated. Because of the large pulmonary capillary reserve, significant damage is necessary before pulmonary decompensation occurs.<sup>14</sup>

Pulmonary arterial pressures increase because of vasoconstriction from actual mechanical obstruction of blood vessels and the release of serotonin and neural sympathetic stimulation in a combined neurohormonal response. Right-sided heart failure occurs because of the high resistance generated by the pulmonary vasculature. Eventually, hypotension occurs as a result of diminished cardiac output.<sup>16</sup>

Actual pulmonary infarction (death of lung parenchyma) occurs only in about 10% to 15% of cases of PE.<sup>16</sup> Pulmonary necrosis is rare, because three sources are available for oxygen supply: the pulmonary arterial circulation, the bronchial arterial circulation, and the airways. Significant underlying pulmonary or cardiac impairment (chronic obstructive pulmonary disease, mitral stenosis) increases the risk for occurrence of pulmonary infarctions.<sup>14,16</sup>

**Clinical manifestations.** Presenting symptoms depend on the size of the embolus, as well as on any underlying cardiopulmonary pathologic conditions. Initial symptoms may include restlessness, apprehension, and anxiety. The most common symptom is dyspnea (75% to 85% of patients).<sup>14,18</sup> In addition, tachycardia (23%) and tachypnea (30%) are often present. Sudden dyspnea and severe chest pain are usually associated with medium-sized to massive pulmonary emboli. Chest pain may be nonpleuritic or pleuritic (infarction).<sup>18</sup> Pain on inspiration is seen in 65% to 75% of patients.<sup>15</sup> Hemoptysis may or may not occur. As the clinical picture worsens, patients experience heart failure, shock, and respiratory arrest.

**Diagnosis.** Because PE is often misdiagnosed, the clinician should have a high index of suspicion when clinical manifestations, combined with factors predisposing to pulmonary embolism (see Box 21-4), are noted.<sup>19,20</sup> Although no simple noninvasive test has both high specificity and high sensitivity, the V<sub>A</sub>/Q̇ lung scan is one of the tests performed to determine the presence of a PE. The scan determines if a mismatch exists between ventilation and perfusion. Adequate ventilation with impaired perfusion (blood flow) to the pulmonary vasculature (mismatch) is indicative of PE, if the scan is performed within 8 hours of symptom onset. Helical angiography is replacing lung scans as the initial diagnostic test for pulmonary thromboembolism. This noninvasive test requires administration of radiocontrast dye.<sup>13,18</sup>

Other screening tools, such as arterial blood gas analyses, ECGs, chest radiographs, and cardiac enzyme determinations, are valuable for ruling out related pathologic processes. Arterial blood gases generally reveal decreased Pao<sub>2</sub> and Paco<sub>2</sub> and increased pH. A chest radiograph may be normal or show an elevated diaphragm, pleural effusion, infiltrates, or atelectasis. An ECG is abnormal in 70% to 85% of cases with acute PE.<sup>14,18</sup> Common electrocardiographic findings are sinus tachycardia, nonspecific T wave and ST-segment changes, and T-wave inversion.<sup>18</sup> The probability of a PE can be estimated by the use of Wells rules (Box 21-5).

risk factors for venous thromboembolus formation are immobility, trauma, pregnancy, cancer, heart failure, and estrogen use.<sup>19,20</sup>

**Pathogenesis.** Thrombi are dislodged from their point of origin by multiple mechanisms, including direct trauma, exercise and muscle

**BOX 21-5 WELLS RULES**

1. Clinical signs/symptoms of deep vein thrombosis (score = 3.0)
2. No alternate diagnoses likely or more likely than PE (score = 3.0)
3. Heart rate >100 beats/min (score = 1.5)
4. Immobilization or surgery in last 4 weeks (score = 1.5)
5. Previous history of DVT or PE (score = 1.5)
6. Hemoptysis (score = 1)
7. Cancer actively treated within last 6 months (score = 1.0)

The probability of a PE is high if total score is >6, moderate if 2-6, and lower if <2.

The conclusive diagnostic test for PE is pulmonary arteriography, but is rarely done. This invasive procedure involves the injection of radiopaque material into the pulmonary artery. If an intraluminal filling deficit can be identified, the test is considered diagnostic for PE. A duplex ultrasonography of the lower extremities to determine the site of deep vein thrombosis should also be performed.

**Treatment.** The primary intervention for PE is prevention. Patients who are at risk for developing one of the factors of Virchow's triad must be treated prophylactically. In the case of prolonged bed rest, active range-of-motion exercises as well as prophylactic low-dose subcutaneous sodium heparin or low-molecular-weight heparins may be used. Intraoperative and postoperative graded compression stockings and intermittent pneumatic leg compression are beneficial in reducing the risk of PE.<sup>13</sup>

Patients with suspected or confirmed PE are given supplemental oxygen or ventilator support with immediate activity limitations to decrease oxygen demand. A continuous heparin IV drip is used as a mainstay of therapy.<sup>13</sup> Although heparin does not dissolve the clot, formation of new clots is prevented. Heparin may also stimulate the intrinsic fibrinolytic system, enhancing the degradation of the PE. Thrombolytic therapy may be used to dissolve the emboli. However, thrombolytics create an increased risk of bleeding, and unless the patient has a massive embolism and is hemodynamically unstable, they are not used.<sup>17</sup>

If patients are thought to be releasing multiple emboli despite adequate heparin therapy, an umbrella filter (Mobin-Uddin) or a "bird's nest" filter may be placed in the inferior vena cava to trap emboli as they migrate toward the pulmonary vasculature.<sup>13,19</sup> Inferior vena cava filters reliably prevent recurrent PE with a recurrence rate of about 1% at 12 days.<sup>19</sup> An embolectomy may be performed on an emergency basis if the hemodynamic consequences of the emboli are life threatening and the patient has refractory hypotension.

**KEY POINTS**

- Pulmonary hypertension usually results from conditions that increase the resistance of the pulmonary vasculature. Disorders that reduce the total cross-sectional area of the lung increase resistance and promote pulmonary hypertension. Destruction of capillaries (emphysema), blockage of vessels (emboli), and vasoconstriction (hypoxemia) are common examples.
- Pulmonary hypertension may occur when left atrial pressure is elevated. Pulmonary arterial pressure must increase to maintain the driving pressure necessary to propel blood through the pulmonary circulation. The excessive pulmonary blood flow that accompanies left-to-right shunting of blood through heart defects may also lead to pulmonary hypertension.
- Cor pulmonale (right ventricular hypertrophy) and right-sided heart failure may develop with sustained high pulmonary vascular resistance. Few symptoms of pulmonary hypertension are manifested until the right side of the heart is affected.

- Treatment centers on efforts to ameliorate the underlying cause if possible (e.g., closure of heart defects, administration of oxygen to reduce hypoxic vasoconstriction). Vasodilators and diuretics may be used to reduce pulmonary arterial pressure and decrease strain on the right side of the heart.
- Pulmonary emboli result in obstruction of blood flow through part of the pulmonary system. When emboli are large or multiple, a significant increase in pulmonary pressure may result, causing right ventricular failure.
- Emboli may be composed of fat, air, amniotic fluid, or thrombi (blood clots). Thrombi are the most common cause. Thrombi generally form in the leg under conditions of venous stasis, enhanced coagulation, or vascular trauma.
- Pulmonary embolism is suspected with sudden dyspnea and chest pain. Symptoms of right-sided heart failure may be present when emboli are large. A ventilation-perfusion scan may be done to confirm the diagnosis.
- Prophylactic anticoagulation in persons at risk for thrombus formation is important to prevent PE. Postoperative pneumatic leg compression also reduces the risk of thrombus formation. Bed rest, oxygen administration, and thrombolytic and anticoagulation therapy are the mainstays of therapy for acute PE. Ventilator support and measures to improve the functioning of the right side of the heart may be necessary in severe cases.

**PULMONARY MALIGNANCIES**

**Etiology.** The incidence of lung cancer in the United States has been increasing in recent years, with greater than 200,000 new cases per year.<sup>21,22</sup> The four major types of lung cancer are large cell carcinoma, small cell carcinoma, squamous cell carcinoma, and adenocarcinoma. Another type of lung cancer is bronchoalveolar, which comprises 5% of lung cancers. Lung cancer is responsible for more than 32% of cancer deaths in men and greater than 25% of cancer deaths in women.<sup>13,21</sup> Among women there has been a 600% increase in the incidence of lung cancer over the last 80 years. Tobacco smoking is the major cause (85%) of lung cancer, with approximately 160,000 deaths reported per year. About 3800 deaths per year are reported in nonsmokers who receive secondary smoke from the environment.<sup>21-24</sup> The remaining percentage of lung cancer is not attributable to smoking. Individuals at highest risk for developing lung cancer are those who started smoking before the age of 25 years, have smoked one or more packs of cigarettes a day for 20 years, work under conditions of asbestos exposure, and are older than 50 years.<sup>21-24</sup> (See Chapter 7 for further discussion of cancer.)

**Pathogenesis.** *Squamous cell epidermoid carcinoma* (20% to 30% of cases) usually originates (in two thirds of cases) in the central bronchi near the hilus as an intraluminal growth.<sup>13,21,22</sup> Cytologic examination of sputum reveals the squamous cell carcinoma, leading to earlier detection of this cancer than with other lung neoplasms. The tumor normally doubles its volume in 100 days and, as it advances, metastasizes to regional lymph nodes in the area.<sup>13</sup>

*Adenocarcinomas* (35% to 40% of cases) usually appear in the periphery of the lung and are not as amenable to early detection as squamous cell carcinoma. Adenocarcinomas are characterized by acinar bronchoalveolar and papillary tumors. Doubling time is about 180 days, with metastasis occurring to distant organs, which may be due to aerosol transmission in the case of bronchoalveolar (2% of cases) carcinoma.<sup>13,21,22</sup>

*Large cell carcinomas* (10% to 15% of cases) develop in the lung periphery and are similar to adenocarcinoma. The tumor cells are large and are arranged in nests or clusters. The tumor doubles in size about every 100 days and metastasizes to distant organs.<sup>13,21,22</sup>

*Small cell (oat cell) carcinoma* (15% to 20% of cases) tends to originate extrinsically in the central bronchus region, thus compressing and narrowing the bronchi. The narrowing may lead to signs and

symptoms of obstruction of a central airway, leading to wheezing. This type of tumor is associated with a lesion on chromosome 3, and grows rapidly, doubling in about 33 days.<sup>13</sup> Widespread metastasis is common with small cell carcinomas and they are the most resistant to therapy.

*Bronchoalveolar* (5%) carcinoma tends to originate in the periphery and metastasize through the lymphatics. There is no correlation with cigarette smoking.

**Clinical manifestations.** Clinical features vary according to the type and the location of the tumor, and whether it has metastasized. Approximately 10% to 25% of cases are asymptomatic.<sup>13</sup> Signs and symptoms can be classified as intrathoracic or extrathoracic.

Extrathoracic manifestations are weight loss, fatigue, anorexia, anemia, and clubbing. Facial and upper extremity edema is noted in cases of tumor compression of the superior vena cava. Superior vena cava syndrome is most commonly caused by bronchogenic carcinoma.<sup>21</sup>

Intrathoracic manifestations include dyspnea, cough, chest pain, hemoptysis, and increased sputum production (with bronchoalveolar carcinoma). Hoarseness may be evident and is caused by pressure of the tumor on the recurrent laryngeal nerve. Phrenic nerve involvement (1% of lung cancer patients) leads to paralysis of the hemidiaphragm on the affected side and the potential for development of atelectasis and pneumonia. Clinical findings of endobronchial obstruction include atelectasis, postobstructive pneumonia, pleural effusion (12% to 33%), and Horner syndrome (miosis, ipsilateral ptosis, and dyshidrosis).<sup>13</sup> Abdominal breathing measures are taught to the patient who does not recover diaphragmatic function from damage to the phrenic nerve.<sup>13</sup> Extension of the cancer cells to the pleural cavity may cause pleural effusion.

**Diagnosis.** Pulmonary function tests may show increased volumes in moderately advanced cases of bronchial carcinoma.<sup>14</sup> Because the tumor blocks the airway, an obstructive pattern of pulmonary disease may lead to increased or decreased functional residual capacity attributable to the effect of the mass lesion.

The definitive diagnosis of cancer requires positive cytologic or histologic findings. Bronchoscopy washings are a common method of diagnosing lung cancer in patients whose lesions are centrally located. Pleural fluid samples show positive findings in 50% to 65% of patients with malignant pleural effusion.<sup>13</sup> Histologic examination of tissue after biopsy of the pleura, lung tissue, or mediastinal lymph nodes may also be helpful in diagnosing lung cancer. (See Chapter 7 for discussion of tumor classification.)

Chest radiographs show abnormal findings in nearly all patients with lung cancer. Common findings are hilar (squamous cell) and/or peripheral (adenocarcinoma) masses, atelectasis, mediastinal widening, infiltrates, pleural effusions, and cavitation (squamous cell epidermoid carcinoma). Chest studies are helpful in evaluating tumor size and nodal involvement. Computed tomography (CT) scans of the chest are used for staging and for follow-up study after treatment. Positron emission tomography (PET) scanning with <sup>18</sup>F-labeled fluorodeoxyglucose, a metabolic marker of malignant tissue, is superior to CT scan in detecting mediastinal and distant metastases in non-small cell lung cancer.<sup>21</sup>

#### KEY POINTS

- Cigarette smoking is the major cause of lung cancer. Lung cancer is usually disseminated at the time of diagnosis and is associated with a high mortality.
- Lung cancers can develop in the bronchial tree (small cell, squamous cell) or in the parenchyma (large cell, adenocarcinoma).
- Lung cancer may be advanced before symptoms become troublesome. Manifestations include cough, hemoptysis, hoarseness, chest pain, and pleural effusion. The diagnosis is based on examination of cells from bronchial secretions or tissue biopsy. Pulmonary masses may be detected by plain radiography or computed tomography of the chest.
- As with other cancers, treatment includes surgical removal of resectable tumors followed by radiation therapy and/or chemotherapy.

**Treatment.** Primary treatment options for pulmonary neoplasms are surgery, chemotherapy, radiation therapy, laser therapy, and tissue-specific therapies for airway lesions. Patients are also strongly encouraged to stop smoking.<sup>21,23</sup>

The treatment of choice for non-small cell carcinoma is surgery. For nonoperable neoplasms, radiation therapy is the secondary choice. Radiotherapy improves survival in patients with nonresectable non-small cell carcinoma.<sup>13,21</sup> Combination chemotherapy is the therapy of choice in patients with extensive small cell carcinoma.<sup>13,21</sup> Combined chemotherapy and chest radiation therapy has proved effective as a cure for patients in whom disease was detected early. Radiation therapy is also used for palliation of symptoms. (See Chapter 7 for other treatment options.)

## SUMMARY

The primary function of the respiratory system is oxygenation of the tissues. This function is accomplished by the movement of O<sub>2</sub> from the atmosphere through the airways to alveolar sacs. The inhaled air is warmed, humidified, and filtered in the upper airway on its way to the alveoli. Once in the alveoli, diffusion of O<sub>2</sub> and CO<sub>2</sub>, a gaseous waste product, occurs and O<sub>2</sub> is transported by means of hemoglobin molecules to the tissues. The respiratory system has numerous control mechanisms that influence its function. For example, the respiratory control centers may be inhibited when a person has a brain injury, thus producing inadequate respiration. Failure of oxygenation is seen in acute respiratory failure. Acute respiratory failure, defined as a Pao<sub>2</sub> less than 60 mm Hg and a Paco<sub>2</sub>

greater than 50 mm Hg at room air, occurs in individuals who have developed ventilation-perfusion mismatching, right-to-left shunt, or hypoventilation. Diseases affecting the pulmonary vasculature include pulmonary hypertension and pulmonary embolism. Pulmonary hypertension is associated with disease processes (e.g., emphysema, PE, hypoxemia) that increase pulmonary vascular resistance. Pulmonary emboli result in obstruction to blood flow in the pulmonary vasculature. The health or disease of a patient's cardiovascular, renal, and hematologic systems also affects the functioning of the respiratory system. Health care professionals have a key role in the prevention and management of respiratory disease and in patient and family education.

## KEY QUESTIONS

- What are the clinical manifestations and common causes of acute airway obstruction?
- What is the role of inflammation in the development of asthma?
- How does the underlying genetic defect in cystic fibrosis lead to pulmonary and exocrine gland dysfunction?
- How does smoking cause both the alveolar destruction of emphysema and the bronchial damage of chronic bronchitis?
- What is the rationale for using drugs such as  $\beta_2$  agonists, acetylcholine antagonists, leukotriene inhibitors, corticosteroids, and mast cell stabilizers to manage obstructive pulmonary disorders?
- What pulmonary function test abnormalities are characteristic of obstructive pulmonary disorders?

## CHAPTER OUTLINE

### Obstruction from Conditions in the Wall of the Lumen, 476

- Asthma, 476*
- Acute Bronchitis, 482*
- Chronic Bronchitis, 483*

### Obstruction Related to Loss of Lung Parenchyma, 487

- Emphysema, 487*

### Obstruction of the Airway Lumen, 489

- Bronchiectasis, 489*

*Bronchiolitis, 490*

*Cystic Fibrosis, 491*

*Acute Tracheobronchial Obstruction, 492*

*Epiglottitis, 493*

*Croup Syndrome, 493*

### Diagnostic Tests, 494

*Pulmonary Function Testing, 494*

*Bronchial Provocation Tests, 495*

Obstructive lung diseases are manifested by increased resistance to airflow. Obstructive diseases of the lung can be classified into those involving (1) obstruction from conditions in the wall of the lumen (e.g., asthma, bronchitis), (2) obstruction resulting from increasing pressure around the outside of the airway lumen (e.g., emphysema secondary to loss of lung tissue and elasticity, enlarged lymph node, or tumor), and (3) obstruction of the airway lumen (e.g., presence of a foreign body, excessive secretions, aspiration of fluids).<sup>1,2</sup>

These classifications are mainly terms of convenience, because many respiratory disease processes involve several areas of the pulmonary system. Involvement of the airways produces narrowing of the passages so that airflow obstruction occurs. The major obstructive airway diseases are asthma, bronchitis, and emphysema.

## OBSTRUCTION FROM CONDITIONS IN THE WALL OF THE LUMEN

### Asthma

**Etiology.** Asthma is a lung disease characterized by (a) airway obstruction that is reversible (but not completely in some patients); (b) airway inflammation; and (c) increased airway reactivity to a variety of stimuli.<sup>2,3</sup> In terms of symptoms, asthma is defined by paroxysms of diffuse wheezing, dyspnea, and cough, resulting from spasmodic contractions of the bronchi. Airway inflammation leads to epithelial denudation, collagen deposition beneath the basement membrane, mast cell activation, mucosal edema, increased viscid secretions, and smooth muscle contraction. With proper treatment, most patients with asthma can control the disease and prevent development of emphysema or bronchitis. Asthma occurs in about 5% to 12% of the U.S. population and is common among children and adults.<sup>2-6</sup> Asthma is the most common chronic disease of childhood.<sup>6,7</sup> High-risk populations include African Americans, inner-city dwellers, and premature or low-birth-weight children.<sup>5,7</sup> The pathophysiology of both intrinsic (non-allergic, sometimes referred to as *adult onset*) and extrinsic (allergic, sometimes referred to as *pediatric onset*) asthma is thought to involve inflammation of the airways. Most cases of asthma can be triggered both by allergens and by stimuli, such as exercise and exposure to cold air. The terms *intrinsic* and *extrinsic* are still used, but many prefer the terms *non-allergic* and *allergic*. The clinical features of all forms are similar.

Asthma is associated with the release of inflammatory chemicals from mast cells in the airways. The mechanisms stimulating mast cell release are allergic, immunoglobulin E (IgE)-mediated triggers for extrinsic/allergic asthma (Figure 22-1). Intrinsic/non-allergic asthma occurs in patients who have no history of allergy.<sup>8</sup> Allergic asthma (extrinsic) comprises approximately one third to one half of all cases.<sup>8,9</sup> Asthma is often associated with a history of hay fever or eczema (atopy), a positive family history of the disease, and positive skin test reactions to allergens (dust mites, cat/dog dander, industrial chemicals).<sup>8,10</sup> Pharmacologic therapy, allergen-specific immunotherapy, and environmental control are usually beneficial.<sup>6,9</sup> Refer to Chapter 10 for details about IgE-mediated mechanisms and hyposensitization methods.

Intrinsic/non-allergic asthma frequently develops in middle age and has a less favorable prognosis. Respiratory tract infections or psychological factors appear to be contributory, whereas antigen-antibody reactions appear to have less of a role in the disease process, although IgE levels may be elevated.<sup>8-10</sup> Attacks are often severe, and patients have a variable response to medical therapy.<sup>10</sup> Allergen-specific immunotherapy and environmental control measures are *not* usually helpful. Airways are hyperreactive, and patients may present with extreme dyspnea, orthopnea, and agitation.

Exercise-induced asthma is common, especially in children and adolescents.<sup>8,9</sup> Bronchospasm often occurs within 3 minutes after the end of exercise and usually resolves in 60 minutes.<sup>9,10</sup> Heat loss, water loss, and increased osmolarity of the lower respiratory mucosa are believed to stimulate mediator release from basophils and tissue mast cells. This mediator release produces airway smooth muscle contraction. Running, jogging, and playing tennis are the most common instigators of exercise-induced asthma. Bicycling and swimming are much less likely to induce symptoms.

Occupational asthma may be accompanied by positive skin test reactions to protein allergens in the work environment. Occupational exposures to allergens, such as fumes from plastic, formaldehyde, isocyanates, some metals, textiles, engine exhaust, sulfur dioxide, fluoride, and western red cedar dust, *do not* provoke skin reactions.<sup>10,11</sup> To prove hypersensitivity, it may be necessary to conduct challenge tests in the patient by inhalation of the suspected dust or fumes in a controlled environment. The individual affected by occupational asthma tends to have progressively more severe attacks with subsequent exposures. Symptoms may clear over a weekend or vacation and recur when the individual returns to the work environment.<sup>10</sup> This repeated history often is sufficient to establish the diagnosis. Hyposensitization in most cases of occupational asthma is ineffective because of lack of an IgE antibody reaction and because the chemicals that cause symptoms usually are toxic when injected.<sup>10,11</sup>

Drug-induced asthma can produce symptoms ranging from mild rhinorrhea to respiratory arrest requiring mechanical ventilation. In patients with nasal polyps, sinusitis, and asthma, ingestion of aspirin may induce severe or occasionally fatal asthmatic attacks. Sometimes anaphylactoid reactions cause a decrease in blood pressure, itching (pruritus), rhinorrhea, or a rash after aspirin ingestion. Aspirin intolerance with asthma usually occurs in adults. Attacks may occur within minutes of ingestion or may be delayed up to 12 hours. Nonsteroidal antiinflammatory drugs such as indomethacin (Indocin), ibuprofen (Motrin, Advil), and related drugs may also induce asthma in the aspirin-intolerant patient. Aspirin reactions are not immunologically mediated. Therefore, skin testing is not useful for diagnosing aspirin intolerance. Because aspirin and nonsteroidal antiinflammatory drugs inhibit the conversion of arachidonic acid to prostaglandins, it is possible that aspirin shunts arachidonic acid breakdown products to the leukotriene system. Leukotrienes, released from mast cells, are slow-reacting substances of anaphylaxis with powerful bronchoconstriction activity (see Figure 22-1). Avoidance is the most practical approach to this problem because testing can be dangerous.

Asthma can occur from ingestion of food additives. Tartrazine (yellow dye no. 5), which is used to color pharmaceuticals, hair products, and food products, may also produce severe asthma in susceptible persons. A complete list of drugs containing tartrazine can be obtained from the Food and Drug Administration.

Monosodium glutamate (MSG), used as a flavor enhancer in foods, can produce faintness, nausea, sweating, a fall in blood pressure, and, occasionally, asthma. Sodium or potassium metabisulfite, used to preserve fruits, vegetables, and meats, can cause anaphylactoid reactions. A challenge with the chemical may be necessary to establish a diagnosis, as metabisulfites are widespread in our society.

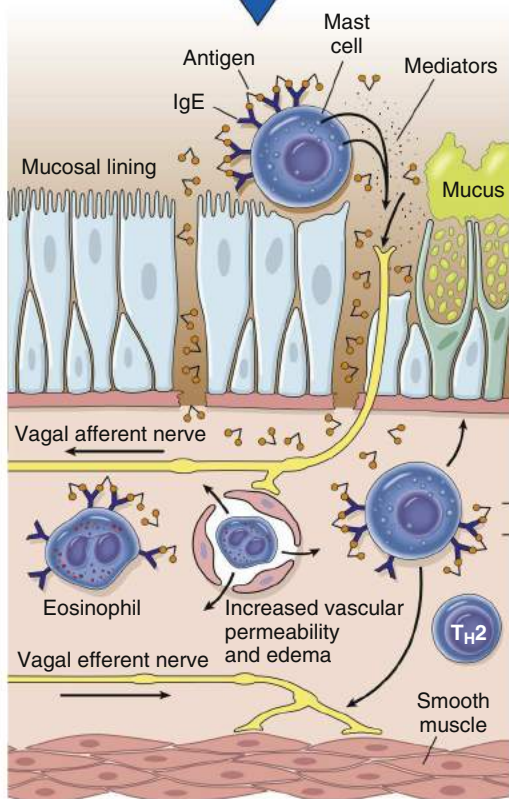

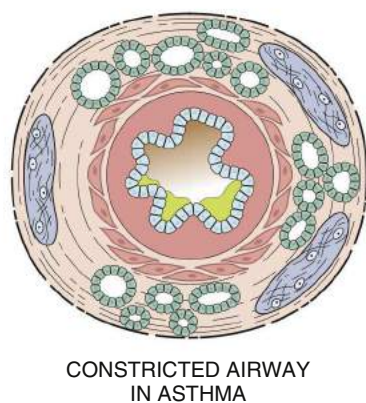

Hops in beer have also been implicated in causing severe bronchospasm. Skin reactivity does not occur, and the mechanism of the problem is not IgE mediated. The diagnosis involves a history of exposure followed by symptoms.

**Pathogenesis.** The immunohistopathologic features of asthma include denudation of airway epithelium, collagen deposition beneath the basement membrane, edema, mast cell activation, and inflammatory cell infiltration by neutrophils, eosinophils, and lymphocytes.<sup>1,3</sup> Inflammation of the airway contributes to acute bronchospasm (bronchoconstriction), mucosal edema, mucous plug formation, and airway

A SENSITIZATION TO ALLERGEN

B ALLERGEN-TRIGGERED ASTHMA

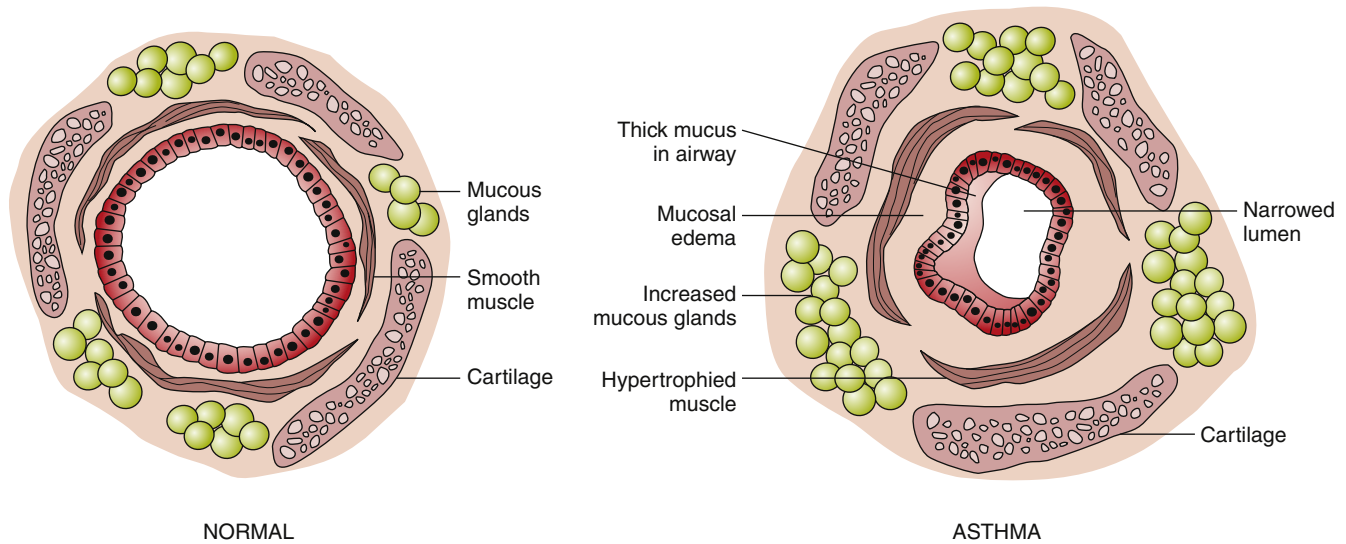

B IMMEDIATE PHASE (MINUTES)

C LATE PHASE (HOURS)

**FIGURE 22-1** **A**, Sensitization to allergen. Inhaled allergens elicit a  $T_H2$ -dominated response favoring IgE production and eosinophil recruitment. **B**, Allergen-triggered asthma (immediate phase). On re-exposure to antigen, the immediate reaction is triggered by cross-linking of IgE bound to receptors on mast cells in the airways. These cells release preformed mediators that inflame epithelial cells. Antigen then enters the mucosa to activate mucosal mast cells and eosinophils, which in turn release additional inflammatory mediators. **C**, Late phase. The arrival of recruited leukocytes signals the initiation of the late phase of asthma and more mediator release, which cause damage to epithelium. (From Kumar V et al, editors: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

**FIGURE 22-2** Common bronchial wall remodeling changes in asthma are hypertrophied smooth muscle, edema, mucous gland hypertrophy, and mucus in the lumen.

wall remodeling (Figure 22-2). Genetic predisposition (chromosomes 5, 11, 14) for atopy and structural predisposition (smaller airways) are the strongest predisposing factors for developing asthma.<sup>3,5</sup> There is a strong association of the *ADAM33* gene with asthmatic bronchial hyperresponsiveness.<sup>8</sup>

With allergic asthma, an IgE-mediated response is common and is manifested by elevated IgE levels, allergic rhinitis, eczema, a positive family history of allergy, and attacks associated with seasonal, environmental, or occupational exposure. The mechanism of action is initiated by exposure to a specific antigen that has previously sensitized mast cells in airway mucosa. When the antigen reacts with the antibody on the surface of the mast cell, packets of chemical mediator substances stored in the cell are released. The chemical mediators that are released include histamine, slow-reacting substances of anaphylaxis (leukotrienes), prostaglandins, bradykinins, eosinophilic chemotactic factor, serotonin, and others.<sup>1-3,7</sup> Figure 22-1 depicts common chemicals that are released by the mast cell and the physiologic effect of these chemicals. Cytokines are probably the most important inflammatory mediators, particularly those associated with  $T_H2$  helper T cell activation (granulocyte-macrophage colony-stimulating factor and interleukins 3, 4, 5, and 13). These cytokines may be responsible for modulating inflammatory and immune cell function.<sup>1,2</sup> Other inflammatory mediators are arachidonic acid metabolites such as leukotrienes and prostaglandins, platelet activating factor (PAF), neuropeptides, reactive oxygen species, histamine, and adenosine. With the release of chemical mediators, the normal respiratory epithelium is denuded and replaced by goblet cells, resulting in mucosal edema, production of inflammatory exudates, and hyperresponsiveness of the airway (bronchoconstriction and leakage).<sup>2,12,13</sup> Alterations in epithelial integrity lead to increased microvascular permeability. A secondary mediator response occurs 6 to 12 hours after the primary asthma attack and is more refractory to treatment. Neutrophil chemotactic factor may be the cause of this secondary response.<sup>10</sup>

Histologic changes in the epithelial basement membrane occur over time. The basement membrane is a complex structure that separates endothelial cells from underlying stroma. The membrane provides tensile strength and physical support to surrounding structures.<sup>8</sup> It also functions as a filter and as a site for cell attachment. In a classic study by Hogg in 1982, the width of the basement membrane was shown to thicken in asthmatic patients over time.<sup>12</sup> The width seen in asthmatic patients is 17.5  $\mu\text{m}$ , whereas that seen in healthy subjects is 7  $\mu\text{m}$ . Airway remodeling

has been detected pathologically. Declines in pulmonary function over time can progress to chronic obstructive pulmonary disease (COPD).<sup>10</sup> Figure 22-1 depicts the pathogenesis of asthma in relation to mast cell release and parasympathetic stimulation by way of the vagus nerve. Vagal stimulation leads to edema, mucus hypersecretion, and bronchoconstriction. The nerve endings of asthmatic patients have been found to be devoid of the bronchodilator neuropeptide vasoactive intestinal peptide.<sup>10</sup>

**Clinical manifestations.** Common symptoms are wheezing, feelings of tightness of the chest, dyspnea, cough, and increased sputum production.<sup>10</sup> Some patients have only a chronic dry cough, and others have a productive cough.<sup>9</sup> Especially in children, cough is often the earliest sign of exacerbation of asthma. Wheezing is caused by vibration in narrowed airways, which act like the vibrating reed of a wind instrument, yielding a musical sound.<sup>14</sup> Because airways naturally widen with inspiration, inspiratory wheezes reflect increased constriction. Sputum is often thick, tenacious, scant, and viscid (sticky). Physical findings vary with the severity of the attack. A mild attack may be associated with a random monophonic expiratory wheezing associated with airway narrowing, tachycardia, and tachypnea. Random monophonic wheezes are located throughout the chest and are intermittent on examination. The area in which the wheezes are heard best is indicative of the area of obstruction (e.g., if they are heard best at the mouth, this is indicative of large airway obstruction).<sup>14,15</sup> Tachycardia is an early sign of hypoxemia. A more severe attack requiring medical assistance may be accompanied by the use of accessory muscles of respiration, intercostal retractions, distant breath sounds with inspiratory wheezing, orthopnea, agitation, tachypnea, and tachycardia. In the severe state, the patient may appear cyanotic, agitated, restless, and confused. The intensity of wheezing is *not* a reliable indicator of blockage of airflow. The measurement of peak expiratory flow rate (PEFR) is the best indicator of reduction in airflow (see discussion under Diagnosis). PEFRs are affected by weight, height, age, gender, ethnicity, posture, effort, smoking, and circadian rhythm.<sup>10</sup> A PEFR of less than 80 L/min indicates severe obstruction.<sup>9,16</sup> When obstruction is the tightest, the patient cannot move enough air with enough velocity to make wheezing sounds. Isolated inspiratory wheezing may be an indicator of large airway obstruction caused by mucus or laryngeal obstruction.<sup>4</sup> A patient with severe respiratory distress, prolonged expiration (indicating that the person is having difficulty moving air out of the lungs), neck and intercostal retractions, and minimal air sounds is critically ill and requires emergency intervention.

Components of Severity		Classification of Asthma Severity ≥12 years of age			
		Intermittent	Persistent		
			Mild	Moderate	Severe
<b>Impairment</b>  Normal FEV <sub>1</sub> /FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%	Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/month	3–4x/month	>1x/week but not nightly	Often 7x/week
	Short-acting beta <sub>2</sub> -agonist use for symptoms control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily, and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV <sub>1</sub> between exacerbations • FEV <sub>1</sub> >80% predicted • FEV <sub>1</sub> /FVC normal	• FEV <sub>1</sub> >80% predicted • FEV <sub>1</sub> /FVC normal	• FEV <sub>1</sub> >60% but <80% predicted • FEV <sub>1</sub> /FVC reduced 5%	• FEV <sub>1</sub> <60% predicted • FEV <sub>1</sub> /FVC reduced >5%
<b>Risk</b>	Exacerbations requiring oral systemic corticosteroids	0–1 year (see note)	≥2/year (see note) →		
		← Consider severity and interval since last exacerbation. → Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV <sub>1</sub> .			
<b>Recommended Step for Initiating Treatment</b>		<b>Step 1</b>	<b>Step 2</b>	<b>Step 3</b>	<b>Step 4 or 5</b>
(See Figure 22-5 for treatment steps.)		In 2–6 weeks, evaluate level of asthma control that is achieved and adjust therapy accordingly.			

Key: FEV<sub>1</sub>, forced expiratory volume in 1 second; FVC, forced vital capacity; ICU, intensive care unit

**Notes:**

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- Level of severity is determined by assessment of both impairment and risk. Assess impairment domain by patient’s/caregiver’s recall of previous 2-4 weeks and spirometry. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate greater underlying disease severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systematic corticosteroids in the past year may be considered the same as patients who have persistent asthma.

**FIGURE 22-3** Classifying asthma severity and initiating treatment in youths ≥12 years of age and adults who are not currently taking long-term control medicines. (From National Institute of Health’s National Heart, Lung, and Blood Institute: 2007 National Asthma Education and Prevention Program: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma*, p 344, Figure 4-6.)

**Diagnosis.** The diagnosis of asthma is based on history, physical findings, sputum examination, pulmonary function tests, blood gas analysis, and chest radiography. Radiographic findings may be normal or may show evidence of hyperinflation with flattening of the diaphragm in progressive disease.<sup>8</sup> Abnormal physical findings include cough, wheezing, a hyperinflated chest, and decreased breath sounds. Asthmatic sputum samples reveal Charcot-Leyden crystals (formed from crystallized enzymes from eosinophilic membranes), eosinophils, and Curschmann spirals (mucous casts of bronchioles).

Forced expiratory volumes decrease during asthma attacks. PEFR is measured to determine the index of airway function. The PEFR is the maximal flow of expired air attained during a forced vital capacity (FVC) procedure.<sup>15</sup> The evaluation of asthma should include the measurement of forced expiratory volume over 1 second (FEV<sub>1</sub>), FVC, and the FEV<sub>1</sub>/FVC ratio before and after administration of a short-acting

bronchodilator.<sup>8</sup> Airflow obstruction is indicated by a FEV<sub>1</sub>/FVC ratio of less than 75%.<sup>9</sup> Classification of asthma severity and control (Figures 22-3 and 22-4) is based on presenting symptoms, frequency of nighttime symptoms, and lung function.<sup>2</sup> Figure 22-5 shows stepped therapy for asthma based on classification.

Arterial blood gas values may be normal during a mild attack, but as the bronchospasm increases in intensity, respiratory alkalosis and hypoxemia become prominent findings. Elevation of arterial partial pressure of carbon dioxide (Paco<sub>2</sub>) is a poor prognostic sign, indicating that the patient’s ability to continue breathing at a rapid rate has diminished and that exhaustion is imminent.

Respiratory failure may be manifested by severe respiratory distress in a patient who shows no radiographic evidence of pneumothorax. As the patient improves, the wheezing becomes louder. When wheezing is no longer heard after an asthma attack, pulmonary function tests may

Components of Control		Classification of Asthma Control (≥12 years of age)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Symptoms	≤2 days/week	>2 days/week	Throughout the day
	Nighttime awakenings	≤2x/month	1–3x/week	≥4x/week
	Interference with normal activity	None	Some limitation	Extremely limited
	Short-acting beta <sub>2</sub> -agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week	Several times per day
	FEV <sub>1</sub> or peak flow	>80% predicted/ personal best	60–80% predicted/ personal best	<60% predicted/ personal best
	Validated questionnaires ATAQ ACQ ACT	0 ≤0.75* ≥20	1–2 ≥1.5 16–19	3–4 N/A ≤15
Risk	Exacerbations requiring oral systemic corticosteroids	0–1 year	≥2/year (see note)	
	Progressive loss of lung function	Consider severity and interval since last exacerbation		
	Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		
Recommended Action for Treatment  (See Figure 22-5 for treatment steps.)		<ul style="list-style-type: none"> <li>• Maintain current step.</li> <li>• Regular followups every 1–6 months to maintain control.</li> <li>• Consider step down if well controlled for at least 3 months</li> </ul>	<ul style="list-style-type: none"> <li>• Step up 1 step and</li> <li>• Reevaluate in 2–6 weeks.</li> <li>• For side effects, consider alternative treatment options.</li> </ul>	<ul style="list-style-type: none"> <li>• Consider short course of oral systemic corticosteroids,</li> <li>• Step up 1–2 steps, and</li> <li>• Reevaluate in 2 weeks.</li> <li>• For side effects, consider alternative treatment options.</li> </ul>

\*ACQ values of 0.76–1.4 are indeterminate regarding well-controlled asthma.

Key: EIB, exercise-induced bronchospasm; ICU, intensive care unit

#### Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient's recall of previous 2–4 weeks and by spirometry/peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g., requiring urgent, unscheduled care, hospitalization, or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Check NIH website for information on ATAQ, ACQ and ACT questionnaires.
- Before step up in therapy:
  - Review adherence to medication, inhaler technique, environmental control, and comorbid conditions.
  - If an alternative treatment option was used in a step, discontinue and use the preferred treatment for that step.

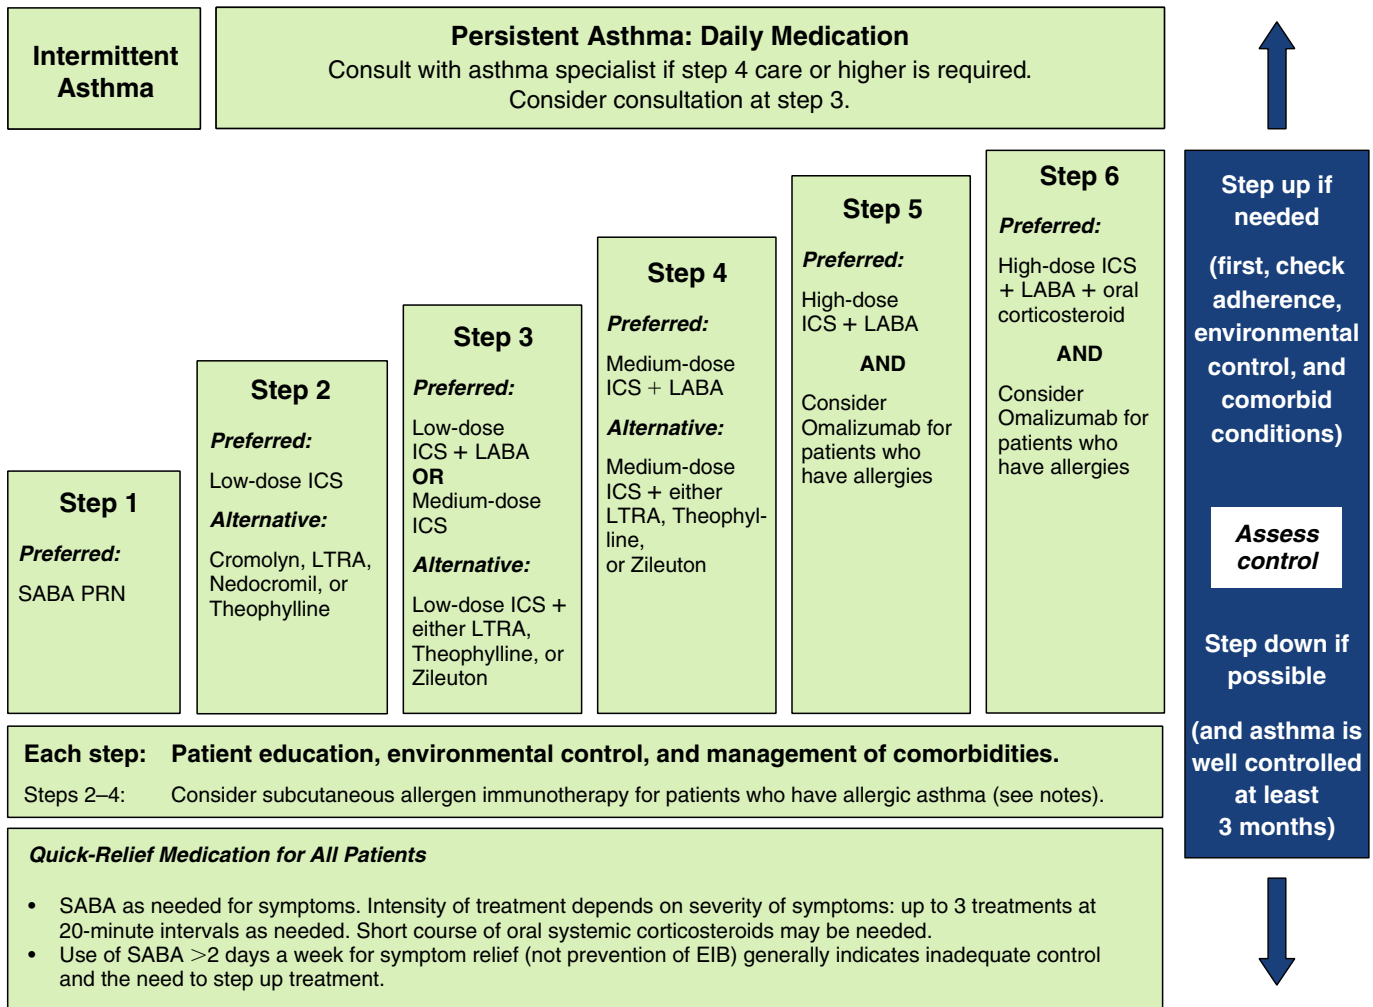

**FIGURE 22-4** Assessing asthma control and adjusting therapy in youths ≥12 years of age and adults. (From National Institute of Health's National Heart, Lung, and Blood Institute: 2007 National Asthma Education and Prevention Program: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma*, p 345, Figure 4-7.)

continue to show obstructive changes for several weeks. Some patients have a slight monophonic wheeze continuously between asthma bouts and still are comfortable and functional.<sup>14</sup>

Determination of allergens is done by skin testing or inhalation of suspected allergens. Skin testing is usually more helpful in young patients who have extrinsic asthma. Bronchial provocation testing with histamine or methacholine<sup>9</sup> may be useful in confirming the diagnosis of asthma in certain cases (see the Diagnostic Tests section later in the chapter).

A complete blood cell count can show an elevated number of white blood cells (WBCs) with an increased number of eosinophils. Eosinophils are prominent in the cellular infiltrate of the bronchioles, the sputum, and the peripheral blood. A decline in the total eosinophil count is a valuable measure of effectiveness of corticosteroid treatment. With effective treatment, the total eosinophil count is depressed below 10/μL.<sup>19</sup>

**Treatment.** Patients should be taught to avoid the objects in the environment that trigger asthma attacks. Environmental control

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, long-acting inhaled beta<sub>2</sub>-agonist; LTRA, leukotriene receptor antagonist; PNR, as needed; SABA, inhaled short-acting beta<sub>2</sub>-agonist.

**Notes:**

- The stepwise approach is meant to assist, not replace, the clinical decisionmaking required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Steps 1, 2, and 3 preferred therapies are based on Evidence A; step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR—2 1997) and Evidence B for omalizumab.
- Immunotherapy for steps 2-4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

**FIGURE 22-5** Stepwise approach for managing asthma in youths ≥12 years of age and adults. (From National Institute of Health’s National Heart, Lung, and Blood Institute: 2007 National Asthma Education and Prevention Program: *Expert Panel Report 3: guidelines for the diagnosis and management of asthma*, p 343, Figure 4-5.)

includes control of dust; removal of allergens such as feathers, molds, and animal dander; and, in some cases, removal of rugs and carpets. Other environmental control factors that help some patients include the use of air purifiers and air conditioners. The patient should also be taught preventive therapy in regard to smoking cessation and

avoidance of passive smoke, aerosols, and odors. Patients should seek early treatment for respiratory tract infections.<sup>17</sup>

Pharmacologic therapy for all three major obstructive disorders is similar and focuses on decreasing inflammation and bronchoconstriction, including β<sub>2</sub> agonists, corticosteroids, leukotriene modifiers, and

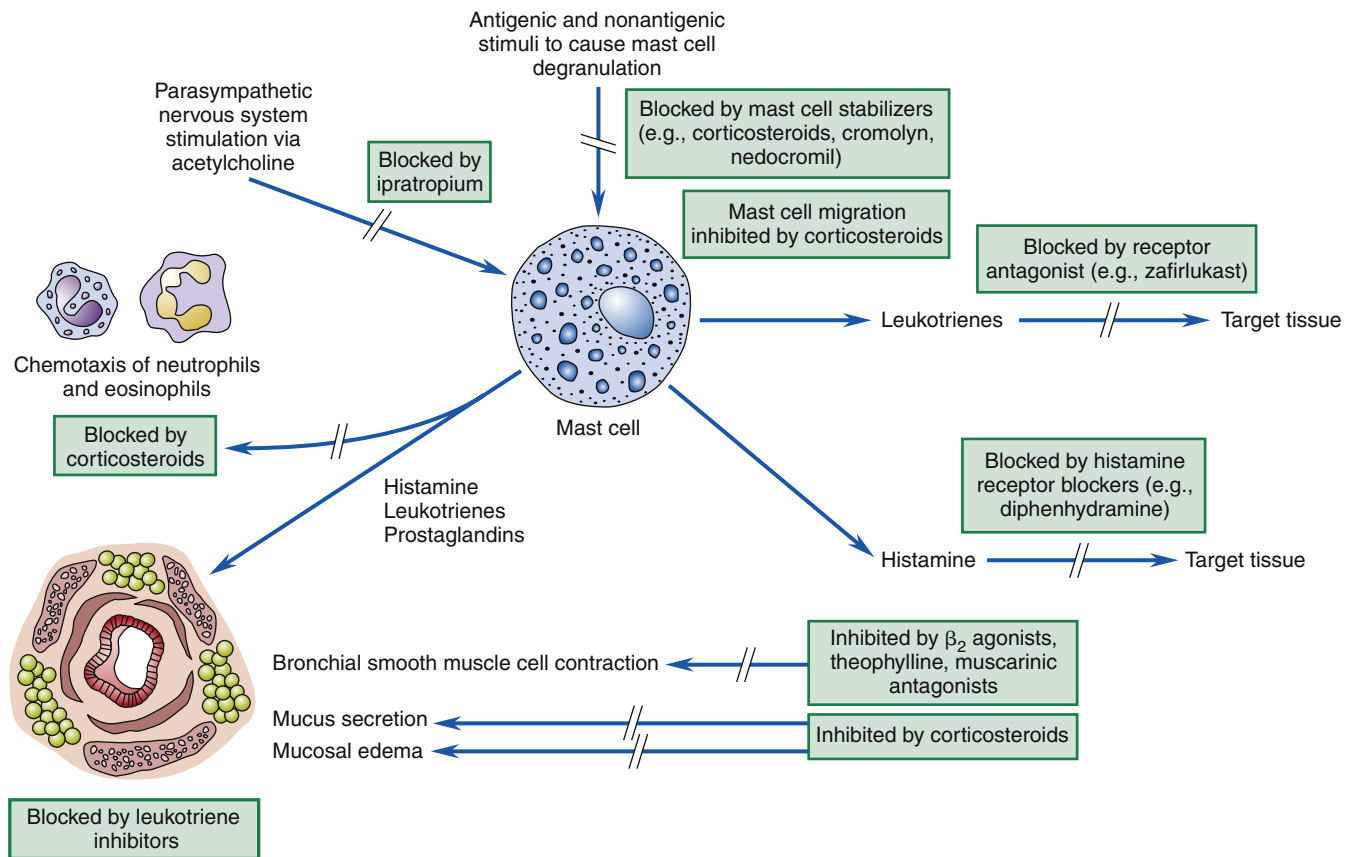

FIGURE 22-6 Pathophysiologic basis of asthma and site of action of drugs used in management.

mast cell inhibitors (Figure 22-6). Other therapies used in patients with more severe asthma include home oxygen therapy and home administration of small-volume nebulizer treatments via intermittent positive-pressure ventilation. At home, peak flow monitoring is helpful to parents or patients in determining a treatment plan and when to seek medical assistance. Peak flow meters are also helpful in monitoring progress of the patient with around-the-clock therapy.<sup>10</sup>

Allergen-specific immunotherapy (hyposensitization) may be used as an adjunct to other therapies. The allergen is first identified by testing with purified allergens using the scratch, prick, or intradermal method. Desensitization therapy has been shown in controlled studies to reduce the frequency and severity of asthmatic episodes when a single offending allergen can be identified.<sup>10</sup>

Status asthmaticus (severe attack unresponsive to routine therapy) requires more rapid and intense therapy, which may include epinephrine, subcutaneous terbutaline, and/or aminophylline. Once airflow has improved, aerosol bronchodilating inhalers may be used. Intravenous corticosteroids are the mainstay of therapy. Oxygen therapy with or without mechanical ventilation may be necessary in severe cases.

The more patients understand about their asthma, the better they are at self-managing their symptoms. Educational materials are available from the American Lung Association, the Asthma and Allergy Foundation of America, and the National Institute of Allergy and Infectious Diseases.

#### KEY POINTS

- An asthma episode may range in severity from mild to life threatening, depending on the degree of airway obstruction. With intense narrowing of the bronchi, severe hypoxemia may result.

- Several types of asthma have been identified. Non-allergic (intrinsic) asthma is precipitated by exercise, stress, and exposure to pulmonary irritants, but no specific allergen can be identified. Drugs such as aspirin and exposure to occupational allergens have also been identified as etiologic agents.
- Allergic (extrinsic) asthma is mediated by IgE, which is produced in response to specific antigens. The IgE binds to mast cells and causes them to release inflammatory chemicals in response to antigen. Skin testing may be helpful in identifying suspected allergens.
- Prevention of asthma attacks is an important part of therapy. Avoidance of precipitating factors and use of prophylactic drug therapy are recommended. Bronchodilators, corticosteroids, and oxygen therapy are mainstays of treatment for an acute attack.

### Acute Bronchitis

**Etiology.** Acute inflammation of the trachea and bronchi is produced most commonly (80% of the 12 million cases per year in the United States) by a variety of viruses such as influenza virus A or B, parainfluenza virus, respiratory syncytial virus, coronavirus, rhinovirus, Coxsackie virus, and adenovirus. Nonviral causes include *Streptococcus pneumoniae*, *Haemophilus influenzae*, mycoplasma, moraxella, and *Chlamydia pneumoniae*.<sup>7,8</sup> Numerous other pathogens as well as heat, smoke inhalation, inhalation of irritant chemicals (e.g., sulfur dioxide or chlorine, bromine, or fluorine gases), and allergic reactions have also been identified.<sup>18</sup> Highest incidences are noted in smokers, young children, and the elderly, with a prevalence in the winter months.<sup>8,19</sup> The swelling of bronchial mucosa in children associated with obstruction, respiratory distress, and wheezing is known as *asthmatic bronchitis*. Acute bronchitis differs from bronchiolitis in the size

**FIGURE 22-7** Histologic features of chronic bronchitis. (Lumen of bronchus is above.) Note slight desquamation of mucosal epithelial cells and marked thickening (approximately twice the normal thickness) of mucous gland layer. Vascular congestion is evident. (From Kumar V et al: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

of the airways affected (i.e., trachea and bronchi as opposed to the small bronchioli).<sup>20</sup>

**Pathogenesis.** The airways become inflamed and narrowed from capillary dilation, swelling from exudation of fluid, infiltration with inflammatory cells, increased mucus production, loss of ciliary function, and loss of portions of the ciliated epithelium. Many viruses and mycoplasmal bacteria inhibit macrophages and lymphocytes, temporarily promoting secondary bacterial invasion. Microorganisms may also induce long-lasting hyperirritability of the respiratory tract with associated episodes of bronchospasm.

**Clinical manifestations.** The presentation of acute bronchitis is usually mild and self-limited, requiring only supportive treatment. Cough may be productive or nonproductive. Associated symptoms include low-grade fever, substernal chest discomfort, sore throat, postnasal drip, and fatigue. In children, the smaller airways are easily obstructed by inflammation, so that severe obstruction may occur.<sup>8</sup> The smallness of airways in proportion to body size is due to a smaller lumen in relation to the vessel wall. Associated inflammation of the larynx and trachea produces croup (see Croup Syndrome section in this chapter for further details).

**Diagnosis.** Diagnosis of acute bronchitis is usually based on the clinical presentation, with recent onset of cough being the distinctive hallmark. Neither the appearance of purulent sputum nor the determination of an increased WBC count is a reliable diagnostic indicator. A chest radiograph is required to distinguish acute bronchitis (normal radiograph) from pneumonia (pulmonary infiltrates on radiograph).

**Treatment.** Acute bronchitis is predominantly caused by viruses (rhinovirus, coronavirus, adenovirus, influenza virus). Viral infections do not respond to antimicrobial therapy, and symptoms resolve spontaneously in most normal, otherwise healthy individuals. Acute bronchitis caused by bacterial organisms responds well to antibiotic therapy. Codeine-containing medications are helpful in relieving the cough associated with bronchitis that interferes with sleep. Nonpharmacologic recommendations are to increase fluid intake, avoid smoke, and use a vaporizer in the bedroom.

The dangers of acute bronchitis include the potential for bacterial invasion, which can worsen symptoms in patients with chronic obstructive pulmonary disease (COPD) and precipitate serious infections in elderly patients or those with debilitating disease.

**FIGURE 22-8** Structure of a normal bronchial wall. In chronic bronchitis, the thickness of the mucous glands increases and can be expressed as the Reid index, given by the following formula:  $(b - c) / (a - d)$ . The ratio is normally less than 0.4. A ratio of 0.7 indicates severe bronchitis.

### Chronic Bronchitis

**Etiology.** The next two sections of this chapter present chronic bronchitis and emphysema. Characteristic pathologic and clinical findings are described for each of these classifications. Clinically, pure forms of emphysema and chronic bronchitis are rare, and most patients present a combination of both of these obstructive processes. Patients with emphysema and chronic bronchitis constitute most cases of COPD.

The major causes of chronic bronchitis are cigarette smoking (90% of cases),<sup>12</sup> repeated airway infections, genetic predisposition, and inhalation of physical or chemical irritants.<sup>8,9,21,22</sup>

Chronic bronchitis (also referred to as type B COPD or the “blue bloater”<sup>8,9,21</sup>) is diagnosed *symptomatically* by hypersecretion of bronchial mucus and a chronic or recurrent productive cough of more than 3 months’ duration and occurring each year for 2 or more successive years in patients in whom other causes have been excluded.<sup>9</sup> For patients with chronic bronchitis and emphysema, airway obstruction is persistent and irreversible. The National Center for Health Statistics reports a 3:1 ratio of annual cases of chronic bronchitis to emphysema.<sup>23</sup>

**Pathogenesis.** Pathologic changes in the airway include chronic inflammation and swelling of the bronchial mucosa resulting in scarring, increased fibrosis of the mucous membrane, hyperplasia of bronchial mucous glands and goblet cells, hypertrophy of bronchial glands and goblet cells, and increased bronchial wall thickness, which potentiates obstruction to airflow. Inflammation appears to predominantly be the result of neutrophil activity.<sup>21</sup> Interleukin-8 levels are elevated, indicating sustained attraction of neutrophils to the site of inflammation. CD8 T-lymphocyte levels are also elevated. During acute exacerbations, bronchial biopsy specimens have a 30-fold increase in the number of eosinophils.<sup>21</sup> Figures 22-7 and 22-8 show the histologic changes seen in chronic bronchitis. Hypertrophy of mucosal glands and goblet cells leads to increased mucus production; the mucus then combines with purulent exudate to form bronchial plugs. Chronic bronchitis patients often display bacterial colonization with *H. influenzae* and *S. pneumoniae*.<sup>21</sup> The mucociliary clearance action is impaired or lost, and some areas of ciliated columnar epithelium are replaced by squamous cells.<sup>21</sup> Ciliary dysfunction occurs because of a decreased number of cilia and decreased action of available cilia.

Often the inflammatory and fibrotic changes extend into the surrounding alveoli. The narrowed airways and the mucous plugs prevent proper oxygenation and potentiate airway obstruction. High airflow resistance increases the work of breathing, leading to increased oxygen demands. In areas of greater obstruction to airflow, alveoli empty and fill more slowly, leading to ventilation-perfusion ( $\dot{V}_A / \dot{Q}$ ) mismatch, thus

## CLINICAL MANIFESTATIONS

- Excess body fluids (edemal plethora)
- Chronic cough
- Shortness of breath on exertion
- Increased sputum
- Cyanosis (late sign)

A

**FIGURE 22-9** **A**, A “blue bloater” with edema from right-sided heart failure. **B**, A patient with chronic obstructive bronchitis. Note the stocky build and the presence of pursed-lip breathing and barrel chest. The slight gynecomastia is a side effect of corticosteroid therapy. The patient’s shoulders are raised because of shortness of breath and increased work of breathing. (**B**, From Black JM, Hawks SJ: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1581.)

lowering arterial oxygenation. The chronic bronchitis patient may appear as the “blue bloater” (Figure 22-9), characterizing the pathophysiologic process of oxygen desaturation (cyanosis) and edema associated with right-sided heart failure in advanced disease or exacerbations.

The involvement of small pulmonary arteries related to inflammation in the bronchial walls and the compensatory vasoconstriction of pulmonary blood vessels from hypoxia produce pulmonary hypertension. In addition, widespread bronchial narrowing and mucous plugging produce ventilation-perfusion mismatch with hypoxemia and hypercarbia from impeded ventilation. The combination of hypoxia and hypercarbia increases pulmonary artery resistance and pulmonary hypertension.<sup>21</sup> While the process of pulmonary hypertension continues, right ventricular end-diastolic pressures increase, leading to right ventricular dilation (cor pulmonale) and right-sided heart failure. An enlarged right heart results in increased venous pressure, liver engorgement, and dependent edema. Manifestations of heart failure may occur during exacerbations of bronchitis and subside with appropriate treatment.<sup>9,21</sup>

Destruction of bronchial walls results in dilation of airway sacs. This is termed *bronchiectasis*. Causes of bronchial wall destruction include infection from severe streptococcal or staphylococcal pneumonia, repeated bouts of acute bronchitis, infection with the mold *Aspergillus fumigatus*, presence of mucous plugs or foreign bodies, or deficiencies in immunologic response. (Refer to the Bronchiectasis section later in this chapter for a more detailed description of this disease process.) The dilated sacs contain pools of infected secretion that do not clear themselves and serve as sources of further infection that can spread to adjacent lung fields by the lymphatics or venous drainage to other areas of the body, commonly the brain. If bronchiectatic lesions are localized, surgical resection of the affected portions of lung may be helpful.

**Clinical manifestations.** The typical patient is an overweight man or woman (1:2 male to female ratio) in his or her thirties or forties<sup>9,21,22,24</sup> (or older) who presents with shortness of breath on exertion, excessive amounts of sputum, chronic cough, evidence of excess body fluids (edema, hypervolemia), and a history of smoking. In addition, the patient often complains of chills, malaise, muscle aches, fatigue, loss of libido, and insomnia.

Sputum production may be variable and worsens with respiratory tract infection. Cough and sputum production are most severe in the mornings. Gradually, patients develop progressive shortness of breath on exertion. Most patients do not seek help until dyspnea becomes troublesome. By the time dyspnea on exertion is present, the disease is well advanced.<sup>21,22</sup>

In the end-stage disease process, the patient presents with signs of right-sided heart failure (distended neck veins, right ventricular heave, right ventricular gallop, and peripheral edema).<sup>21</sup> Hypoxia leads to pulmonary hypertension. Cyanosis is a late sign.

**Diagnosis.** Measures used to confirm the diagnosis include chest radiography, which may show increased bronchial vascular markings, congested lung fields, an enlarged horizontal cardiac silhouette, and evidence of previous pulmonary infection. Pulmonary function tests show normal total lung capacity (TLC), increased residual volume (RV), and decreased FEV<sub>1</sub>. Early pulmonary function testing before the onset of symptoms shows increased closing volume and a decrease in the maximal midexpiratory flow rate.<sup>21</sup> Arterial blood gas (ABG) evaluation may show elevated PaCO<sub>2</sub> and decreased PaO<sub>2</sub> (often below 65 mm Hg); abnormal ABGs develop early in the disease process. The electrocardiogram may reveal atrial dysrhythmias and evidence of right ventricular hypertrophy. Secondary polycythemia (increased numbers of red blood cells) related to continuous or nocturnal hypoxemia is common.<sup>9,21</sup> Hypoxemia leads to a compensatory production of red blood cells in an attempt to carry more oxygen to the body tissues.

Depending on the severity of the disease, the physical examination may reveal scattered crackles, rhonchi, and wheezes; use of accessory muscles to breathe; jugular vein distention; clubbing; and pedal and ankle edema. Table 22-1 lists the distinguishing features of both emphysema and chronic bronchitis.

**Treatment.** Because bronchitis and emphysema are most frequently seen in combination, the therapies are similar. The overall goals are to (1) block the progression of the disease, (2) return the patient to optimal respiratory function, and (3) return the patient to usual activities of daily living.

**TABLE 22-1 COMMON DISTINGUISHING FEATURES OF EMPHYSEMA AND CHRONIC BRONCHITIS\***

PATIENT DATA	EMPHYSEMA (COPD TYPE A)	BRONCHITIS (COPD TYPE B)
<b>History</b>		
Lifestyle	Smoker	Smoker
Weight	Weight loss	Overweight
Onset of symptoms	Usually after age 50 years	Usually after age 40 years
Sputum	Mild, mucoid	Excessive, purulent
Cough	Minimal or absent	Chronic; more severe in mornings
Dyspnea	Progressive exertional dyspnea	Mild to moderate, but may gradually progress to severe exertional dyspnea
Patient complaints	Dyspnea on exertion, fatigue, insomnia	Chronic cough with mucopurulent sputum, chills, malaise, muscle aches, fatigue, insomnia, loss of libido
<b>Physical Signs</b>		
Edema	Absent	Present
Central cyanosis	Absent	Present in advanced disease
Use of accessory muscles to breathe	Present	Absent until end stage
Body build	Thin, wasted	Stocky, overweight
Anteroposterior chest diameter	“Barrel chest,” 1:1 ratio anteroposterior chest diameter	Normal
Auscultation of chest	Decreased breath sounds, decreased heart sounds, prolonged expiration	Wheezes, crackles, rhonchi, depending on severity of disease
Percussion	Hyperresonance	Normal
Jugular vein distention	Absent	Present
Other	Pursed-lip breathing	Evidence of right-sided heart failure (cor pulmonale)
<b>General Diagnostic Tests</b>		
Chest radiography	Narrowed mediastinum; normal or small vertical heart; hyperinflation; low, flat diaphragm; presence of blebs or bullae	Congested lung fields, increased bronchial vascular markings, enlarged horizontal heart
Arterial blood gas analysis	Decreased Pao <sub>2</sub> (60-80 mm Hg); increased Paco <sub>2</sub> with advancing disease	Decreased Pao <sub>2</sub> (<65 mm Hg); increased Paco <sub>2</sub>
Electrocardiography	Normal or tall symmetric P waves; tachycardia, if hypoxic	Right axis deviation, right ventricular hypertrophy, atrial dysrhythmias
Hematocrit	Normal	Polycythemia
<b>Pulmonary Function Tests</b>		
Functional residual capacity	Increased	Normal or slight increase
Residual volume	Increased	Increased
Total lung capacity	Increased	Normal
Forced expiratory volume	Decreased	Decreased
Vital capacity	Decreased	Normal or slight decrease
Static lung compliance	Increased	Normal

\*Clinically, features of bronchitis and emphysema are not clear-cut because most patients with COPD have a combined disease process. COPD, Chronic obstructive pulmonary disease.

Pharmacologic treatment involves the use of inhaled short-acting β<sub>2</sub> agonists and inhaled anticholinergic bronchodilators, cough suppressants, and antimicrobial agents for infections. Inhaled or oral corticosteroids may also be used in the treatment of some patients for acute exacerbations. Theophylline products are used less frequently because of their narrow therapeutic range and toxicity. However, many patients derive significant benefits from theophylline.<sup>21,22</sup>

Low-dose oxygen therapy is recommended for patients with Pao<sub>2</sub> levels less than 55 mm Hg.<sup>21,22</sup> Mechanical ventilation may become necessary to get the patient over a crisis period of acute exacerbation. Although traditionally the mechanism of carbon dioxide retention with oxygen therapy was thought to be related to a diminished ventilatory drive, current research suggests that oxygen therapy may instead cause increased  $\dot{V}_A / \dot{Q}$  imbalance, precipitating a rise in carbon dioxide concentration. It is important to remember that not all patients with a

history of COPD are carbon dioxide retainers and most can use oxygen safely. Home oxygen therapy has been demonstrated to retard the development of pulmonary hypertension and cor pulmonale in chronic bronchitis.<sup>9,21</sup> Portable oxygen saturation monitors for evaluating the effectiveness of oxygen administration at home may also be used.

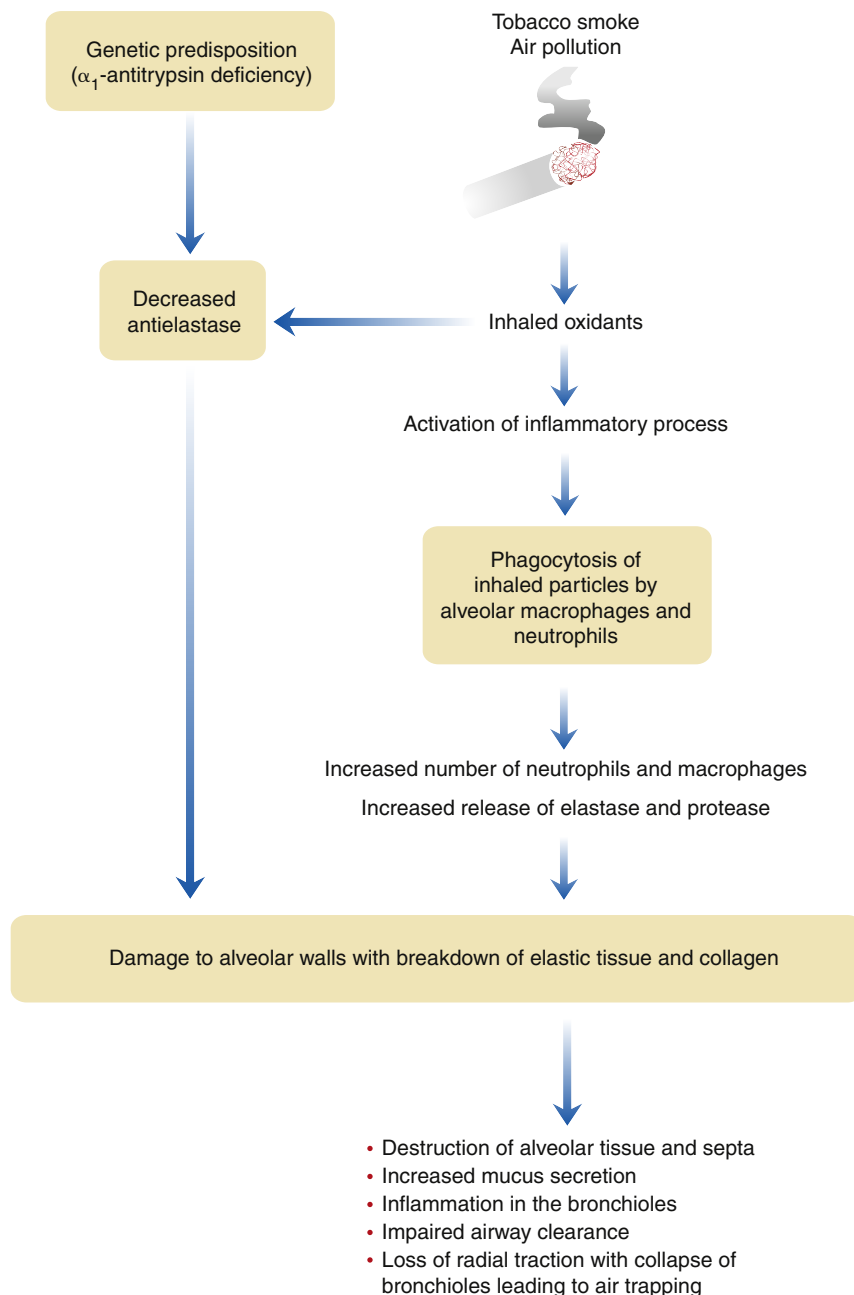

Smoking cessation is essential to decreasing the progression of the disease. A reduction in exposure to inhaled pulmonary irritants is also advised.<sup>22</sup> Supportive therapies include adequate rest, proper hydration (8 to 12 glasses of water per day unless the patient has congestive heart failure), and physical reconditioning programs using a treadmill or stationary bicycle. Alternating rest and exercise improves results on pulmonary function tests. Walking has proved to be the best form of exercise for increasing duration and intensity of activity. All COPD patients also benefit from yearly influenza vaccine and pneumococcal vaccine.

**KEY POINTS**

- Acute bronchitis results from temporary inflammation of the tracheobronchial tree. Inflammation may be due to viral, bacterial, fungal, or chemical causes. Symptoms are caused by narrowing of inflamed airways and increased mucus production. Dyspnea on exertion and cough are common.
- Chronic bronchitis is an inflammatory disorder of the airways that most commonly results from long-term cigarette smoking. It is defined as a productive cough lasting more than 3 months per year for 2 or more consecutive years. Resultant airway damage is not reversible.
- Chronic bronchitis is associated with persistent narrowing of the airways attributable to chronic inflammation, scarring, and excessive mucus production. Airway obstruction leads to poor ventilation of alveoli and impaired exchange of oxygen

and carbon dioxide. Blood gases are characterized by low  $P_{aO_2}$  and high  $P_{aCO_2}$  values. Persistent hypoxemia causes a compensatory increase in red blood cell production (polycythemia). Cyanosis may be evident.

- Alveolar hypoxia leads to generalized pulmonary vasoconstriction, pulmonary hypertension, and right ventricular hypertrophy (cor pulmonale) in the person with chronic bronchitis. Right-sided heart failure may occur because of the high pulmonary resistance.
- The management of chronic bronchitis centers on removing the etiologic factors (e.g., cigarette smoke), providing bronchodilator therapy, removing secretions, preventing respiratory muscle fatigue, and providing low-dose supplemental oxygen. High-dose oxygen must be used cautiously because it may increase  $\dot{V}_A/\dot{Q}$  imbalance and  $P_{aCO_2}$  levels in some patients.

**FIGURE 22-10** Pathogenesis of smoke-induced emphysema.

## OBSTRUCTION RELATED TO LOSS OF LUNG PARENCHYMA

### Emphysema

**Etiology.** Emphysema (also referred to as type A COPD or the “pink puffer”) is defined *pathologically* by destructive changes of the alveolar walls and abnormal enlargement of the distal air sacs.<sup>8,9,21,22</sup> Emphysema is frequently associated with chronic bronchitis. According to the National Center for Health Statistics (2005 data), of the 12.7 million Americans with COPD, 8.9 million primarily have chronic bronchitis and 3.8 million primarily have emphysema.<sup>24</sup> The etiologies of emphysema include smoking, air pollution, certain occupations (e.g., welding, mining, and working with or near asbestos), and  $\alpha_1$ -antitrypsin deficiency (1%). Emphysema tends to develop over a long period and thus is seen more frequently in persons older than 50. Cigarette smoking in excess of 70 pack-years is highly predictive of COPD.<sup>21</sup> The normal aging process, starting at about age 30, reflects changes similar to those seen in emphysema, including a loss of alveoli, an increase in the size of alveolar ducts, a loss of gas-exchanging surface area (4% per decade), and a decrease in bronchiolar musculature.<sup>21</sup>

When emphysema occurs in young to middle-aged adults or before the age of 50 in a smoker, it may be associated with a deficiency of  $\alpha_1$ -antitrypsin activity in the lung.  $\alpha_1$ -Antitrypsin deficiency is a hereditary disorder characterized by low serum levels (25 to 50 mg/dl) of  $\alpha_1$ -antitrypsin.<sup>21,22</sup>  $\alpha_1$ -Antitrypsin is a protective enzyme that inhibits

**FIGURE 22-11** Loss of radial traction in emphysema leads to airway collapse. **A**, Terminal bronchiole in cross-section. **B**, Terminal bronchiole with narrowed lumen resulting from loss of surrounding alveoli, leading to decreased radial traction and airway collapse.

**FIGURE 22-12** Gross appearance of emphysematous lung. *Left*, Normal lung tissue from a nonsmoker. *Right*, Lung tissue from a smoker who has developed emphysema.

proteolytic breakdown of alveolar tissue. The protease enzymes (neutrophil-derived elastase) that break down lung protein are released from neutrophils that migrate to the lung during inflammation, causing alveolar wall destruction.<sup>21</sup>

Emphysema may follow bacterial lung infections, which involve secretion of proteases that destroy the elastin proteins responsible for the normal elasticity of the lung tissue. Bacterial infections block mechanisms that normally inhibit the release of proteolytic enzymes from degenerating neutrophilic granulocytes.

**Pathogenesis.** The pathologic changes leading to alveolar destruction are associated with the release of proteolytic enzymes from inflammatory cells such as neutrophils and macrophages. Smoking is commonly associated with emphysema. Smoking causes alveolar damage in two ways: (1) it leads to inflammation in the lung tissue (parenchyma), thus initiating a chain of events leading to the release of proteolytic enzymes that directly damage alveolar tissue; and (2) it inactivates  $\alpha_1$ -antitrypsin, which normally acts to protect the lung parenchyma.<sup>21,22</sup> Figure 22-10 illustrates the pathogenesis of emphysema.

With the loss of alveolar walls, there is also a marked reduction in the pulmonary capillary bed, which is essential for exchange of oxygen and carbon dioxide between the alveolar air and capillary blood. There is also a loss of elastic tissue in the lung, which leads to a decrease in the size of the smaller bronchioles. The loss of lung tissue leads to a loss of *radial traction*, which normally holds the airway open, and to increasing pressure around the outside of the airway lumen, which in turn increases airway resistance and decreases airflow. Figure 22-11 shows the effect of decreased radial traction on the size of small bronchioles. Air then becomes trapped in distal alveoli, leading to distended air sacs, which adds to the collapsing pressure on more proximal bronchi and increases airway obstruction. Loss of alveolar walls and air trapping leads to the formation of bullae (large, thin-walled cysts in the lung) that further rob the lung of its gas transport function. The histologic appearance of the lung and lung tissue from typical emphysematous patients is shown in Figures 22-12 and 22-13.

Three major classifications of emphysema exist: (1) centrilobular (also called *centrilobular*), which is associated with both smoking and chronic bronchitis and destroys the respiratory bronchioles; (2) panacinar (also called *panlobular*), which destroys the alveoli; and (3) paraseptal, which affects the peripheral lobules. Some of the classifications of emphysema and the topographic distribution of emphysema in lung tissue are shown in Figure 22-14.

**FIGURE 22-13** Pulmonary emphysema. There is a marked enlargement of air spaces with thinning and destruction of alveolar septa. (From Kumar V et al: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

**FIGURE 22-14** Types of Emphysema. (From Black JM, Hawks SJ: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1580.)

**Clinical manifestations.** Patients with emphysema commonly seek help because of progressive exertional dyspnea. The typical patient with advanced disease is a thin man or woman around 55 years of age who has complained of increasing shortness of breath for the past 3 to 4 years. As with chronic bronchitis, the incidence of emphysema is increasing in women who smoke. Patients become thin due to

increased respiratory effort and resulting caloric expenditure with decreased ability to consume adequate calories. The difficulty in breathing is evidenced by the use of accessory muscles to breathe, progressive dyspnea, and the use of pursed-lip breathing in an effort to exhale more air over a longer period of time before the small airways collapse. Cough may be minimal or absent. Digital clubbing is common. The appearance of overinflation (barrel chest) is from an increase in lung volume, which can be confirmed by pulmonary function testing. With the loss of alveolar walls and the formation of bullae, the patient is at risk for developing a pneumothorax and may present with chest pain on the affected side and dyspnea. Decreased arterial oxygen saturation remains minor until late in the course of the disease. Late in the disease process, the major symptom is dyspnea on exertion. These patients may be referred to as “pink puffers” (Figure 22-15), a term related to the physiologic matching of ventilation and perfusion that allows near normal gas exchange. Ventilation-perfusion matching and a sustained high respiratory effort produce a relatively normal arterial oxygen level until late stages of the disease.<sup>1,2,9,21,22</sup>

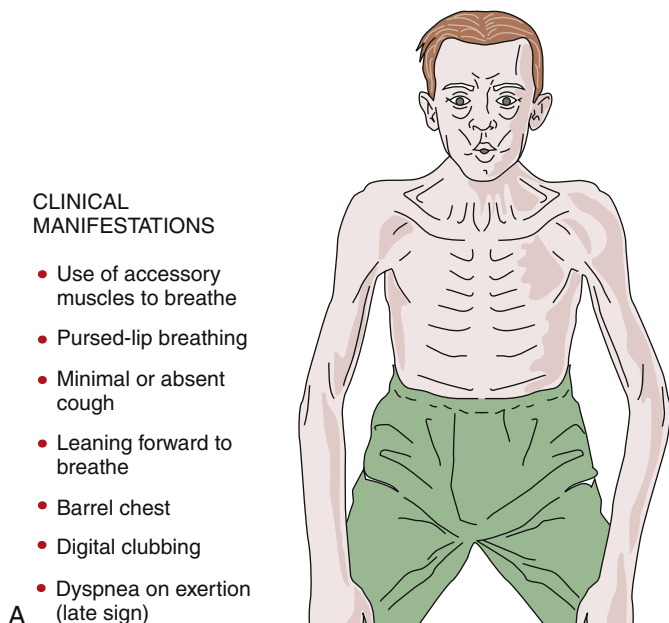

**Diagnosis.** The diagnosis of emphysema is based on the patient’s history and physical findings, pulmonary function tests, chest radiographs, arterial blood gases, and electrocardiogram. Changes seen on pulmonary function tests include an increased functional residual capacity, increased RV, increased TLC, decreased FEV<sub>1</sub>, and decreased FVC.<sup>9,21</sup> Chest radiographs show hyperinflation; a low, flat diaphragm; the presence of blebs or bullae; a narrow mediastinum; and a normal or small “vertical” heart (see Table 22-1). Electrocardiographic findings may be normal or show tall P waves. Sinus tachycardia may be the first sign of decreased oxygenation. Supraventricular dysrhythmias (atrial tachycardia, atrial flutter, and atrial fibrillation) and ventricular irregularities may also occur.<sup>9</sup> Arterial blood gas values typically reveal a mild decrease in Pao<sub>2</sub> (65 to 75 mm Hg) and a low or normal Paco<sub>2</sub> until late stages.<sup>25</sup>

Physical examination shows a thin, wasted individual who is using accessory muscles to breathe and sits slightly hunched forward in an effort to breathe better. Auscultation and percussion of the lung fields reveal decreased breath sounds and lack of crackles and rhonchi, decreased heart sounds, prolonged expiration, decreased diaphragmatic excursion, and hyperresonance of the chest. Pursed-lip breathing, chronic morning cough because of mucus buildup at night, and an increased anteroposterior chest diameter (barrel chest) are also common findings. Weight loss occurs because of anorexia and lack of energy to eat. Bronchoconstriction leads to wheezing.

**Treatment.** Refer to the Treatment section under Chronic Bronchitis earlier in this chapter for detailed treatment modalities common to both chronic obstructive lung diseases. An excellent patient teaching manual called *Better Breathing: A Self-Teaching Manual* is available from PAL Medical, Inc., Maitland, Florida. Poor prognosis is associated with weight loss, so treatment is focused on maintaining proper nutrition.

#### KEY POINTS

- Emphysema is a form of chronic obstructive pulmonary disease (COPD) that results from destruction of alveoli and small airways. Emphysema occurs primarily in cigarette smokers and is often seen in association with chronic bronchitis.
- Alveolar destruction is due to release of inflammatory proteolytic enzymes that degrade lung proteins. Smoking also inhibits a protective enzyme,  $\alpha_1$ -antitrypsin, that normally inhibits the proteolytic enzymes. Genetic deficiency of  $\alpha_1$ -antitrypsin is an uncommon possible cause of emphysema.
- Emphysema causes two major problems with respiration: (1) a decrease in surface area for gas exchange and (2) airway collapse attributable to loss of radial traction. Airway collapse is greater on expiration, resulting in air trapping and hyperinflation.

**FIGURE 22-15** **A**, The “pink puffer.” Note the use of accessory muscles and pursed-lip breathing in an effort to get more air out of the lungs. **B**, A patient with emphysema. Note the thin appearance and the presence of continuous oxygen therapy. The use of accessory muscles of respiration (neck and shoulder muscles) reflects the patient’s shortness of breath and increased work of breathing necessary to increase minute ventilation and to maintain adequate arterial blood gas values. (**B**, From Black JM, Hawks SJ: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1581.)

- Emphysema is characterized by dyspnea, weight loss, use of accessory muscles to breathe, a low, flat diaphragm, and a barrel chest. Cyanosis is not present until late stages of the disease. By sustaining high ventilatory effort, a patient can have blood oxygen levels that are generally maintained near normal. Carbon dioxide levels may be normal or low as a result of hyperventilation until late in the disease.
- Therapy for emphysema is similar to that for chronic bronchitis. Cessation of smoking is necessary to prevent progression of the disease. Present damage is irreversible. Oxygen therapy improves activity tolerance and quality of life.

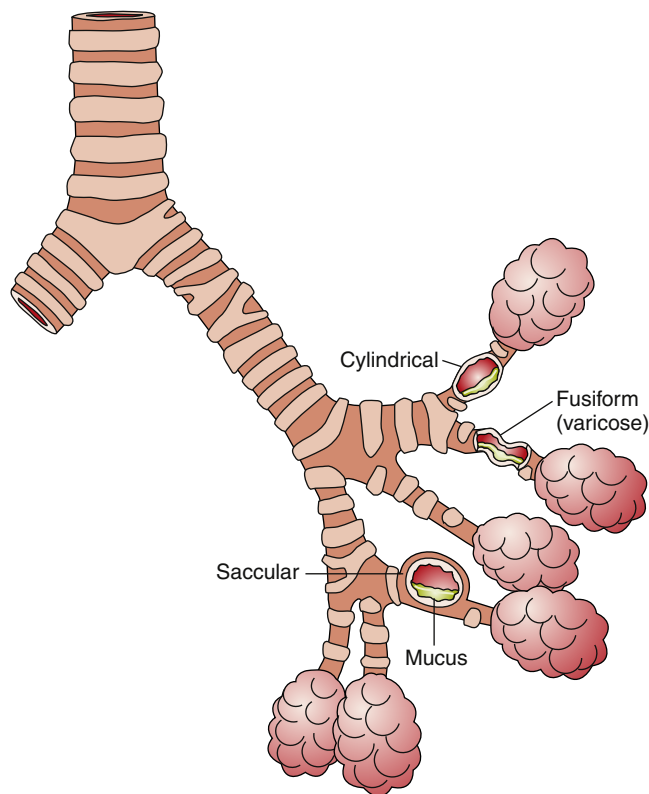

## OBSTRUCTION OF THE AIRWAY LUMEN

### Bronchiectasis

**Etiology.** Bronchiectasis means dilation of bronchi. It is either acquired or congenital, and is classified as both an obstructive and a suppurative (pus-forming) disorder. Acquired bronchiectasis is now rare in the United States because of rapid diagnosis and management of bronchopulmonary infections. Fifty percent of the cases of bronchiectasis are associated with cystic fibrosis.<sup>26</sup> Children are at higher risk for development of bronchiectasis because of anatomic factors such as small, soft, elastic bronchi. Bronchi in children are easily damaged by overinflation and distention from inflammation and infection.

Bronchiectasis can be classified according to bronchial shape: sacular (with cavity-like dilatations) or cylindrical, and with widening of the bronchial walls. A fusiform shape is a combination of sacular and cylindrical changes. These anatomic changes are shown in **Figure 22-16**. Little clinical or pathophysiologic difference in the three types has been demonstrated.

**Pathogenesis.** Bronchiectasis is characterized by recurrent infection and inflammation of bronchial walls, which leads to persistent

**FIGURE 22-16** Bronchial dilatations attributable to bronchiectasis. The sacular form occurs in the segmental bronchi, which are severely dilated and end blindly. The varicose form resembles varicose veins with irregular dilatations and constriction. The cylindrical form shows uniform slight dilatation.

**FIGURE 22-17** Bronchographic features of varicose and cystic bronchiectasis. **A**, A left tracheobronchogram in a shallow posterior oblique projection reveals mild dilatation and slightly irregular bronchi that terminate after four to six generations of branchings from the trachea in a squared or bulbous appearance (*arrowheads*). The findings are those of varicose bronchiectasis. **B**, A bilateral tracheobronchogram in the anteroposterior projection demonstrates a multitude of contrast material–filled cystic spaces resembling a cluster of grapes (*arrowheads*), a characteristic feature of cystic bronchiectasis. Note that the cystic spaces appear after only two to three bronchial generations. Less severe bronchiectasis of the varicose type is present in the right lower lobe (*open arrows*). (From Fraser RG et al: *Diagnosis of diseases of the chest*, ed 3, vol 3, Philadelphia, 1990, Saunders, p 2199.)

dilatation of the medium-sized bronchi and bronchioles. Inflammation results in destruction of the walls of central bronchi and obliteration of peripheral bronchi and bronchioles.<sup>23</sup> *H. influenzae* is the most common cause of bacterial infections.<sup>23,26</sup> The destructive process leads to loss of ciliated columnar epithelium, with transformation to a squamous cell and pus formation, which in turn leads to obstruction of airflow. Lung tissue of a patient with cystic fibrosis complicated by varicose bronchiectasis is shown in Figure 22-17.

**Clinical manifestations.** The child usually presents with a chronic productive cough with copious amounts of purulent, foul-smelling, green or yellow sputum. The sputum has the characteristic of separating into three distinct layers in a sputum cup.<sup>23,26</sup> Other clinical features are hemoptysis, fever, night sweats, moist crackles including bases, rhonchi, halitosis (bad breath), skin pallor, and, infrequently, digital clubbing. Clubbing is caused by prolonged decreased oxygenation, which leads to fibrous tissue hyperplasia in the area between the nail and distal portion of each digit. Clubbing is associated with lymphocytic extravasation, increased vascularity, and edema. The severity of clubbing parallels the severity of pulmonary disease.<sup>20</sup> Digital clubbing can be identified by two methods, as seen in Figure 22-18. Hypoxemia is seen in severe cases. Complications of bronchiectasis are malnutrition, recurrent pneumonia, right ventricular failure, and secondary visceral abscesses.<sup>9</sup>

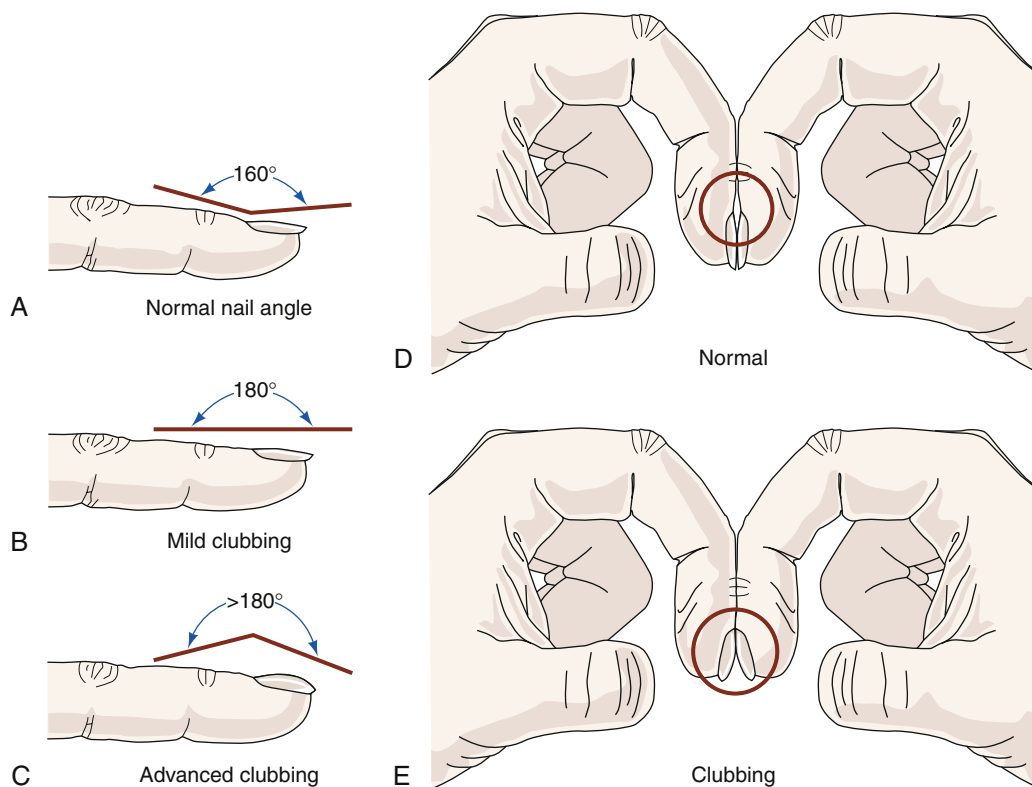

**Diagnosis.** Generally, the diagnosis of bronchiectasis is based on a history of chronic productive cough. The patient complains about producing copious amounts of foul-smelling, purulent sputum. Radiographic abnormalities may reveal small cysts, thickening of bronchial walls, and increased bronchial markings (areas of intensity

showing bronchi, which are usually not distinct). Pulmonary function tests show decreased airflow and vital capacity in advanced cases. Arterial blood gas analyses reveal decreased  $P_{aO_2}$  and increased  $P_{aCO_2}$  values from obstruction to airflow. High-resolution computed tomography is the test of choice for diagnosing bronchiectasis.<sup>9</sup>

**Treatment.** Antibiotic therapy accompanied by inhalation of bronchodilators followed by vigorous chest percussion and postural drainage is the mainstay of treatment. Proper hydration and nutrition are important in promoting liquefaction of secretions and preventing increased susceptibility to infection resulting from malnutrition. Maintaining adequate nutrition is problematic because of fatigue and the energy required for eating. (Refer to the Cystic Fibrosis section later in the chapter for further discussion on treatment.) In severe cases, when other measures fail, bronchoscopy with bronchial lavage may be necessary to remove thick, purulent secretions. In the child with severe sacular bronchiectasis, removal of the affected area of the lung may be necessary. Patient education materials can be obtained from the Cystic Fibrosis Foundation.<sup>27</sup> Childhood immunizations have led to a decreased incidence of bronchiectasis attributable to pertussis.<sup>28</sup>

### Bronchiolitis

**Etiology.** Bronchiolitis is characterized by widespread inflammation of bronchioles attributable to infectious agents such as respiratory syncytial virus (RSV) (50% of cases),<sup>28</sup> influenza virus (type A, B, or C), or bacteria (*H. influenzae*, pneumococci, or hemolytic streptococci), and occasionally is produced by allergic reactions. RSV infection is a common cause of hospitalization in infants.<sup>23</sup> Other organisms that may cause bronchiolitis include mycoplasma, chlamydia, ureaplasma,

**FIGURE 22-18** Clubbing. **A**, Normal fingernail angle is 160 degrees. **B**, Early mild clubbing appears as a flattened angle between nail and skin (180 degrees). **C**, Advanced clubbing shows a rounded (clubbed) fingertip and nail. To assess clubbing by Schamroth's diagnostic method (**D** and **E**), place the nails of the second digits together. Obliteration of the normal diamond-shaped space between the nails is an abnormal finding, signifying clubbing.

and *Pneumocystis (carinii) jiroveci*.<sup>29</sup> RSV occurs in yearly epidemics in winter to spring, usually in children younger than 2 years.<sup>30</sup> The average incubation period is 5 days, with inoculation occurring through the nose and eyes.<sup>9,29</sup> In adults, bronchiolitis is commonly associated with smoking, toxic fumes, and immunosuppression.<sup>9</sup>

**Pathogenesis.** Once initiated by the causal agent, proliferation and necrosis of bronchiolar epithelium occur, producing obstruction and increased mucus production.<sup>9</sup> Production of thick, tenacious mucus leads to airway obstruction, atelectasis, and hyperinflation. Three possible mechanisms of airway obstruction may follow the inflammatory process. They include (1) development of inflammatory exudate, which may displace surfactant, leading to airway obstruction; (2) release of chemical mediators, which may produce bronchiolar constriction; and (3) development of inflammation, which may induce fibrosis and narrowing of the airway.<sup>1,23</sup> Goblet cell metaplasia and increased bronchial muscle mass may also occur, resulting in further airway narrowing.

**Clinical manifestations.** The severity and course of the disease are variable, ranging from mild to fatal. Common clinical features include wheezing attributable to bronchospasm, crackles, decreased breath sounds, retractions, increased sputum, dyspnea, tachypnea (rapid, shallow respirations), and low-grade fever. Otitis media is a common complication often associated with *S. pneumoniae*.<sup>29</sup>

**Diagnosis.** Patients commonly have an elevated WBC count. The chest radiograph may show enlarged air sacs, interstitial infiltrates, atelectasis, or severe hyperinflation. Pulmonary function tests reveal severe obstruction to airflow. Rapid diagnosis of RSV may be made by identifying the viral antigen from nasal washings or nasal swab culture of secretions, using an enzyme-linked immunosorbent assay or immunofluorescent assay.

**Treatment.** Adequate oxygenation is maintained by providing humidified oxygen, monitoring blood gases or oxygen saturation, and administering oral, inhaled, or intravenous bronchodilator agents and, in selected cases, corticosteroids.<sup>23</sup> General information about pharmacologic agents commonly used in the management of various respiratory disorders is listed in other texts. Use of these agents depends on the severity of the diagnosis and prescriber preference.

Other therapies include sedation for anxiety, hydration, and the administration of appropriate antivirals and antibiotics. Patients are encouraged to stop smoking and to avoid passive smoke exposure. The use of eye-nose goggles by health care workers is recommended to control the spread of RSV. The virus is spread through the air or by contact with secretions from the eye, nose, or mouth, and transmission may not be prevented by the use of masks and gowns.

### Cystic Fibrosis

**Etiology.** Cystic fibrosis (mucoviscidosis) is an autosomal recessive disorder of the exocrine glands. It is the most common genetic lung disease in the United States, with an incidence of 1 in 2000 to 3300 Caucasian births.<sup>9,23,26,31</sup> One in 25 Caucasians are heterozygous carriers of the cystic fibrosis gene.<sup>9</sup> The incidence in African Americans is rare (1 in 17,000 live births), and in Native Americans the incidence is 1 in 80,000 births.<sup>31,32</sup> It is almost never seen in the Asian population.<sup>16,32</sup> About 35% of the 30,000 cases of cystic fibrosis in the United States involve individuals older than 18 years.<sup>9,16</sup> Cystic fibrosis can be classified either as an airflow obstructive disorder or as a suppurative (pus-forming) disorder. Hypersecretion of abnormal, thick mucus that obstructs exocrine glands and ducts is a characteristic finding in the disease.<sup>8</sup>

With advances in antibiotic therapy and early recognition and management of complications, patients with cystic fibrosis are living longer into adulthood. The median survival age is now 31 years.<sup>9,23,26</sup> Some patients are now having families.

**Pathogenesis.** Cystic fibrosis is classified as an autosomal recessive disorder. More than 800 mutations in the gene that encodes for the cystic fibrosis transmembrane conductance regulator (CFTR) have been described.<sup>9,23</sup> One genetic defect associated with cystic fibrosis involves deletion of three base pairs in codon 508 (AF508) that code for phenylalanine on chromosome 7 (band q31).<sup>16</sup> With the loss of these three base pairs, the CFTR gene is dysfunctional.<sup>9,23</sup> This is the most common genetic mutation causing cystic fibrosis and occurs in 60% to 75% of cystic fibrosis patients tested.<sup>9,23</sup> CFTR encodes a membrane chloride channel and is expressed in the sweat glands, the lungs, and the pancreas. Mutations in the CFTR gene result in alteration in chloride and water transport across the apical surface of epithelial cells.<sup>9,23</sup> Cystic fibrosis primarily affects the pancreas, intestinal tract, sweat glands, and lungs, and in males causes infertility.<sup>28</sup> The mucus-producing glands in the gastrointestinal tract enlarge, generating excessive secretions. The thick eosinophilic mucous secretions plug the glands and ducts of the pancreatic acini, intestinal glands, intrahepatic bile ducts, and the gallbladder, causing dilation and fibrosis.<sup>31,32</sup> These changes result in decreased production of pancreatic enzymes necessary for digestion of fats, carbohydrates, and proteins, thus leading to increased fat and protein in the stool.<sup>31,32</sup>

The bronchopulmonary system is also affected by the thick, tenacious mucus that results from failure of chloride channels to function in the apical membranes of mucosal cells. Decreased flow of ions and water results in viscid mucus.<sup>9,32</sup> High concentrations of DNA in airway secretions (attributable to inflammation and lysis of neutrophils) increase sputum viscosity.<sup>9,31,32</sup> The thick mucus causes airway obstruction, atelectasis, and hyperinflation and also decreases ciliary action, thus contributing to mucus stasis, which provides a medium for pulmonary infection. Sweat glands, salivary glands, and lacrimal glands are also affected, leading to high concentrations of sodium and chloride in these secretions.<sup>9,31,32</sup>

**Clinical manifestations.** Typical findings include a history of cough in a young adult or child; thick, tenacious sputum; recurrent pulmonary infections (commonly *Pseudomonas aeruginosa*); and recurrent episodes of bronchitis. These processes ultimately progress to pneumonia and bronchiectasis, right-sided heart failure (cor pulmonale), and exercise intolerance.

Physical examination may reveal digital clubbing (late sign), dyspnea, tachypnea, sternal retractions, unequal breath sounds, moist basilar crackles and rhonchi, and a barrel chest that is hyperresonant to percussion.<sup>9</sup> Other findings that may be present are pancreatic insufficiency (85% to 90%), cirrhosis of the liver (15% to 20%), diabetes mellitus (8% to 15%), gallstones (30% to 35%), nasal polyps (15%), and failure of development of the vas deferens in males.<sup>9,16,23,31-33</sup> Infants frequently present with a history of multiple respiratory tract infections, meconium ileus (stool retained in intestine), failure to thrive, jaundice, salt depletion, and edema.<sup>9,16,23</sup>

Nutritional assessment reveals depleted fat stores, steatorrhea (fatty stools), anorexia, decreased growth rate in children (weight, height, head circumference), and decreased midarm indices.<sup>16,23</sup>

**Diagnosis.** The diagnosis of cystic fibrosis is based on clinical and laboratory findings. Diagnostic studies that are routinely performed include arterial blood gas measurements, pulmonary function tests, sputum culture and sensitivity with Gram stain, and chest radiography. Specific diagnostic tests for cystic fibrosis include stool examination for fat, pilocarpine iontophoresis (sweat test), and genetic testing. A 72-hour stool collection combined with the dietary history during

that time is used to determine fat absorption and fecal fat excretion. A coefficient of fat absorption of less than 95% (85% in infants) can be used to define steatorrhea (fatty stools).<sup>34</sup> Arterial blood gas analyses commonly show hypoxemia and hypercapnia because of airway obstruction. Pulmonary function tests reveal decreased vital capacity, decreased airflow rates, increased airway resistance, increased functional residual capacity, and decreased tidal volume. Chest radiographs show evidence of patchy atelectasis, bronchiectasis, obstructive emphysema, cystic lung fields, and peribronchial thickening.<sup>1,16,23,31-33</sup>

The quantitative pilocarpine iontophoresis sweat test reveals elevated sodium and chloride levels, with more than 98% of patients having levels greater than 60 mEq/L in children and greater than 80 mEq/L in adults.<sup>8,33</sup> A diagnostic blood test for the genetic marker AF508 may be useful for confirming the diagnosis and providing genetic information to the family.<sup>8</sup>

**Treatment.** Management of cystic fibrosis involves an interdisciplinary approach. A comprehensive program that focuses on multiorgan derangements is recommended. Because pulmonary disease accounts for the majority of morbidity and mortality associated with cystic fibrosis, treatment is aimed at aggressive pharmacologic management of pulmonary infection. Treatment includes the use of bronchodilators, and mobilization of the thick mucus by postural drainage and chest physiotherapy (percussion and vibration) is a priority. Alternative methods for mucus removal include the forced expiratory technique, which involves coughing (huffing) with an open glottis.<sup>33</sup> Recombinant human deoxyribonuclease I (dornase alfa) acts by digesting extracellular DNA (released from lysed neutrophils) present in the viscid sputum of cystic fibrosis patients to decrease the viscoelasticity of sputum, thus improving pulmonary function and decreasing the risk of infection.<sup>8,9,33,35</sup>

High-dose antibiotic therapy is used for acute exacerbations of respiratory tract infections to decrease bacterial growth in the lungs. An annual influenza vaccine is recommended because of the increased risk of complications associated with infection.<sup>9,31</sup>

Nutritional therapy includes unrestricted fat consumption (approximately 30% of caloric intake), ingestion of a high-protein diet, and use of vitamin supplements (especially the fat-soluble vitamins A, D, E, and K). Other pharmacologic therapy related to nutrition is aimed at replacement of pancreatic enzymes (pancreatin or pancrelipase). Maintenance of weight in children with cystic fibrosis often requires an intake of 150% of the normal calories recommended for healthy children.<sup>31</sup> In some cases, enteral feedings or intravenous nutrition may be necessary on a short-term basis. Salt supplementation may be necessary in hot weather.

Heart-lung or lung transplantation is currently the only definitive treatment.<sup>9</sup> More than 200 cystic fibrosis patients worldwide have undergone transplantation, with a 3-year survival of 55%.<sup>9</sup> Patients receiving transplants showed marked improvement in mobility, energy, and quality of life.

Identification of the disease-related gene, the cystic fibrosis transmembrane conductance regulator gene (CFTR), has advanced prospects for corrective gene therapy. One limiting factor is that the therapeutic gene has a short-term expression.

### Acute Tracheobronchial Obstruction

**Etiology.** Acute tracheobronchial obstruction requires immediate treatment. Causes frequently include aspiration of a foreign body (e.g., a piece of meat, peanut, coin), malpositioned endotracheal tube, laryngospasm, epiglottitis, trauma, swelling from smoke inhalation, postsurgical blood clot, and compression of the bronchus or trachea by tumors or enlarged lymph nodes. With inhaled foreign bodies, the right side of the lung is affected more often than the left because of the angle of the anatomic extension of the right main bronchus from the trachea.

**Pathogenesis.** Obstruction by one of the etiologic agents listed earlier can be partial or complete. The health care worker must be prepared to assess the situation rapidly and act immediately to clear the airway.

**Clinical manifestations.** With complete obstruction, no air movement will be heard on auscultation, but the patient may still be making inspiratory chest movements. Other clinical features of complete obstruction include inability to talk, tachycardia, cyanosis, and rapid progression to unconsciousness unless the problem is quickly reversed.

With partial obstruction of the airway, the patient usually presents with stridor, sternal and intercostal retractions, wheezing, nasal flaring, tachypnea, dyspnea, tachycardia, and use of accessory muscles to breathe. Cyanosis is a late sign that usually indicates exhaustion or complete obstruction.

**Diagnosis.** The diagnosis of airway obstruction is based on clinical features and arterial blood gas analyses. Arterial blood gas values frequently show hypoxemia and hypercarbia. Chest radiographs may reveal the location of the obstruction.

**Treatment.** Treatment involves opening the obstructed airway as quickly as possible. Blows to the patient's back or use of abdominal thrusts (previously called the Heimlich maneuver) may be necessary for the foreign body to be expelled. Aspirated contents occluding the airway are suctioned to relieve obstruction. If these methods are unsuccessful, an emergency tracheostomy should be performed in the case of a suspected upper airway obstruction in the subglottic region or above.

## Epiglottitis

**Etiology.** Epiglottitis is a rapidly progressive cellulitis of the epiglottis and adjacent soft tissues. Acute epiglottitis is suspected when odynophagia (pain with swallowing) seems out of proportion to pharyngeal findings. Inability to swallow saliva with evidence of drooling is common. Epiglottitis is classified as a subtype of croup. The causative organism is primarily *H. influenzae* type B (Hib). It is most often seen in children 2 to 4 years old. Pneumococci, streptococci, and staphylococci are also causal agents.<sup>23,36</sup> The role of viruses in epiglottitis is unclear.<sup>36</sup>

**Pathogenesis.** The infecting agent localizes in the supraglottic area in the epiglottis and pharyngeal structures, causing rapid and potentially fatal inflammation with swelling and airway obstruction.

**Clinical manifestations.** The patient frequently presents with acute respiratory difficulty that has progressed rapidly over several hours. Common signs and symptoms include drooling, dysphagia, rapid onset of fever, dysphonia, inspiratory stridor, and inspiratory retractions. The child often sits in a “sniffing dog” position, which provides the best airway patency. The oropharynx is edematous and cherry red.<sup>28,36</sup>

**Diagnosis.** Definitive diagnosis is obtained by direct or fiberoptic visualization of the epiglottis. Lateral neck radiographs assist in making a definitive diagnosis and reveal a classic “thumbprint sign” (swollen epiglottis that looks like a thumbprint). A complete blood count may reveal leukocytosis with a shift to the left.<sup>36</sup>

**Treatment.** This condition is a true medical emergency and may necessitate intubation. Antibiotic therapy should be started immediately. Preventive treatment with the Hib vaccine has been the key to decreasing the incidence of this disease.

## Croup Syndrome

**Etiology.** Croup syndrome describes a number of acute viral and inflammatory diseases of the larynx. Croup diseases include laryngotracheobronchitis (viral croup) and bacterial tracheitis. Viral croup

affects the larynx, trachea, and bronchi. It is often caused by parainfluenza virus type 1. Other potential infecting organisms include parainfluenza types 2 and 3, RSV, influenza virus, adenovirus, and *Mycoplasma pneumoniae*.<sup>23</sup> Croup usually occurs in the fall and early winter, affecting children ages 6 months to 3 years.<sup>35</sup>

**Pathogenesis.** The infectious agent causes inflammation along the entire airway, leading to edema formation in the subglottic area.<sup>1,2</sup>

**Clinical manifestations.** The child presents with a history of upper respiratory tract infection or cold that has developed into a barking cough with stridor. Fever is low grade or absent. In severe cases the child may present with stridor at rest, retractions, and cyanosis.

**Diagnosis.** Diagnosis is based on clinical manifestations and lateral neck films to rule out epiglottitis. Direct laryngoscopy is also used to confirm the presence of epiglottitis because the clinical presentation is similar to that of croup. Lateral neck radiographs show subglottic narrowing and a normal epiglottis. The classic steeple sign associated with viral croup shows narrowing below the vocal cords.<sup>23,37</sup>

**Treatment.** Supportive treatment is used for viral croup. Mist therapy, oral hydration, and avoidance of stimulation are used in outpatient therapy. Hospitalized children are managed with oxygen therapy and pulse oximetry. Nebulized epinephrine is effective in relieving airway obstruction. Endotracheal intubation may be required for children with respiratory failure.

### KEY POINTS

- Obstructive disorders are associated with increased resistance to airflow, particularly during exhalation.
- Bronchiectasis is associated with recurrent inflammation of the bronchial walls, chronic cough, and aneurysm-like dilatations of the bronchioles. These bronchiolar dilatations serve as pockets of infection, producing purulent, foul-smelling sputum. Treatment centers on use of antibiotic therapy and removal of secretions.
- Bronchiolitis refers to widespread bronchiolar inflammation, often associated with smoking and a number of infectious agents. Inflammation results in mucosal swelling, excessive mucus production, and bronchial muscle constriction—all of which narrow the airway lumen and may lead to wheezing and dyspnea. Treatment centers on administration of bronchodilating agents and management of the underlying cause.
- Cystic fibrosis is an autosomal recessive disorder of exocrine glands and mucus cells. Secretions are excessively thick because of insufficient chloride and water transport. Thick secretions cause airway obstruction, atelectasis, and air trapping. Associated symptoms resulting from dysfunction of the exocrine pancreas are apparent. Treatment centers on removal of secretions and provision of antibiotic therapy for complicating respiratory tract infections.
- Obstruction of the trachea or large bronchi may occur acutely, requiring immediate treatment. Usual causes include foreign body aspiration, trauma, and inflammation. With complete obstruction, no movement of air occurs, even though inspiratory efforts may be observed. Partial airway obstruction is associated with wheezing, retractions, and stridor. Treatment centers on removing the obstruction, if possible, or creating a patent airway by a tracheostomy.
- Epiglottitis is a medical emergency. *Haemophilus influenzae* type B, the primary organism associated with epiglottitis, invades the supraglottic structures (epiglottis and arytenoids), causing inflammation and edema, leading to obstruction. Key points in the clinical diagnosis are rapid onset of fever, pain and difficulty swallowing, and drooling. Lateral neck x-ray films reveal a classic thumbprint sign, which is indicative of epiglottal

swelling. Airway maintenance via endotracheal intubation or tracheostomy and antibiotic therapy are the primary treatments. The Hib vaccine has greatly decreased the number of cases seen in the pediatric population.

- Croup is usually from a viral infection of the subglottic area. Children ages 6 months to 3 years present with cough and stridor following an upper respiratory tract infection. Humidification, oxygenation, and inhaled epinephrine are the primary treatment modalities.

## DIAGNOSTIC TESTS

### Pulmonary Function Testing

The primary criterion in diagnosing obstructive disease is the demonstration of obstruction to airflow in the lungs. Table 22-2 lists common ventilatory parameters referred to in spirometry.

Spirometry is performed by asking the patient to inhale deeply and then to exhale as quickly as possible until maximal air is exhaled. The total volume of air exhaled is known as the *forced vital capacity (FVC)*. To determine flow, the time required for exhaling the air is also measured. The volume exhaled in the first second is a reliable and reproducible index of obstructive airway disease. This value is the *forced expiratory volume in 1 second (FEV<sub>1</sub>)*. Figure 22-19 presents spirogram examples of normal, restrictive, and obstructive graphs for FEV<sub>1</sub> and FVC. For all spirometric studies, normal values are based on large population studies of healthy volunteers and are adjusted for height, weight, age, and gender. Results are compared to predicted values and reported as percent of predicted.

A simple formula has been developed to define and quantify airflow obstruction. If the FEV<sub>1</sub>/FVC ratio is 75% or greater, no significant obstruction of airflow is present. If the value obtained is between 60% and 70%, then mild obstruction of airflow is present. Moderate obstruction is defined as a value of 50% to 60%; and severe obstruction is present when the FEV<sub>1</sub>/FVC ratio is less than 50%. Therefore, using a spirometer and measuring both volume and time, the diagnosis of chronic obstructive pulmonary disease can be made and the severity quantified.

From the spirometric ventilatory measurements (see Table 22-2), other determinations of airflow can be made from the middle to later parts of a FVC maneuver. These measures are helpful in determining the presence of small airways disease. Some investigators believe that small airways disease may be a precursor to the development of chronic bronchitis and emphysema.<sup>1,21</sup>

Frequently, an inhaled bronchodilator, such as albuterol or metaproterenol, may be given, with testing repeated in 15 to 20 minutes. If the FEV<sub>1</sub> improves by 15% or more, the patient is considered to have a

**TABLE 22-2 COMMON VENTILATORY PARAMETERS MEASURED BY SPIROMETRY**

PARAMETER*	DEFINITION
Tidal volume	Volume of air inspired and expired with a normal breath (400-500 ml or 5 ml/kg of body weight)
Residual volume	Volume of gas left in lung after maximal expiration; stabilizes alveoli
Vital capacity or forced vital capacity (FVC)	Maximal air that can be expired after a maximal inspiratory effort; includes inspiratory reserve volume, tidal volume, and expiratory reserve volume
Functional residual capacity	Volume of air left in lungs after a normal expiration; includes expiratory reserve volume and residual volume
Forced expiratory flow rate (FEF <sub>25</sub> , FEF <sub>50</sub> , FEF <sub>75</sub> )	Volume of air forcibly exhaled per unit time (liters per second or liters per minute) at 25%, 50%, and 75% of FVC
Peak expiratory flow rate	Highest rate of flow sustained for 10 msec or more at which air can be expelled from lungs

\*See Figures 21-10 and 22-19 for normal values.

**FIGURE 22-19** Comparison of spirometry for normal lungs, restrictive lung disease, and obstructive lung disease. FEV<sub>1</sub>, Forced expiratory volume in 1 second; FVC, forced vital capacity.

**TABLE 22-3 NORMAL ARTERIAL BLOOD GAS VALUES**

PARAMETER	ADULT*	PREGNANCY	NEWBORN	COPD (LATE FINDINGS)
Pao <sub>2</sub> (mm Hg)	80-100	75-100	60-70	Decreased
Paco <sub>2</sub> (mm Hg)	34-45	30-37	35-45	Increased
pH	7.35-7.45	7.35-7.45	7.30-7.40	Decreased
HCO <sub>3</sub> <sup>-</sup> (mEq/L)	24-30	20-26	20-26	Increased
Base excess (mEq/L)	±2	—	—	—
O <sub>2</sub> saturation (%)	96-100	95-100	90-100	Decreased

\*For elderly patients, Pao<sub>2</sub> can be estimated by the following formulas<sup>24</sup>: 104 – (patient's age × 0.42) for patients lying supine; and 104 – (patient's age × 0.27) for patients sitting.

COPD, Chronic obstructive pulmonary disease.

positive bronchodilator response, indicative of partially reversible bronchospasm of the smooth muscles of the airways. This is most often the case with asthma or asthmatic bronchitis.

A second pulmonary function test known as the *diffusion capacity* measures the ability of the alveolar gases to diffuse into the capillary blood. The technical details of this test are beyond the scope of this book, but it is a valuable test for determining either thickening (fibrosis) of the alveolocapillary membrane or destruction (emphysema) of the membrane.

By breathing mixtures of an inert gas, such as helium, the TLC can be determined. This volume is composed of the FVC and the RV. The RV is the volume of air that remains in the lung after a person has forcefully exhaled all of the air from the lungs (see Figure 21-10). RV/TLC is normally 30% to 35%. In some patients with airflow obstruction, air tends to get trapped in the lungs, thereby increasing the RV and resulting in overinflation of lung tissue.

Arterial blood gases are also useful as a pulmonary function measurement. Using these values, a careful assessment of both the oxygenation and the acid-base status can be determined. The normal pH is 7.40, the normal  $P_{aCO_2}$  is 40 mm Hg, and the normal  $P_{aO_2}$ , at sea level, is 80 to 100 mm Hg. In COPD, especially in the severe stage,  $P_{aO_2}$  falls and  $P_{aCO_2}$  rises. Table 22-3 lists normal arterial blood gas values for various groups. A thorough discussion of arterial blood gas analysis can be found in Chapter 25.

### Bronchial Provocation Tests

The controlled induction of bronchospasm by inhalation of various agents is occasionally used to identify patients with hyperreactive

airways and to prove whether certain inhaled substances can produce bronchospasm. Usually a series of inhalations is administered, followed by a series of ventilation measurements. Generally the test is stopped when the  $FEV_1$  falls at least 20% more than the control measurement. This should only be done where emergency support services are available. Bronchoprovocation is contraindicated if the patient is already exhibiting symptoms or requires continual asthma medication. Allergens can be administered as solutions, dusts, or fumes. The amount administered should be no more than the patient would normally encounter in the environment. If symptoms occur, they can be readily reversed by two to four inhalations of albuterol or metaproterenol.

General hyperreactivity of the bronchi can be detected by having the patient inhale histamine phosphate solutions or methacholine (related to acetylcholine) or nebulized distilled water. A decline of more than 20% in the  $FEV_1$  is indicative of hyperreactivity.

#### KEY POINTS

- Obstructive disorders are associated with characteristic abnormalities on pulmonary function testing. These include the following:
  - Decreased  $FEV_1$
  - Low  $FEV_1/FVC$  ratio (<70%)
  - Improvement in  $FEV_1$  after use of a bronchodilator (asthma)
  - Increased residual volume
  - Increased functional residual capacity

## SUMMARY

Health care professionals have a key role in the management of respiratory disorders in the hospital and in the community. Obstructive pulmonary diseases presented in this chapter include airway obstruction, obstruction from conditions affecting the tracheobronchial walls, and loss of lung parenchyma (emphysema). Obstructive pulmonary disorders are characterized by increased resistance to airflow. With bronchiectasis, obstruction is due to inflammation, infection, and dilatation of the bronchioles. Similarly, bronchiolitis is associated with inflammation; however, in this situation, inflammation leads to mucosal edema and excessive mucus production. Airway obstruction from cystic fibrosis is related to production of excessive, thick secretions. Obstruction of the airway in croup is the

result of edema and increased secretions caused by viral infection. Similarly, epiglottitis is an infectious process requiring emergency treatment. The primary organism causing epiglottitis is *H. influenzae*. The incidence of epiglottitis has been greatly reduced with the advent of the Hib vaccine.

An inflammatory process is also seen in asthma and bronchitis. The inflammation is associated with increased mucus production and edema of the tracheal bronchial mucosa in asthma and bronchitis. Bronchospasm of the tracheobronchial tree attributable to exposure to allergens, pulmonary irritants, stress, and exercise may result in hypoxemia. Obstruction to airflow in emphysema is due to loss of alveoli and small airways. The most common cause is cigarette smoking.

- Review Questions and Answers
- Glossary (with audio pronunciations for selected terms)
- Animations
- Case Studies
- Key Points Review

## KEY QUESTIONS

- How do fibrotic lung disorders develop?
- How is the pathogenesis of acute (adult) respiratory distress syndrome similar to that of infant respiratory distress syndrome?
- How do abnormal accumulations in the pleural space affect lung function?
- What neuromuscular disorders are associated with reduced lung compliance?
- What is the pathogenesis of tuberculosis?
- What pulmonary function test abnormalities are characteristic of restrictive pulmonary disorders?

## CHAPTER OUTLINE

**LUNG PARENCHYMA DISORDERS, 498****Fibrotic Interstitial Lung Diseases, 498***Diffuse Interstitial Lung Disease, 498**Sarcoidosis, 499**Hypersensitivity Pneumonitis, 500**Occupational Lung Diseases, 501***Atelectatic Disorders, 503***Acute (Adult) Respiratory Distress Syndrome, 503**Infant Respiratory Distress Syndrome, 505***PLEURAL SPACE DISORDERS, 507***Pneumothorax, 507**Pleural Effusion, 508***NEUROMUSCULAR, CHEST WALL, AND OBESITY DISORDERS, 509****Neuromuscular Disorders, 509***Poliomyelitis, 509**Amyotrophic Lateral Sclerosis, 509**Muscular Dystrophies, 509**Guillain-Barré Syndrome, 510**Myasthenia Gravis, 510***Chest Wall Deformities, 510***Kyphoscoliosis, 510**Ankylosing Spondylitis, 511**Flail Chest, 511**Disorders of Obesity, 512***INFECTION OR INFLAMMATION OF THE LUNG, 512***Pneumonia, 512**Severe Acute Respiratory Syndrome, 514**Pulmonary Tuberculosis, 515*

Restrictive pulmonary diseases result from decreased expansion of the lungs attributable to alterations in the lung parenchyma, pleura, chest wall, or neuromuscular function. These disorders may be classified as pulmonary or extrapulmonary and represent acute or chronic patterns of lung dysfunction, rather than a single clinical disease. Table 23-1 lists the various disease processes that can be classified as restrictive. These diseases are characterized by a decrease in total lung capacity (TLC), vital capacity (VC), functional residual capacity (FRC), and residual volume (RV). The greater the decrease in lung volume, the greater the severity of the disease.<sup>1</sup> Blood gas analysis often shows decreased arterial partial pressure of oxygen (Pao<sub>2</sub>) and normal or decreased arterial partial pressure of carbon dioxide (Paco<sub>2</sub>), resulting in increased pH (respiratory alkalosis). This chapter presents information related to restrictive pulmonary diseases, including lung parenchyma disorders, pleural space disorders, neuromuscular and chest wall disorders, pneumonia, and tuberculosis. Specific lung parenchyma disorders, including interstitial fibrosis, sarcoidosis, hypersensitivity pneumonitis, and pneumoconiosis, as well as atelectatic disorders, including acute (adult) respiratory distress syndrome (ARDS) and infant respiratory distress syndrome (IRDS), are presented. Pleural space disorders, divided into pneumothorax and pleural effusions, are discussed. The section on neuromuscular and chest wall disorders is divided into neuromuscular weakness, chest wall deformities, and obesity. The final section presents etiologic factors, pathogenesis, clinical manifestations, diagnosis, and management of pneumonia, tuberculosis, and severe acute respiratory syndrome (SARS). Table 23-2 describes variations in respiratory parameters that affect restrictive lung disease in infant and elderly populations.

**TABLE 23-1 RESTRICTIVE PULMONARY DISORDERS**

DISORDER TYPE	REPRESENTATIVE EXAMPLES
<b>Diseases of the Lung Parenchyma</b>	
Neoplastic disease	—
Pneumonia	Pneumonia (viral, bacterial, fungal), hypersensitivity pneumonitis
Granulomatous disease	Sarcoidosis, tuberculosis, coccidioidomycosis, blastomycosis
Pneumoconioses	Occupational lung disease
Acute interstitial pneumonitis	—
Collagen disease	Rheumatoid arthritis, scleroderma, systemic lupus erythematosus
Atelectasis	—
Pulmonary resection	—
<b>Vascular Diseases</b>	
Acute respiratory distress syndrome	Pulmonary edema, pulmonary embolism
<b>Diseases of Extrapulmonary Restriction</b>	
Chest wall disease	Kyphoscoliosis, ankylosing spondylitis, obesity
Neuromuscular disease	Quadriplegia, hemiplegia, Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, muscular dystrophy
Pleural diseases	Pleural effusion, hemothorax, pneumothorax, chylothorax
Other	Abdominal distention, surgery, pregnancy

## LUNG PARENCHYMA DISORDERS

### FIBROTIC INTERSTITIAL LUNG DISEASES

The term *interstitial lung disease* describes a group of more than 180 disorders characterized by acute, subacute, or chronic infiltration of alveolar walls by cells, fluid, and connective tissue.<sup>1-4</sup> If left untreated, the inflammatory process may progress to irreversible fibrosis.<sup>4</sup> The incidence of interstitial lung disease is 20 cases per 100,000 persons in the general population and 175 per 100,000 in people more than 75 years of age.<sup>3</sup>

#### Diffuse Interstitial Lung Disease

**Etiology.** Diffuse interstitial lung disease (*diffuse interstitial pulmonary fibrosis*) is the name typically used for restrictive diseases characterized by thickening of the alveolar interstitium.<sup>2</sup> Synonyms frequently presented in the literature include *interstitial pneumonia*, *diffuse parenchymal lung disease*, *Hamman-Rich syndrome*, *intrinsic fibrosing alveolitis*, *cryptogenic fibrosing alveolitis*, and *idiopathic pulmonary fibrosis*.

**Pathogenesis.** Pathogenesis of the disease is not well understood, but is possibly related to an immune reaction that usually begins with injury to the alveolar epithelial or capillary endothelial cells.<sup>1,2</sup> Pathophysiologic changes may include interstitial and alveolar wall thickening and increased collagen bundles in the interstitium (Figure 23-1). Lung tissue becomes infiltrated by lymphocytes, macrophages, and plasma cells. Persistent alveolitis may lead to obliteration of alveolar capillaries, reorganization of the lung parenchyma, and irreversible fibrosis.<sup>2</sup> These changes in turn lead to the formation of large air-filled sacs (cysts) accompanied by dilated terminal and respiratory bronchioles. The immune response noted in interstitial lung disease is characterized by three pathologic patterns in the alveoli: inflammation, fibrosis, and destruction.

The inflammatory pattern occurs early and is potentially reversible.<sup>4,5</sup> The triggering event (occupational exposure, tobacco abuse, drug ingestion, connective tissue disease) causes an inflammatory response leading to increased numbers of inflammatory cells (neutrophils, lymphocytes, macrophages).<sup>1,2,4</sup> An associated injury to the alveolar capillary basement membrane from the triggering event leads to increased membrane permeability and movement of fluid and debris into the alveoli. The initial injury, in association with the inflammatory pattern, leads to fibroblastic proliferation and deposition of large amounts of collagen. The fibrotic pattern is manifested by increases in the number of mesenchymal cells and fibroblasts in the interstitium, and alveolar walls become thickened with increased amounts of fibrous tissue.<sup>5,6</sup> Physiologic restriction leads to reduced compliance and increased elastic recoil. The lung destruction pattern is manifested by loss of alveolar walls. Radiographically, this appears as a “honeycomb lung” and indicates end-stage disease.<sup>2</sup> Ground-glass appearance on chest radiograph is often an early finding.<sup>3</sup> The fibrotic and honeycomb patterns respond poorly to treatment.<sup>5</sup>

**Clinical manifestations.** The most common patient complaint is progressive dyspnea with nonproductive cough.<sup>3,5</sup> Clinical features also include rapid, shallow breathing; dyspnea; clubbing of the nail beds (40% to 80% cases)<sup>4</sup>; bibasilar end-expiratory<sup>3,4</sup> crackles (Velcro rales); and marked dyspnea with exercise. Cyanosis is a late finding. Anorexia and weight loss are noted on physical exam. While the disease progresses, patients exhibit an inability to increase cardiac output with exercise as evidenced by low maximal heart rate and high peripheral vascular resistance. Arterial oxygen desaturation occurs with exercise.<sup>4</sup>

**Diagnosis.** Chest radiographs show a honeycomb appearance and a coarse reticular pattern indicating late stage of disease.<sup>2,3,5,6</sup> Ground-glass haziness is indicative of the presence of infiltrates. High-resolution computed tomography (HRCT) and bronchoalveolar lavage are the

primary diagnostic tests used to evaluate interstitial lung disease.<sup>6</sup> Open lung biopsy or transbronchial biopsy and gallium-67 scanning may be used for diagnostic evaluation.<sup>3</sup> Results of pulmonary function tests are usually consistent with restrictive lung disease (decreased vital capacity, reduced total lung capacity, and decreased diffusing capacity).<sup>3</sup>

**Treatment.** The patient should be encouraged to avoid tobacco use and environmental exposure to the offending agent.<sup>2-4</sup> Primary therapy consists of administration of antiinflammatory and immunosuppressive agents. Immunosuppressive agents have been useful in reducing the dosage of corticosteroids required. Oxygen therapy is needed in patients with hypoxemia. Lung transplantation has been successful in selected patients.<sup>3,5-9</sup>

**Sarcoidosis**

**Etiology.** Sarcoidosis is categorized as an acute or chronic systemic disease of unknown cause, although an immunologic basis appears likely.<sup>1,9</sup> A common feature of sarcoidosis is the presence of CD4<sup>+</sup> T cells.<sup>9</sup> Activation of the alveolar macrophage from an unknown antigen trigger is a possible cause.<sup>1</sup> The acute process occurs more commonly in women in the second or third decades of life.<sup>1,2</sup> The chronic form is seen more commonly in the third to fourth decades of life, with the highest incidence seen in North American blacks (35.5/100,000) and northern European whites (11.9/100,000).<sup>2</sup> Having a first-degree relative with sarcoidosis increases the risk for disease fivefold.<sup>9</sup>

**Pathogenesis.** The disease is characterized by the development of multiple, uniform, noncaseating epithelioid granulomas that affect multiple organ systems, most commonly lymph nodes and lung tissue. Noncaseating granulomas are fibrotic and surrounded by large

histiocytes.<sup>1,2,9</sup> Sarcoid granulomas may also develop in the bronchial airways. Abnormal T cell function is noted with this disease.<sup>9</sup> Other systems/organs frequently involved are the skin, eyes, spleen, liver, kidney, and bone marrow.<sup>1,9</sup>

**Clinical manifestations.** Sarcoidosis is characterized by malaise, fatigue, weight loss, fever, chest discomfort, dyspnea of insidious onset, and a dry, nonproductive cough.<sup>2,9</sup> Other features include erythema nodosum (lesions marked by the formation of painful nodes on the lower extremities); macules, papules, hyperpigmentation, and subcutaneous nodules; hepatosplenomegaly; and lymphadenopathy. Patients with acute disease usually present with enlarged lymph nodes and arthritis, although some patients experience no symptoms.<sup>9</sup> Skin lesions and lacrimal and parotid gland involvement are also noted in the acute process.<sup>1</sup> Iritis, uveitis (65% of patients), blurred vision, conjunctivitis, and ocular discomfort may develop.<sup>9</sup>

**Diagnosis.** Common laboratory findings in patients with sarcoidosis include leukopenia, anemia, increased eosinophil count, elevated sedimentation rate, and increased calcium levels (seen in 11% of patients).<sup>2,9</sup> Serum levels of liver enzymes may also be elevated. Approximately 70% of patients exhibit anergy (decreased sensitivity to specific antigens such as *Trichophyton*, *Candida*, mumps virus, and tuberculin).<sup>2</sup> Patients with active disease also demonstrate elevated levels of angiotensin-converting enzyme (40% to 80% of cases).<sup>2</sup> Chest radiographs can be used to differentiate stages of the disease process: stage 0, normal; stage I, hilar adenopathy alone; stage II, hilar adenopathy and bilateral pulmonary infiltrates; and stage III, pulmonary infiltrates without adenopathy. Stage IV is characterized by advanced fibrosis with evidence of honeycombing, hilar retraction, bullae, cysts, and emphysema.<sup>7</sup> Gallium-67

**TABLE 23-2 AGE-RELATED FEATURES CONTRIBUTING TO RESTRICTIVE LUNG DISEASE**

ANATOMIC SITE	IMPACT ON RESTRICTIVE DISEASE
<b>Infant</b>	
Sternum and ribs are cartilaginous with soft chest wall	Diminishes effect of restrictive disease in infants
Ribs are horizontally oriented so that ribs move in and out easily	Diminishes effect of restrictive disease in infants
Accessory muscles of respiration are poorly developed	Majority of respiratory movement relies on diaphragm; restrictive diseases that compromise diaphragmatic excursion affect respiratory status; e.g., thoracic or abdominal surgery, paralysis, and abdominal masses all affect diaphragmatic excursion
Diaphragm rests horizontally and draws lower ribs inward in supine position so that diaphragmatic excursion is decreased	Leads to compromised effort of breathing
Cartilage of infant larynx is soft, so airway is compressed when neck is flexed or hyperextended	Increases airway resistance
During first month of life, neonate is obligate nose breather	Nasal obstruction may lead to respiratory distress from decreased airflow
Small diameter of airway leads to increased resistance to airflow	Mucus or edema in the airway may lead to significant increase in resistance and decrease in airway diameter
Fewer alveoli than in adults, leading to decreased radial traction applied to airways	Increased tendency of airways to collapse
Pores of Kohn and channels of Lambert are underdeveloped, leading to fewer collateral ventilation pathways	May lead to respiratory compromise, reducing ventilatory support with restrictive diseases
<b>Elderly</b>	
Decreased ciliary activity	Increased incidence of infection; decreased mucus clearance in all types of respiratory disorders
Decreased chest wall compliance and decreased lung elasticity in some areas of lung	Leads to a reduction in lung volume; leads to decreased expansion of lungs and to decreased matching of ventilation and perfusion
Decreased stress tolerance	Increased incidence of disease and trauma with age
Decreased muscle tone	Decreased physical conditioning
Impaired immunity as evidenced by decreased T cell function; increased autoantibodies	Decreased resistance to infection
Decreased oxygen uptake	Decreased oxygen level in blood
Decreased vital capacity	Decreased alveolar expansion
Decreased cough reflex	Impaired ability to clear secretions and inhaled particulate matter

**FIGURE 23-1** Possible schema of the pathogenesis of idiopathic pulmonary fibrosis. (From Kumar V et al, editors: *Robbin's basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 483.)

scans will localize areas of granulomatous infiltrates. Pleural effusion is noted in 10% of cases of sarcoidosis.<sup>1,2,9</sup> Pulmonary function test results may be normal or show evidence of restrictive disease and/or obstructive disease.<sup>9</sup> Transbronchial lung biopsy demonstrates noncaseating granulomas, thus providing a definitive diagnosis (75% to 90% cases). Bronchoalveolar lavage may be used to monitor cell content in patients with sarcoidosis.<sup>1,9</sup> The lavage fluid is characterized by increased lymphocytes and a high CD4/CD8 cell ratio.<sup>2</sup>

**Treatment.** Administration of corticosteroids and management of symptoms is the mainstay of treatment for patients whose disease process does not resolve spontaneously and in whom progressive lung disease or evidence of extrapulmonary sarcoidosis develops. For patients with progressive disease that does not respond to corticosteroids, immunosuppressive agents may be used.<sup>9</sup> Hydroxychloroquine is effective for treatment of disfiguring skin lesions, hypercalcemia, and neurologic involvement.<sup>9</sup> The prognosis is best for stage I disease. Death attributable to pulmonary insufficiency occurs in about 5% to 7% of patients.<sup>2,9</sup>

### Hypersensitivity Pneumonitis

**Etiology.** Hypersensitivity pneumonitis, also called *extrinsic allergic alveolitis*, is classified as a restrictive and occupational disease. Numerous (greater than 300) inhaled organic agents are responsible for the inflammatory process.<sup>10</sup> Table 23-3 lists various allergens related to the disease. Unlike other pulmonary diseases, hypersensitivity pneumonitis has a predominance in nonsmokers (80% to 95% of cases).<sup>10</sup>

**Pathogenesis.** The causative agent is suggested by the patient's history and confirmed by demonstration of precipitating antibodies in the serum directed to the causative antigen. The causative antigen combines with the serum antibody in the alveolar walls, leading to a type III hypersensitivity reaction. Type III hypersensitivity diseases are caused by the formation of antigen-antibody complexes<sup>1,10</sup> (see Chapter 10). These antigen-antibody complexes then elicit the granulomatous inflammation that leads to lung tissue injury, as evidenced by thickening of alveolar walls; formation of exudate in the bronchiolar lumen; and infiltration by lymphocytes, plasma cells, and eosinophils.<sup>1,10,11</sup> Fibrotic lung changes occur in advanced cases. Many individuals develop precipitating antibodies (precipitin) from organic dust exposure, but only a few develop pneumonitis.<sup>11</sup> Genetic predisposition may be involved in an exaggerated response to the offending agent. Experiments in animals show that a delayed hypersensitivity (type IV) reaction to the antigen is also required before pneumonitis can occur.<sup>11</sup>

**Clinical manifestations.** In the acute stage of the disease, symptoms start 4 to 6 hours after exposure and resolve in 18 to 24 hours.<sup>10</sup> General symptoms may include chills, sweating, shivering, myalgias, nausea, lethargy, headache, and malaise.<sup>1,11,12</sup> The patient may have a fever. Respiratory symptoms may include dyspnea at rest, dry cough, tachypnea, and chest discomfort. Physical findings may include cyanosis (a late sign) and crackles (rales) in the lung bases.<sup>1,3</sup>

In the chronic form, progressive diffuse pulmonary fibrosis develops in the upper lobes—the hallmark of the disease.<sup>1</sup> In the intermediate

**TABLE 23-3 CAUSES OF HYPERSENSITIVITY PNEUMONITIS**

DISEASE	ANTIGEN	ALLERGEN SOURCE
Farmer's lung	<i>Thermophila</i> , <i>Actinomyces</i>	Moldy hay, silage
Bird fancier's lung	Parakeet, pigeon, chicken	Bird excreta, feathers, and animal protein
Bagassosis	Thermophilic bacteria	Moldy sugarcane pulp
Mushroom, cork, maple bark, or malt hypersensitivity; cheese maker's lung, redwood lung	Various fungi	Handling moldy products
Grain handler's lung	Wheat weevil	Insect-infected grain
Pituitary extract hypersensitivity	Heterologous pituitary and serum proteins	—
Fish-meat worker's lung	Protein, fungi	Animal food
Humidifier lung (fever)	Thermophilic bacteria, amoebae, and fungi	Humidifiers and evaporative air coolers

form, the disease may manifest with acute febrile episodes and progressive pulmonary fibrosis with cough, dyspnea, fatigue, and, eventually, cor pulmonale (right-sided heart enlargement attributable to lung disorders).<sup>10</sup>

**Diagnosis.** During the acute/subacute phase, transient bilateral pulmonary infiltrates or increased bronchial markings with alveolar nodular infiltrates may be found on chest radiographs. In the chronic phase, diffuse reticulonodular infiltrates and fibrosis are present.<sup>11</sup> Skin testing with the causative antigen may produce a red, indurated, hemorrhagic reaction 4 to 12 hours after injection that lasts several days.<sup>1</sup> This reaction suggests precipitin-mediated sensitivity. Skin testing for most precipitating antigens is impractical because most produce irritating reactions before the precipitin reaction occurs, and many individuals without the disease have precipitating antibodies. Common laboratory findings include an increased white blood cell count and a decreased  $\text{PaO}_2$ . Elevations in erythrocyte sedimentation rate and the level of C-reactive protein are often present. Hypoxemia worsens with exercise. Pulmonary function tests show decreased lung volumes, diffusing capacity, and static compliance.<sup>1,10</sup>

**Treatment.** The goal of therapy is to identify the offending agent and prevent further exposure. This may require a change in environment or occupation. Oral corticosteroids may be used to decrease the inflammatory process.<sup>10,12</sup>

#### KEY POINTS

- Diffuse interstitial pulmonary fibrosis is a restrictive disorder characterized by thickening of the alveolar interstitium. The disorder is an immune-mediated disorder that follows an initial lung injury.
- Lung tissues are characteristically infiltrated by immune cells (macrophages and lymphocytes). Excess fibrin deposition results in stiff, noncompliant lungs. Vital capacity, tidal volume, FRC, and diffusion capacity are generally reduced. Respiratory rate increases to compensate for the small tidal volume.
- Treatment centers on administration of drugs to depress immune system activity, such as corticosteroids.

- Sarcoidosis is a restrictive disorder associated with abnormal protein deposits (granulomas) in the lung. Granulomas are fibrotic and are associated with immune cells (histiocytes). The cause is unknown.
- Symptoms include progressive dyspnea, fever, enlarged lymph nodes, and generalized symptoms of inflammation. Pulmonary lymph nodes may be primarily affected, with progression to parenchymal involvement. Pulmonary function test results are consistent with a restrictive disorder, demonstrating reduced lung volumes and increased respiratory rate.
- Treatment centers on alleviation of the symptoms. Corticosteroids may be used to reduce inflammation.
- Hypersensitivity pneumonitis includes a group of inflammatory lung disorders associated with inhalation of organic particles. Antibodies are produced in response to the inhaled particles; then antigen-antibody complexes deposit in the lung, initiating inflammation and granuloma production.
- Hypersensitivity pneumonitis is characterized by general symptoms of inflammation (e.g., fever, chills, malaise), dyspnea, dry cough, and tachypnea. Chronic exposure leads to progressive fibrosis and pulmonary dysfunction characteristic of restrictive parenchymal disease.

### Occupational Lung Diseases

**Etiology.** Occupational lung diseases result from the inhalation of toxic gases or foreign particles. Traditionally, occupational lung diseases included pathologic conditions that were associated with the effects of exposure to inhaled dusts. However, a holistic approach to these diseases requires consideration of atmospheric pollutants as well as natural genetic resistance and compliance with health maintenance behaviors. The distinction between occupational and environmental respiratory diseases is becoming increasingly difficult. The integration of multiple environmental areas (home, work, and leisure) further compounds the complexity of defining occupational respiratory diseases. Although atmospheric pollutants (toxic gases) are not discussed in detail here, their impact on occupational respiratory diseases must not be minimized. The sources, potential clinical manifestations, and potential pathologic processes associated with common atmospheric pollutants are presented in Table 23-4.

**Pneumoconiosis** is defined as parenchymal lung disease caused by the inhalation of inorganic dust particles. The greater the exposure to the dust, the worse the pathologic consequences. Anthracosis (coal miner's lung or black lung), silicosis (silica inhalation), asbestosis (asbestos inhalation), and acute beryllium disease are common examples of occupational lung diseases. However, exposure to several other dusts may also impair respiratory function. Included in this list are antimony ore, barium, iron, tin, fuller's earth (clay), kaolin (china clay), and talc. Hairdressers exposed to bleach and hair spray are at risk for developing obstructive lung disease. Asthma caused by occupational exposures is seen in 16.3% of all adult-onset asthma.<sup>13</sup> Many workers are exposed to "pathogenic dust" through the processing, packaging, or manufacturing of a specific product.<sup>10,14</sup> Predisposing factors such as history of preexisting lung disease, exposure to atmospheric pollutants, duration of dust exposure, amount of dust concentration, and size of dust particles affect the onset and severity of the respiratory impairment.

**Pathogenesis.** The respiratory tract is protected by two interrelated systems: the mucociliary system and alveolar macrophages. The inhalation of inorganic particles has little effect on the mucociliary system. However, atmospheric pollutants (sulfur oxides, nitrogen oxides, and tobacco smoke) interfere with and can paralyze ciliary action.<sup>1</sup> As a result, the clearance effect is impaired, and inorganic particles cannot be removed. Alveolar macrophages attempt to engulf and remove inorganic dust by one of the following methods: (1) migrating to small airways to use the mucociliary escalator; (2) engulfing dust and exiting through the lymph

and/or blood system; (3) passing through bronchial walls, depositing dust particles in extraalveolar tissue; or (4) destroying the particle (silica).<sup>1,14</sup>

Macrophage impairment is the primary mechanism through which inorganic particles initiate lung diseases. In an attempt to maintain a sterile alveolar environment, macrophages secrete lysozymes to control foreign particle activity. These enzymes, released in response to the particulate stimuli, eventually damage the alveolar walls, which may cause deposition of fibrous materials. Although the type of inorganic particle inhaled individualizes the pathophysiologic response, the general response is similar in the context of occupational lung diseases. Silica is one of the most toxic particles to alveolar macrophages. Dense deposits of collagen material are formed around the silica particles, resulting in marked fibrotic tissue deposition and restrictive lung disease. Coal dust and asbestos initiate a similar, although less severe, response. The pathologic processes and clinical features for each of the major occupational lung diseases are summarized in Table 23-5.

**Clinical manifestations.** Pneumoconioses (anthracosis, asbestosis, silicosis) generally produce no symptoms in the early stages. Physical evidence of the disease occurs when the pulmonary circulation is impaired because of increased pulmonary vascular resistance or development of a pulmonary infection. Workers may remain symptom free for up to 10 to 20 years with chronic exposure.<sup>1,2,14</sup> Once again, symptom manifestation is dependent on the predisposing factors. As pneumoconioses progress, patients present with a progressive, productive cough and dyspnea, especially with exercise. In addition, patients may complain of progressive weakness and fatigue. Clubbing of fingers may also be present. Late clinical features include chronic hypoxemia, cor pulmonale, and respiratory failure.

**Diagnosis.** The reliability of pulmonary changes noted on chest radiographs varies with the severity of the disease. When the patient is symptom free, no changes may be noted. However, as the pneumoconioses progress, micronodular mottling and haziness become apparent.<sup>1</sup> In addition, nodules, fibroses, and calcifications resulting from dust particle deposition are noted. Pneumoconioses usually produce one of three radiographic findings: nodular, reticular, or linear. However, because of the insidious progression of occupational lung diseases, radiographs negative for lung disease do not exclude the presence of the disease process. Changes in pulmonary function tests demonstrate predominantly restrictive impairment (see Figure 22-19) with a component of obstructive functional impairment, depending on the severity and type of dust inhalation.<sup>1</sup>

Finally, hypoxemia is evident from arterial blood gas measurements in the late disease stages. Falling  $P_{aO_2}$  levels are accompanied by decreased  $P_{aCO_2}$  levels as the body initially compensates for the hypoxemia with an increased respiratory drive. However, as the disease progresses, both hypoxemia and hypercapnia are evident.

**Treatment.** Preventive measures are the key to limiting the onset and severity of occupational lung diseases. Adherence to federal standards for exposure to dust and particulate matter, as well as continuing education of workers and employers, could dramatically impact the incidence of respiratory diseases. The use of respirators and water sprays for miners to decrease airborne particles in mines are two prevention techniques. Early evaluation of a work environment predisposed to occupational lung diseases is where “treatment” must begin.<sup>14</sup> Two primary goals in the management of active occupational lung diseases are to prevent further parenchymal damage and to relieve

**TABLE 23-4 COMMON ATMOSPHERIC POLLUTANTS CONTRIBUTING TO LUNG DISEASE**

POLLUTANT	SOURCE	CLINICAL MANIFESTATIONS	POTENTIAL DISEASE PROCESSES
Carbon monoxide	Automobile exhaust (incomplete fossil fuel combustion)	Lethargy, impairs mental skills, cherry-red mucous membranes, headache	Hypoxemia, respiratory failure
Sulfur oxides	Factories (corrosive, poisonous by-products of combustion of sulfur-containing fuels)	Inflamed mucous membranes, eyes, upper respiratory tract, bronchial mucosa; cough	Pulmonary edema, bronchitis
Photochemical oxidants (ozone, hydrocarbons, or nitrogen oxides)	By-product of exposure of hydrocarbons and/or nitrogen oxides (from fossil fuel combustion with high temperatures) to sunlight	Inflammation of eyes, upper respiratory tract; cough	Tracheitis, bronchitis, pulmonary edema
Cigarette smoke	Cigarettes (carbon monoxide, nicotine, “tars”)	Impaired exercise tolerance, decreased mental activity, tachycardia, hypertension, sweating	Bronchial carcinoma, chronic bronchitis, emphysema, coronary heart disease
Particulate matter	Factories/power stations; small particles, visible smoke and soot	Cough; dyspnea; itchy, watery eyes; irritated mucous membranes	Bronchitis, tracheitis, asthma

**TABLE 23-5 MAJOR OCCUPATIONAL LUNG PNEUMOCONIOSES**

PNEUMOCONIOSES	PATHOLOGIC FINDINGS	CLINICAL FEATURES
Anthracosis (coal miner’s lung)	<i>Early:</i> Collection of coal particles with small amount of dilation of airway <i>Late:</i> Progressive, massive fibrosis, with condensed areas of black fibrous tissue	<i>Early:</i> Minimal to no symptoms; may be seen with dyspnea with cough but often due to unrelated bronchitis or emphysema <i>Late:</i> Worsening dyspnea on exertion, productive cough, respiratory failure
Silicosis	Dense collagen deposits in respiratory bronchioles and alveoli and along lymphatics	<i>Early:</i> No symptoms noted <i>Late:</i> Productive cough, dyspnea, especially with exercise; increased risk for tuberculosis
Asbestosis	Fibrous deposits secondary to long, thin fibers, allowing deep lung penetration	Progressive dyspnea on exertion, weakness, clubbing of fingers; pleural thickening with plaque development

signs and symptoms, when possible. Ideally, if the problematic dust can be identified, the individual should be removed from the environment. However, if a job change is unrealistic, every possible measure must be implemented to prevent further inhalation of dust particles. Included in this treatment is the evaluation of current health maintenance behaviors. Treatment consists of corticosteroids, inhaled bronchodilators, oxygen therapy, and respiratory treatments (intermittent positive-pressure ventilation, postural drainage, and deep breathing exercises). The effectiveness and utilization of these therapies depend on the patient's condition and the stage of disease. Rarely are those pathologic conditions reversed with medical treatment. The primary goal is to halt symptom progression.

**KEY POINTS**

- Occupational lung diseases result from chronic inhalation of gases and inert particles. Commonly identified particles include coal, silica, and asbestos. Smoking and environmental pollutants may be contributing factors because they depress the ciliary function necessary to remove inhaled particles.
- The presence of inert particles in the alveoli initiates macrophage activity and inflammation. Inert particles cannot be digested by phagocytes, so they are walled off by deposition of fibrous proteins.
- Manifestations of pneumoconioses are related to the restrictive nature of the pulmonary dysfunction. Progressive dyspnea, decreased vital capacity and FRC, and increased respiratory rate are common. Blood gas analyses show progressive hypoxemia; carbon dioxide levels may remain normal or low until late in the disease.
- Treatment includes prevention of further exposure and administration of corticosteroids, bronchodilators, and oxygen therapy.

**ATELECTATIC DISORDERS**

**Acute (Adult) Respiratory Distress Syndrome**

**Etiology.** Acute (adult) respiratory distress syndrome is characterized by damage to the alveolar-capillary membrane. In the United

States there are more than 150,000 cases per year. Mortality statistics range from 30% to 63%.<sup>1,2,15,16</sup> Clinically, ARDS is associated with a decline in the Pao<sub>2</sub> that is refractory (does not respond) to supplemental oxygen therapy. Damage to the alveolar-capillary membrane causes widespread protein-rich alveolar infiltrates (visible on chest radiographs) and severe dyspnea. Patients who recover from the acute injury can expect to return to relatively normal lung function.<sup>1,15</sup> Follow-up studies (9 months to 4 years) in ARDS survivors show a mild restrictive pulmonary function accompanied by cough, dyspnea, and excess sputum production.<sup>2,4</sup> Some individuals continue to have abnormalities in diffusing capacity, oxygenation, and lung mechanics.<sup>2,4</sup> ARDS is associated with severe trauma, sepsis (greater than 40% of cases), aspiration of gastric acid (greater than 30% of cases), fat emboli syndrome, and shock from any cause (Box 23-1). The precise mechanism of lung injury is not known, but the common denominator appears to be increased permeability of the pulmonary vasculature and flooding of the alveoli with proteinaceous fluid, leading to the development of protein-rich pulmonary edema (noncardiogenic pulmonary edema). The acute lung injury triggers the immune system to activate the complement system and to initiate neutrophil sequestration in the lung (Figure 23-2).

**Pathogenesis.** The pathogenetic sequence of events in ARDS is shown in Figure 23-2. The initial injury to the alveolar-capillary membrane may be caused by direct damage, as seen in aspiration of acidic gastric contents, or by indirect damage, as occurs in shock from any cause. Therapeutic interventions (high oxygen and overhydration) may act to compound the effects of the initial lung injury. The resulting injury leads to an increase in alveolar-capillary permeability, which results in interstitial and alveolar edema. The four characteristic pathophysiologic abnormalities of ARDS involve: (1) injury to the alveoli from a wide variety of disorders, (2) changes in alveolar diameter, (3) injury to the pulmonary circulation, and (4) disruptions in oxygen transport and utilization.<sup>15,16</sup> Common findings in this type of injury include (1) severe hypoxemia caused by intrapulmonary shunting of blood; (2) a decrease in lung compliance; (3) a decrease in FRC; (4) diffuse, fluffy alveolar infiltrates on the chest radiograph; and (5) noncardiogenic pulmonary edema.<sup>1,9,15,16</sup>

**BOX 23-1 MAJOR DISORDERS ASSOCIATED WITH ARDS**

Shock (any process leading to a low blood flow state)

- Infectious causes
- Sepsis syndrome (primarily from gram-negative bacteria) with or without sustained hypotension (>40% cases)
- Pneumonia (viral, bacterial, fungal, mycobacterial)
- Miliary tuberculosis
- Bronchiolitis obliterans—organizing pneumonia

Trauma: pulmonary contusion

Embolism

- Fat emboli
- Air emboli
- Thrombus formation
- Amniotic fluid embolism

Head injury (increased intracranial pressure)

Aspiration (>30% of cases)

- Gastric contents
- Drowning (fresh/salt water)

Drug overdose

- Heroin
- Methadone
- Propoxyphene
- Barbiturates, salicylates, thiazides, colchicine

Inhaled toxins

- Smoke inhalation
- High concentrations of oxygen (iatrogenic)
- Corrosive chemicals (ammonia, sulfur dioxide, chlorine, nitrogen dioxide)
- Free-base cocaine smoking

Radiation

Hematologic disorders

- Disseminated intravascular coagulation
- Massive blood transfusion
- Post-cardiopulmonary bypass
- Thrombotic thrombocytopenic purpura

Metabolic disorders

- Pancreatitis
- Uremia
- Paraquat ingestion

Burns

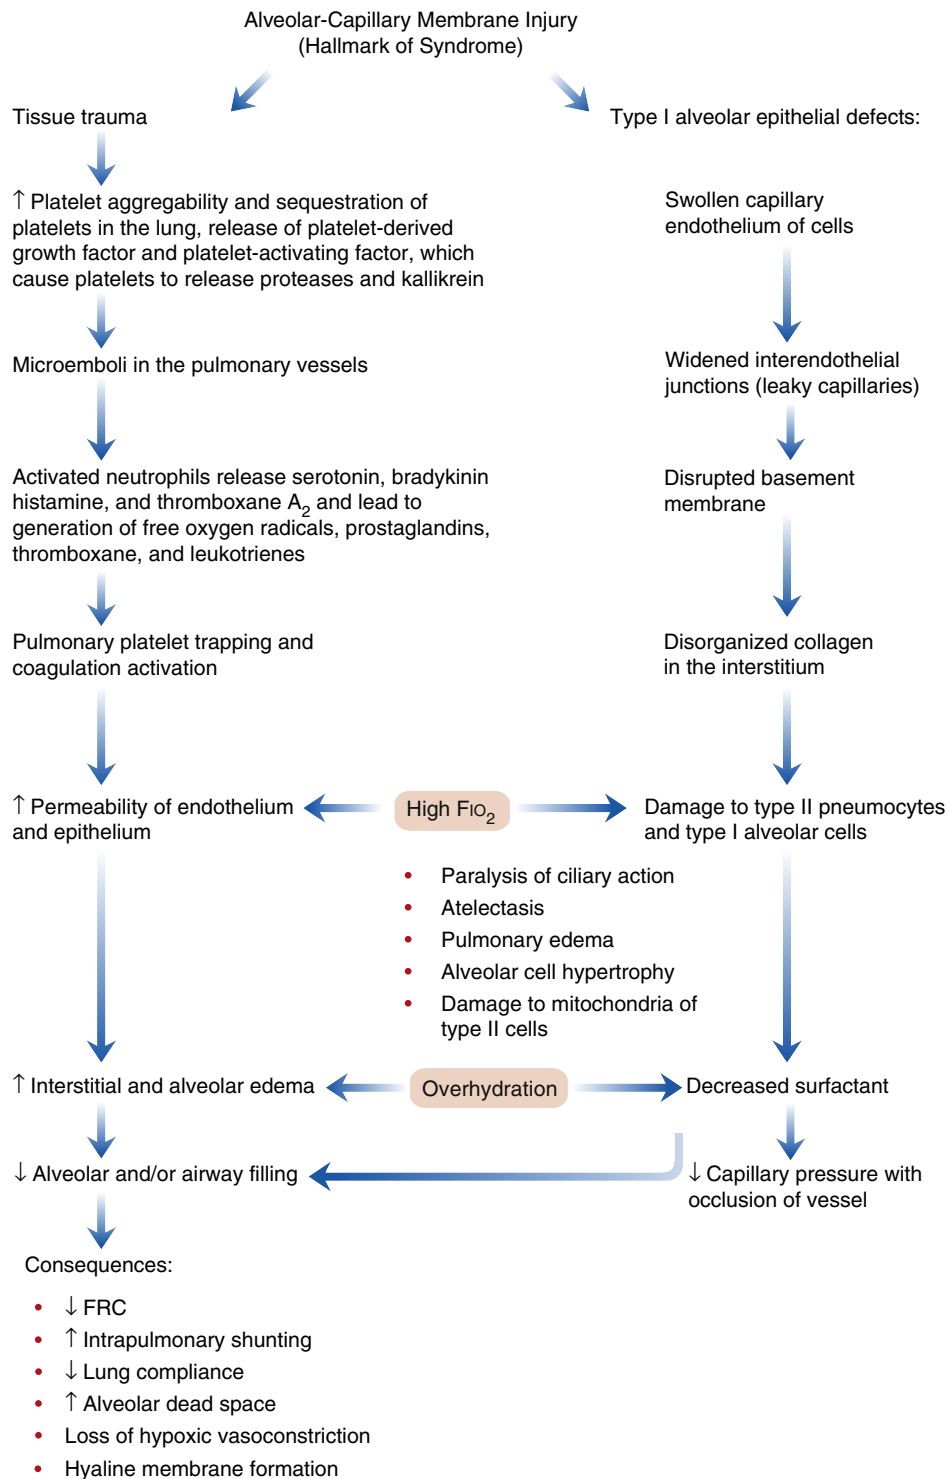

Cancer

Anaphylaxis

Eclampsia

Radiation pneumonitis

High-altitude exposure

**FIGURE 23-2** Pathogenesis of acute respiratory distress syndrome. *FRC*, Functional residual capacity.

The mechanism by which the *FRC* is decreased appears to be the result of stiff, noncompliant lungs associated with the presence of alveolar edema and exudate, which exaggerate surface tension forces.<sup>1,2,15,16</sup> Early alveolar closure and continued closure lead to atelectasis and loss of lung volume.<sup>1</sup> The decrease in lung compliance, often severe in ARDS, is reflected in the high ventilatory pressures required to deliver an adequate volume of gas. It is thought that this decrease in lung compliance is due to loss or inactivation of surfactant with subsequent increased

recoil pressure of the lungs.<sup>1,2,15,16</sup> In addition, proteinaceous fluid fills the alveoli and impairs ventilation. **Figure 23-3** shows alveolar damage attributable to ARDS. Alveoli contain dense proteinaceous debris, desquamated cells, and hyaline membranes. The decrease in  $P_{aO_2}$  is a result of perfusion of large numbers of alveoli that are poorly ventilated (areas of low ventilation-perfusion ratio) or not ventilated (areas of shunt).

**Clinical manifestations.** The clinical features of ARDS usually include a history of a precipitating event that has led to a low blood

volume state (“shock” state) 1 or 2 days before the onset of respiratory failure. The patient may complain of sudden marked respiratory distress.<sup>1,2</sup> Early signs and symptoms include a slight increase in pulse rate, dyspnea, and a low  $P_{aO_2}$ . The initial presenting sign may be shallow, rapid breathing. With progression of the disease, the patient demonstrates tachycardia, tachypnea, hypotension, marked restlessness, decreased mental status, and production of frothy secretions. On auscultation of lung fields, crackles and rhonchi are heard. The patient may be using accessory muscles to breathe and demonstrating intercostal and sternal retractions. A late sign is cyanosis.

**FIGURE 23-3** Diffuse alveolar damage (acute respiratory distress syndrome), shown in photomicrograph. Some of the alveoli are collapsed; others are distended. Many contain dense proteinaceous debris, desquamated cells, and hyaline membranes (*arrow*). (From Kumar V et al, editors: *Robbin's basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 483.)

**Diagnosis.** The hallmark of ARDS is hypoxemia that is refractory to increasing levels of supplemental oxygen. Uncorrected hypoxemia is associated with hypotension, decreased urine output, respiratory and metabolic acidosis, and eventual cardiopulmonary arrest. Arterial blood gas determinations reveal hypoxia, acidosis, and hypercapnia.<sup>16</sup> The chest radiograph may initially be normal but progresses to a bilateral diffuse “whiteout” (**Figure 23-4**) indicative of diffuse alveolar infiltrates. The infiltrates characteristically spare the costophrenic angles.<sup>2</sup> Blood and urine cultures will help determine if infection is the etiology. Pulmonary function tests show a marked decreased in FRC, decreased lung volumes, decreased lung compliance, and a ventilation-perfusion ( $\dot{V}_A/\dot{Q}$ ) mismatch with a large right-to-left shunt.<sup>1</sup> Histologic changes found on open lung biopsy reveal atelectasis, hyaline membranes, cellular debris, and interstitial and alveolar edema<sup>1,15,16</sup> (see **Figure 23-3**).

**Treatment.** The management of ARDS entails identifying the underlying cause, addressing the cause (e.g., sepsis), maintaining fluid and electrolyte balance, and providing adequate oxygenation with the use of a volume ventilator utilizing pressure support and positive end-expiratory pressure (PEEP). Patients may require fraction of inspired oxygen ( $F_{IO_2}$ ) levels of 1.0. The goal is to keep the  $P_{aO_2}$  value above 60 mm Hg. Because of increased permeability of the alveolar-capillary membrane, excessive fluid administration can produce or intensify pulmonary edema. High-frequency jet ventilation (HFJV), inverse ratio ventilation (IRV), and inhaled nitric oxide administration have also been used to treat ARDS.<sup>4,16</sup> ARDS can be prevented experimentally by blocking systemic inflammatory cells. Numerous agents have been investigated.<sup>16</sup>

### Infant Respiratory Distress Syndrome

**Etiology.** Infant respiratory distress syndrome, also known as *hyaline membrane disease*, has features similar to those of ARDS. It is a syndrome of premature neonates, characterized by hemorrhagic pulmonary edema, patchy atelectasis, and hyaline (glassy) membranes.<sup>1</sup> Hypoxemia that is refractory to increasing levels of oxygen supplementation is the hallmark of the syndrome. The incidence is 60% in infants

**FIGURE 23-4** Chest radiograph of a 28-year-old man who was involved in an automobile accident. The patient presented with multiple bilateral rib fractures and bilateral pneumothorax. Within 24 hours, severe acute respiratory distress syndrome developed (note diffuse “whiteout”).

**KEY POINTS**

- ARDS causes profound hypoxemia and a greatly increased work of breathing, often requiring mechanical ventilation and high-level oxygen therapy to maintain the  $P_{aO_2}$  value greater than 60 mm Hg.
- ARDS occurs in association with other pathophysiologic processes, such as trauma, sepsis, or shock. These disorders increase the risk of development of disseminated pulmonary inflammation leading to ARDS. ARDS is associated with a death rate of about 50%.
- ARDS is a consequence of widespread pulmonary inflammation leading to three major pathophysiologic processes:
  1. Noncardiogenic pulmonary edema associated with “leaky” pulmonary capillaries
  2. Atelectasis associated with lack of surfactant (surfactant normally decreases surface tension in small alveoli and prevents them from collapsing)
  3. Fibrosis (hyaline membranes) associated with inflammatory deposition of proteins
- ARDS is associated with profound alterations in pulmonary function, including decreased vital capacity, decreased FRC, decreased compliance, and decreased tidal volume. Respiratory rate is increased, and symptoms of tissue hypoxia may be apparent.
- Noncardiogenic pulmonary edema is evident as “whiteout” on chest radiograph. Crackles and wheezing may be heard throughout the chest. Profound dyspnea and the use of accessory muscles for breathing are common. Atelectasis and pulmonary edema result in right-to-left pulmonary shunting. Blood gas determinations show hypercarbia and hypoxemia, which do not improve significantly with oxygen therapy.
- Therapy is mostly supportive—to enhance tissue oxygenation until the inflammatory process resolves. Mechanical ventilation with PEEP and supplemental oxygen is the mainstay of therapy. PEEP is used to increase FRC and prevent alveolar collapse at end-expiration. PEEP may also force edema fluid out of the alveoli. High levels of oxygen (>60%) may contribute to ARDS because of absorption atelectasis. The  $F_{iO_2}$  value should be reduced as soon as possible.

born at less than 30 weeks’ gestation who are not treated with corticosteroids and decreases to 35% for infants receiving antenatal steroids.<sup>17</sup> The incidence in infants older than 34 weeks is 5%.<sup>17,18</sup> High-risk factors include birth earlier than 25 weeks’ gestation, birth at advanced gestational age, poorly controlled diabetes in the mother, deliveries after antepartum hemorrhage, cesarean section without antecedent labor, or the presence of perinatal asphyxia, multiple births, previous infant with RDS, and Rh factor incompatibility.<sup>17</sup> The increased risk of respiratory morbidity may be due to lack of hormones associated with labor. During normal labor there is a decrease in secretion of fetal lung liquid and an increase in absorption of lung liquid. Labor also stimulates the release of surfactant. During normal labor there is an increase in catecholamine release. Loss of catecholamine release may put the neonate at increased risk of respiratory morbidity.<sup>19</sup>

**Pathogenesis.** The primary cause of IRDS is a lack of pulmonary surfactant, leading to increased alveolar surface tension and decreased lung compliance.<sup>17</sup> Surfactant, a phospholipid, is produced by type II alveolar cells in increasing quantities after 32 weeks’ gestation. With IRDS, lung compliance is decreased to one fifth to one tenth of normal.<sup>1,17,18</sup> The neonate with IRDS must generate high intrathoracic pressures (25 to 30 mm Hg) to maintain patent alveoli. The premature neonate has a soft, compliant chest that is drawn inward with each inspiratory contraction of the diaphragm, making it difficult to maintain the high pressures needed to ensure adequate oxygenation. The end result from increased work of breathing and decreased ventilation is progressive atelectasis, increased pulmonary vascular resistance, profound hypoxemia, and acidosis.<sup>1</sup> Surfactant also functions to maintain pulmonary fluid balance.

Alteration of surface tension forces, normally maintained by surfactant, causes further leakage of proteinaceous fluid into the alveoli. This fluid contains fibrin and cellular debris, which causes hyaline membrane formation. Surfactant normally decreases surface tension in the alveolus during expiration, allowing the alveolus to remain partially open, thus maintaining FRC.<sup>18</sup> A secondary cause of IRDS is immaturity of the capillary blood supply, which leads to  $\dot{V}_A/\dot{Q}$  mismatch, thus adding to the problems of hypoxemia and metabolic acidosis. In addition, a right-to-left shunt from an open foramen ovale or patent ductus arteriosus may increase the hypoxemia.<sup>2</sup> Histologically, there is progressive damage to the basement membrane and respiratory epithelial cells. With increasing edema and loss of epithelial cells, patchy areas of atelectasis develop. Cellular damage from the disease process, excess fluid administration, and high values of  $F_{iO_2}$  lead to increased capillary permeability and leakage of high-protein fluid into the alveoli.

**Clinical manifestations.** The typical neonate presents with shallow respirations; intercostal, subcostal, or sternal retractions; diminished breath sounds; flaring of nares; hypotension; peripheral edema; low body temperature; oliguria; tachypnea (60 to 120 breaths/min); and bradycardia.<sup>17,18</sup> Late findings include frothy sputum, central cyanosis, and an expiratory grunting sound. Nasal flaring is a physiologic response mechanism used to increase airway diameter in an attempt to overcome airway resistance. An expiratory grunt is a physiologic response mechanism reflecting an attempt to create a physiologic PEEP by exhaling against a partially closed glottis. Paradoxical respirations (“see-saw” movement of the chest wall) may also be noted, indicating increased work of breathing. During the first 48 to 72 hours of life, neonates with IRDS need progressively higher levels of  $F_{iO_2}$  to maintain adequate (60 to 80 mm Hg) oxygen levels.<sup>17,18,20</sup> As work of breathing increases and oxygen levels decrease, metabolic acidosis occurs.<sup>21</sup>

**Diagnosis.** Initial arterial blood gas determinations reveal hypoxemia and metabolic acidosis attributable to lactic acid formation by hypoxic tissues. As the disease progresses, hypercapnia and respiratory acidosis develop. Chest radiographs progress from normal, shortly after birth, to a diffuse whiteout or ground-glass appearance indicative of diffuse bilateral atelectasis and alveolar edema. Generalized hypoinflation of the lungs is also seen on chest x-ray. Measurement of the lecithin/sphingomyelin (L/S) ratio and the desaturated phosphatidylcholine concentration in amniotic fluid may be done to determine the ability of the fetus to secrete surfactant. If the L/S ratio is  $\geq 2:1$  (3:1 in mothers with diabetes), the incidence of RDS is less than 5%.<sup>22</sup> The presence of phosphatidylglycerol in the amniotic fluid is indicative of pulmonary maturity.<sup>22</sup> Administration of glucocorticoids before delivery may stimulate lung maturation and improve the L/S ratio.

**Treatment.** Prevention of IRDS is aimed at the use of prenatal corticosteroids. Antenatal steroids significantly increase respiratory compliance (about 23%) and decrease the risk of development of IRDS.<sup>23</sup> The mainstay of therapy is mechanical ventilation with PEEP or continuous positive-airway pressure. Prevention is a primary goal. The therapeutic goal, as in the adult with ARDS, is to maintain adequate oxygen levels between 50 and 90 mm Hg.<sup>1,2,20</sup> The lowest  $F_{iO_2}$  settings should be used to maintain adequate arterial oxygen levels. High  $F_{iO_2}$  (100%) delivered for extended periods of time may result in further alveolar damage, primary persistent pulmonary hypertension, and retrolental fibroplasia (failure of the peripheral retina to vascularize, leading to blindness).<sup>20</sup> Exogenous surfactant (bovine, porcine, or synthetic) administration to premature infants has decreased the death rate in IRDS by 50%.<sup>17</sup> Surfactant decreases surface tension, thereby reducing the amount of pressure required to open the alveoli. High-frequency ventilation has proved to be effective in infants with severe IRDS by providing more uniform lung inflation, improving lung mechanics, and enhancing gas exchange. Infants receiving high-frequency ventilation require lower

mean airway pressures and have better gas exchange than those ventilated conventionally.<sup>21</sup> General supportive therapy of adequate intravenous nutrition, fluid and electrolyte balance, minimal handling, and a neutral thermal environment should be maintained. Broad-spectrum antibiotics are prescribed for infections after cultures have been done or prophylactically until blood cultures prove negative.<sup>20</sup>

#### KEY POINTS

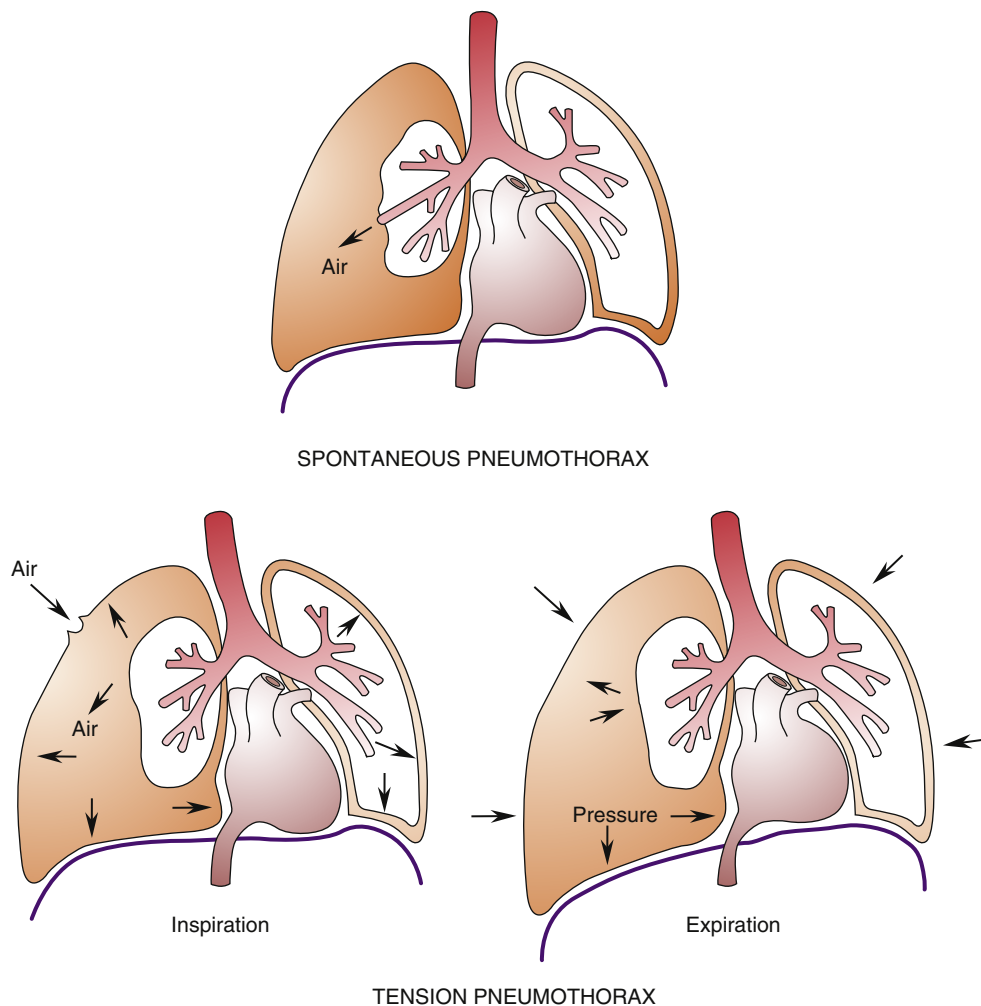

- The symptoms of IRDS are similar to those of ARDS. IRDS occurs most commonly in premature infants born before adequate development of their surfactant-producing pneumocytes (25 weeks' gestation). The maturity of surfactant-producing cells can be estimated from the L/S ratio in amniotic fluid. An L/S ratio of less than 2:1 is associated with a higher risk of IRDS.
- Lack of surfactant causes atelectasis and increased work of breathing as a result of high alveolar surface tension. Leakage of inflammatory exudate into the alveoli results in formation of hyaline membranes.
- Symptoms of IRDS include nasal flaring, expiratory grunt, thoracic retractions, and rapid, shallow respirations. Chest radiographs demonstrate a "whiteout." As in ARDS, blood gas values are poor, indicating severe hypoxemia and acidosis.
- Therapy for IRDS includes supportive measures, such as mechanical ventilation with PEEP or continuous positive airway pressure, and use of supplemental oxygen as well as specific measures to increase alveolar surfactant levels.

## PLEURAL SPACE DISORDERS

### Pneumothorax

**Etiology.** Spontaneous pneumothorax (SP) is characterized by the accumulation of air in the pleural space. A primary pneumothorax is classified as spontaneous, occurring mainly in tall, thin men between ages 20 and 40 years without underlying disease factors.<sup>1,2,24</sup> Cigarette smoking increases the risk of spontaneous pneumothorax.<sup>24</sup> A secondary pneumothorax occurs as a result of complications from preexisting pulmonary disease (such as asthma, emphysema, cystic fibrosis, infectious disease [pneumonia or tuberculosis], or interstitial lung disease). In the United States, there are approximately 20,000 new cases annually. SP is 6 times more common in men than women.<sup>24</sup> A specific category of secondary pneumothorax associated with menstruation is called *catamenial pneumothorax* (pathogenesis unknown). A catamenial pneumothorax occurs primarily in the right hemithorax, and is associated with endometriosis.<sup>25</sup> A third classification (tension pneumothorax) is traumatic in origin, resulting from penetrating or non-penetrating injury. A tension pneumothorax is a medical emergency. Other examples of traumatic pneumothorax have iatrogenic causes, such as placement of central lines, thoracentesis (6%),<sup>26</sup> percutaneous lung biopsy, and mechanical ventilation.<sup>2</sup>

**Pathogenesis.** Primary spontaneous pneumothorax (Figure 23-5) results from rupture of small subpleural blebs in the apices.<sup>1</sup> When

**FIGURE 23-5** Top, Spontaneous pneumothorax. Bottom, Tension pneumothorax: air builds up under pressure, leading to collapse of the ipsilateral lung and shift of the mediastinum to the contralateral side.

**FIGURE 23-6** Subcutaneous emphysema (air in the tissues) from tracheobronchial disruption and injuries of the esophagus. (From Kirsh MM, Sloan H: *Blunt chest trauma: general principles and management*, Boston, 1977, Little, Brown, p 109.)

air enters the pleural space, the lung collapses and the rib cage springs out.<sup>1</sup> The subpleural blebs are believed to occur in the apices as a result of negative mechanical pressures in the upper third of the upright lung field. Secondary pneumothorax occurs as a result of complications from an underlying lung problem and may be due to rupture of a cyst or bleb.<sup>1,2</sup> Tension pneumothorax (see [Figure 23-5](#)) results from the buildup of air under pressure in the pleural space. Air enters the pleural space during inspiration but cannot escape during expiration.<sup>1</sup> The lung on the ipsilateral (same) side collapses and forces the mediastinum toward the contralateral (opposite) side, thus decreasing venous return and cardiac output (see [Figure 23-5](#)). With an open, “sucking” chest wall wound, air enters during inspiration but cannot escape during expiration, leading to a shift of the mediastinum (contents of the septum between the two lungs) and the trachea.

**Clinical manifestations.** The clinical features of pneumothorax include tachycardia, decreased or absent breath sounds on the affected side, hyperresonance, sudden chest pain on the affected side (90%), and dyspnea (80%).<sup>24</sup> Small pneumothoraces (less than 20%) are usually not detectable on physical examination.<sup>25</sup> Tension pneumothorax and a large spontaneous pneumothorax are emergency situations, with patients presenting with severe tachycardia, hypotension, a tracheal shift to the contralateral side, neck vein distention, hyperresonance, and subcutaneous emphysema. [Figure 23-6](#) shows severe subcutaneous emphysema (air in the tissues attributable to tracheobronchial rupture).

**Diagnosis.** The chest radiograph shows depression of the hemidiaphragm on the side of the pneumothorax and a pleural line with absence of vessel markings peripheral to this line.<sup>2,24,25</sup> Chest radiography should be done with the patient standing. Expiratory films show a better demarcation of the pleural line than inspiratory films. The diagnosis may be based on clinical features without radiographic confirmation. However, a chest radiograph is usually obtained. A chest

**FIGURE 23-7** Upright posteroanterior chest radiograph showing a right-sided tension pneumothorax. Note marked deviation of trachea and cardiac silhouette into the left side of the chest. There is also depression of the right hemidiaphragm. (From Kirsh MM, Sloan H: *Blunt chest trauma: general principles and management*, Boston, 1977, Little, Brown, p 62.)

radiograph in tension pneumothorax shows a mediastinal shift ([Figure 23-7](#)). The electrocardiogram may show axis deviations, nonspecific ST-segment changes, and T-wave inversion.<sup>27</sup> Arterial blood gas analysis shows a decreased Pao<sub>2</sub> and acute respiratory alkalosis.

**Treatment.** The management of pneumothorax depends on the severity of the problem and the cause of the air leak. If the lung collapse is less than 15% to 25%, the patient may or may not be hospitalized. Typically, the patient is treated symptomatically.<sup>2,25</sup> A nonhospitalized patient should be monitored closely.<sup>27,28</sup> The expectation is for complete resolution within several weeks. If the collapse is greater than 15% to 25%, chest tube placement with water seal and suction is recommended.<sup>1,2,24,28</sup> Also, 100% oxygen should be administered to reduce the partial pressure of nitrogen in pleural capillaries, thus quadrupling the rate of pneumothorax absorption.<sup>24</sup> Chemical pleurodesis may be indicated for patients with recurrent spontaneous pneumothorax to promote adhesion of the visceral pleura to the parietal pleura to prevent further ruptures.<sup>1,2,26,27</sup> Patients with a previous pneumothorax should be warned about a possible recurrence at high altitudes, from scuba diving, and from smoking. A thoracotomy may be performed on patients in whom further spontaneous pneumothorax and blebs develop. Surgery permits stapling or laser pleurodesis of ruptured blebs.<sup>1,2,28</sup> Smoking cessation should be advised. Approximately 25% of patients with primary pneumothorax will have a recurrence within 2 years.<sup>24</sup>

### Pleural Effusion

**Etiology.** Pleural effusion is not a disease, but a pathologic collection of fluid or pus in the pleural cavity as a result of another disease

process. Normally, 5 to 15 ml of serous fluid is contained in the pleural space.<sup>2</sup> There is a constant movement of pleural fluid from parietal pleural capillaries to the pleural space, which is then reabsorbed into the parietal pleural lymphatics. The pleural membrane is a porous mesenchymal serous membrane that allows for movement of interstitial fluid. The fluid has a mucoid characteristic allowing for easy movement of the lungs.<sup>29</sup> The five major types of pleural effusion are: (1) transudates, (2) exudates, (3) empyema attributable to infection in the pleural space, (4) hemothorax or hemorrhagic pleural effusions, and (5) chylothorax or lymphatic pleural effusions.<sup>2</sup> Transudates have low concentrations of both protein (ratio of pleural fluid protein to serum protein is less than 0.5) and lactate dehydrogenase (LDH; pleural fluid LDH/serum LDH ratio less than 0.6), and have a specific gravity below 1.016.<sup>30,31</sup> Transudates are frequently associated with severe heart failure or other edematous states, such as cirrhosis with ascites, nephrotic syndrome, and myxedema.<sup>2</sup> Exudates have high concentrations of both protein (>0.5 mg/dl) and LDH (pleural fluid LDH/serum LDH ratio >0.6).<sup>28,30-32</sup> Common causes of exudates are malignancies, infections (especially pneumonia), pulmonary embolism, sarcoidosis, post-myocardial infarction syndrome, and pancreatic disease. Empyema is a high-protein exudative effusion resulting from infection in the pleural space. Hemothorax (the presence of blood in the pleural space) is often the result of chest trauma. Hemorrhagic pleural effusion contains a mixture of blood and pleural fluid. If the hematocrit of the fluid is greater than 50% of the hematocrit of peripheral blood, the fluid collection is called a *hemothorax*.<sup>1,2</sup> Chylothorax or chylous pleural effusion is an exudative process that develops from trauma as a result of leakage of chyle (lymph fluid) from the thoracic duct or from rheumatoid pleural effusion or tuberculous pleuritis.<sup>1,2</sup>

**Pathogenesis.** Pathophysiologic changes associated with the various types of effusions relate to changes in pleural capillary hydrostatic pressure, colloid oncotic pressure, or intrapleural pressure. Transudates can be caused by increased hydrostatic or decreased oncotic pressure. Exudates are associated with increased production of fluid as a result of increased permeability of the pleural membrane (inflammation) or impaired lymphatic drainage.<sup>2,30,31</sup> The imbalance in these pressures is associated with fluid formation exceeding fluid removal.

**Clinical manifestations.** Clinical features vary depending on the cause and size of the effusion. Small effusions may be asymptomatic (which is common) in patients with less than 300 ml of fluid in the pleural cavity.<sup>28,30</sup> General features include dyspnea, pleuritic pain that is sharp and worsens with inspiration, dry cough, decreased chest wall movement, absence of breath sounds, dullness to percussion, and decreased tactile fremitus over the affected area.<sup>28,32</sup> The most useful physical findings are dullness to percussion and tactile fremitus.<sup>33</sup> A massive pleural effusion may lead to a contralateral tracheal shift.<sup>28</sup>

**Diagnosis.** Thoracentesis should be done to analyze the fluid and to reduce the amount of fluid in the pleural cavity. Evaluation of the pleural fluid is done to determine its characteristics, which acts as an additional indicator of its origin. Pleural fluid should be analyzed for chemistry (pH, LDH, and glucose) and presence of pathogenic bacteria. Chest radiography should be done to detect pleural-based densities, infiltrates, signs of congestive heart failure (CHF), hilar adenopathy, and loculation of fluid. Computed tomography and ultrasonographic tests assist in the diagnosis of complicated effusions and distinguish a mass from a large effusion.<sup>28,30-32</sup> Ultrasonography is also useful for thoracentesis guidance.

**Treatment.** Treatment is directed at the underlying cause of the effusion and relief of symptoms. Closed chest tube drainage in adults or thoracentesis is indicated if the effusion is large. Closed chest drainage in pediatric cases is controversial.<sup>25</sup> A thoracotomy to control bleeding may be required in patients with excessive bleeding (greater than 200 ml/hr).<sup>34</sup>

### KEY POINTS

- The pleural space is usually a potential space, containing only a small amount of fluid for lubrication. Accumulations of air (pneumothorax), pus (empyema), blood (hemothorax), lymph (chylothorax), or transudate in the pleural space can restrict lung expansion.
- Tension pneumothorax occurs when pleural air progressively accumulates and develops a positive pressure in the pleura. The ipsilateral (same side) lung collapses, and mediastinal structures (trachea, heart) are shifted to the opposite side. Breath sounds are diminished or absent on the affected side.
- Tension pneumothorax and a large, simple (spontaneous) pneumothorax are medical emergencies requiring treatment to remove pleural air and reexpand the lung. This usually requires insertion of a chest tube. Chemical pleurodesis may be done in persons prone to spontaneous pneumothorax.
- A number of disease processes may result in accumulation of fluid in the pleural space. Analysis of the type of fluid (e.g., transudates, exudates, blood, pus) indicates the underlying disease process. General manifestations include dyspnea, cough, pleuritic pain, and diminished breath sounds and dullness to percussion over the effusion.

## NEUROMUSCULAR, CHEST WALL, AND OBESITY DISORDERS

### NEUROMUSCULAR DISORDERS

Diseases affecting the muscles of respiration or their nerve supply can lead to dyspnea and respiratory failure. Table 23-6 summarizes the features of these disorders.

#### Poliomyelitis

Poliomyelitis is a viral disease in which the poliovirus attacks motor nerve cells of the spinal cord and brainstem. The incidence of poliomyelitis in the United States is approximately eight cases per year. All of these cases have been related to the oral polio vaccine (OPV).<sup>35</sup> The diaphragm and intercostal muscles can be affected, resulting in weakness or paralysis and respiratory failure. At least 95% of infections are asymptomatic.<sup>35</sup> Patients with minor symptoms present with fever, headache, vomiting, diarrhea, constipation, and sore throat.<sup>36</sup> Respiratory muscle function generally recovers, although occasionally patients have chronic respiratory insufficiency from previous disease. As the result of mass vaccination of the population, new cases are quite rare and usually occur in unvaccinated immigrants.<sup>35</sup>

#### Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a degenerative disease of the nervous system that involves both upper and lower motor neurons. ALS occurs in males more than females (2:1) and has a prevalence of 0.5 to 2 cases in 100,000 persons. Onset is often between the ages of 50 and 70 years of age. Only 5% of ALS cases are familial.<sup>37</sup> Commonly, muscles innervated by both spinal nerves and cranial nerves are affected. Clinically, progressive muscle weakness and wasting develop, eventually leading to profound weakness of respiratory muscles and death. Although the course of the disease is variable from patient to patient, the natural history is one of irreversibility and progressive deterioration<sup>2,37</sup> (see Chapter 45).

#### Muscular Dystrophies

Duchenne muscular dystrophy is a hereditary disease, passed from mothers to sons (X-linked recessive) and occurs in 1 per 3500 male births. The disease is characterized by progressive muscular weakness, initially in the lower extremities, and wasting. In later years (twenties

TABLE 23-6 NEUROMUSCULAR DISORDERS AFFECTING THE RESPIRATORY SYSTEM

DISEASE	ETIOLOGY	PATHOPHYSIOLOGY	CLINICAL FEATURES
Poliomyelitis (myelitis is inflammation of spinal cord)	Develops from an enteral virus acquired by ingestion or respiratory droplet	After a 1- to 3-week period, virus invades intestinal blood supply; once in circulation, virus invades all areas of body; invasion of central nervous system leads to neural damage and initiation of an inflammatory reaction	General symptoms are tremors, muscle weakness; bulbar poliomyelitis affects respiratory muscle nerves, leading to respiratory paralysis; patients usually exhibit shoulder girdle paralysis first, followed by intercostal and diaphragm muscle paralysis; paralysis may be rapid or slowly progressive; also seen are diplopia, facial weakness, dysphagia, difficulty chewing, nasal voice, and loss of gag reflex
Amyotrophic lateral sclerosis	Cause unknown; current theories include autoimmune disease and a slow virus	Affects anterior horn cells of both upper and lower motor neurons	Progressive weakness affecting distal more than proximal muscles; atrophy, fasciculations, and spasticity are noted; involvement of respiratory muscles leads to respiratory dysfunction requiring mechanical ventilation
Muscular dystrophies (most common is Duchenne type)	Hereditary disease (X-linked recessive) passed from mothers to sons	Progressive muscular weakness noted initially in lower extremity muscles; in later years (twenties and thirties) respiratory muscles become involved; patients are at risk for respiratory tract infections	Progressive muscular weakness and wasting; skeletal deformities are also common; involvement of respiratory muscles (diaphragm, intercostals, and accessory muscles) leads to hypoxia and hypercapnia
Guillain-Barré syndrome (acute idiopathic polyneuropathy)	Exact cause unknown, but thought to be an autoimmune disease triggered by a viral infection	Disease usually follows an infection or vaccination; peripheral nerves are affected, leading to neural inflammation, demyelination, and axon destruction	Progressive weakness and loss of motor function beginning in feet and legs and ascending upward; sensory loss may also be noted but is not as dramatic as motor loss; loss of respiratory muscle control leads to respiratory failure, which frequently requires mechanical ventilation; autonomic nervous system symptoms may also be noted (tachycardia, dysrhythmias, hypotension or hypertension, loss of ability to sweat)
Myasthenia gravis	Considered an autoimmune disease with both humoral (B cell) and cell-mediated (T cell) components	Autoantibodies and T cells bind to and damage acetylcholine receptors, leading to decreased functioning of receptors	Common symptoms are diplopia, ptosis, difficulty swallowing, increased weakness with activity, nasal voice, slurred speech, and weakness of proximal extremities; as disease progresses, respiratory muscles become involved, leading to respiratory failure; pneumonia may result from respiratory failure and immobility

to thirties), respiratory muscles become involved, leading to hypoxia, hypercapnia, and frequent respiratory tract infections (see Chapter 51).<sup>2</sup>

### Guillain-Barré Syndrome

Guillain-Barré syndrome, also called *acute polyneuritis*, is a disorder that is presumed to have an immunologic basis. Infection involving *Campylobacter jejuni* often precedes the diagnosis. Guillain-Barré syndrome is characterized by demyelination of peripheral nerves. Frequently, patients have a history of recent viral or bacterial illness (66% of cases) followed by development of ascending paralysis.<sup>38</sup> Clinically, weakness and paralysis begin symmetrically in the lower extremities and progress or ascend proximally to the upper extremities and trunk. In severe cases, respiratory muscle weakness accompanies limb and trunk symptoms. Generally, the natural history of the disease leads to recovery, with minor residual motor deficits occurring in 15% to 20% of patients. Mortality is about 5% to 10% worldwide (see Chapter 45).<sup>38</sup>

### Myasthenia Gravis

Patients with myasthenia gravis experience weakness and fatigue of voluntary muscles, most frequently those innervated by cranial nerves, but peripheral and respiratory muscles can also be affected. The hallmark of the disorder is weakness made worse by exercise and improved by rest. The incidence in the United States is 2 to 5 cases per year per 1 million persons. Females are more affected than males (3:2). The primary abnormality is found at the neuromuscular junction, where transmission of impulses from nerve to muscle is impaired by a

decreased number of receptors on the muscle. Although myasthenia gravis is a chronic illness, the manifestations can often be managed by appropriate therapy, and individual episodes of respiratory failure are potentially reversible.<sup>2</sup> Respiratory failure in this disorder can be due to increasing severity of illness or overmedication (see Chapter 51).

## CHEST WALL DEFORMITIES

### Kyphoscoliosis

**Etiology.** Kyphoscoliosis may develop from an unknown cause (idiopathic) or may be related to congenital (Pott disease) or neuromuscular disease (muscular dystrophy, Marfan syndrome, neurofibromatosis, Friedreich ataxia, or poliomyelitis).<sup>39</sup> Most idiopathic cases of scoliosis are found in adolescents (11 years or older). The female to male ratio is 7:1.<sup>40</sup>

**Pathogenesis.** Commonly, a bony deformity of the chest wall occurs as a result of kyphosis (hunchback appearance; posterior curvature deformity) and scoliosis (lateral curvature deformity) (Figure 23-8). The higher the deformity in the vertebral column, the greater the compromise of respiratory status. Lung volumes are compressed, leading to atelectasis,  $\dot{V}_A/\dot{Q}$  mismatch, and hypoxemia.<sup>2</sup>

**Clinical manifestations.** Common clinical features include dyspnea on exertion; rapid, shallow breathing; and chest wall deformity as evidenced by ribs protruding backward, flaring on the convex side, and being crowded on the concave side. Hypoxemia develops later, and eventually carbon dioxide retention occurs.<sup>1</sup>

**Diagnosis.** Diagnostic findings include hypercapnia, hypoxemia (due to  $\dot{V}_A/\dot{Q}$  mismatch), and decreased lung volumes and lung capacities as

**FIGURE 23-8** Kyphosis (**A**) and scoliosis (**B** and **C**) are structural deformities that can interfere with ventilation. (From Delp MH, Manning RT, editors: *Major's physical diagnosis*, ed 9, Philadelphia, 1981, Saunders.)

evidenced by decreased values on pulmonary function tests. Also noted are increased pulmonary arterial pressures because of the associated pulmonary hypoxemia. Radiographs show accentuated bony curves.<sup>1,39,40</sup> Screening for scoliosis and kyphoscoliosis in school-aged children has proved to be an excellent method of early diagnosis of these conditions.

**Treatment.** Treatment depends on the severity of the deformity and the age of the patient. Kyphosis in elderly persons, especially women, is commonly because of osteoporosis. Curvatures of less than 20 degrees should be monitored on a regular basis.<sup>40</sup> A postural exercise program for mild scoliosis and external braces for moderate scoliosis are recommended. For more advanced cases with curvatures greater than 40 degrees, electrical stimulation of the paraspinal muscles, spinal fusion, and spinal instrumentation (Harrington rod) placement for surgical stabilization are recommended treatments. Curvatures of greater than 60 degrees correlate with poor pulmonary function in later life.<sup>40</sup>

### Ankylosing Spondylitis

**Etiology.** Ankylosing spondylitis occurs in both genders (male/female ratio of 3:1) and is commonly seen in the second or third decade of life.<sup>1,41</sup> It is characterized by chronic inflammation at the site of ligamentous insertion into the spine or sacroiliac joints. The precise cause is unknown. Ninety percent of patients with the disease have a positive HLA-B27 antigen (Chapter 10).<sup>41</sup> The respiratory system is affected by limited chest expansion and by the formation of pulmonary fibrosis in the upper lobes, which later develops into bronchiectasis and cavitation.<sup>41</sup> Transient acute arthritis of the peripheral joints occurs in about 50% of cases.<sup>41</sup>

**Pathogenesis.** Ankylosing spondylitis is a progressive inflammatory disease leading to immobility of the vertebral joints and fixation of the ribs.<sup>1</sup> The inflammatory process affects the articular processes, costovertebral joints, and sacroiliac joints by inducing a fibrotic response leading to joint calcification, ligament ossification, and skeletal immobility.

**Clinical manifestations.** Initial symptoms include low to middle back pain and stiffness that is more severe after prolonged rest. With exercise, the pain and stiffness decrease. As the disease process advances, rib cage movement is greatly reduced, leading to restrictive lung dysfunction.

Chest wall muscular atrophy is common and leads to further restriction of rib cage expansion. Breathing is largely accomplished by excursion of the diaphragm as the rib cage becomes immobilized. Associated problems seen with the disease include arthritis, uveitis, spondylitic heart disease, pulmonary fibrosis, and polyarteritis.<sup>41</sup>

**Diagnosis.** Pulmonary function tests show decreased vital capacity, decreased total lung capacity, and decreased compliance of the

respiratory system, mainly the chest wall. Radiographs show destruction of cartilage, erosion of bone, calcification, and bony bridging of joint margins. The earliest radiologic changes are usually seen in the sacroiliac joints.<sup>41</sup> Laboratory findings, although not diagnostic of the disease, include an elevated sedimentation rate in 85% of cases as well as a decreased red blood cell count and an increased white blood cell count. HLA-B27 antigen is seen in 90% of cases.<sup>41</sup> However, 8% to 10% of the normal population have a positive HLA-B27.<sup>41</sup>

**Treatment.** General therapy includes development of an exercise program that includes breathing exercises and mobility exercises. Pharmacologic management with nonsteroidal antiinflammatory agents provides symptomatic relief of pain and stiffness and promotes function.

### Flail Chest

**Etiology.** Flail chest results from multiple rib fractures as a result of trauma to the chest wall. The ribs are fractured at two distant sites, resulting in an unstable, free-floating chest wall segment that moves paradoxically inward on inspiration and outward on expiration. Bilateral costochondral separation and sternal fractures can also cause a flail segment.<sup>42</sup> Flail chest frequently occurs from the impact of the driver's chest with the steering wheel during an automobile accident.

**Pathogenesis.** Chest wall instability attributable to fracture at two distant sites on the same rib leads to an impairment of negative intrapleural pressure generation, causing decreased lung expansion on inspiration. The trauma commonly results in lung parenchymal injury, which may lead to pulmonary contusion, decreased lung compliance, and respiratory failure.<sup>42</sup> Interstitial and alveolar hemorrhage leads to abnormalities.

**Clinical manifestations.** Patients present after a trauma with paradoxical motion of the chest wall, either unilateral or bilateral. The injury to the chest wall is identified by careful inspection and palpation. Common features are marked shortness of breath, pain on inspiration, hypotension, cyanosis, and hypoxemia. The arterial  $PO_2$  value is often low before clinical symptoms appear.<sup>42</sup> Pneumothorax, hemothorax, and subcutaneous emphysema are common (see Figure 23-5).

**Diagnosis and treatment.** Serial blood gas results help determine the treatment regimen. Flail chest, with large flail segments, resulting in acute respiratory failure is managed with mechanical ventilation.<sup>35</sup> Mechanical ventilation is achieved by positive pressure, which causes the entire chest, including the flail section, to move as a unit rather than paradoxically. Pain management may be accomplished by continuous epidural anesthesia.<sup>42</sup>

## Disorders of Obesity

**Etiology.** Obesity is defined as excessive body fat, with a body mass index (BMI) greater than 30 kg/m<sup>2</sup> based on body weight and height. Overweight is defined as a BMI of 25 to 29.9 kg/m<sup>2</sup>.<sup>43</sup> Obesity results from excessive caloric intake and/or reduced caloric expenditure. The National Health and Nutrition Exam survey reported that 59.4% of men and 49.9% of women are overweight. The findings for obesity were 19.9% of men and 25.1% of women.<sup>44,45</sup> A higher prevalence of obesity was found in blacks than in whites and in persons with lower incomes than in those with higher incomes.<sup>43-45</sup> Obese patients are at risk for a variety of disorders, the most common of which are diabetes mellitus, coronary artery disease, degenerative joint disease, gallstones, certain cancers (colon, rectum, and prostate in men; uterus, biliary tract, breast, and ovary in women), and pulmonary impairment. Persons with a BMI of  $\geq 30$  kg/m<sup>2</sup> have an all-cause increase in mortality of 50% to 100% compared to persons with a BMI between 20 and 25 kg/m<sup>2</sup>.<sup>43</sup>

**Pathogenesis.** Endocrine causes of obesity are rare.<sup>10</sup> Hypothyroidism, the use of corticosteroids, and hypothalamic lesions all can lead to weight gain; however, the major cause of obesity is excess caloric intake in relation to caloric expenditure. Several hormones act on brain receptors to regulate appetite and metabolism. Leptin binds to brain receptors, causing the release of neuropeptides that promote satiety and increase metabolic rate. Ghrelin stimulates appetite. Genetic diseases such as familial partial lipodystrophy, Prader-Willi syndrome, Laurence-Moon syndrome, Bardet-Biedl syndrome, and Cohen syndrome are associated with obesity.<sup>43-46</sup> Obesity may be associated with hypoventilation. The mechanisms of obesity hypoventilation are reduced ventilatory drive and increased work of breathing. Some patients are thought to have an abnormality in the central nervous system.<sup>1</sup> In addition, the increased abdominal size can force the abdominal contents upward into the chest cavity, thus decreasing lung expansion and diaphragmatic shortening. Obesity hypoventilation is also called pickwickian syndrome, named after the obese boy in *Pickwick Papers* written by Charles Dickens. Pickwickian syndrome is associated with hypoventilation and airway obstruction.<sup>1</sup> An additional factor that contributes to the overall clinical picture in many obese patients is upper airway obstruction during sleep, the obstructive form of sleep apnea syndrome. Soft-tissue deposits in the neck and tissues surrounding the upper airway predispose the person to episodes of complete upper airway obstruction during sleep. In a large percentage of cases, the daytime somnolence that occurs in patients who have the obesity hypoventilation syndrome is related to obstructive sleep apnea.<sup>44</sup>

**Clinical manifestations.** Obesity hypoventilation is characterized by decreased alveolar ventilation, somnolence, severe hypoxemia, polycythemia, and cor pulmonale. Patients complain of daytime somnolence, impotence, shortness of breath, headache, and enuresis.

**Diagnosis.** The diagnosis of obesity is self-evident on examination. Tests for hypothyroidism, Cushing syndrome, insulinoma, diabetes, and hyperlipidemia may be done to identify comorbid factors.<sup>43</sup> For persons with hypoventilation, arterial blood gas analyses may reveal hypoxemia and hypercapnia. Chest wall compliance, vital capacity, total lung capacity, and expiratory reserve volume are all decreased. Patients may also have an increased red blood cell count and show signs and symptoms of cor pulmonale and pulmonary hypertension.

**Treatment.** Primary treatment for obesity consists of a weight loss program that includes the family members. Caloric intake that promotes an energy deficit of 500 to 1000 kcal/day is recommended. Aerobic exercise preserves lean body mass and increases energy expenditure.<sup>43,44</sup> Oxygen delivery through a nasal cannula or mechanical ventilation may be necessary for patients with morbid obesity. Surgical intervention with gastric stapling or gastric bypass to decrease the

gastric volume and size has proved successful in some patients.<sup>1</sup> These operations are intended to permanently curtail food intake.

### KEY POINTS

- Neuromuscular diseases affect the muscles of respiration, leading to muscular weakness, increased risk of pulmonary infections, and respiratory failure.
- Kyphoscoliosis is a deformity of the bony structure of the chest wall characterized by hunchback and lateral curvature of the spine. The abnormal shape of the chest interferes with the normal mechanics of breathing, resulting in small lung volumes, compression atelectasis, and hypoxemia. Compensatory tachypnea is usually present.
- Ankylosing spondylitis is a progressive inflammatory disease affecting vertebrae and ribs. Chronic inflammation leads to chest wall fibrosis and immobility. Chest wall muscle atrophy and rib cage stiffening result in pulmonary dysfunction characteristic of restrictive disorders.
- Obesity may interfere with the normal mechanics of breathing because of excessive chest weight and abdominal impingement on the chest cavity. Pickwickian syndrome is a disorder of obesity associated with hypoventilation and upper airway obstruction during sleep.

## INFECTION OR INFLAMMATION OF THE LUNG

### Pneumonia

**Etiology.** The term *pneumonia* (from the Greek *pneuma*, which means “breath”) refers to an inflammatory reaction in the alveoli and interstitium of the lung, usually caused by an infectious agent. Pneumonia can result from three different sources: (1) aspiration of oropharyngeal secretions composed of normal bacterial flora and/or gastric contents (25% to 35% of all pneumonias); (2) inhalation of contaminants (virus, *Mycoplasma*); or (3) contamination from the systemic circulation.<sup>2,47-49</sup>

There are several ways to classify pneumonia. Pneumonias are typically classified as community acquired or hospital acquired. The incidence of community-acquired pneumonia is 1 in 100 persons. Approximately 15% to 20% of persons presenting with pneumonia require hospitalization.<sup>50</sup> Pneumonia is further classified as bacterial, atypical, and viral. The bacterial pneumonias may be grouped as either gram-positive or gram-negative, based on the staining characteristics of the organism. *Staphylococcus* and *Streptococcus* (including pneumococci) are the predominant gram-positive organisms. Gram-negative bacteria that may cause pneumonia include *Haemophilus influenzae*, *Klebsiella* species, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Escherichia coli*, and *Proteus* species.

Patients at risk of pneumonia include the elderly; those with a diminished gag reflex; seriously ill, hospitalized patients; hypoxic patients; and immunocompromised patients.<sup>50</sup> Anaerobic bacteria may present clinically as a lung abscess, necrotizing pneumonia, or empyema. These diseases are usually caused by aspiration of normal oral bacteria (such as *Bacteroides* and *Fusobacterium*) into the lung.<sup>2</sup> Mycoplasmal pneumonia is more commonly seen in the summer and fall in young adults. About half of the cases of pneumonia in persons between 5 and 20 years of age can be classified as mycoplasmal pneumonia. Other causes of pneumonia occur less frequently in the general population. Legionnaires disease, for example, is a severe systemic illness characterized by fever, diarrhea, abdominal pain, liver and kidney failure, and pulmonary infiltrates. The causative organism for legionnaires disease lives in water and is transmitted by means of potable water, condensers, and cooling towers.<sup>2</sup> The current treatment of choice is administration of a macrolide antibiotic. Patients whose immune systems have been

compromised by disease or by drug therapy may be susceptible to the development of opportunistic pneumonia.<sup>50</sup> For example, *Pneumocystis (carinii) jiroveci* pneumonia, an opportunistic fungal infection, is commonly found in patients with cancer or with human immunodeficiency virus (HIV). (See Chapter 12 for further discussion of acquired immunodeficiency syndrome [AIDS].)

*Aspergillus*, an opportunistic fungus that is widespread in nature, may cause progressive pneumonia. *Aspergillus* is released from the walls of old buildings under reconstruction. Attention should be given when old hospitals are renovated and when susceptible patients are located in a reconstruction area.<sup>49</sup> To assist the reader in differentiating among the various types of pneumonia, Table 23-7 presents the etiologic factors, common clinical features with age-related characteristics, radiologic findings, and antibiotic therapies for 11 forms of the disease.<sup>2</sup> There are many other types of pneumonia that are not listed.

**Pathogenesis.** Normally, pulmonary defense mechanisms (immune responses, cough reflex, sneezing, mucociliary clearance) protect individuals from pneumonia. Community-acquired pneumonia occurs when defense mechanisms are compromised.<sup>2,46</sup> A highly virulent organism may also overwhelm a person's defense mechanisms. Community-acquired pneumonias are commonly bacterial in origin.<sup>46</sup> After microbial agents enter the lung, they multiply and trigger pulmonary inflammation. Alveolar air spaces fill with an exudative fluid, and inflammatory cells invade the alveolar septa. Acute bacterial pneumonia may be associated with significant  $\dot{V}_A/\dot{Q}$  mismatching and hypoxemia because inflammatory exudate collects in the alveolar spaces. Alveolar exudate tends to consolidate and becomes difficult to expectorate. Viral pneumonia does not produce exudative fluids.<sup>2</sup> Figure 23-9 shows the histologic progression of acute bacterial pneumonia. Patients with chronic illnesses and those who are immobile or immunosuppressed or have a decreased level of consciousness are at

TABLE 23-7 DIFFERENTIATING FEATURES OF TYPES OF PNEUMONIA

ETIOLOGIC ORGANISM	COMMON CLINICAL FEATURES	CHEST RADIOGRAPH	ANTIBIOTIC TREATMENT
<i>Staphylococcus aureus</i> ; gram-positive cocci in clumps	Follows upper respiratory tract infection; fever, chills, pleuritic chest pain, cough, yellow purulent sputum; seen in patients in chronic care facilities	Consolidation, may have cavitation	Methicillin-susceptible strains: nafcillin or oxacillin with or without rifampin; methicillin-resistant strains: vancomycin with or without rifampin; alternative choice: cephalosporins, clindamycin, vancomycin
<i>Streptococcus pneumoniae</i> ( <i>pneumococcus</i> ); gram-positive diplococci	More common in alcoholics; also seen with chronic cardiopulmonary disease; fever, chills, pleuritic chest pain, cough, rust-colored sputum	Patchy infiltrates	Procaine penicillin G or aqueous penicillin G, amoxicillin; alternative choice: macrolides, cephalosporins, doxycycline, quinolones; prophylactic vaccine available
<i>Haemophilus influenzae</i> ; pleomorphic gram-negative coccobacilli	Upper respiratory tract symptoms, fever, vomiting, irritability, cough, purulent sputum, dyspnea; affects children and older adults; affects people with chronic cardiorespiratory problems	Consolidation	Cefotaxime, ceftriaxone, doxycycline, azithromycin, TMP-SMX; alternative choice: quinolones or clarithromycin
<i>Klebsiella pneumoniae</i> ; gram-negative encapsulated rods	Seen frequently in middle-aged men and associated with alcoholism and diabetes mellitus; rust-colored sputum	Consolidation	Aminoglycoside plus third-generation cephalosporin; alternative: aztreonam, imipenem, quinolone
<i>Pseudomonas aeruginosa</i> ; gram-negative rods	Chronic obstructive pulmonary disease, cystic fibrosis, and mechanical ventilation; fever, chills, and copious greenish, foul-smelling sputum	Infiltrates, small pleural effusion	Aminoglycoside plus ticarcillin/clavulanate or piperacillin/tazobactam or aztreonam or imipenem
<i>Escherichia coli</i> ; gram-negative rods	Complication of gastrointestinal surgery	Infiltrates, may have pleural effusion	Aminoglycoside plus third-generation cephalosporin; alternative: aztreonam, imipenem, quinolone
Virus	Fever, malaise, headache, nonproductive cough	Patchy infiltrates	Amantadine, rimantadine
<i>Legionella</i> species; no bacteria	Acute onset with fever, diarrhea, myalgia, and abdominal pain	Consolidation	Macrolides with or without rifampin; alternative: TMP-SMX, quinolone
<i>Mycoplasma pneumoniae</i> (atypical pneumonia); monocytes and neutrophils; no bacteria	Ages 5-25 years; most common in young adults; associated with otitis media and myringitis; sore throat, headache, myalgia, dry cough, fatigue, low-grade fever	Infiltrates	Erythromycin, doxycycline; alternative: quinolone or other macrolide
<i>Pneumocystis (carinii) jiroveci</i> (fungus)	Immunosuppressed patients (infants, children, and adults); 60% of patients have AIDS	Diffuse infiltrates, or chest x-ray may appear normal	TMP-SMX or pentamidine; isethionate plus prednisone; alternative: dapsone plus TMP-SMX, clindamycin plus primaquine
Anaerobic pneumonia (aspiration pneumonia); mixed flora	Predisposition to aspiration, fever, weight loss, malaise; risk increases with decreased level of consciousness, artificial airway, and sedation; seen in individuals with poor dental hygiene	Infiltrates in dependent lung fields	Penicillin G; alternative choices: clindamycin, metronidazole, cefoxitin

AIDS, Acquired immunodeficiency syndrome; TMP-SMX, trimethoprim-sulfamethoxazole.

**FIGURE 23-9** **A**, Acute bacterial pneumonia. The congested septal capillaries and extensive neutrophil exudation into the alveoli correspond to early red hepatization. Fibrin nets have not yet formed. **B**, Early organization of intraalveolar exudate, seen in areas to be streaming through pores of Kohn. **C**, Advanced organizing pneumonia corresponding to gray hepatization and featuring transformation of exudates to fibromyxoid masses richly infiltrated by macrophages and fibroblasts. (From Kumar V et al, editors: *Robbin's basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

highest risk for developing pneumonia.<sup>26</sup> Disruption of the body's normal defense mechanisms leads to increased risk of pneumonia. Other patients at risk are those who have undergone thoracic or abdominal surgery or have received a general anesthetic.

**Clinical manifestations.** Clinically, the pathogenic cause, severity of the disease, and age of the patient may cause variations in the presentation of pneumonia. Some patients present with fever only.<sup>30</sup> Crackles (rales) and bronchial breath sounds may be heard over the affected lung tissue. Patients may present with chills, cough, purulent sputum, and an abnormal chest radiograph. Patients with viral pneumonia may present with an upper respiratory prodrome (fever, coryza, cough, hoarseness) accompanied by wheezing and/or rales.<sup>26</sup> Typical features of *Chlamydia* pneumonia are cough, tachypnea, rales, wheezes, and absence of fever. *Mycoplasma* pneumonia is a common cause of pneumonia in older children and adults.<sup>26</sup> Signs and symptoms include fever, cough, headache, and malaise.

**Diagnosis.** The chest radiograph demonstrates parenchymal infiltrates (white shadows) in the involved area, indicative of inflammatory alveolar processes.<sup>2,26,47</sup> In a patient with symptoms and clinical findings of pneumonia, a Gram stain of expectorated sputum from deep in the lungs may be obtained to distinguish bacterial from viral pneumonia and gram-negative from gram-positive organisms. If the patient had been previously healthy, the cause of the majority of these infections would be either viral, mycoplasmal, or the gram-positive pneumococcal bacterium. However, if the patient had been hospitalized or has other illnesses such as emphysema, diabetes, or alcoholism, then gram-negative organisms should be suspected.

“CURB-65” may be used to determine whether the patient should be hospitalized. “CURB-65” includes (1) confusion, (2) BUN >19.6 mg/dl, (3) respiratory rate >30 breaths/min, (4) systolic blood pressure (BP) <90 mm Hg and diastolic BP ≤60 mm Hg, and (5) age ≥65 years. Blood cultures are positive in approximately 20% of hospitalized patients.<sup>49</sup> Because 24 to 48 hours may be required for culture of the etiologic agent, antibiotic therapy should be started empirically.<sup>2</sup> Once culture and sensitivity results are obtained, antibiotic therapy may be changed. Diagnosis is based on the chest radiograph, white blood cell count (greater than 15,000/μL for acute bacterial pneumonia<sup>26</sup>), and sputum culture, coupled with clinical features of fever with recurrent chills, cough, dyspnea, and rales.

**Treatment.** Once the organism has been cultured, specific antibiotic selection is based on sensitivity of the organism to different antibiotics. Empirical treatment, before culture results for community-acquired pneumonia, consists of levofloxacin or a macrolide antibiotic. Table 23-7 presents treatment options.<sup>49</sup> The chest x-ray should be repeated 6 to 8 weeks after the infection has been treated.<sup>50</sup>

### Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) was first reported in February 2003 as a severe form of pneumonia occurring in Asia. In that year, the disease spread to more than two dozen countries in North America, South America, Europe, and Asia before the global outbreak was contained.<sup>51,52</sup> According to the World Health Organization, a total of 8089 people became sick with SARS worldwide and 774 died. Extensive efforts at identification and containment prevented further

spread of the disease, and the epidemic abated in mid-2003. Only eight confirmed SARS cases occurred in the United States during the epidemic.<sup>51,52</sup> Active global surveillance for SARS in human beings had detected no further confirmed person-to-person transmission of the disease between July 2003 and August 2004. However, two cases of SARS occurred in persons working in laboratories in southern China.

**Etiology.** SARS is caused by a coronavirus called SARS-associated coronavirus (SARS-CoV).<sup>51,52</sup> The primary mode of transmission appears to be through close person-to-person contact, most likely through respiratory droplets that are produced when a person coughs or sneezes. The virus also can spread through contact with contaminated objects or surfaces followed by touching the mouth, nose, or eyes.

**Pathogenesis.** The SARS virus epidemic was associated with milder disease in infants and children, and most of those with severe respiratory forms of the disease were adults. The median incubation period is about 4 to 6 days, and most patients become ill within 10 days after exposure.<sup>50,51</sup> Early clinical features of SARS are similar to those of other viral illnesses and include systemic signs and symptoms of an inflammatory response including fever, headache, and muscle aches. Respiratory complaints are also nonspecific and include nonproductive cough and shortness of breath. Nearly all patients develop radiographic evidence of pneumonia by days 7 to 10 of the illness, and the majority also develop lymphopenia (reduced number of lymphocytes in the blood).<sup>51,52</sup> The pneumonia can be severe with significant hypoxemia and an overall mortality of about 10%. In persons older than 60 years, the mortality may be close to 50%.<sup>51,52</sup>

**Clinical manifestations.** Most patients present with fever (temperature >100.4° F), myalgias, headache, nonproductive cough, and dyspnea, often without symptoms of an upper respiratory tract infection (no nasal drainage). Evidence of pneumonia on chest x-ray is usually apparent within 1 week of symptom onset. Lymphopenia may be evident on the complete blood count differential. There are no specific clinical manifestations for SARS, and it is unlikely as a cause of pneumonia unless there is a known history of exposure or travel to high-risk areas (mainland China, Hong Kong, or Taiwan). In the severe form of the disease, arterial blood gases reflect poor ventilation (low Pao<sub>2</sub> and increased Paco<sub>2</sub> measurements).

**Diagnosis.** No specific laboratory or clinical clues differentiate SARS-associated pneumonia from other forms of pneumonia at presentation of the patient. Early recognition and containment rely on a high index of suspicion based on clinical and epidemiologic factors. The vast majority of SARS cases during the epidemic had a clear history of exposure to a SARS patient or to a setting in which SARS-CoV transmission was known to have occurred. Patients presenting with manifestations of viral pneumonia severe enough to require hospitalization and a history of possible exposure should be tested for SARS. If known cases of SARS are occurring in the world, a lower threshold for testing may be instituted. Although not diagnostic, the following laboratory abnormalities have been seen in some patients with SARS: lymphopenia with a normal or low white blood cell count, elevated levels of liver enzymes, elevated creatine kinase concentration, elevated lactate dehydrogenase concentration, and prolonged activated partial thromboplastin time. Definitive diagnosis requires laboratory confirmation of SARS-CoV.<sup>50,51</sup> Respiratory specimens (e.g., from the nasopharynx, oropharynx, and sputum), blood, and stool can be tested for the presence of SARS virus.

**Treatment.** Currently, there are no definitive treatment recommendations for SARS. Patients with symptoms of pneumonia requiring hospitalization need supportive care, which may include administration of supplemental oxygen and mechanical ventilation. Evaluation for and treatment of other possible sources of pneumonia that may be responsive to antimicrobial therapy are recommended. Isolation precautions should be instituted in cases suspicious for SARS and discontinued only after consultation with local public health authorities.

### KEY POINTS

- Pneumonia is an inflammation of the lung that is usually associated with an infectious agent. The most common types of pneumonia are bacterial, mycoplasmal, and viral. A productive cough is the primary differentiating feature between bacterial pneumonia and viral pneumonia, in which coughing is nonproductive.
- Acute bacterial pneumonia may be associated with significant  $\dot{V}_A/\dot{Q}$  mismatching and poor blood gas values because inflammatory exudate collects in the alveolar spaces. Alveolar exudate tends to consolidate and becomes difficult to expectorate. Viral pneumonia does not produce exudative fluids.
- Manifestations of bacterial pneumonia may include fever, chills, cough with purulent sputum, crackles, and areas of consolidation on chest radiograph. Dyspnea may be significant.
- The treatment of bacterial pneumonia centers on antibiotic therapy to eliminate the organism and supportive therapy to enhance ventilation and oxygenation. Most cases of viral pneumonia (influenza) are managed symptomatically, because no effective antibiotic therapy is available.
- Fungal and protozoal pneumonias are uncommon and tend to occur in immunocompromised individuals.
- SARS is an acute respiratory tract infection caused by a coronavirus. The pneumonia is severe and has a mortality of 10%.

### Pulmonary Tuberculosis

**Etiology.** Worldwide, 3 million people die of tuberculosis each year. There are an estimated 10 million people in the United States infected with tuberculosis.<sup>2,53</sup> More than 90% of cases involve reactivation of prior infection; the remainder are new infections. The majority of new cases occur in malnourished individuals, those living in overcrowded conditions, immunosuppressed individuals, incarcerated persons, immigrants (36% of new cases in the United States),<sup>53</sup> and elderly persons. Two thirds of all new cases are found in racial and ethnic minorities.<sup>53</sup> During the past 40 years, there has been a shift in the care of such patients from specialized tuberculosis hospitals to outpatient therapy. Hospitalization of such patients may be necessary with implementation of isolation precautions for a period of 2 to 4 weeks (longer for multidrug-resistant tuberculosis [MDR-TB]). In some countries, specialized tuberculosis hospitals have reopened owing to increasing resistance of the organism to treatment and an increasing number of cases. India and China account for nearly 50% of MDR-TB cases worldwide.<sup>53</sup> Tuberculosis cases should be reported to local and state health departments.

Tuberculosis is caused by the bacterium *Mycobacterium tuberculosis*, an acid-fast aerobic bacillus. Any organ system can be affected by the disease, but the most common sites are the lungs and the lymph nodes. Tuberculosis is subdivided into two major classifications: primary (usually clinically and radiographically silent<sup>2</sup>) and reactivating. Primary disease (initial infection) may lie dormant for many years or decades.<sup>2</sup> When the person's immune system becomes impaired, reactivation may occur. HIV, corticosteroid use, silicosis, and diabetes mellitus have been found to be associated with reactivation.<sup>2</sup> Reactivation may occur many years after the primary infection. Distant organ systems may be involved as a result of hematogenous spread during the primary or reactivation phase of infection. In addition, there may be disseminated disease, known as miliary tuberculosis, again resulting from hematogenous dissemination of the organisms. Strains of *M. tuberculosis* are becoming resistant to one or more first-line antituberculosis drugs.<sup>45</sup> MDR-TB accounts for 15% of the tuberculosis cases in the United States. Mortality rates range from 70% to 90% in hospitals or correctional facilities in Florida and New York, with a median survival of 4 to 16 weeks.<sup>2</sup> Entry into the body

**FIGURE 23-10** Morphologic spectrum of tuberculosis. A characteristic tubercle at low magnification (**A**) and in detail (**B**) illustrates central granular caseation surrounded by epithelioid and multinucleated giant cells. This is the usual response seen in patients who have developed cell-mediated immunity to the organism. Occasionally, even in immunocompetent individuals, tubercular granulomas may not show central caseation (**C**). Therefore, irrespective of the presence or absence of caseous necrosis, special stains for acid-fast organisms need to be performed when granulomas are present in histologic sections. In immunosuppressed individuals, tuberculosis may not elicit a granulomatous response ("nonreactive tuberculosis"); instead, sheets of foamy histiocytes are seen, packed with mycobacteria that are demonstrable with acid-fast stains (**D**). (From Kumar V et al, editors: *Robbin's basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 519. **D**, Courtesy Dr. Dominick Cavuoti, Department of Pathology, University of Texas Southwestern Medical School, Dallas.)

is by inhalation of small (2 to 10  $\mu\text{m}$ ) droplets containing the bacteria. Infected droplets are expelled when an infected person coughs, sneezes, or talks.

**Pathogenesis.** After entrance of *Mycobacterium* into the lung tissue of the susceptible person, alveolar macrophages ingest and process the microorganisms. The organisms either are destroyed or persist and multiply. Once the infection becomes established, lymphatic and hematogenous dissemination occurs. T cells and macrophages surround the organisms in granulomas that limit multiplication and spread.<sup>53</sup> Dormant organisms persist for years. Reactivation may occur if the patient's immune system becomes impaired.<sup>2,53</sup> *Mycobacterium tuberculosis* is a slow-growing aerobic, non-spore-forming, nonmobile bacillus. It has a lipid-rich cell wall that lacks pigment and produces niacin growth in liquid media (BACTEC), requiring 9 to 16 days for culture results.<sup>53</sup> The pathologic manifestation of

pulmonary tuberculosis is the Ghon tubercle or complex, which has parenchymal and lymph components. The parenchymal component is composed of a well-circumscribed necrotic nodule that later becomes fibrotic and calcified. The lymph component is found in the lymph nodes. Primary pulmonary tuberculosis is shown in [Figure 23-10](#).

**Clinical manifestations.** Clinical features of reactivated disease include a history of contact with an infected person, low-grade fever, cough, night sweats, fatigue, weight loss, malaise, and anorexia. Chronic cough is the most common symptom.<sup>2,54</sup> As the disease progresses, the patient develops a productive cough with purulent sputum. Physical examination of the lung fields reveals apical crackles (rales) (*M. tuberculosis* organisms prefer lung apices because of the higher concentration of oxygen in the apices) or bronchial breath sounds over the region of lung consolidation. The patient appears malnourished and chronically ill.<sup>2</sup> Common sites of extrapulmonary tuberculosis are

**FIGURE 23-11** Cavitory pulmonary tuberculosis in a 23-year-old man. (From Kersten LD: *Comprehensive respiratory nursing*, Philadelphia, 1989, Saunders, p 146.)

the peritoneum, gastrointestinal tract, liver, spleen, bone, joints, lymph nodes, central nervous system, and genitourinary system.<sup>54</sup> (Refer to Chapter 12 for a discussion of tuberculosis in HIV-infected patients.) Results of pulmonary function tests are characteristic of restrictive diseases, with decreased lung volumes and decreased compliance.

**Diagnosis.** Definitive diagnosis is made by results of sputum culture or by identification of the organism by DNA or RNA amplification techniques.<sup>54</sup> Three consecutive morning sputum specimens are obtained to identify the slow-growing acid-fast bacillus. Expectoration of sputum in the early morning is ideal because the sputum is more concentrated and more plentiful. Cultures require 1 to 3 weeks for determination.<sup>54</sup> Gastric washings or bronchial washings may also be used for diagnostic culturing. Chest radiographs usually show nodules with infiltrates in the lung apex and posterior segments of the upper lobes. Elderly patients may present with lower lobe infiltrates with or without pleural effusion. Figure 23-11 shows the radiographic appearance of cavitory tuberculosis in a 23-year-old man. A miliary pattern (diffuse, small nodular densities) is seen with dissemination of the organism in miliary tuberculosis.<sup>2</sup> Another diagnostic test is the tuberculin

(Mantoux test) skin test (5 tuberculin units/0.1 ml of purified protein derivative [PPD] injected intradermally). This test does not distinguish between current disease and past infection. If the induration in a person with HIV infection is 5 mm or greater, if the patient has close contact with individuals with tuberculosis, and if the patient has a chest radiograph consistent with tuberculosis, the likelihood of active disease is high.<sup>1</sup> An induration of 10 mm or greater is the reaction size for other high-risk individuals, such as intravenous drug abusers, individuals who are debilitated, children younger than 4 years or with immunosuppression, and individuals living in countries with a high incidence of the disease (Asia, Africa, Latin America). An induration of 15 mm or greater is considered positive for tuberculosis in all other persons.<sup>2,54</sup>

False-positive PPD results may occur in persons with other mycobacterial infections or if they have received bacille Calmette-Guérin (BCG), a live attenuated strain of *Mycobacterium bovis* that provides active immunity against tuberculosis. False-negative results may also occur in patients who are malnourished, elderly, or immunocompromised.<sup>2</sup> Immunocompromised patients may not be able to mount a response (wheal) to injection of the organism.

**Treatment.** Primary therapy for active tuberculosis consists of (1) administering multiple drugs to which the organism is susceptible; (2) adding at least two new agents to the drug regimen, when treatment failure is suspected; (3) providing the safest, most effective therapy for the shortest period of time; and (4) ensuring adherence to therapy by utilizing directly observed therapy.<sup>2</sup> Nonadherence to therapy because of adverse drug reactions is a major cause of treatment failure. HIV-negative individuals without MDR-TB are typically treated for 6 to 9 months.

#### KEY POINTS

- Tuberculosis is caused by inhalation or ingestion of the bacterium *Mycobacterium tuberculosis*. The organism spreads through the lymph and blood. Bacteria are ingested by macrophages and walled off by inflammatory proteins (granulomas). The organisms may not be killed and can persist in a dormant state for years. These walled-off areas of inflammatory cells and bacteria become fibrotic and calcified, forming Ghon tubercles—the hallmark of tuberculosis.
- Symptoms are somewhat nonspecific: low-grade fever, cough, night sweats, fatigue, and weight loss. With progression of the disease, the cough is productive of purulent sputum.
- The diagnosis is based on a positive purified protein derivative skin test for tuberculosis, positive sputum cultures, and characteristic nodules on chest radiographs.
- Antibiotics are used for managing tuberculosis. Drug therapy continues for 9 to 12 months for active disease and may be used for shorter periods in persons exposed to tuberculosis but having no active disease.

## SUMMARY

Restrictive pulmonary disorders are those in which lung expansion is restricted. Restrictions are commonly caused by diseases that affect the lung parenchyma (e.g., diffuse interstitial pulmonary fibrosis), chest wall disorders, neuromuscular disorders, pleural space disorders,

pneumonia, and tuberculosis. These diseases are characterized by a reduced vital capacity and a small residual lung volume. They differ from obstructive diseases, covered in Chapter 22, in that airway resistance is not increased.

## KEY QUESTIONS

- What physiologic and pathophysiologic conditions predispose an individual to disturbances in fluid intake?
- How do the compositions of plasma and interstitial fluids differ? How are they similar?
- What regulates water and electrolyte movement between plasma and interstitial fluids? Across cell membranes?
- What are the usual and pathologic routes of fluid exit from the body?
- Under what conditions are extracellular volume deficit and excess likely to occur, and what are the characteristic clinical findings?
- Under what conditions are hyponatremia (water excess) and hypernatremia (water deficit) likely to occur, and what are the characteristic clinical findings?
- What capillary-level mechanisms cause edema?
- What physiologic and pathophysiologic conditions can lead to alterations in electrolyte intake, absorption, distribution, or excretion? How do these differ between specific electrolytes?
- What are the characteristic clinical findings of plasma excesses and deficits of potassium, calcium, magnesium, and phosphate ions?

## CHAPTER OUTLINE

### Body Fluid Homeostasis, 520

- Fluid Intake and Absorption, 520
- Fluid Distribution, 521

The fluid of the body flows in arteries, veins, and lymph vessels; it is secreted into specialized compartments as diverse as joints, cerebral ventricles, and the intestinal lumen; it both surrounds and permeates the cells. Body fluid serves as a lubricant and as a solvent for the chemical reactions that we call *metabolism*; it transports oxygen, nutrients, chemical messengers, and waste products to their destinations; it plays an important role in the regulation of body temperature. Because the fluid within the body is so widespread and serves so many functions, it is not surprising that abnormalities in the volume, concentration, or electrolyte composition of body fluid cause clinical problems.

Disorders of fluid or electrolyte homeostasis occur as a result of many different pathophysiologic conditions. In severe cases, these disorders cause death. Although these disorders develop from many specific causes in different patient populations, these specific causes fall into general categories that arise from the principles of normal fluid and electrolyte homeostasis. This chapter first presents the principles of normal fluid homeostasis and then, building on that foundation, continues with a discussion of fluid imbalances. Similarly, it explains the principles of electrolyte homeostasis before presenting plasma electrolyte imbalances.

## BODY FLUID HOMEOSTASIS

The term **body fluid**, as used in this chapter, pertains to water within the body and the particles dissolved in it. The body fluid is contained in two major compartments: **extracellular** (outside the cells) and **intracellular** (inside the cells). In all age groups except infants, approximately two thirds of body fluid is intracellular.<sup>1</sup> The other one third of body fluid is extracellular. Infants have more extracellular fluid than intracellular fluid; this proportion reverses within a few months as the infant grows. The extracellular fluid lies between the cells (**interstitial** compartment), in the blood vessels (**vascular** compartment), in dense connective tissue and bone, and in several minor compartments that are collectively termed the **transcellular** fluids (e.g., synovial, cerebrospinal, and gastrointestinal fluids). The major body fluid compartments are depicted in Figure 24-1.

The fluids in the various body compartments have different compositions, although their total particle concentration is equal. The intracellular fluid is relatively rich in potassium and magnesium ions,

inorganic and organic phosphates, and proteins. It is relatively low in sodium and chloride ions. In contrast, the extracellular fluid in the vascular and interstitial compartments is relatively rich in sodium, chloride, and bicarbonate ions and relatively low in potassium, magnesium, and phosphate ions. The vascular portion of the extracellular fluid contains many proteins, whereas the interstitial and transcellular portions of the extracellular fluid contain very few proteins. Most transcellular fluids are secreted by epithelial cells; their composition varies according to their function.

Total body water is the total amount of water in all fluid compartments. The percentage of body weight that is water varies according to a person's age and proportion of body fat (Figure 24-2). A full-term newborn infant is about 75% water by weight. (Preterm infants have an even higher percentage of water.) This percentage decreases with age. In a standard adult man, body water is about 60% of body weight. The percentage is less (about 50%) in women because they have a greater proportion of body fat than men of the same weight. In obese adults, with a much larger proportion of body fat, less of the body weight is water. With normal aging there is a relative increase in body fat, so that in older men, 50% of the body weight is typically composed of water; in older women, it is even less.

One liter of water weighs 1 kg (2.2 lb). Thus, a lean, middle-aged, healthy adult man who weighs 70 kg (154 lb) has approximately 42 L of body water. Of this amount, approximately 25 L is intracellular water. The approximately 17 L of extracellular water is distributed as 3 L of plasma water, 8 L of interstitial and lymph water, 5 L of water trapped in dense connective tissue and bone, and 1 L of transcellular water.

Fluid homeostasis is a dynamic process. This process may be viewed as the net result of four subprocesses: *fluid intake*, *fluid absorption*, *fluid distribution*, and *fluid excretion*. In some individuals who have pathophysiologic conditions, loss of fluid through abnormal routes also occurs. The interplay of these subprocesses is fluid homeostasis (Figure 24-3).

## Fluid Intake and Absorption

Fluid intake is entry of fluid into the body by any route. People normally ingest fluids orally, both by drinking and by eating (water contained in food). They also synthesize a small amount of water through cellular metabolism of the foods they eat. Fluid intake by drinking is

**FIGURE 24-1** Factors that influence body fluid distribution. Fluid distribution between the vascular and interstitial compartments is the net result of filtration across permeable capillaries. The distribution of fluid between the interstitial and intracellular compartments occurs by osmosis rather than by filtration.

**FIGURE 24-2** Percentage of total body water by age. The percentage of body weight that is water is high in infancy and decreases with increasing age.

**FIGURE 24-3** Fluid homeostasis. Fluid homeostasis is the interplay of fluid intake and absorption, fluid distribution, fluid excretion, and fluid loss through abnormal routes.

influenced by habit, social factors, and thirst. Physiologic triggers of thirst include increased **osmolality** (concentratedness) of extracellular fluid (osmoreceptor-mediated thirst); decreased circulating blood volume (baroreceptor-mediated and angiotensin II-mediated thirst); and dryness of the mucous membranes of the mouth and possibly other

visceral signals.<sup>2</sup> In older adults, cerebral osmoreceptor-mediated thirst diminishes; thus, older adults who do not have a habit of drinking fluids throughout the day may not have sufficient fluid intake to meet their needs.<sup>3</sup>

Additional routes of fluid intake that may occur in patients who have various pathophysiologic conditions include intravenous intake; intake tubes into the gastrointestinal tract, other body cavities, subcutaneous tissue, or bone marrow; rectal intake (such as tap water enema); and, occasionally, intake through the lungs (such as near-drowning). Health care professionals often control fluid intake by many of these routes.

Unless fluid intake occurs intravenously, the fluid must be absorbed before it reaches the vascular compartment. Fluid absorption from the gastrointestinal tract partially depends on osmotic forces generated by absorption of electrolytes and other particles.

### Fluid Distribution

Much of the fluid that reaches the vascular compartment then distributes into other fluid compartments. *Fluid distribution between the vascular and interstitial compartments is the net result of filtration across permeable capillaries.* At the capillary level, two forces tend to move fluid from the capillaries into the interstitial compartment: capillary hydrostatic pressure (the outward push of vascular fluid against the capillary walls) and interstitial fluid osmotic pressure (the inward-pulling force of particles in the interstitial fluid). Concurrently, two forces tend to move fluid from the interstitial compartment into the capillaries: capillary osmotic pressure (the inward-pulling force of particles in vascular fluid) and interstitial fluid hydrostatic pressure (the outward push of interstitial fluid against the outside of the capillary walls).<sup>1</sup>

The distribution of fluid between the vascular and interstitial compartments is analogous to two groups of people pushing on opposite sides of a swinging door—the strongest “push” will determine in which direction the door will swing. Thus, at any one point along a capillary, the direction and amount of fluid flow between the vascular and

interstitial compartments are determined by the net result of opposing forces. These forces are illustrated in Figure 24-1.

In contrast, *the distribution of fluid between the interstitial and intracellular compartments occurs by osmosis, rather than by filtration.* Cell membranes are semipermeable membranes. This means that they are permeable to water but not to electrolytes, many of which require specialized transport mechanisms to cross a cell membrane. Thus, water can move freely through a cell membrane, but electrolytes and other particles cannot. When there is a difference in particle concentration (osmolality) inside and outside cells because the particles cannot move freely, the *water* crosses the membrane rapidly to equalize the osmolality. Osmosis occurs until the intracellular osmotic pressure and the interstitial fluid osmotic pressure become equal, as in Figure 24-1.

The direction of movement of water by osmosis is determined by the particle concentrations on the two sides of the semipermeable cell membrane. If, on the one hand, the particle concentration (osmolality) of the interstitial fluid becomes higher than the particle concentration inside cells, water will move by osmosis from the cells to the interstitial fluid to equalize the osmolality in the two compartments. If, on the other hand, the osmolality of the interstitial fluid becomes lower than the osmolality of the intracellular fluid, then water will move from the interstitial compartment to the intracellular compartment to equalize the osmolality. In this way, changes in the osmolality of the interstitial and intracellular compartments control the distribution of water between them.<sup>1</sup>

Distribution of fluid between the intracellular and transcellular compartments is controlled by processes within the epithelial cells that secrete these fluids.

## Fluid Excretion

The fourth component of fluid homeostasis is fluid excretion. Fluid excretion normally occurs through the urinary tract, bowels, lungs, and skin. Fluid is excreted through the skin as visible sweat (which may or may not occur) and as insensible perspiration (which always occurs). Another obligatory route of excretion of water is through the lungs as a person exhales. Fecal excretion of fluid occurs with normal bowel function and increases dramatically in a person who has diarrhea. In most circumstances, the largest volume of fluid is excreted in the urine.

The amount of fluid excreted in the urine is controlled primarily by the hormones antidiuretic hormone (ADH), aldosterone, and natriuretic peptides (e.g., A-type natriuretic peptide [ANP]), and to a lesser degree by minor hormones such as renal prostaglandins and by the renal sympathetic nerves. ADH is synthesized by cells in the supraoptic and paraventricular nuclei of the hypothalamus. The axons of these cells extend down the median eminence of the pituitary stalk. The release of ADH thus occurs from the posterior pituitary gland. Factors that increase release of ADH into the blood include increased osmolality (concentratedness) of the extracellular fluid, decreased circulating fluid volume, pain, nausea, and physiologic and psychological stressors. The hormone circulates to the distal tubules and collecting ducts in the kidneys where, consistent with its name, ADH causes reabsorption of water that dilutes the blood and other body fluids. Reabsorption of water decreases the urine volume and makes the urine concentrated, thus decreasing fluid excretion. Factors that decrease ADH release (such as decreased osmolality of the extracellular fluid and ethanol intake) allow a large, dilute urine volume.

Aldosterone is another hormone that influences urine volume. Aldosterone is synthesized and secreted by cells in the adrenal cortex. The major stimuli for its release are angiotensin II (from the renin-angiotensin system, which is activated by decreased circulating blood volume) and an increased concentration of potassium ions in the plasma.<sup>4</sup> Aldosterone causes the renal tubules to reabsorb sodium and water (saline), which expands the extracellular fluid volume. This renal action decreases fluid excretion, although by a different mechanism

than ADH. When more aldosterone is secreted, the urine volume is smaller; decreased secretion of aldosterone causes a larger urine volume.

A comparison of ADH and aldosterone is useful to remember their actions. ADH is the tap water hormone. It causes the kidneys to reabsorb water. Renal reabsorption of water caused by ADH makes a smaller volume of more concentrated urine and dilutes body fluids. Aldosterone is the salt water hormone. It causes the kidneys to reabsorb sodium and water. Renal reabsorption of sodium and water caused by aldosterone makes a smaller volume of urine and expands extracellular fluid volume.

ANP normally is stored in granules in the cardiac atrial cells and released when the atria are stretched. B-type natriuretic peptide (BNP) is synthesized and released from ventricular cells when ventricular diastolic pressure increases abnormally, as in heart failure. ANP and BNP cause natriuresis (sodium excretion in the urine), which is accompanied by water excretion. Thus, these natriuretic peptides (NPs) promote fluid excretion in the urine. When the vascular volume increases, the heart is stretched, and more NPs are released to cause renal excretion of the excess fluid.<sup>5</sup> When the vascular volume is decreased, the heart is less stretched; therefore, fewer NPs are released and the kidneys excrete less fluid. NPs oppose the action of aldosterone, but they are not as strong as aldosterone.

The urine volume that an individual produces also is highly dependent on having adequate blood pressure to perfuse the kidneys and on the glomerular filtration rate. Thus, renal excretion of fluid is the end result of several factors, including hormones that respond to different stimuli and have different actions on the renal tubules.

## Fluid Loss Through Abnormal Routes

People who have pathophysiologic conditions often experience loss of fluid through abnormal routes. Examples of these routes are emesis; tubes in the gastrointestinal tract or other body cavities; hemorrhage; drainage from fistulas, wounds, or open areas of skin; and paracentesis. Fluid lost through abnormal routes may be a significant factor in disturbing fluid homeostasis.

If the body's physiologic mechanisms are functioning well, the processes of fluid homeostasis maintain normal body fluid status. If fluid intake is large, fluid excretion increases by the mechanisms described previously that increase urine volume (large volume of dilute urine). If fluid intake is diminished or if fluid is lost through abnormal routes, fluid excretion decreases (small volume of concentrated urine), and thirst may cause an increase in fluid intake.

If pathophysiologic processes interfere with normal fluid homeostasis or if the normal processes become overwhelmed, then fluid imbalances result. For example, a person who has a pathophysiologic process that prevents the kidneys from excreting much fluid may accumulate too much fluid unless the fluid intake is reduced. The opposite problem will occur in a person whose fluid intake is too small to replace a large amount of fluid excreted or lost through abnormal routes.

### KEY POINTS

- Fluid homeostasis is a dynamic process that includes fluid intake and absorption, fluid distribution across body fluid compartments, fluid excretion, and, in some individuals, fluid loss through abnormal routes.
- Habit and thirst are important regulators of fluid intake. Individuals who are unable to control their own fluid intake (such as those receiving fluids intravenously and immobile or unconscious patients) are at high risk for fluid imbalance.
- Fluid (water and small particles) moves back and forth between the vascular and interstitial areas by filtration at the capillaries. Capillary hydrostatic pressure is the primary force promoting fluid movement from the capillaries to the interstitial fluid. Plasma colloid osmotic pressure is the primary force that causes interstitial fluid to move back into the capillaries.

- Water moves in and out of cells by osmosis. Electrolytes do not move freely across cell membranes but are transported by membrane channels and carriers.
- Fluid excretion may be visible (urine, feces, sweat) or invisible (respiration and insensible perspiration). Fluid loss may occur through abnormal routes such as emesis and wound drainage. To maintain fluid balance, fluid intake must counterbalance fluid excretion and loss through abnormal routes.
- Healthy kidneys adjust fluid excretion in response to blood pressure and several hormones. Aldosterone induces the kidneys to conserve saline (salt and water), which expands the extracellular fluid volume; natriuretic peptides (ANP and BNP) promote saline excretion. ADH causes the kidneys to retain water, thus concentrating the urine and diluting the body fluids. Urine volume and concentration are important indicators of body fluid balance.

## FLUID IMBALANCES

If fluid homeostasis is disturbed by pathophysiologic processes or other factors (such as medications), fluid imbalances may occur. Fluid imbalances fall into two major categories: imbalances of extracellular fluid volume (**saline imbalances**) and imbalances of body fluid concentration (**water imbalances**).

### Extracellular Fluid Volume

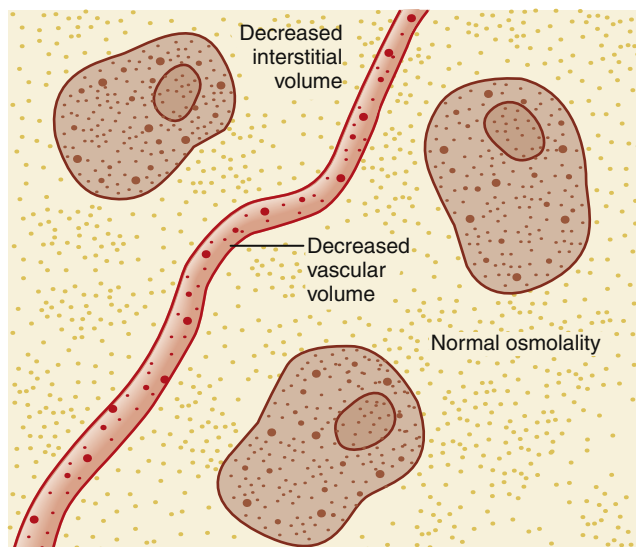

In some circumstances, individuals have too much or too little extracellular fluid. These disorders are called **extracellular fluid volume (ECV) imbalances** because they involve a change in the *amount* (volume) of the extracellular fluid. These disorders also are termed *saline imbalances* because they are disorders of **isotonic** salt water. (Isotonic saline is salt water in the same concentration as the normal plasma concentration.) In an ECV imbalance, the *concentration* of the extracellular fluid may be normal; there is simply too much or too little of it. Some individuals have an ECV imbalance and an imbalance of body fluid concentration at the same time. In this case, both the volume and serum sodium concentration of the extracellular fluid are abnormal. This section discusses only the isotonic volume imbalances; the concentration imbalances are discussed separately because they may occur separately.

### Volume Deficit

ECV deficit is caused by removal of a sodium-containing fluid from the body. It is a decrease in saline (isotonic salt water) in the same concentration as the normal extracellular fluid, which is why the condition sometimes is termed **saline deficit**. In an uncomplicated ECV deficit, the serum sodium concentration is normal. The *concentration* of the extracellular fluid is normal; the *amount* of the extracellular fluid is abnormally decreased (Figure 24-4).

**Etiology.** Specific causes of ECV deficit are listed in Box 24-1. All causes of ECV deficit involve removal of a sodium-containing fluid from the extracellular compartment. The sodium-containing fluid usually is removed from the body; however, it may be sequestered in a “third space” in the body that is outside the extracellular compartment. For example, ascites (fluid in the peritoneal cavity) that develops rapidly may deplete the ECV. Another example is fluid that accumulates rapidly in the bowel during an acute intestinal obstruction. Although the fluid in these examples remains in the body, it no longer is part of the extracellular fluid, and signs and symptoms of ECV deficit occur.

**Clinical manifestations.** Signs and symptoms of ECV deficit are the result of decreased fluid volume in the vascular and interstitial areas. These clinical manifestations include sudden weight loss, postural blood pressure decrease with concurrent increased heart rate, flat neck veins (or veins collapsing with inspiration) when a patient is supine, prolonged small-vein filling time, prolonged capillary refill time, lightheadedness, dizziness, syncope, and oliguria. If the kidneys are responding

**FIGURE 24-4** Extracellular fluid volume deficit. Decreased volume of extracellular fluid in vascular and interstitial compartments is characteristic of extracellular fluid volume deficit.

## BOX 24-1 CAUSES OF EXTRACELLULAR FLUID VOLUME DEFICIT

### Gastrointestinal Excretion or Loss of Sodium-Containing Fluid

Emesis  
Diarrhea (includes laxative abuse)  
Gastric suction or intestinal decompression  
Fistula drainage

### Renal Excretion of Sodium-Containing Fluid

Adrenal insufficiency  
Salt-wasting renal disorders  
Extensive diuretic use  
Bed rest

### Other Loss of a Sodium-Containing Fluid

Hemorrhage  
Massive diaphoresis  
Third-space fluid accumulation  
Paracentesis and similar procedures  
Burns

normally, the small volume of urine will be concentrated (and thus quite yellow). An ECV deficit that develops slowly also may be manifested by decreased skin turgor (skin tenting when it is pinched up over the sternum), dryness of oral mucous membranes between cheek and gum, hard stools, soft sunken eyeballs, longitudinal furrows in the tongue, and absence of tears and sweat. An infant who develops ECV deficit has a sunken fontanel; neck veins are not reliably assessed in infants.

Sudden weight loss is a sensitive measure of ECV deficit. One liter of saline weighs 1 kg; therefore, a person who loses 1 kg in 24 hours has excreted 1 L of fluid or lost it through an abnormal route. It is not possible to lose a kilogram of fat overnight; a sudden weight loss of this magnitude results only from fluid loss, if the body weight is measured accurately. An ECV deficit may occur without a weight loss if fluid is sequestered in a third space somewhere in the body, as with ascites or intestinal obstruction.

**FIGURE 24-5** Extracellular fluid volume excess. Increased volume of extracellular fluid in vascular and interstitial compartments is characteristic of extracellular fluid volume excess.

### BOX 24-2 CAUSES OF EXTRACELLULAR FLUID VOLUME EXCESS

#### Excessive Intravenous Infusion of Sodium-Containing Isotonic Solutions

Normal saline (0.9% sodium chloride)  
Ringer injection  
Lactated Ringer injection

#### Renal Retention of Sodium and Water

Primary hyperaldosteronism  
Chronic heart failure  
Cirrhosis  
Acute glomerulonephritis  
Chronic end-stage renal disease  
Cushing disease  
Corticosteroid therapy

A postural blood pressure decrease with concurrent increased heart rate that is measured when a previously supine person stands, or sits with legs dependent, is a good indicator of fluid volume depletion in the vascular compartment. Severe ECV deficit may lead to hypovolemic shock, which can be fatal if not treated effectively with fluid replacement.

#### Volume Excess

ECV excess is essentially the opposite of an ECV deficit. It is the condition in which the amount of extracellular fluid is abnormally increased. Both the vascular and the interstitial areas have too much isotonic fluid (Figure 24-5). In an uncomplicated ECV excess, the *concentration* of the extracellular fluid is normal, but an excessive *amount* of that fluid is present.

**Etiology.** ECV excess is caused by addition or retention of saline (salt water in the same concentration as normal plasma). For this reason, it sometimes is termed **saline excess**. As mentioned previously, the hormone aldosterone causes the kidneys to retain saline. ECV excess, therefore, may be caused by conditions that involve excessive aldosterone secretion. For example, increased aldosterone secretion is a compensatory mechanism that commonly accompanies chronic heart failure and eventually leads to ECV excess.<sup>6</sup> Additional causes of ECV excess are presented in Box 24-2.

**Clinical manifestations.** Signs and symptoms of ECV excess are sudden weight gain, edema, and manifestations of circulatory overload: bounding pulse, neck vein distention in a person in the upright position, crackles in the dependent portions of the lungs, dyspnea, orthopnea, and even the frothy sputum of pulmonary edema. An infant who develops ECV excess has a bulging fontanel; assessment of neck veins is not effective in infants.

Sudden weight gain is a sensitive measure of ECV excess. It is impossible to gain a kilogram of fat overnight; such a sudden weight gain is an accumulation of saline. People who eat salty food in a restaurant weigh more the next day because the water they drank combined with the salt in the food to make isotonic saline. The isotonic saline expands the extracellular fluid, causing a mild saline excess until it is excreted by the kidneys. This is the reason that low-sodium diets are prescribed for people who have pathophysiologic processes that cause saline excess (e.g., compensated heart failure).

#### Body Fluid Concentration

In contrast to the ECV disorders just discussed, imbalances of body fluid concentration are disorders of the *concentration* rather than of the *amount* of extracellular fluid. Body fluid concentration disorders also are called **water imbalances**. The serum sodium concentration reflects the osmolality (concentratedness) of the blood. Imbalances of body fluid concentration are recognized by abnormal serum sodium concentration. The normal serum sodium concentration is 135 to 145 mEq/L (may vary slightly with different laboratories). Many individuals develop imbalances of both ECV and serum sodium concentration at the same time. Isolated imbalances of serum sodium concentration may also occur. This section discusses the concentration imbalances separately.

#### Hyponatremia

*Natrium* is the Latin word for sodium. A serum sodium concentration below the lower limit of normal indicates hyponatremia. When hyponatremia is present, the extracellular fluid contains relatively too much water for the amount of sodium ions present; it is more dilute than normal.

**Etiology.** Hyponatremia is caused by factors that produce a relative excess of water in proportion to salt in the extracellular fluid. Because the serum sodium concentration reflects the osmolality of the blood, the reduced serum sodium concentration of hyponatremia

**BOX 24-3 CAUSES OF HYPONATREMIA****Gain of Relatively More Water Than Salt**

Excessive antidiuretic hormone  
 Excessive intravenous infusion of 5% dextrose in water (D<sub>5</sub>W)  
 Hypotonic irrigating solutions  
 Tap water enemas  
 Psychogenic polydipsia (compulsive water drinking)  
 Forced excessive water ingestion (child abuse or club initiation)  
 Excessive beer ingestion (beer potomania)  
 Near-drowning in fresh water  
 Selective serotonin reuptake inhibitors (SSRIs)

**Loss of Relatively More Salt Than Water**

Diuretics, especially thiazides  
 Salt-wasting renal disease  
 Replacement of water but not salt lost through emesis, diarrhea, gastric suction, diaphoresis, or burns

indicates that the extracellular fluid has a reduced osmolality; it is too dilute. Hyponatremia also is called *hypotonic syndrome*, *hypoosmolality*, and *water intoxication*. All of these terms reflect the abnormally dilute concentration of the extracellular fluid that results when the normal proportion of salt to water in the extracellular fluid is disrupted by gaining more water than salt or losing relatively more salt than water.

A *gain of relatively more water than salt* will cause hyponatremia. As mentioned previously, the hormone ADH causes the kidneys to retain water (not sodium and water) in the body. This hormone is part of the system that normally regulates the osmolality of extracellular fluid. However, circumstances that cause prolonged or excessive release of ADH cause the kidneys to retain too much water, which effectively dilutes the blood; hyponatremia is the result. ADH secretion is excessive in the syndrome of inappropriate secretion of ADH (SIADH). ADH also may be produced **ectopically**. For example, small cell (oat cell) carcinoma is a type of lung tumor that frequently synthesizes and releases ADH. This ectopic production of ADH from a tumor is not subject to the feedback inhibition of normal ADH release, so inappropriate amounts of ADH are released. With continually high levels of ADH being produced by the tumor, the kidneys retain excessive amounts of water—a gain of water relative to salt. Pain, nausea, and other physical and psychological stressors also increase ADH release, which can be significant in hospitalized patients, especially in the postoperative period. Recent research links the proinflammatory cytokine interleukin-6 (IL-6) to increased ADH release during inflammatory conditions.<sup>7</sup> Although it is difficult to drink enough water to cause hyponatremia, water intake that exceeds renal excretory capacity is seen in some situations. For example, the hyponatremia of beer potomania arises when people habitually drink 14 or more cans of beer daily with very little food intake.<sup>8</sup> Factors that cause hyponatremia by gain of water relative to salt are presented in Box 24-3.

Hyponatremia also may be caused by a *loss of relatively more salt than water*. If salt is removed from the body while water remains, then the extracellular fluid once again will become too dilute; hyponatremia results. Factors that cause hyponatremia by loss of salt relative to water also are presented in Box 24-3. Although Box 24-3 separates causes of hyponatremia into two categories, some types of hyponatremia are due to simultaneous gain of water and loss of salt. For example, hyponatremia in marathon runners occurs from loss of salt through heavy sweating and gain of water from excessive water intake plus inappropriate renal water reabsorption caused by increased ADH secretion.<sup>9</sup>

**FIGURE 24-6** Cell swelling in hyponatremia. Decreased osmolality (concentration) of extracellular fluid in hyponatremia causes water to move into cells by osmosis.

**Clinical manifestations.** Clinical manifestations of hyponatremia are nonspecific manifestations of central nervous system dysfunction.<sup>10</sup> They vary from malaise, anorexia, nausea, vomiting, and headache to confusion, lethargy, seizures, and coma. Profound hyponatremia causes fatal cerebral herniation. The signs and symptoms are caused by swelling of neurons and glial cells as a result of the decreased osmolality of extracellular fluid. When the extracellular fluid becomes too dilute, the intracellular fluid initially is more concentrated. Therefore, water moves into cells by osmosis (Figure 24-6). The severity of the signs and symptoms depends on how rapidly hyponatremia develops as well as on the absolute value of the serum sodium concentration. A rapid decrease in osmolality produces more severe manifestations than a slow decline, other factors being equal.

**Hypernatremia**

Hypernatremia is a serum sodium concentration above the upper limit of normal (145 mEq/L). When hypernatremia is present, the extracellular fluid contains relatively too little water for the amount of sodium ions present; it is too concentrated. Hypernatremia also is called *water deficit*, *hypertonic syndrome*, and *hyperosmolality*. These terms all reflect the relative deficit of water to salt in the extracellular fluid that occurs in hypernatremia.

**Etiology.** Hypernatremia is caused by a *gain of relatively more salt than water* or by a *loss of relatively more water than salt*. Both of these processes cause the body fluids to become too concentrated. Patients who receive concentrated tube feedings without enough water, especially older adults, are at high risk for hypernatremia because they gain relatively more solute than water, which causes an obligatory loss of relatively more water than salt in the urine. Hypernatremia can be prevented in these individuals by administering water between feedings. Other specific factors that cause hypernatremia are presented in Box 24-4 under the two major categories.

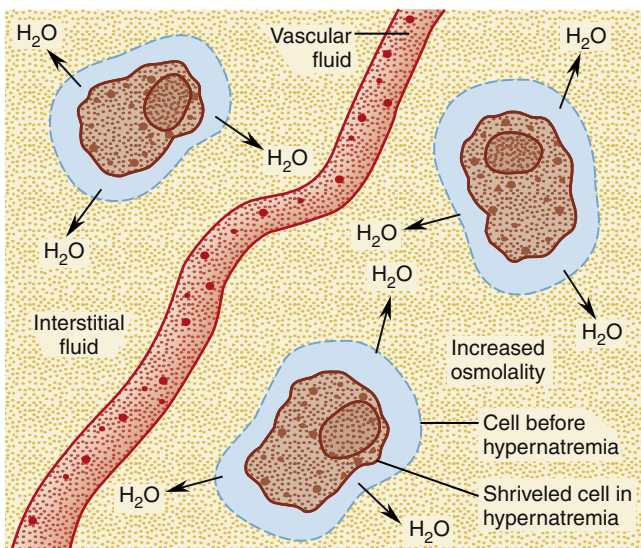

**Clinical manifestations.** Signs and symptoms of hypernatremia are similar to those of hyponatremia in that they are nonspecific manifestations of central nervous system dysfunction.<sup>10</sup> In hypernatremia, the increased osmolality of the extracellular fluid causes neurons and glial cells to shrivel because water moves from the cells to the interstitial fluid by osmosis (Figure 24-7). The dysfunction ranges from confusion and lethargy to seizures and coma. Thirst and oliguria (except for hypernatremia of renal origin) are common. Severe hypernatremia may cause death.

**BOX 24-4 CAUSES OF HYPERNATREMIA****Gain of Relatively More Salt Than Water**

Tube feeding  
 Intravenous infusion of hypertonic solution  
 Near-drowning in salt water  
 Overuse of salt tablets  
 Food intake with reduced fluid intake  
 Difficulty swallowing fluids  
 No access to water  
 Inability to respond to thirst

**Loss of Relatively More Water Than Salt**

Diabetes insipidus (deficient antidiuretic hormone)  
 Tube feeding (causes obligate water loss in urine)  
 Osmotic diuresis  
 Prolonged emesis, diarrhea, or diaphoresis without water replacement

**FIGURE 24-7** Cell shriveling in hypernatremia. Increased osmolality (concentration) of extracellular fluid in hypernatremia causes water to move from cells by osmosis.

**Both Volume and Concentration****Clinical Dehydration**

Clinical dehydration is a combination of two fluid disorders: ECV deficit and hypernatremia. A person who has clinical dehydration has too small a volume of fluid in the extracellular compartment (vascular and interstitial), and the body fluids are too concentrated (Figure 24-8).

**Etiology.** Clinical dehydration occurs commonly in individuals who have vomiting and diarrhea and do not know how (or are unable) to replace the salt and the water that is exiting the body. Fluid excreted in diarrhea and lost by vomiting, plus the normal daily respiratory, skin, and urine excretion, is the equivalent of hypotonic sodium-containing fluid (isotonic saline with extra water added). Removal of the saline portion of this fluid from the body causes ECV deficit, and removal of the extra water from the body causes hypernatremia. The combination of these two imbalances is clinical dehydration.

**Clinical manifestations.** Signs and symptoms of clinical dehydration are the combination of the signs and symptoms of the two separate disorders. Therefore, a person who is clinically dehydrated will have clinical manifestations as listed in Box 24-5. Infants and older adults are at highest risk for clinical dehydration, although it can occur at any age.

**FIGURE 24-8** Clinical dehydration. Decreased volume of extracellular fluid in vascular and interstitial compartments plus cell shriveling from increased osmolality of extracellular fluid are combined in clinical dehydration.

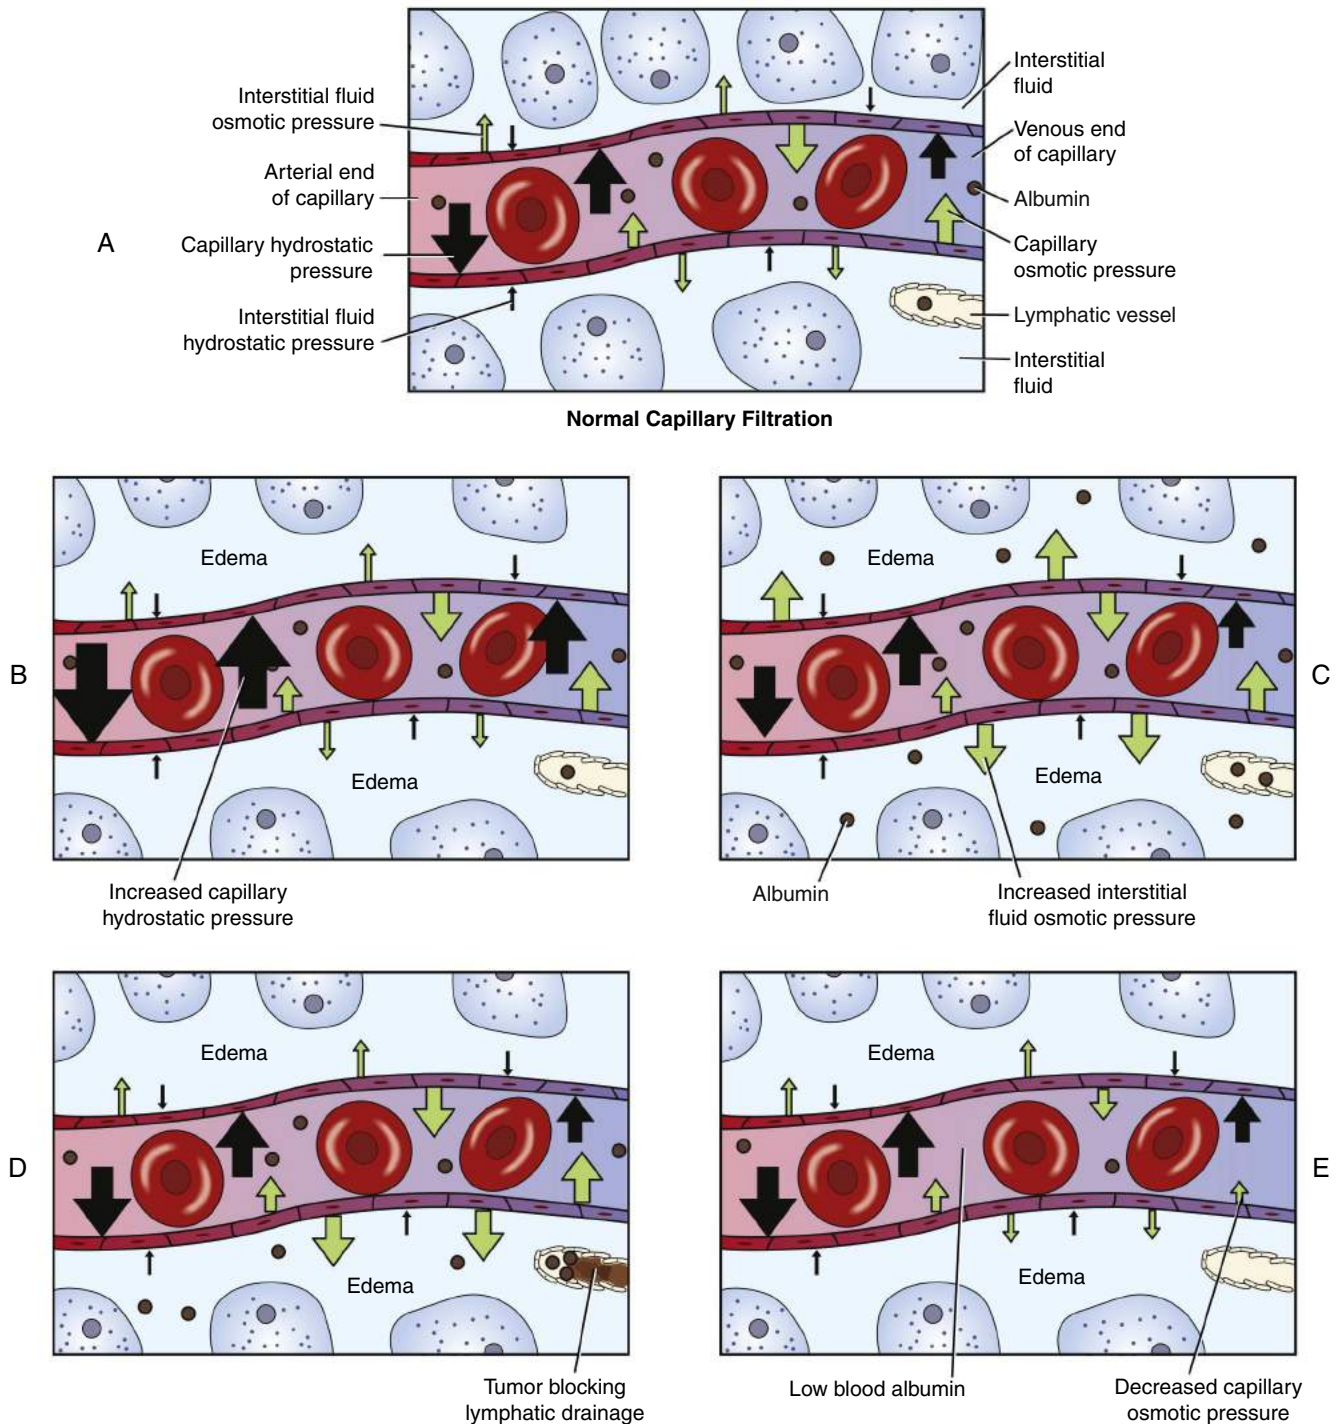

**BOX 24-5 SIGNS AND SYMPTOMS OF CLINICAL DEHYDRATION**

Sudden weight loss  
 Postural blood pressure decrease with concurrent increased heart rate  
 Lightheadedness, dizziness, or syncope upon standing  
 Flat neck veins when supine or neck veins that collapse during inspiration (older children and adults)  
 Sunken fontanel (infants)  
 Rapid, thready pulse  
 Prolonged small-vein filling time  
 Prolonged capillary refill time  
 Oliguria  
 Decreased skin turgor  
 Dryness of oral mucous membranes  
 Absence of sweat and tears  
 Hard stools  
 Soft, sunken eyeballs  
 Longitudinal furrows in the tongue  
 Thirst  
 Increased serum sodium concentration  
 Confusion, lethargy  
 Coma  
 Hypovolemic shock

**Interstitial Fluid Volume****Edema**

Edema is an excess of fluid in the interstitial compartment. It may be a manifestation of ECV excess or it may arise from other mechanisms. Forces that determine the distribution of fluid between the vascular and interstitial compartments are described previously in this chapter (see the Fluid Distribution section). An increase in the forces that tend to move fluid from the capillaries into the interstitial compartment or a decrease in forces that tend to move fluid from the interstitial compartment into the capillaries will cause edema by altering normal fluid distribution between the vascular and interstitial compartments.

**FIGURE 24-9** Causes of edema. **A**, Normal capillary filtration without edema. **B**, Edema caused by increased capillary hydrostatic pressure. **C**, Edema caused by increased interstitial fluid osmotic pressure from increased capillary permeability. **D**, Edema caused by blocked lymphatic drainage. **E**, Edema caused by decreased capillary osmotic pressure from hypoalbuminemia.

Thus, edema may arise from increased capillary hydrostatic pressure, increased interstitial fluid osmotic pressure, blockage of lymphatic drainage, or decreased capillary osmotic pressure (Figure 24-9). Edema may be localized or generalized (existing in many areas of the body simultaneously).

*Increased capillary hydrostatic pressure* is caused by increased ECV, by the increased local capillary flow that accompanies inflammation, and by venous congestion. *Increased interstitial fluid osmotic pressure*

occurs when inflammation increases vascular permeability and proteins leak into the interstitial fluid. Lymphatic drainage normally removes minute amounts of protein that enter the interstitial fluid. *Blockage of lymphatic drainage* (e.g., by a tumor, parasites, fibrosis from radiation therapy, or surgical removal of lymph nodes) also causes edema when the interstitial accumulation of protein increases interstitial fluid osmotic pressure.<sup>11</sup> This type of edema is called lymphedema and may be persistent.<sup>12</sup> Edema caused by increased interstitial

fluid osmotic pressure or blockage of lymphatic drainage frequently is localized. *Decreased capillary osmotic pressure* occurs when the concentration of plasma proteins is decreased, as in malnutrition or liver disease (decreased protein synthesis). Edema from this cause usually is generalized.

In summary, edema represents increased interstitial fluid volume, a condition that may be local or generalized. Edema may be a sign of ECV excess (which causes increased capillary hydrostatic pressure), or it may be caused by other factors that alter the distribution of fluid between the vascular and interstitial compartments.

#### KEY POINTS

- ECV deficit (saline deficit) occurs when sodium-containing fluids are lost from the body (e.g., emesis). It is an abnormally reduced volume of the vascular and interstitial fluids. ECV deficit is characterized by normal serum sodium concentration and manifestations of volume deficit (weight loss, poor skin turgor, postural hypotension, oliguria).
- ECV excess (saline excess) commonly is due to processes that cause the kidneys to retain sodium and water. It is an abnormally increased volume of the vascular and interstitial fluids. ECV excess is characterized by a normal serum sodium concentration and manifestations of volume excess (weight gain, peripheral edema, distended neck veins, dyspnea).
- Hyponatremia is associated with excessive ADH secretion or hypotonic fluid intake. It is characterized by a low serum sodium concentration, which indicates that body fluids are abnormally dilute. Clinical manifestations (confusion, lethargy, seizure, coma) occur because of cell swelling.
- Hypernatremia is associated with inadequate water intake or excessive water excretion or loss. It is characterized by a high serum sodium level, which indicates that body fluids are too concentrated. Clinical manifestations (confusion, lethargy, seizure, coma) occur because of cell shriveling.
- Clinical dehydration occurs commonly in individuals who have gastroenteritis or other conditions that remove hypotonic sodium-containing fluids from the body. It is the combination of ECV deficit and hypernatremia. The clinical manifestations are those of both fluid disorders.
- Edema occurs when there is too much fluid in the interstitial compartment. It may be localized or generalized. The causes of edema at the capillary level are increased capillary hydrostatic pressure, increased interstitial fluid osmotic pressure, blockage of lymphatic drainage, and decreased capillary osmotic pressure.

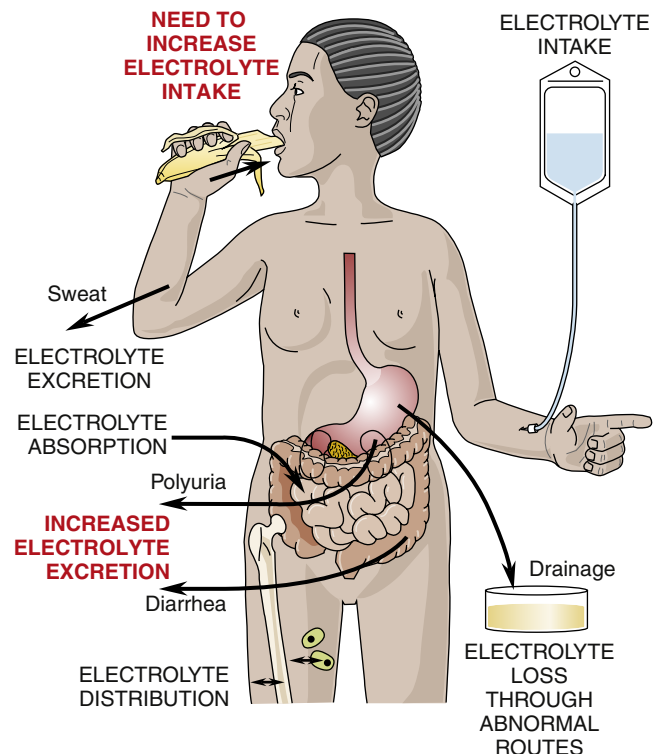

## PRINCIPLES OF ELECTROLYTE HOMEOSTASIS

**Electrolytes** are ionized salts dissolved in water. The most clinically important electrolytes are the ions sodium, potassium, calcium, magnesium, chloride, bicarbonate, and phosphate. Although sodium ions are electrolytes, serum sodium imbalances are osmolality (concentration) imbalances, as explained previously in this chapter. This section discusses homeostasis and imbalances of potassium, calcium, magnesium, and phosphate ions. Bicarbonate is discussed in Chapter 25 because it is important in acid-base balance and imbalances.

The concentration of an electrolyte in the plasma is different from its concentration inside cells. For normal body function, the electrolyte concentration must be normal in both areas. In clinical situations, the plasma (or serum) concentration of an electrolyte is measured. Normal serum electrolyte concentrations are listed in Table 24-1. The concentration of an electrolyte in the plasma is the net result of four processes: *electrolyte intake*, *electrolyte absorption*, *electrolyte distribution*, and *electrolyte excretion*. These processes work together in a dynamic fashion to maintain electrolyte concentrations within their

**TABLE 24-1** NORMAL SERUM ELECTROLYTE CONCENTRATIONS

ELECTROLYTE	NORMAL CONCENTRATION RANGE
Calcium (total)	9-11 mg/dl (4.5-5.5 mEq/L)
Magnesium	1.5-2.5 mEq/L
Phosphate	2.5-4.5 mg/dl (adults and older children) 4.5-6.5 mg/dl (children) 4.3-9.3 mg/dl (neonates)
Potassium	3.5-5.0 mEq/L 3.9-5.9 mEq/L (neonates)
Sodium	135-145 mEq/L 135-162 mEq/L (neonates)

**FIGURE 24-10** Electrolyte homeostasis. Electrolyte homeostasis is the interplay of electrolyte intake and absorption, electrolyte distribution, electrolyte excretion, and electrolyte loss through abnormal routes. If electrolyte excretion or loss through abnormal routes increases, electrolyte intake also must increase to prevent electrolyte imbalance.

normal limits (Figure 24-10). Thus, if intake of a specific electrolyte increases, excretion of that electrolyte also may increase and normalize the plasma levels. Similarly, if electrolyte intake decreases dramatically, electrolytes may be redistributed into the plasma to maintain the normal plasma concentration.

### Electrolyte Intake and Absorption

Electrolyte intake normally occurs orally, through food and drink. It is important to remember that oral medications (e.g., magnesium antacids) also may be an important source of electrolyte intake. Intravenous fluids and nutritional solutions are common sources of parenteral intake of electrolytes. Blood transfusions may provide significant

amounts of electrolytes. Less common, but important if it occurs, is intramuscular injection of the electrolyte magnesium.

Some patients have electrolyte intake through tubes into body cavities. The most obvious examples are nasogastric and gastrointestinal feeding tubes, but more unusual situations may cause significant electrolyte intake in specific individuals (e.g., irrigation of the renal pelvis with magnesium-rich solutions). Rarely, electrolyte intake may occur through such unusual routes as the lungs (e.g., near-drowning in salt water, which is rich in magnesium) or the skin (e.g., through application of ointments to large areas of broken or burned skin). Electrolyte intake is controlled by the individual and by health care providers.

If electrolyte intake occurs orally, the electrolyte must be absorbed before it is physiologically useful. Absorption of some electrolytes, such as potassium ions, depends on concentration gradients. Absorption of other electrolytes, such as calcium, depends on the availability of binding proteins, which is influenced by the activity of vitamin D.<sup>1</sup> The contents of the gastrointestinal tract may influence electrolyte absorption. Many agents bind electrolytes and prevent them from being absorbed. For example, undigested fat in the intestines binds calcium and magnesium ions contained in food and prevents them from being absorbed. The pH of intestinal contents also influences the absorption of certain electrolytes, especially calcium ions. Medications often alter electrolyte absorption. Surgical removal of portions of the gastrointestinal tract can decrease electrolyte absorption.

### Electrolyte Distribution

Every fluid compartment contains electrolytes. However, the electrolyte composition differs in these various compartments. The concentrations of potassium, magnesium, and phosphate ions are higher inside cells than in the fluid outside the cells. Although calcium ion concentration is higher inside cells, much of the intracellular calcium is bound to other molecules; the concentration of physiologically active ionized calcium ions is higher in the extracellular fluid. The bones serve as an important reservoir of calcium, magnesium, and phosphate ions. The cells and the bones are often called the *electrolyte pools*.

Distribution of electrolytes between the extracellular fluid and the electrolyte pools is influenced primarily by hormones such as epinephrine (potassium ions), insulin (potassium and phosphate ions), and parathyroid hormone (calcium ions). Certain medications also influence electrolyte distribution. Significant movement of electrolytes between the cells and the extracellular fluid may occur within minutes.<sup>1</sup> In the absence of changes in electrolyte intake and excretion, a shift of electrolytes from the extracellular fluid into the electrolyte pools will decrease the plasma electrolyte concentration. Conversely, a shift of electrolyte from an electrolyte pool into the extracellular fluid will increase the plasma electrolyte concentration.

### Electrolyte Excretion

Electrolyte excretion occurs through urine, feces, and sweat. Urinary excretion of some electrolytes is influenced by hormones (e.g., aldosterone increases potassium ion excretion), although factors such as the flow rate of renal tubular fluid are also influential. Many different medications alter the rate of urinary excretion of electrolytes.<sup>13</sup> For example, commonly used drugs that increase urinary excretion of potassium include corticosteroids, such as prednisone, and potassium-wasting diuretics, such as furosemide and hydrochlorothiazide. Drugs that increase urinary magnesium excretion include diuretics and aminoglycoside antibiotics, such as gentamicin. Conversely, thiazide diuretics, such as hydrochlorothiazide, decrease urinary excretion of calcium.

Fecal excretion of electrolytes is influenced by the type of feces produced. Diarrhea increases the excretion of potassium and magnesium

ions in particular. The composition of the feces also influences the amount of electrolyte excretion. Undigested fat in the intestines binds calcium and magnesium ions that are secreted into the gastrointestinal tract and prevents them from being reabsorbed. Thus, these electrolytes are excreted in the feces.

### Electrolyte Loss Through Abnormal Routes

When electrolytes exit the body through routes other than the normal urine, feces, and sweat, this may be termed *electrolyte loss through abnormal routes*. This factor alters electrolyte homeostasis in patients who have diverse pathophysiologic conditions. Examples of electrolyte loss through abnormal routes are emesis, nasogastric suction, paracentesis, hemodialysis, wound drainage, and fistula drainage. Loss of electrolytes through abnormal routes may be uncontrollable or may result from therapeutic procedures.

Electrolyte homeostasis is a dynamic interplay between the processes of electrolyte intake, electrolyte absorption, electrolyte distribution, and electrolyte excretion. In some people, electrolyte loss through abnormal routes becomes an important factor that requires adjustment of electrolyte intake and/or electrolyte excretion to prevent development of electrolyte imbalances. Individuals who have acute or chronic illnesses have many factors that tend to cause electrolyte imbalances by disrupting or interfering with electrolyte intake, absorption, distribution, or excretion. As a result, they may develop single or multiple electrolyte imbalances.

#### KEY POINTS

- The electrolyte composition of the body is maintained by a careful balance of electrolyte intake, absorption, distribution, and excretion. Electrolyte imbalances result from disruption of one or more of these processes or from electrolyte loss through abnormal routes.
- The plasma concentration of an electrolyte may not reflect the intracellular concentration. Cells contain higher concentrations of potassium, calcium, magnesium, and phosphate ions, whereas the extracellular fluid contains higher concentrations of sodium, chloride, and bicarbonate ions.

## ELECTROLYTE IMBALANCES

Electrolyte imbalances are widespread in many pathophysiologic conditions. An electrolyte imbalance may be a total body imbalance or it may be an imbalance in the distribution of electrolytes within compartments, with the total body amount remaining normal. Based on the principles of electrolyte homeostasis explained in the previous section of this chapter, an excess of electrolytes in the extracellular fluid may be caused by increased electrolyte intake or absorption, shift of electrolytes from an electrolyte pool into the extracellular fluid, and decreased electrolyte excretion, either singly or in combination. Conversely, a deficit of electrolytes in the extracellular fluid may be caused by decreased electrolyte intake or absorption, shift of electrolytes from the extracellular fluid to an electrolyte pool, increased electrolyte excretion, loss of electrolytes through abnormal routes, or some combination of these factors.

### Plasma Potassium

The normal concentration of potassium ions in serum is 3.5 to 5.0 mEq/L (may vary slightly with different laboratories), except in neonates, in whom it may be higher. Most of the potassium ions in the body are inside cells; the standard serum potassium measurement gives only the concentration of the small portion of potassium ions in the extracellular fluid. Because a number of factors cause potassium

ions to move into or out of body cells, concentration of potassium in the plasma and total body potassium content are not necessarily correlated. Whether or not they are accompanied by total body potassium imbalances, plasma potassium imbalances may cause clinically significant signs and symptoms.

### Hypokalemia

Hypokalemia denotes a decreased potassium ion concentration in the extracellular fluid. A decrease in the plasma potassium concentration does not necessarily denote a decrease in total body potassium. Thus, hypokalemia may coexist with a total body potassium deficit, a total body potassium excess, or a normal total body potassium ion concentration.

**Etiology.** Hypokalemia is caused by factors that decrease potassium intake, shift potassium from the extracellular fluid into the cells, increase potassium excretion through the normal routes, and cause potassium loss from the body by some abnormal route. Potassium-wasting diuretics and corticosteroids such as prednisone are well-known causes of hypokalemia from increased renal potassium excretion. The hormone aldosterone increases potassium excretion in urine; hypokalemia is associated with pathophysiologic conditions such as compensated heart failure and cirrhosis that are accompanied by increased aldosterone levels. Black licorice contains a substance that increases renal potassium excretion. Many traditional Chinese medicines and other herbal preparations contain black licorice, and excessive ingestion of these agents or black licorice candy leads to hypokalemia.<sup>14</sup> In many cases, several factors lead to hypokalemia. For example, some people follow a fad diet (decreased potassium intake) and abuse diuretics (increased potassium excretion) in an attempt to lose weight. Specific causes of hypokalemia are listed in Box 24-6.

**Clinical manifestations.** The resting membrane potential of muscle cells is determined by the ratio of intracellular to extracellular potassium ion concentration. For this reason, potassium imbalances cause altered function of muscles (skeletal, smooth, and cardiac). In hypokalemia, both smooth and skeletal muscle cells are hyperpolarized (more electrical charge than usual across the cell membrane). Therefore, these muscles are less reactive to stimuli. The resulting clinical manifestations include abdominal distention, diminished bowel sounds, paralytic ileus, postural hypotension, skeletal muscle weakness, and flaccid paralysis. The skeletal muscle weakness of hypokalemia is bilateral weakness that typically begins in the lower extremities and ascends. It may involve the respiratory muscles, causing respiratory paralysis more commonly than does hyperkalemia.

Many types of cardiac dysrhythmias arise from hypokalemia. Cardiac muscle cells usually become hyperpolarized with hypokalemia. However, with very low plasma potassium concentrations, hypopolarization of cardiac muscle occurs, most likely because of decreased potassium conductance. Hypokalemia also increases the rate of diastolic depolarization, which may give rise to ectopic beats, decreases conduction velocity in the atrioventricular node, prolongs cardiac action potentials by decreasing the rate of repolarization, shortens the absolute refractory period, and prolongs the relative refractory period.<sup>15</sup> Cardiac dysrhythmias in severe hypokalemia may cause sudden cardiac death.<sup>16</sup>

Hypokalemia also may cause polyuria by interfering with the action of ADH at the renal tubules. The plasma potassium concentration at which the various clinical manifestations of hypokalemia appear depends on individual responsiveness and the presence of other concurrent electrolyte and acid-base disorders. Chronic hypokalemia can cause rhabdomyolysis (skeletal muscle breakdown), selective myocardial cell necrosis, and nephropathy.<sup>17</sup>

## BOX 24-6 CAUSES OF HYPOKALEMIA

### Decreased Potassium Intake

- Anorexia
- NPO (nothing by mouth) orders and intravenous solutions without potassium
- Fasting
- Unbalanced diet

### Shift of Potassium from Extracellular Fluid to Cells

- Alkalosis
- Excess insulin (e.g., during total parenteral nutrition)
- Excess  $\beta$ -adrenergic stimulation
- Hypokalemic familial periodic paralysis

### Increased Potassium Excretion Through Normal Routes

#### Renal Route

- Potassium-wasting diuretics
- Corticosteroid therapy
- Cushing disease
- Hyperaldosteronism
- Excessive ingestion of black licorice (glycyrrhizin)
- Hypomagnesemia
- Parenteral ticarcillin or similar agents
- Amphotericin B, cisplatin, cyclosporine, and many other drugs

#### Fecal Route

- Diarrhea (includes laxative abuse)

#### Skin Route

- Excessive diaphoresis

### Loss of Potassium Through Abnormal Routes

- Emesis
- Gastric suction
- Fistula drainage

### Hyperkalemia

If the serum potassium concentration rises above 5.0 mEq/L (the upper limit of normal), hyperkalemia is present. Hyperkalemia denotes an elevation of potassium ion concentration in the extracellular fluid. As mentioned previously, most of the potassium ions in the body are inside cells, and many factors cause potassium ions to move into or out of the cells. Thus, total body potassium content may be increased, normal, or decreased in hyperkalemia, depending on its cause.

**Etiology.** Hyperkalemia is caused by factors that increase potassium intake, shift potassium from the cells into the extracellular fluid, and decrease potassium excretion. For example, massive blood transfusion can cause hyperkalemia by increased potassium intake because the transfused fluid surrounding the red blood cells (RBCs) is high in potassium that was released from the RBCs during storage.<sup>18</sup> Large numbers of potassium ions shifting from cells into the extracellular fluid after a crushing injury or massive cell death from cytotoxic chemotherapy will cause hyperkalemia.<sup>19</sup> People who take two or more drugs that can increase plasma potassium concentration need monitoring for hyperkalemia.<sup>20</sup> Several factors together can cause hyperkalemia, such as when an individual who develops decreased potassium excretion because of oliguric chronic kidney disease continues to have a normal dietary potassium intake.<sup>21</sup> Specific causes of hyperkalemia are summarized by category in Box 24-7.

**Clinical manifestations.** As might be expected from the role of potassium ions in establishment of the resting membrane potential of muscle cells, hyperkalemia causes muscle dysfunction. As hyperkalemia develops, smooth muscle and skeletal muscle cells become hypopolarized.

**BOX 24-7 CAUSES OF HYPERKALEMIA****Increased Potassium Intake**

Excessive or too-rapid intravenous potassium infusion  
 Insufficiently mixed intravenous potassium infusion  
 Large transfusion of stored blood  
 Massive doses of potassium penicillin G

**Shift of Potassium from Cells to Extracellular Fluid**

Acidosis caused by nonorganic acids  
 Insufficient insulin  
 Crushing injury  
 Cytotoxic drugs (tumor lysis syndrome)  
 Hyperkalemic periodic paralysis  
 $\beta$ -Adrenergic blockade and prolonged strenuous exercise

**Decreased Potassium Excretion**

Oliguria (such as in hypovolemia, acute kidney injury, or chronic end-stage renal disease)  
 Potassium-sparing diuretics  
 Adrenal insufficiency  
 Renin-deficient states  
 Drugs that reduce aldosterone effects (direct renin inhibitors, angiotensin-converting enzyme [ACE] inhibitors, angiotensin II receptor antagonists, and selective aldosterone blockers)  
 Nephrotoxic drugs

**BOX 24-8 CAUSES OF HYPOCALCEMIA****Decreased Calcium Intake or Absorption**

Diet with insufficient calcium and vitamin D  
 Chronic kidney disease (deficient activated vitamin D)  
 Excessive dietary phytates or oxalates  
 Steatorrhea  
 Pancreatitis  
 Chronic diarrhea (includes laxative abuse)  
 Malabsorption syndromes

**Decreased Physiologic Availability of Calcium**

Hypoparathyroidism  
 Excessive phosphate intake  
 Tumor lysis syndrome (high phosphate)  
 Hypomagnesemia  
 Alkalosis  
 Large transfusion of citrated blood or fresh frozen plasma  
 Rapid infusion of plasma expanders that bind calcium  
 Elevated plasma free fatty acids  
 Chronic kidney disease

**Increased Calcium Excretion Through Normal Routes**

Steatorrhea  
 Pancreatitis

The main clinical manifestation at this stage is mild intestinal cramping and diarrhea, which occurs only in some individuals. As hyperkalemia worsens, skeletal muscle cells become hypopolarized to the extent that their resting membrane potentials lie above their threshold potential; once they have discharged, they are unable to contract again. This situation causes the typical skeletal muscle weakness and flaccid paralysis of hyperkalemia. The skeletal muscle weakness is an ascending weakness that appears first in the lower extremities.<sup>22</sup> Both hypokalemia and hyperkalemia cause skeletal muscle weakness and/or paralysis, but the underlying alterations in the resting membrane potentials are different.

Cardiac muscle undergoes the same changes in resting membrane potential as skeletal muscle in hyperkalemia. In addition, hyperkalemia decreases the duration and rate of rise of cardiac action potentials and decreases conduction velocity in the heart. These pathophysiologic mechanisms underlie the cardiac dysrhythmias of hyperkalemia.<sup>15</sup> Severe hyperkalemia causes cardiac arrest.<sup>23</sup>

The plasma potassium concentration at which each of these clinical manifestations occurs varies, depending on the rapidity of rise of the potassium concentration, the causes of the hyperkalemia, and other concurrent electrolyte or acid-base imbalances. Patients who have chronic end-stage renal disease often undergo potassium adaptation and have relatively mild symptoms at high plasma potassium concentrations that would be disabling in other persons. The mechanisms of potassium adaptation include increased aldosterone levels that increase potassium excretion by the colon and shift potassium ions from extracellular fluid into cells, helping to normalize resting membrane potentials.

**Plasma Calcium**

Calcium in the plasma is present in three forms: some calcium ions are bound to plasma proteins (such as albumin); some are bound to small organic ions (such as citrate); and the rest are unbound. Only the free ionized calcium is physiologically active. Two laboratory measurements are available for calcium: total serum calcium and ionized calcium. The *total serum calcium* measurement includes all of the calcium (bound

plus unbound). The normal range of total serum calcium concentration in adults is 9 to 11 mg/dl or 4.5 to 5.5 mEq/L (may vary slightly with different laboratories). Unless a calcium value specifies ionized calcium, it is total calcium. The *ionized calcium* measurement includes only the unbound ionized form. The normal range of ionized calcium in adults is 4.0 to 5.0 mg/dl, about half of the total calcium (varies with different laboratories). Clinically significant calcium imbalances are caused by alterations in the plasma concentration of unbound ionized calcium.

**Hypocalcemia**

Hypocalcemia occurs if the serum calcium concentration drops below the lower limit of normal. If the fraction of unbound ionized calcium in the blood is decreased by more calcium binding to plasma proteins or other organic ions such as citrate, the total serum calcium concentration (the usual laboratory measurement) may be normal, but *ionized* hypocalcemia is present and may cause signs and symptoms. Ionized hypocalcemia is common with massive transfusion of blood or fresh frozen plasma because citrate is part of the anticoagulant used to preserve both of these solutions.<sup>24</sup>

**Etiology.** Hypocalcemia is caused by factors that decrease calcium intake or absorption, decrease the physiologic availability of calcium, and increase calcium excretion. For example, hypocalcemia in pancreatitis arises from impaired fat digestion caused by lack of pancreatic lipase in the intestines. Both dietary calcium and calcium ions secreted into the intestine from the extracellular fluid bind to undigested fat in the intestine and are excreted in the feces. Thus, both decreased calcium absorption and increased calcium excretion play a part in hypocalcemia associated with pancreatitis. In addition, calcium ions can bind to necrotic tissue in the pancreas, decreasing their physiologic availability. Ionized hypocalcemia is common in intensive care unit patients, again due to multiple factors.<sup>25</sup> Parathyroid hormone increases plasma calcium concentration; people who have hypoparathyroidism thus develop hypocalcemia. **Box 24-8** lists specific causes of hypocalcemia organized according to the general etiologic factors.

**Clinical manifestations.** Calcium ions play an important role in determining the speed of ion fluxes through nerve and muscle cell membranes. Thus, calcium imbalances alter normal neuromuscular excitability. Clinical manifestations of hypocalcemia are those of increased neuromuscular excitability: positive Trousseau sign, positive Chvostek sign, paresthesias, muscle twitching and cramping, hyperactive reflexes, carpal spasm, pedal spasm, tetany, laryngospasm, seizures, and cardiac dysrhythmias.<sup>26</sup> The increased neuromuscular excitability of hypocalcemia is caused by a decrease in the threshold potential of excitable cells, so that action potentials are generated more easily. Cardiac effects of hypocalcemia arise from the prolonged plateau phase of the cardiac action potential, impaired atrioventricular and intraventricular conduction, and impaired myocardial contractility, which can cause heart failure.<sup>15,27</sup>

Positive Trousseau sign is occurrence of a carpal spasm after occlusion of arterial blood flow to the hand for approximately 3 minutes. Positive Chvostek sign is spasm of muscles in the cheek and corner of the mouth produced by tapping the facial nerve in front of the ear. Positive Trousseau and Chvostek signs are general indicators of increased neuromuscular excitability from any cause, so they must be interpreted in the context of other clinical manifestations and specific risk factors for hypocalcemia. Chvostek sign may be positive in neonates without electrolyte imbalances.

### Hypercalcemia

Hypercalcemia occurs when the serum calcium concentration rises above the upper limit of normal (11 mg/dl or 5.5 mEq/L). It indicates an elevation of the calcium concentration of the extracellular fluid.

**Etiology.** Hypercalcemia is caused by factors that increase calcium intake or absorption, cause a shift of calcium from bone to extracellular fluid, and decrease calcium excretion. Because parathyroid hormone shifts calcium out of bone, hyperparathyroidism causes hypercalcemia. Many malignant tumors produce chemicals that circulate in the blood and shift calcium from bones into extracellular fluid.<sup>28</sup> These bone-resorbing factors include parathyroid hormone–related peptide and prostaglandins. In addition, circulating factors in malignancy may decrease renal excretion of calcium ions, which also contributes to hypercalcemia. Specific causes of hypercalcemia are listed by category in Box 24-9.

**Clinical manifestations.** Hypercalcemia causes decreased neuromuscular excitability. Clinical manifestations of hypercalcemia include anorexia, nausea, emesis, constipation, fatigue, polyuria, muscle

weakness, diminished reflexes, headache, confusion, lethargy, personality change, and cardiac dysrhythmias. The decreased neuromuscular excitability is caused by elevation of the threshold potential of excitable cells. Cardiac effects of hypercalcemia include shortened plateau phase of the action potential, increased rate of diastolic depolarization of sinus node cells, and delayed atrioventricular conduction.<sup>15</sup> Renal calculi may occur as a result of the high calcium concentration of the urine. Hypercalcemia caused by bone resorption may lead to pathologic fractures.

### Plasma Magnesium

The normal serum magnesium concentration is 1.5 to 2.5 mEq/L (may vary slightly with different laboratories). Similarly to calcium, magnesium ions also are present in the blood as bound (physiologically inactive) and unbound ionized (physiologically active) forms. Measurement of ionized magnesium levels is available in some research settings. Plasma magnesium concentration imbalances may occur concurrent with or in the absence of total body magnesium content imbalances.

### Hypomagnesemia

If the serum magnesium concentration decreases below the lower limit of normal (1.5 mEq/L), hypomagnesemia is present. Hypomagnesemia indicates a decreased magnesium concentration of the extracellular fluid and does not necessarily indicate a total body magnesium deficit (although the two may occur concurrently).

**Etiology.** Causes of hypomagnesemia are decreased magnesium intake or absorption, decreased physiologic availability of magnesium, increased magnesium excretion, and loss of magnesium by an abnormal route. Chronic alcoholism is a major risk factor for hypomagnesemia because it is associated with decreased magnesium intake, decreased physiologic availability of magnesium, increased urinary and fecal magnesium excretion, and magnesium loss through emesis.<sup>29</sup> Hypomagnesemia often causes hypokalemia by increasing urinary excretion of potassium. In such cases, correction of hypomagnesemia is necessary before the hypokalemia can be corrected. Specific causes of hypomagnesemia are listed in Box 24-10.

**Clinical manifestations.** Magnesium ions in the extracellular fluid normally depress the release of acetylcholine at neuromuscular junctions. If too few magnesium ions are present, excessive amounts of acetylcholine are released (Figure 24-11). Therefore, the clinical manifestations of hypomagnesemia are those of increased neuromuscular excitability. Such manifestations may include insomnia, hyperactive reflexes, muscle cramps, muscle twitching, grimacing, positive Chvostek sign, positive Trousseau sign, nystagmus, dysphagia, ataxia, tetany, and seizures. Cardiac dysrhythmias also occur.

Hypomagnesemia causes decreased activity of the enzyme that drives the  $\text{Na}^+$ - $\text{K}^+$  pump in cell membranes, so that intracellular potassium concentration decreases in the myocardium. Increased spontaneous firing in the sinus node, shortening of the absolute refractory period, and lengthening of the relative refractory period contribute to cardiac dysrhythmias in hypomagnesemia.<sup>15</sup>

### Hypermagnesemia

If the serum magnesium concentration rises above the upper limit of normal (2.5 mEq/L), hypermagnesemia is present. Hypermagnesemia indicates an excess of magnesium in the extracellular fluid.

**Etiology.** The major causes of hypermagnesemia are increased magnesium intake and decreased magnesium excretion. Shift of magnesium from bones to extracellular fluid is seen transiently in some stages of hyperparathyroidism. More commonly, hypermagnesemia from excessive intake of magnesium in laxatives and antacids occurs in

#### BOX 24-9 CAUSES OF HYPERCALCEMIA

##### Increased Calcium Intake or Absorption

Milk-alkali syndrome  
Vitamin D overdose (includes shark cartilage supplements)

##### Shift of Calcium from Bone to Extracellular Fluid

Hyperparathyroidism  
Immobilization  
Paget disease  
Bone tumors  
Multiple myeloma  
Leukemia  
Nonosseous malignancies that produce bone-resorbing factors

##### Decreased Calcium Excretion

Thiazide diuretics  
Familial hypocalciuric hypercalcemia

people of any age who have unrecognized renal impairment or receive high doses.<sup>30</sup> Older adults are at high risk from these magnesium-containing medications. Individuals who have oliguria, as in chronic end-stage renal disease, are another high-risk group for development of hypermagnesemia. Specific causes of hypermagnesemia are summarized in Box 24-11.

### BOX 24-10 CAUSES OF HYPOMAGNESEMIA

#### Decreased Magnesium Intake or Absorption

- Chronic alcoholism
- Malnutrition
- Prolonged intravenous therapy without magnesium supplementation
- Ileal resection
- Chronic diarrhea (includes laxative abuse)
- Malabsorption syndromes
- Steatorrhea
- Pancreatitis

#### Decreased Physiologic Availability of Magnesium

- Elevated plasma free fatty acids

#### Increased Magnesium Excretion Through Normal Routes

##### Renal Route

- Diabetic ketoacidosis
- Chronic alcoholism
- Hyperaldosteronism
- Diuretic therapy
- Aminoglycoside (e.g., gentamicin) toxicity
- Amphotericin B, cisplatin, and many other drugs

##### Fecal Route

- Steatorrhea
- Pancreatitis

#### Magnesium Loss Through Abnormal Routes

- Emesis
- Gastric suction
- Fistula drainage

**Clinical manifestations.** Too many magnesium ions in the extracellular fluid depress neuromuscular function by decreasing the release of acetylcholine at neuromuscular junctions (see Figure 24-11). Thus manifestations of hypermagnesemia include decreased deep tendon reflexes, lethargy, hypotension, flushing, diaphoresis, drowsiness, flaccid paralysis, respiratory depression, bradycardia, cardiac dysrhythmias, and even cardiac arrest. Mechanisms that cause the cardiac effects of hypermagnesemia include decreased cardiac conduction and depression of membrane excitability.<sup>15</sup>

### Plasma Phosphate

The normal range of phosphate concentration in adult plasma is 2.5 to 4.5 mg/dl (may vary slightly with different laboratories). Symptomatic phosphate imbalances are less common than other electrolyte imbalances, but, like other electrolyte imbalances, they may be fatal if untreated.

### Hypophosphatemia

Hypophosphatemia is present when the phosphate concentration in the plasma decreases below the lower limit of normal (2.5 mg/dl). However, the clinical manifestations of hypophosphatemia are often not observed unless the plasma phosphate concentration is less than 1.0 mg/dl. Persons whose plasma phosphate concentration is less than 1.0 mg/dl are said to have *severe symptomatic hypophosphatemia*.

**Etiology.** Hypophosphatemia is caused by factors that decrease phosphate intake, shift phosphate from extracellular fluid to cells,

### BOX 24-11 CAUSES OF HYPERMAGNESEMIA

#### Increased Magnesium Intake or Absorption

- Ingestion or aspiration of seawater
- Excessive ingestion of magnesium-containing medications (e.g., laxatives, antacids)
- Excessive intravenous infusion of magnesium

#### Decreased Magnesium Excretion

- Oliguric renal disease
- Adrenal insufficiency

**FIGURE 24-11** Acetylcholine (ACh) release at neuromuscular junctions is altered in magnesium imbalances. **A**, Normal magnesium concentration suppresses the release of acetylcholine at neuromuscular junctions to normal levels. **B**, In hypomagnesemia, more acetylcholine is released at neuromuscular junctions, causing increased neuromuscular excitability. **C**, In hypermagnesemia, less acetylcholine is released at neuromuscular junctions, causing decreased neuromuscular excitability.

**BOX 24-12 CAUSES OF HYPOPHOSPHATEMIA****Decreased Phosphate Intake or Absorption**

Chronic alcoholism  
 Chronic diarrhea  
 Malabsorption syndromes  
 Excessive or long-term use of antacids that bind phosphate

**Shift of Phosphate from Extracellular Fluid to Cells**

Refeeding after starvation (includes anorexia nervosa)  
 Total parenteral nutrition  
 Hyperventilation (respiratory alkalosis)  
 Insulin  
 Epinephrine  
 Intravenous glucose, fructose, bicarbonate, or lactate

**Increased Phosphate Excretion Through the Normal Renal Route**

Alcohol withdrawal  
 Diuretic phase after extensive burns  
 Diabetic ketoacidosis  
 Diuretic therapy

**Phosphate Loss Through Abnormal Routes**

Emesis  
 Hemodialysis

increase phosphate excretion, and cause loss of phosphate through abnormal routes. Frequently, many factors combine to produce severe symptomatic hypophosphatemia. Any factor that causes a rapid increase in cellular metabolism will cause phosphate to shift from extracellular fluid into cells. Patients who are severely malnourished (such as cancer patients with advanced disease) are at high risk for severe symptomatic hypophosphatemia after nutritional replacement is started because of their increased cellular metabolism and previously depleted phosphate stores.<sup>31</sup> Specific factors that cause hypophosphatemia are summarized in **Box 24-12**.

**Clinical manifestations.** Phosphate is an important component of adenosine triphosphate (ATP), the major source of energy for many cellular processes. The signs and symptoms of severe symptomatic hypophosphatemia are due, in part, to decreased amounts of ATP within the cells. Another contributing mechanism is tissue hypoxia caused by decreased amounts of 2,3-biphosphoglycerate (2,3-BPG) in the red blood cells. Signs and symptoms include anorexia, malaise, paresthesias, hemolysis, diminished reflexes, muscle aches, muscle weakness, respiratory failure, confusion, stupor, seizures, coma, and impaired cardiac function. The impaired cardiac function of severe hypophosphatemia results from decreased cardiac contractility and stroke work concurrent with increased left ventricular end-diastolic pressure and may cause congestive cardiomyopathy.<sup>15</sup>

**Hyperphosphatemia**

Hyperphosphatemia is an increase of the serum phosphate concentration above the upper limit of normal (4.5 mg/dl).

**Etiology.** Hyperphosphatemia may be caused by increased phosphate intake, shift of phosphate from cells or bones to extracellular fluid, and decreased phosphate excretion. Examples of specific causes in these categories are listed in **Box 24-13**. Hyperphosphatemia is common in people who have oliguric renal disease, either acute or chronic. In chronic kidney disease, renal phosphate excretion is severely

**BOX 24-13 CAUSES OF HYPERPHOSPHATEMIA****Increased Phosphate Intake or Absorption**

Overzealous phosphate therapy  
 Excessive use of phosphate-containing enemas or laxatives

**Shift of Phosphate from Cells to Extracellular Fluid**

Tumor lysis syndrome  
 Crushing injury  
 Rhabdomyolysis

**Decreased Phosphate Excretion**

End-stage renal disease  
 Oliguric acute kidney injury  
 Adrenal insufficiency

decreased but intestinal absorption of dietary phosphate continues. In addition, elevated parathyroid hormone in chronic kidney disease shifts phosphate from bones into extracellular fluid.<sup>32</sup>

**Clinical manifestations.** Clinical manifestations of hyperphosphatemia depend on the effect of the elevated phosphate ion concentration on calcium ions. Typically, hyperphosphatemia causes hypocalcemia. The signs and symptoms are thus the manifestations of increased neuromuscular excitability that were presented in the discussion of hypocalcemia. However, in some patients, especially those who have chronic kidney disease, hyperphosphatemia causes deposition of calcium phosphate salts in the soft tissues of the body. These patients develop signs and symptoms such as aching and stiffness of joints, itching (pruritus), and conjunctivitis, depending on the areas in which these salts precipitate.

**KEY POINTS**

- Plasma electrolyte deficits are caused by factors that decrease electrolyte intake or absorption, shift electrolytes from the extracellular fluid to an electrolyte pool, increase electrolyte excretion, and cause loss of electrolytes through abnormal routes.
- Plasma electrolyte excesses are caused by factors that increase electrolyte intake or absorption, shift electrolytes from an electrolyte pool to the extracellular fluid, and decrease electrolyte excretion.
- Abnormalities in plasma electrolyte concentrations may profoundly affect cellular function. Excitable cells, such as nerve and muscle, are particularly sensitive to electrolyte imbalances.
- Manifestations of potassium imbalances are due to changes in resting membrane potentials. Hypokalemia causes hyperpolarization; hyperkalemia causes hypopolarization. Both hyperkalemia and hypokalemia cause skeletal muscle weakness, flaccid paralysis, and cardiac dysrhythmias.
- Manifestations of calcium imbalances are caused by changes in the threshold potential of nerve and muscle cells. Hypocalcemia decreases the threshold potential, causing hyperexcitability (twitching, tetany); hypercalcemia increases the threshold potential, causing neuromuscular depression (hyporeflexia).
- Manifestations of magnesium imbalances are similar to those of calcium imbalances. Magnesium ions normally inhibit release of acetylcholine at neuromuscular junctions. Hypomagnesemia increases neuromuscular excitability (hyperreflexia and twitching), and hypermagnesemia depresses neuromuscular excitability (hyporeflexia and flaccid paralysis).
- Severe symptomatic hypophosphatemia is characterized by manifestations of generalized cellular ATP deficiency. Hyperphosphatemia may cause hypocalcemia, with resulting increased neuromuscular excitability, or it may be associated with precipitation of calcium phosphate into soft tissues of the body.

## SUMMARY

This chapter presents the principles of fluid and electrolyte homeostasis and imbalances. The boxes below summarize pediatric and geriatric considerations, respectively. Fluid and electrolyte homeostasis involves the continuous interplay of intake, absorption, distribution, and excretion of fluid and electrolytes. Loss of fluid and electrolytes through abnormal routes may also occur. When the normal mechanisms are impaired or overwhelmed, fluid and electrolyte imbalances

occur. Fluid imbalances may involve the volume or the concentration of body fluid. Plasma electrolyte imbalances may be deficits or excesses and may not reflect total body electrolyte deficits or excesses. Signs and symptoms of fluid and electrolyte imbalances are summarized in Table 24-2. The pathophysiology of specific fluid and electrolyte imbalances can be derived from a working knowledge of normal fluid and electrolyte homeostasis.

## PEDIATRIC CONSIDERATIONS

### *Fluid and Electrolyte Homeostasis and Imbalances*

- Infants have more extracellular fluid than intracellular fluid; this proportion reverses by a few months of age.
- About 75% of the body weight of a term infant is water; this percentage is even higher in preterm infants. The percentage of body weight that is water decreases as the child ages.
- In the first few days after birth, an infant loses fluid equal to 5% to 10% of its body weight; this is a normal process during adjustment to extrauterine life.
- Neonates have a high metabolic rate and thus a high turnover rate of water.
- Infants have increased insensible water excretion caused by proportionately large body surface area, proportionately large respiratory mucosa surface area, vasomotor immaturity, and increased skin permeability. Preterm infants have even greater insensible water excretion through the skin because of flaccid extended posture (and thus greater exposed body surface area) and greater vasomotor immaturity.
- Use of phototherapy and radiant heat warmers increases insensible water excretion.
- Glomerular filtration rate is lower in infants than in adults.
- The kidneys of infants have limited ability to concentrate urine or to dilute it; thus, infants are unable to excrete a large load of water effectively or to conserve fluid when needed.
- Infants communicate thirst by crying, which may not be understood by their caregivers.
- Assessment of extracellular volume imbalances in infants should focus on the tension of the fontanel rather than the degree of filling of neck veins.
- Infants whose caregivers use powdered formula are at high risk for hypernatremia if the formula is reconstituted with extra powder to “strengthen” the baby.
- Laboratory normal ranges of electrolytes generally are wider for infants than older children and adults.
- Neonatal hypocalcemia may occur in infants who needed resuscitation at birth or have high-risk conditions.
- Preterm infants may have reduced body calcium stores because fetal calcium stores are built during the last trimester of pregnancy; these infants have increased incidence of neonatal hypocalcemia.
- Assessment of increased neuromuscular excitability (hypocalcemia and hypomagnesemia) in infants should not include Chvostek sign; this sign is often positive in normal neonates. Increased neuromuscular excitability in infants includes jitteriness, hyperactive reflexes, and a high-pitched cry.
- Neonates whose mothers were given magnesium sulfate for eclampsia in the 24 hours before birth may be born with hypermagnesemia. Hypermagnesemic infants lie in a flaccid, extended posture.

## GERIATRIC CONSIDERATIONS

### *Fluid and Electrolyte Homeostasis and Imbalances*

- Older adults have less body water than middle-aged adults because body composition changes with increasing age (decreased muscle mass, increased fat in internal organs). About 50% of the body weight of a lean older man is water and about 45% of the body weight of a lean older woman is water; the percentage is lower in obese older adults.
- Glomerular filtration rate is lower in older adults than in middle-aged adults.
- The kidneys of older adults are less able to concentrate urine and thus less able to conserve fluid when needed. This decreased ability to concentrate urine is also responsible for nocturia, since a larger than normal volume of urine is produced at night.
- Older adults have a reduced thirst response when the osmolality of body fluids increases; thus, they may not be aware that they are becoming dehydrated.
- Older adults are a high-risk group for clinical dehydration.
- Decreased skin turgor is not reliable as a sign of extracellular fluid volume depletion in older adults, because of age-related changes in collagen and elastin. Decreased skin turgor (skin tenting when pinched) may occur in older adults who have normal fluid volume.
- Older adults who receive tube feedings are at higher risk for hypernatremia than middle-aged adults.
- Older adults probably absorb more magnesium from antacids and cathartics than do middle-aged adults. With age-related changes in renal excretion, older adults who use oral magnesium laxatives or antacids regularly are at high risk for hypermagnesemia.

TABLE 24-2 SUMMARY OF SIGNS AND SYMPTOMS OF FLUID AND ELECTROLYTE IMBALANCES

IMBALANCE	HEART	BLOOD VESSELS	INTERSTITIAL AREA	CNS	LUNGS
↓ Extracellular volume	Tachycardia	Postural blood pressure decrease with concurrent heart rate increase, flat neck veins, ↑ small-vein filling time, thready pulse	↓ Skin turgor; soft, sunken eyeballs; longitudinal furrows in tongue	Lightheadedness, syncope	
↑ Extracellular volume		Distended neck veins, bounding pulse	Edema		Crackles, dyspnea, orthopnea, frothy sputum
↓ Na <sup>+</sup>				Confusion, lethargy, coma, seizures	
↑ Na <sup>+</sup>				Confusion, lethargy, coma, seizures	
↓ K <sup>+</sup>	Dysrhythmias	Postural hypotension			
↑ K <sup>+</sup>	Dysrhythmias, cardiac arrest				
↓ Ca <sup>++</sup>	Dysrhythmias, impaired myocardial contractility			Seizures	
↑ Ca <sup>++</sup>	Dysrhythmias			Confusion, lethargy, personality change	
↓ Mg <sup>++</sup>	Dysrhythmias			Insomnia, seizures	
↑ Mg <sup>++</sup>	Bradycardia, dysrhythmias, cardiac arrest	Hypotension, flushing		Drowsiness, lethargy	Respiratory depression
↓ Pi	Impaired cardiac function, decreased cardiac output			Confusion, stupor, coma, seizures	Respiratory failure
↑ Pi (may cause ↓ Ca <sup>++</sup> )					

CNS, Central nervous system; ECV, extracellular fluid volume; Pi, inorganic phosphate.

## CHAPTER 24 Fluid and Electrolyte Homeostasis and Imbalances

SKELETAL MUSCLE	NEUROMUSCULAR EXCITABILITY	GASTROINTESTINAL TRACT	KIDNEYS	OTHER
		Dry oral mucous membranes, hard stools	Oliguria	Sudden weight loss, sunken fontanel (infants), no tears or sweat, thirst with severe ↓ ECV
		Hepatomegaly		Sudden weight gain, bulging fontanel (infants)
		Anorexia, nausea, emesis		Malaise, headache
			Oliguria	Thirst
Ascending weakness, flaccid paralysis		Abdominal distention, bloating, ↓ bowel sounds, constipation, paralytic ileus	Polyuria	
Ascending weakness, flaccid paralysis		Mild cramping, diarrhea		
Twitching, cramping, carpal spasm, pedal spasm	Increased excitability, Trousseau sign, Chvostek sign, paresthesias, hyperactive reflexes, tetany			Laryngospasm
Weakness	Decreased excitability, depressed reflexes	Anorexia, nausea, emesis, constipation	Polyuria	Fatigue, headache
Twitching, cramping, grimacing, tremors	Increased excitability, Trousseau sign, Chvostek sign, hyperactive reflexes, tetany	Dysphagia		Nystagmus, ataxia
Flaccid paralysis	Depressed reflexes			Diaphoresis
Aching, weakness	Paresthesias, depressed reflexes	Anorexia		Malaise, hemolysis
			If Ca <sup>++</sup> remains high, damage from deposition of crystals	If Ca <sup>++</sup> remains high, pruritus, conjunctivitis, arthritis

### KEY QUESTIONS

- What are the chemistry and functional importance of the bicarbonate buffer system?
- What is the role of the respiratory system in regulating carbonic acid (carbon dioxide)?
- What is the role of the kidneys in regulating bicarbonate ion and acids other than carbonic acid?
- How do the lungs compensate for acid-base imbalances caused by altered levels of metabolic acids?
- How do the kidneys compensate for acid-base imbalances caused by altered levels of carbonic acid?
- How are arterial blood gas values used to categorize an acid-base disorder as acidosis or alkalosis, respiratory or metabolic, compensated or uncompensated?
- What pathophysiologic conditions predispose an individual to each of the four primary acid-base imbalances?

- *Metabolic Alkalosis*, 546
- *Respiratory Alkalosis*, 546
- Mixed Acid-Base Imbalances, 547

When the pH of body fluids becomes abnormal, cellular function is impaired. The pH of a fluid reflects its degree of acidity or alkalinity. Technically, pH is the negative logarithm of the hydrogen ion ( $H^+$ ) concentration. The normal hydrogen ion concentration of the blood is about 40 nmol/L ( $40 \times 10^{-9}$  mol/L)—a very small number.<sup>1</sup> The pH (negative logarithm) of this number is 7.40, which is easier to use in clinical settings. An alteration in pH is a change in the hydrogen ion concentration. A high pH indicates few hydrogen ions, meaning that the solution is alkaline (basic). A low pH indicates a large amount of hydrogen ions, meaning that the solution is acidic.

An acid releases hydrogen ions. The more hydrogen ions present, the more acidic the solution. The normal pH of adult blood

ranges from 7.35 to 7.45 (may vary slightly with different laboratories). The range is somewhat wider in infants and children. Table 25-1 lists normal laboratory values for pH and other acid-base parameters. If the blood and other body fluids become too acidic (reflected by pH decreased below the lower limit of the normal range), dysfunction occurs; if the pH of the blood falls below 6.9, death is likely to occur. Similarly, if the body fluids become too alkaline, as reflected by pH increased above the upper limit of the normal range, dysfunction also occurs. If the pH of the blood rises above 7.8, death is likely.

Normal cellular metabolism continually releases acids (carbonic and metabolic) that must be excreted from the body to prevent body

**TABLE 25-1 NORMAL LABORATORY VALUES FOR ACID-BASE PARAMETERS**

CHARACTERISTIC	NORMAL RANGE
Paco <sub>2</sub> (arterial blood)	36-44 mm Hg (adults) 30-34 mm Hg (infants)
HCO <sub>3</sub> <sup>-</sup> (serum)	22-26 mEq/L (adults) 19-23 mEq/L (infants)
pH (arterial blood)	7.35-7.45 (adults) 7.11-7.36 (neonates) 7.36-7.41 (infants)

fluids from becoming too acidic. This chapter discusses the normal mechanisms of acid-base homeostasis and the acid-base imbalances that arise when these homeostatic mechanisms become dysfunctional or overwhelmed.

## ACID-BASE HOMEOSTASIS

Three major mechanisms regulate the acid-base status of the body: buffers, the respiratory system, and the renal system. Laboratory measurements such as arterial blood gas values are useful indicators of the acid-base status of extracellular fluids. The partial pressure of carbon dioxide in arterial blood (Paco<sub>2</sub>) is an indicator of the respiratory component of acid-base balance. The plasma bicarbonate ion (HCO<sub>3</sub><sup>-</sup>) concentration is an indicator of the renal (metabolic) component of acid-base balance.<sup>1</sup> The pH of the blood indicates the net result of normal acid-base regulation, any acid-base imbalance, and the body's compensatory responses. It is important to remember that the pH measured clinically is that of the blood and may not reflect the pH inside cells or in cerebrospinal fluid.

### Buffers

Buffers are chemicals that help control the pH of body fluids. Each buffer system consists of a weak acid, which releases hydrogen ions when the fluid is too alkaline, and a base, which takes up hydrogen ions when the fluid is too acidic. In this way, potential changes in pH are adjusted immediately by the action of buffers. All body fluids contain buffers. Chief among them are bicarbonate buffers (in the extracellular fluid), phosphate buffers (in intracellular fluid and urine), hemoglobin buffers (inside erythrocytes), and protein buffers (in intracellular fluid and the blood). These buffers are the first line of defense against pH imbalances.

The bicarbonate buffer system is the most important buffer in the extracellular fluid. Bicarbonate ion (HCO<sub>3</sub><sup>-</sup>) is the base portion and carbonic acid (H<sub>2</sub>CO<sub>3</sub>) is the weak acid portion. These two components of the bicarbonate buffer system are in chemical equilibrium in the extracellular fluid.<sup>2</sup> If too much acid (e.g., lactic acid) is present, the bicarbonate ions take up hydrogen ions (H<sup>+</sup>) released by the acid and become carbonic acid. Through the action of the enzyme carbonic anhydrase, the carbonic acid then is excreted through the respiratory system in the form of carbon dioxide and water. Thus the excess acid is neutralized when bicarbonate ions are used in the buffering process.

Conversely, if too little acid is present in the extracellular fluid, the carbonic acid portion of the bicarbonate buffer system releases

hydrogen ions. This action helps to keep the pH from becoming too high or at least minimizes the increase.

The pH of any fluid is determined by the relative amounts of acids and bases contained in it. For the pH of the blood to be within the normal range, the ratio of bicarbonate ions to carbonic acid must be 20:1, which means that 20 bicarbonate ions must be present for every carbonic acid molecule. This relationship is explained formally by the Henderson-Hasselbalch equation, which is a mathematical description of the pH of a buffered solution, here written specifically for the bicarbonate buffer system.

$$\text{pH} = \text{pK}_a + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

Square brackets, used throughout this chapter, are a standard notation for concentration. pK<sub>a</sub> is the dissociation constant for any particular acid; it equals 6.1 for carbonic acid.<sup>2</sup> If the normal 20:1 ratio of bicarbonate ions to carbonic acid is present, the pH will be 7.4.

$$\text{pH} = 6.1 + \log 20$$

$$\text{pH} = 6.1 + 1.3$$

$$\text{pH} = 7.4$$

The 20:1 ratio of bicarbonate ions to carbonic acid necessary for a normal pH is an important concept in understanding the compensatory mechanisms for acid-base imbalances that are discussed later in this chapter.

### Respiratory Contribution

The respiratory system is the second defense against acid-base disorders. Body cells continuously produce carbon dioxide (CO<sub>2</sub>). Together, CO<sub>2</sub> and water (H<sub>2</sub>O) make carbonic acid (H<sub>2</sub>CO<sub>3</sub>). The lungs excrete carbon dioxide and water from the body. Therefore, during the process of exhalation the lungs effectively excrete carbonic acid. The respiratory system adjusts the amount of carbonic acid that remains in the body by altering rate and depth of respiration.

The rate and depth of respiration are influenced strongly by chemoreceptors that sense the Paco<sub>2</sub>, Pao<sub>2</sub>, and pH of the blood. If too much carbonic acid begins to accumulate in the blood of a healthy person, the rate and depth of respiration increase and excess carbonic acid is removed. This response corrects the imbalance and restores blood chemistry to normal. If, on the other hand, too little carbonic acid is present in the blood, the rate and depth of respiration decrease to retain carbonic acid until it once more is present in normal amounts. Again, the imbalance is corrected and the blood chemistry returns to normal. Thus the body's correction of a carbonic acid excess or deficit is dependent on normal function of all components of the respiratory system, including the chemoreceptors, respiratory neurons in the brainstem, motor nerves to respiratory muscles, diaphragm and other respiratory muscles, chest wall, and, of course, the airways, lungs, and pulmonary circulation. In older adults, the chemoreceptor response to increased Paco<sub>2</sub> may occur more slowly.

The Paco<sub>2</sub> indicates how effectively the respiratory system is excreting carbonic acid. If the Paco<sub>2</sub> is elevated above the upper limit of the normal range, carbonic acid has accumulated in the blood. In other words, the respiratory rate and depth have been insufficient or lung disease has prevented sufficient carbonic acid (carbon dioxide and water) excretion.<sup>3</sup> Similarly, if the Paco<sub>2</sub> is decreased below the

**TABLE 25-2 RESPIRATORY RESPONSES TO CHANGES IN CARBONIC AND METABOLIC ACIDS**

STIMULUS	RESPIRATORY RESPONSE	RESULT
Increased $P_{aCO_2}$ , decreased pH	Hyperventilation	Correction of imbalance
Decreased $P_{aCO_2}$ , increased pH	Hypoventilation	Correction of imbalance
Decreased pH from excess of metabolic acids	Hyperventilation	Compensation for imbalance
Increased pH from deficit of metabolic acids	Hypoventilation	Compensation for imbalance

lower limit of the normal range, the lungs have excreted more carbonic acid than usual. In other words, the respiratory rate and depth have been excessive.<sup>4</sup>

Carbonic acid is known as a volatile acid because it can be excreted as gases ( $CO_2$  and  $H_2O$ ). It is the only volatile acid in the body. Other acids that accumulate in the body, such as lactic acid and acetoacetic acid, are nonvolatile. They are organic acids that have no gaseous form. The lungs can excrete only carbonic acid; they cannot excrete nonvolatile acids that may accumulate in the body. If a nonvolatile acid (such as lactic acid) accumulates in the blood, the rate and depth of respiration will increase because the excess hydrogen ions stimulate the chemoreceptors. This hyperventilation does not excrete lactic acid (which would correct the problem), but it does remove carbonic acid from the blood. Removing carbonic acid from the blood when another acid is present in excess helps keep the pH from dropping too low. However, this response makes other values abnormal. The respiratory response to an imbalance of any acid except carbonic acid is called *compensation*. A compensatory response does not correct a pH disorder but it does compensate for it by adjusting the pH back toward normal, even though other blood chemistry values are made abnormal in the process.

The compensatory response to a deficit of any acid except carbonic acid is hypoventilation.<sup>1,5</sup> By decreasing rate and depth of respiration, the body retains carbonic acid. This carbonic acid accumulation helps keep blood pH from rising to a fatal level when another acid is deficient in the body. Respiratory compensation for an imbalance of metabolic acid begins in minutes but requires at least several hours for full effectiveness. Respiratory responses to changes in carbonic and metabolic acids are summarized in Table 25-2.

### Renal Contribution

The third defense against acid-base disorders is the kidneys. The kidneys can excrete any acid from the body except carbonic acid (which is excreted by the lungs). These acids that are not carbonic acid are called metabolic acids because cells continuously produce them during normal metabolism. The kidneys normally excrete metabolic acids. If a metabolic acid begins to accumulate in the blood, the kidneys increase their acid excretion mechanisms to correct the problem. If a metabolic acid is deficient in the blood, the kidneys slow their acid excretion mechanisms to allow acid to accumulate to normal levels. The body's ability to correct an excess or deficit of a metabolic acid depends on normal function of the renal system. Infants excrete more bicarbonate in their urine than do older children or adults; their kidneys are less effective in excreting acid. The renal response to a large acid load also is less efficient in older adults.

The kidneys have several mechanisms that accomplish acid excretion.<sup>2</sup> Understanding these mechanisms requires a knowledge of basic renal physiology. Briefly, at the glomerulus, fluid filtered from the blood enters the glomerular (Bowman) capsule, which is the beginning of the nephron. The cells that line the lumen of the renal tubule modify the fluid inside the nephron (renal tubular fluid). Renal tubular fluid that passes through the entire nephron becomes the urine. Renal tubular epithelial cells have different membrane structures on opposite sides of the cells. The luminal membrane (next to the renal tubular fluid) contains different transporter proteins than the basolateral membrane (next to the interstitial fluid). This structure allows these cells to secrete certain substances into the renal tubular fluid and move other substances into the interstitial fluid.

In the proximal tubules, renal tubular epithelial cells excrete metabolic acid by secreting both the anion portion of the metabolic acid (e.g., lactate) and the hydrogen ions into the tubule lumen. For every hydrogen ion ( $H^+$ ) that is secreted into the renal tubular fluid, one bicarbonate ion ( $HCO_3^-$ ) is moved into the interstitial fluid.<sup>6</sup> The fluid filtered from the blood at the glomerulus contains many bicarbonate ions and most or all of that bicarbonate is reabsorbed (returned to the blood) during secretion of hydrogen ions. Renal tubular cells are able to secrete additional hydrogen ions into the tubular fluid to excrete large amounts of hydrogen ions from metabolic acid.

Once the  $H^+$  are in the renal tubular fluid, most of them combine with other chemicals: bicarbonate ions, which were filtered at the glomerulus, as described previously; urine buffers, such as phosphate, which were filtered at the glomerulus; or ammonia ( $NH_3$ ), which is produced by renal tubular cells. Net  $H^+$  excretion occurs after  $HCO_3^-$  has been reabsorbed in the amount that was filtered at the glomerulus. Thus net  $H^+$  excretion is accomplished in the form of buffered  $H^+$  (called *titratable acidity*) and  $H^+$  attached to ammonia (ammonium ions,  $NH_4^+$ ). Figure 25-1 illustrates these processes. Some of these processes operate also in the thick ascending limb of the loop of Henle and the distal nephron, where the intracellular chemistry differs slightly but the overall processes are the same.

When the kidneys need to excrete more hydrogen ions, renal tubular cells increase their production of ammonia ( $NH_3$ ). Ammonia, a gas, moves easily into the renal tubular fluid where it combines with hydrogen ions to become ammonium ions ( $NH_4^+$ ). Ammonium ions are not lipid soluble, so they do not cross easily from the renal tubular fluid back to the blood. Only free hydrogen ions contribute to the acidity of the urine, not those that are part of ammonium ions. Consequently, increased production of ammonia is an effective way of excreting more hydrogen ions in the renal tubular fluid without making the urine too acidic.

The concentration of  $HCO_3^-$  in plasma reflects the effectiveness of renal regulation of metabolic acids. If metabolic acids are accumulating in the blood, they will be buffered by  $HCO_3^-$  and the  $HCO_3^-$  concentration will drop below normal. Thus, a decreased concentration of  $HCO_3^-$  in plasma indicates a relative excess of metabolic acids. An increased  $HCO_3^-$  concentration in the plasma indicates a relative deficit of metabolic acids (in other words, a relative excess of base).

Although the kidneys are unable to excrete carbonic acid, they can compensate for carbonic acid imbalances by adjusting the excretion of metabolic acids.<sup>7</sup> For example, if carbonic acid accumulates in the blood, the kidneys can increase the excretion of metabolic acids. This compensatory action helps keep the pH of the blood from becoming too abnormal. Similarly, if a deficit of carbonic acid in the blood is prolonged, the kidneys will decrease the excretion of metabolic acids. As these metabolic acids accumulate in the blood, they will compensate for the lack of carbonic acid and return the pH of the blood toward normal. The body's compensatory response to an imbalance of one

**FIGURE 25-1** **A**, Diagram of a nephron. **B**, Renal proximal tubule mechanisms for excretion of metabolic acid. Hydrogen ions secreted into the renal tubular lumen combine with filtered bicarbonate (which then is reabsorbed), buffers (phosphate buffer illustrated here), or ammonia (forming ammonium ions). CA, Carbonic anhydrase, an enzyme; Gln, glutamine, an amino acid. (A, From Solomon EP: *Introduction to human anatomy and physiology*, ed 3, St Louis, 2009, Mosby, p 266.)

**TABLE 25-3 RENAL RESPONSES TO CHANGES IN METABOLIC AND CARBONIC ACIDS**

STIMULUS	RENAL RESPONSE	RESULT
Decreased pH from excess of metabolic acids	Secrete more H <sup>+</sup> into renal tubules Make more ammonia	Correction of imbalance
Increased pH from deficit of metabolic acids	Secrete fewer H <sup>+</sup> into renal tubules Excrete HCO <sub>3</sub> <sup>-</sup> Make less ammonia	Correction of imbalance
Decreased pH from excess of carbonic acid	Secrete more H <sup>+</sup> into renal tubules Make more ammonia	Compensation for imbalance
Increased pH from deficit of carbonic acid	Secrete fewer H <sup>+</sup> into renal tubules Excrete HCO <sub>3</sub> <sup>-</sup> Make less ammonia	Compensation for imbalance

kind of acid thus returns the pH of the blood toward normal by creating an imbalance of another kind of acid. The renal compensatory response to an imbalance of carbonic acid requires several days to be fully operative. Renal responses to changes in metabolic and carbonic acids are summarized in Table 25-3.

**KEY POINTS**

- Normal cellular metabolism produces both carbon dioxide and metabolic acids. Carbon dioxide (CO<sub>2</sub>) combines with water (H<sub>2</sub>O) to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>). Both carbonic and metabolic acids must be excreted to maintain acid-base homeostasis.
- Buffers are chemicals (a weak acid plus its base) that prevent large changes in pH by releasing or taking up hydrogen ions (H<sup>+</sup>). The bicarbonate buffer system is the most important buffer in the extracellular fluid. The normal ratio of bicarbonate to carbonic acid is 20:1. Any deviation from this ratio alters the pH of the blood.
- The lungs excrete carbon dioxide. Rate and depth of respiration normally are adjusted by chemoreceptors in response to acid-base and oxygen status. Increased ventilation (hyperventilation) decreases the amount of carbon dioxide in blood and thus reduces the amount of carbonic acid. Decreased ventilation (hypoventilation) allows carbon dioxide to accumulate and thus increases the amount of carbonic acid in the blood.
- The kidneys excrete metabolic acids. They can secrete H<sup>+</sup> into the renal tubular fluid and retain HCO<sub>3</sub><sup>-</sup> in the body or may allow some HCO<sub>3</sub><sup>-</sup> to be excreted, depending on homeostatic demands. Most H<sup>+</sup> in the urine is buffered (titratable acidity) or in the form of ammonium ions. The concentration of HCO<sub>3</sub><sup>-</sup> in plasma reflects the relative amount of metabolic acid in the blood.
- The lungs compensate for acid-base imbalances resulting from altered levels of metabolic acids; the kidneys compensate for acid-base imbalances resulting from altered levels of carbonic acid. With compensation, the pH returns toward normal but PaCO<sub>2</sub> and HCO<sub>3</sub><sup>-</sup> levels are abnormal.

**ACID-BASE IMBALANCES**

The four primary acid-base disorders are metabolic acidosis, respiratory acidosis, metabolic alkalosis, and respiratory alkalosis. *Acidosis* is the presence of a condition that tends to decrease the pH of the blood below normal (make the blood relatively more acidic). If blood pH actually is decreased, *acidemia* also is present. *Alkalosis* is the presence

**BOX 25-1 COMMON CAUSES OF METABOLIC ACIDOSIS****Increase in Metabolic Acid**

Ketoacidosis (diabetes mellitus, starvation, alcoholism)  
Severe hyperthyroidism  
Burns  
Circulatory shock  
Tissue anoxia (lactic acidosis)  
Oliguric acute kidney injury or end-stage chronic kidney disease  
Excessive intake of acids or acid precursors (e.g., salicylates, methanol, ethylene glycol)

**Decrease in Base (Bicarbonate)**

Severe or prolonged diarrhea  
Gastrointestinal fistula that drains intestinal or pancreatic secretions  
Intestinal decompression  
Renal tubular acidosis

of any factor that tends to increase the pH of the blood above normal (make the blood relatively more alkaline). The term *alkalemia* denotes an increased blood pH. The pathophysiology of the four primary acid-base disorders can be reasoned logically from the principles of acid-base homeostasis.

**Metabolic Acidosis**

**Etiology.** Metabolic acidosis is a condition that tends to cause a relative excess of any acid except carbonic acid.<sup>8</sup> Metabolic acidosis may be caused by an increase in acid (not carbonic), by a decrease in base, or by a combination of the two. These mechanisms decrease the normal 20:1 ratio of HCO<sub>3</sub><sup>-</sup> to H<sub>2</sub>CO<sub>3</sub>.

An increase of any acid except carbonic acid will decrease the normal ratio of bicarbonate to carbonic acid because the bicarbonate ions are used up in buffering the excess acid. For example, when caloric intake is insufficient, as with prolonged fasting, the body begins to use its fat stores for energy. If too little glucose is ingested, the fat is metabolized incompletely and ketoacids accumulate in the blood. This condition is termed *starvation ketoacidosis*.<sup>9</sup>

Bicarbonate ions are a type of base. Any condition that causes excessive removal of bicarbonate ions from the body may cause metabolic acidosis. For example, the intestinal fluid is rich in bicarbonate ions, which originate from pancreatic secretions. Diarrhea causes removal of this base from the body and thus contributes to the development of metabolic acidosis.<sup>10</sup>

Other causes of metabolic acidosis are listed in Box 25-1 under the two general mechanisms discussed: increase in metabolic acid (any acid except carbonic acid) and decrease in base (bicarbonate). Either mechanism tends to make the blood overly acidic. The pathophysiology of diarrhea and other disorders that may cause metabolic acidosis is discussed in other chapters of this text.

**Clinical manifestations.** Signs and symptoms of metabolic acidosis include headache, abdominal pain, and central nervous system depression (confusion, lethargy, stupor, coma).<sup>11</sup>

Central nervous system depression that occurs in patients with metabolic acidosis is due primarily to the decreased pH of the cerebrospinal and interstitial fluid in the brain. When the pH of the interstitial fluid falls, intracellular pH decreases, the protein structure and enzyme activity in cells are altered, and cellular dysfunction results. Other factors specific to the cause of the acidosis also may induce central nervous system depression, such as hyperosmolality with diabetic ketoacidosis. Severe metabolic acidosis predisposes to tachycardia,

ventricular dysrhythmias (from myocardial intracellular acidity), and decreased cardiac contractility, which may be fatal.<sup>8</sup> Death from brainstem dysfunction usually occurs when the pH falls below 6.9.

Arterial blood gases in metabolic acidosis show a bicarbonate concentration below normal. If metabolic acidosis is uncompensated, the pH also is below normal because the usual 20:1 ratio is decreased.

**Uncompensated metabolic acidosis:**

$$\frac{\text{Decreased } [\text{HCO}_3^-]}{\text{Unchanged } [\text{H}_2\text{CO}_3]} = \text{pH low}$$

**Compensatory response.** The respiratory compensation for metabolic acidosis is hyperventilation. The low blood pH stimulates the peripheral chemoreceptors, which then stimulate ventilatory neurons in the brainstem.<sup>2</sup> The end result is increased rate and depth of respiration. As the rate and depth of respiration increase, more carbonic acid (carbon dioxide and water) is excreted. Although hyperventilation does not remove metabolic acid from the body, it does change the ratio of bicarbonate ions to carbonic acid in a favorable direction. Because the bicarbonate ion concentration already is decreased by the

metabolic acidosis, the compensatory decrease in carbonic acid brings the ratio (and thus the pH) back toward normal.

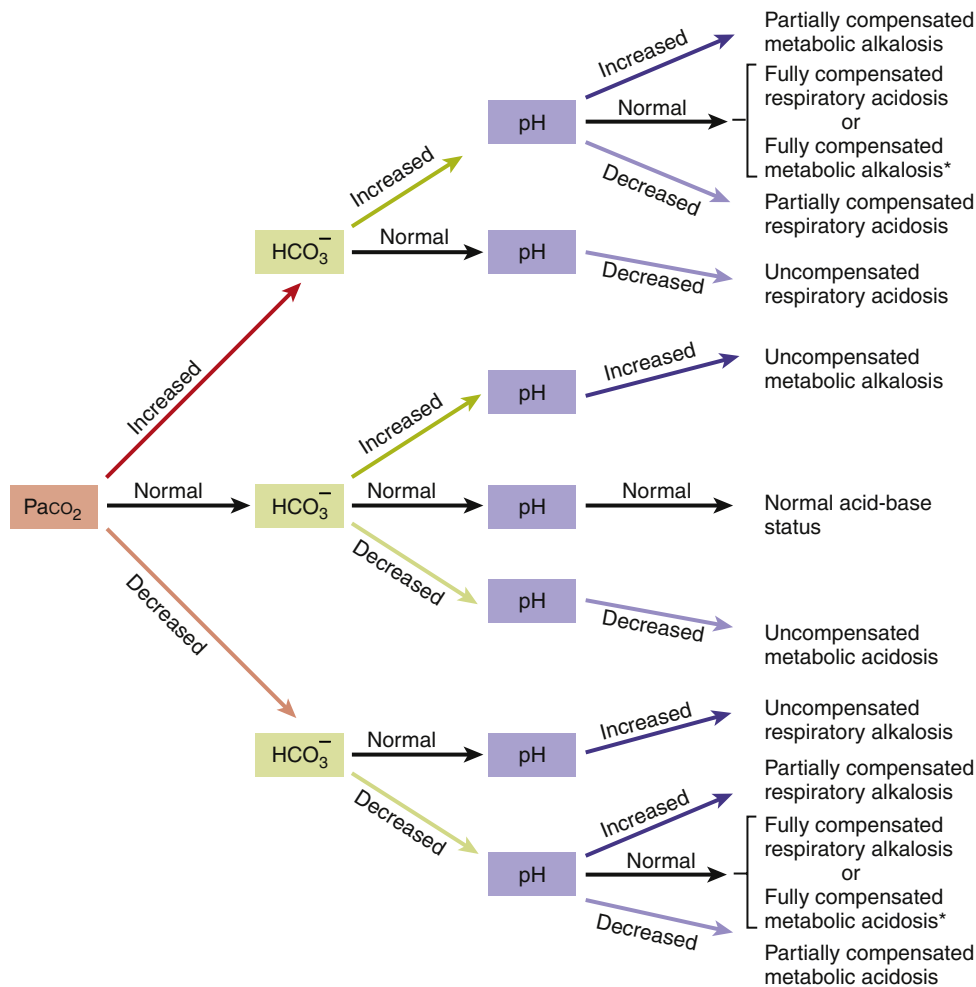

The arterial blood gases of a person who has compensated metabolic acidosis show decreased bicarbonate concentration (the primary imbalance), decreased  $\text{Paco}_2$  (compensation), and decreased or even normal pH, depending on the degree of compensation. A flowchart for interpreting laboratory measures specific to acid-base imbalances is presented in Figure 25-2. Sample laboratory values for people with metabolic acidosis are presented in Table 25-4.

**Compensated metabolic acidosis:**

$$\frac{\text{Decreased } [\text{HCO}_3^-] \text{ (primary)}}{\text{Decreased } [\text{H}_2\text{CO}_3] \text{ (compensatory)}} = \begin{matrix} \text{pH somewhat low} \\ \text{(partially compensated)} \\ \text{or pH in the normal range} \\ \text{(fully compensated)} \end{matrix}$$

**Respiratory Acidosis**

**Etiology.** Respiratory acidosis is a condition that tends to cause an excess of carbonic acid.<sup>8</sup> This condition is aptly named because

\*To differentiate between possible fully compensated imbalances with the pH in the normal range, look at the previous laboratory values for the patient. If no previous values are available, choose the acidosis if the pH is below 7.40 and the alkalosis if the pH is above 7.40.

**FIGURE 25-2** Flowchart for interpretation of laboratory measurements specific for acid-base imbalances. Use this flowchart to determine the primary acid-base imbalance from a set of laboratory values. Begin on the left with  $\text{Paco}_2$  and follow the arrows. This flowchart does not include mixed acid-base imbalances.

carbonic acid is excreted by the lungs in the form of carbon dioxide and water during exhalation.

Respiratory acidosis is caused by factors that impair the respiratory excretion of carbonic acid. Such factors include impaired gas exchange, inadequate neuromuscular function, and impairment of respiratory control in the brainstem. Box 25-2 provides examples of factors that may cause respiratory acidosis. These factors all decrease the normal 20:1 ratio of bicarbonate ion to carbonic acid (and thus decrease the pH of the blood) by increasing the carbonic acid portion of the ratio. Chronic respiratory acidosis often develops in people

who have type B chronic obstructive pulmonary disease (COPD). If an acute respiratory infection also develops, the acidosis may worsen.<sup>3</sup> Such a condition is termed *acute-on-chronic respiratory acidosis*. The pathophysiology of COPD and other disorders that may cause respiratory acidosis is discussed in other chapters of this text.

**Clinical manifestations.** Signs and symptoms of respiratory acidosis are headache, tachycardia, cardiac dysrhythmias, and neurologic abnormalities such as blurred vision, tremors, vertigo, disorientation, lethargy, or somnolence.

Headache occurs because of dilation of blood vessels in the brain. This cerebral vasodilation increases cerebrospinal fluid pressure; papilledema may result. Neurologic manifestations usually are more prominent in patients with respiratory acidosis than in those with metabolic acidosis because carbonic acid (in the form of carbon dioxide and water) crosses the blood-brain barrier relatively easily.<sup>11</sup> The neurologic manifestations are due to the decreased pH of the cerebrospinal fluid and interstitial fluid in the brain. This decreased interstitial fluid pH causes decreased intracellular pH, with resulting cellular dysfunction. Cardiac dysrhythmias in patients with respiratory acidosis occur because of decreased pH inside myocardial cells.<sup>8</sup> Severe respiratory acidosis causes peripheral vasodilation and hypotension may result, especially if cardiac dysrhythmias also are present.

Arterial blood gases in patients with respiratory acidosis show  $\text{Paco}_2$  above normal. If respiratory acidosis is uncompensated, the pH is below normal because the usual 20:1 ratio is decreased.<sup>1</sup>

**Uncompensated respiratory acidosis:**

$$\frac{\text{Unchanged } [\text{HCO}_3^-]}{\text{Increased } [\text{H}_2\text{CO}_3]} = \text{pH low}$$

**Compensatory response.** The compensatory response to respiratory acidosis is increased renal excretion of metabolic acid. This mechanism requires several days to be effective. Although the kidneys cannot excrete carbonic acid, their ability to excrete more metabolic acid changes the ratio of bicarbonate ions to carbonic acid in a favorable direction so that the pH moves toward normal. As the kidneys excrete more metabolic acid, the bicarbonate concentration increases because fewer bicarbonate ions are used for buffering. Because carbonic acid concentration already is increased, the compensatory

**TABLE 25-4 SAMPLE LABORATORY VALUES FOR PEOPLE WITH ACID-BASE IMBALANCES**

LABORATORY VALUE FOR IMBALANCE	EXPLANATION
<b>Partially Compensated Metabolic Acidosis (Diabetic Ketoacidosis)</b>	
$\text{Paco}_2$ 30 mm Hg	Decreased because of compensatory hyperventilation
$\text{HCO}_3^-$ 12 mEq/L	Decreased because of buffering of ketoacids
pH 7.22	Decreased because of excess metabolic acids; would be even lower without respiratory compensation
<b>Uncompensated Respiratory Acidosis (Acute Asthma Episode)</b>	
$\text{Paco}_2$ 55 mm Hg	Increased because of impaired gas exchange
$\text{HCO}_3^-$ 24 mEq/L	Normal; renal compensation has not yet occurred in this acute condition
pH 7.26	Decreased because of excess carbonic acid
<b>Fully Compensated Respiratory Acidosis (Type B COPD)</b>	
$\text{Paco}_2$ 60 mm Hg	Increased because of impaired gas exchange
$\text{HCO}_3^-$ 36 mEq/L	Increased because of renal compensation in this chronic condition
pH 7.35	Normal because of renal compensation, but below 7.4
<b>Uncompensated Metabolic Alkalosis (Repeated Emesis and ECV Depletion)</b>	
$\text{Paco}_2$ 42 mm Hg	Normal, but increasing because of compensatory hypoventilation
$\text{HCO}_3^-$ 36 mEq/L	Increased because of loss of $\text{H}^+$ from emesis and renal retention of $\text{HCO}_3^-$ from ECV depletion
pH 7.52	Increased because of metabolic acid deficit
<b>Uncompensated Respiratory Alkalosis (Hypoxemia from Pulmonary Embolism)</b>	
$\text{Paco}_2$ 28 mm Hg	Decreased because of hyperventilation caused by chemoreceptor response to decreased $\text{Pao}_2$
$\text{HCO}_3^-$ 24 mEq/L	Normal; renal compensation has not yet occurred in this acute condition
pH 7.52	Increased because of carbonic acid deficit

ECV, Extracellular fluid volume.

Respiratory muscle fatigue

**Impaired Respiratory Control (Brainstem)**

Respiratory depressant drugs (opioids, barbiturates)

### BOX 25-3 COMMON CAUSES OF METABOLIC ALKALOSIS

#### Increase in Base (Bicarbonate)

Excessive intake of bicarbonate or bicarbonate precursors (acetate, citrate, lactate)

Massive transfusion with citrated blood

Mild or moderate extracellular fluid volume deficit

#### Decrease in Metabolic Acid

Emesis

Gastric suction

Mild or moderate extracellular fluid volume deficit

Hyperaldosteronism

Hypokalemia

increase in bicarbonate concentration tends to normalize the ratio of  $\text{HCO}_3^-$  to  $\text{H}_2\text{CO}_3$ . The arterial blood gases of a person who has compensated respiratory acidosis show increased  $\text{Paco}_2$  (the primary imbalance), increased bicarbonate concentration (compensation), and decreased or even normal pH, depending on the degree of compensation. Table 25-4 presents sample laboratory values for people with respiratory acidosis.

#### Compensated respiratory acidosis:

$$\frac{\text{Increased } [\text{HCO}_3^-] \text{ (compensatory)}}{\text{Increased } [\text{H}_2\text{CO}_3] \text{ (primary)}} = \begin{array}{l} \text{pH somewhat low} \\ \text{(partially compensated)} \\ \text{or pH in the normal range} \\ \text{(fully compensated)} \end{array}$$

### Metabolic Alkalosis

**Etiology.** Metabolic alkalosis is a condition that tends to cause a relative deficit of any acid except carbonic acid.<sup>8</sup> Metabolic alkalosis may be caused by an increase in base (bicarbonate), by a decrease in acid, or by a combination of the two. Bicarbonate may be ingested in antacids such as baking soda and over-the-counter bicarbonate products (e.g., effervescent antacids). With overuse of these agents, enough bicarbonate is absorbed from the gastrointestinal tract to increase the blood bicarbonate concentration, thus increasing the pH.<sup>12</sup>

In addition to a gain in bicarbonate, metabolic alkalosis also may be caused by a decrease in acid. The stomach is a major reservoir of acid. Emesis and gastric suction remove acid from the body and create a relative excess of base; this situation is, by definition, metabolic alkalosis.<sup>13</sup> Increased renal excretion of acid with retention of bicarbonate occurs in extracellular fluid volume deficit. Metabolic alkalosis caused by mild or moderate extracellular fluid volume deficit often is called *contraction alkalosis* and is common during diuretic therapy.<sup>14</sup> (Severe extracellular fluid volume deficit is associated with tissue anoxia, circulatory shock, and metabolic acidosis.) Hypokalemia causes metabolic alkalosis by shifting hydrogen ions into cells and increasing renal excretion of acid.<sup>15</sup>

Causes of metabolic alkalosis are summarized in Box 25-3. The pathophysiology of the disorders that may cause metabolic alkalosis is discussed in other chapters of this text.

**Clinical manifestations.** Signs and symptoms in patients who have metabolic alkalosis may arise from the extracellular fluid volume depletion that caused the alkalosis. Thus postural hypotension may be present. Hypokalemia frequently coexists with metabolic alkalosis.<sup>15</sup> As described previously, hypokalemia may cause metabolic alkalosis. In addition, metabolic alkalosis that arises from another cause frequently

induces hypokalemia by shifting potassium ions into cells. Regardless of whether the hypokalemia preceded or followed the metabolic alkalosis, the bilateral muscle weakness of hypokalemia frequently is evident in individuals who have metabolic alkalosis.

In people who experience signs and symptoms from the metabolic alkalosis itself, the initial manifestations are those of increased neuromuscular excitability. Fingers and toes may tingle; signs of tetany may progress to seizures.<sup>11</sup> Increased interstitial pH causes increased excitability of nerve cell membranes. In addition, alkalosis causes more ionized calcium to bind to albumin, thus causing an ionized hypocalcemia that contributes to increased neuromuscular excitability. People who develop metabolic alkalosis may become quite belligerent. With severe metabolic alkalosis, initial excitation may change to central nervous system depression. Confusion, lethargy, and coma may ensue from dysfunction of brain cells. Death usually occurs when the pH is around 7.8.<sup>16</sup> The plasma bicarbonate concentration is elevated in people who have metabolic alkalosis.

#### Uncompensated metabolic alkalosis:

$$\frac{\text{Increased } [\text{HCO}_3^-]}{\text{Unchanged } [\text{H}_2\text{CO}_3]} = \text{pH high}$$

**Compensatory response.** The compensatory response to metabolic alkalosis is hypoventilation.<sup>5</sup> This shallow breathing retains carbonic acid within the body, thus increasing the lower portion of the bicarbonate ion to carbonic acid ratio. Because the upper portion of the ratio has been increased by the elevated bicarbonate concentration of metabolic alkalosis, the respiratory compensation tends to move the pH toward normal. However, respiratory compensation for metabolic alkalosis usually is incomplete. The need for oxygen drives ventilation, even though the increased pH tends to depress it. Thus the arterial blood gases of a person who has compensated metabolic alkalosis usually show increased bicarbonate concentration (the primary imbalance), increased  $\text{Paco}_2$  (compensation), and increased pH. Table 25-4 presents sample laboratory values for people with metabolic alkalosis.

#### Compensated metabolic alkalosis:

$$\frac{\text{Increased } [\text{HCO}_3^-] \text{ (primary)}}{\text{Increased } [\text{H}_2\text{CO}_3] \text{ (compensatory)}} = \begin{array}{l} \text{pH somewhat high} \\ \text{(partially compensated)} \end{array}$$

### Respiratory Alkalosis

**Etiology.** Respiratory alkalosis is a condition that tends to cause a carbonic acid deficit.<sup>8</sup> With a deficit of carbonic acid, the blood is relatively too alkaline.

Respiratory alkalosis is caused by hyperventilation.<sup>4</sup> Carbonic acid is excreted during exhalation; when respirations are excessively rapid and deep (hyperventilation), too much carbonic acid is excreted. The resulting deficit of carbonic acid is respiratory alkalosis. For example, in gram-negative sepsis, respiratory neurons in the brainstem often are stimulated abnormally, causing hyperventilation. Hypoxemia, acute pain, and psychological distress are important clinical causes of hyperventilation that leads to respiratory alkalosis. Other causes of hyperventilation (and thus of respiratory alkalosis) are listed in Box 25-4.

**Clinical manifestations.** Clinical manifestations of respiratory alkalosis arise from increased neuromuscular excitability. Paresthesias (numbness and tingling) often occur in the fingers and around the mouth; carpal and pedal spasms may occur. Increased extracellular pH has a direct effect of increasing membrane excitability in both central and peripheral neurons. In addition, increased pH of

### BOX 25-4 COMMON CAUSES OF RESPIRATORY ALKALOSIS (HYPERVENTILATION)

Hypoxemia  
 Acute pain  
 Anxiety, psychological distress  
 Prolonged sobbing  
 Alcohol withdrawal  
 Stimulation of the brainstem (salicylate overdose, meningitis, head injury, gram-negative sepsis)

the cerebrospinal fluid and cerebral interstitial fluid alters brain cell function, causing excitation and/or confusion in some people.<sup>11</sup> Respiratory alkalosis causes cerebral vasoconstriction, which reduces blood flow in the brain.<sup>17</sup> The alkalosis also decreases the availability of ionized calcium, which contributes to increased neuromuscular excitability.

The increased excretion of carbonic acid in people with respiratory alkalosis causes the  $P_{aCO_2}$  to be abnormally low. If the imbalance is uncompensated, the pH is abnormally high.

#### Uncompensated respiratory alkalosis:

$$\frac{\text{Unchanged } [HCO_3^-]}{\text{Decreased } [H_2CO_3]} = \text{pH high}$$

**Compensatory response.** The compensatory response to respiratory alkalosis is decreased renal excretion of metabolic acid.<sup>7</sup> As metabolic acids accumulate in the blood, the bicarbonate ion concentration decreases because bicarbonate ions are used for buffering. Because the carbonic acid concentration already is decreased, renal compensation for respiratory alkalosis tends to return the ratio of bicarbonate ions to carbonic acid, and thus the pH, toward normal. Renal compensatory mechanisms take several days to be fully effective. Many of the causes of respiratory alkalosis, such as acute hypoxemia, pain, and psychological distress, are short-lived; for that reason, they may not be compensated renally. Arterial blood gases of a person who has compensated respiratory alkalosis show decreased  $P_{aCO_2}$  (the primary imbalance), decreased bicarbonate concentration (compensation), and increased or (rarely) normal pH, depending on the degree of compensation. Table 25-4 presents sample laboratory values for people with respiratory alkalosis.

#### Compensated respiratory alkalosis:

$$\frac{\text{Decreased } [HCO_3^-] \text{ (compensatory)}}{\text{Decreased } [H_2CO_3] \text{ (primary)}} = \begin{array}{l} \text{pH somewhat high} \\ \text{(partially compensated)} \\ \text{or pH in the normal range} \\ \text{(fully compensated)} \end{array}$$

### Mixed Acid-Base Imbalances

In most people, only one of the four primary imbalances discussed in this chapter arises at a time. If the imbalance persists, a compensatory

imbalance arises as well. This situation was discussed previously in this chapter. Occasionally, however, two primary imbalances arise in the same person. This latter situation is termed a *mixed acid-base imbalance*.<sup>18</sup> For example, a patient who has bacterial pneumonia may develop respiratory acidosis. If severe *Clostridium difficile*-associated diarrhea develops during antibiotic therapy for the pneumonia, a concurrent metabolic acidosis may arise. In this mixed imbalance, the pH is likely to be very low because the two types of primary acidosis impair the effectiveness of the usual compensatory mechanisms. Specifically, the usual compensatory mechanism for metabolic acidosis is hyperventilation, which causes increased excretion of carbonic acid from the body. With bacterial pneumonia, however, the effectiveness of alveolar ventilation already is impaired and carbonic acid is being retained in the blood. Analogously, patients who have both types of primary alkalosis often have a very high pH because their usual compensatory mechanisms are impeded by the concurrent acid-base disorders.

Mixed acid-base disorders may also occur with a nearly normal pH if a primary acidosis and a primary alkalosis are involved. An example of this type of mixed disorder is a head-injured patient whose treatment includes hyperventilation by mechanical ventilation to reduce intracranial pressure (respiratory alkalosis) but who at the same time has a metabolic acidosis from oliguric acute kidney injury. In this situation, the  $P_{aCO_2}$  is decreased (respiratory alkalosis), the plasma bicarbonate concentration is decreased (metabolic acidosis), and the pH depends on the relative severity of the two imbalances.

#### KEY POINTS

- Acidosis is a condition that tends to cause a relative excess of acid. Alkalosis is a condition that tends to cause a relative excess of base (bicarbonate).
- Metabolic acidosis is characterized by pH below 7.40 and abnormally low  $HCO_3^-$  concentration. It is caused by processes that lead to metabolic acid accumulation (e.g., lactic acidosis) or loss of  $HCO_3^-$  (e.g., diarrhea). Compensatory hyperventilation decreases the  $P_{aCO_2}$ .
- Metabolic alkalosis is characterized by pH above 7.40 and abnormally high  $HCO_3^-$  concentration. It is caused by processes that lead to metabolic acid loss (e.g., vomiting) or gain of  $HCO_3^-$  (e.g., bicarbonate antacids). Compensatory hypoventilation increases the  $P_{aCO_2}$ .
- Respiratory acidosis is characterized by pH below 7.40 and abnormally high  $P_{aCO_2}$ . It is caused by processes that lead to hypoventilation by impairing gas exchange (e.g., lung diseases), neuromuscular function of the chest (e.g., hypokalemic muscle paralysis), or respiratory control mechanisms in the brainstem (e.g., opioid overdose). Compensatory excretion of  $H^+$  and retention of  $HCO_3^-$  by the kidneys increase the  $HCO_3^-$  concentration.
- Respiratory alkalosis is characterized by pH above 7.40 and abnormally low  $P_{aCO_2}$ . It is caused by processes that lead to hyperventilation (e.g., hypoxemia, pain, anxiety). Compensatory retention of  $H^+$  and excretion of  $HCO_3^-$  by the kidneys decrease the  $HCO_3^-$  concentration.
- Mixed acid-base disorders occur when two primary acid-base disorders are present independently. They may arise from simultaneous dysfunction of the respiratory system and kidneys. Depending on the combination of disorders, the pH may be nearly normal or grossly abnormal.

## SUMMARY

Acid-base homeostasis involves the interplay of buffers, the respiratory system, and renal mechanisms. Metabolic acids are produced continually by cellular metabolism. These metabolic acids enter the blood, where they are buffered, and eventually are excreted by the kidneys. In healthy people, the kidneys adjust the rate of excretion of metabolic acids to meet the demands of the acid load being produced. The concentration of bicarbonate ions in the blood indicates the effectiveness of renal excretion of metabolic acids. Cellular metabolism also produces carbonic acid (carbon dioxide and water) that is excreted by the lungs. In healthy people, changes in the respiratory rate and depth adjust the rate of excretion of carbonic acid appropriately. The  $P_{aCO_2}$  indicates the effectiveness of respiratory excretion of carbonic acid.

If one of the two acid excretion mechanisms becomes dysfunctional or overwhelmed, the other mechanism can produce a compensatory response that will help normalize the pH of the extracellular fluid, even though it will not correct the acid-base imbalance. Thus the kidneys adjust their excretion of metabolic acids when respiratory excretion of carbonic acid is altered abnormally. Similarly, the respiratory system adjusts the rate of excretion of carbonic acid if renal excretion of metabolic acids is impaired or overwhelmed. The pH of the blood at any time is the net result of the operation of these regulatory and compensatory mechanisms.

 PEDIATRIC CONSIDERATIONS
**Acid-Base Imbalance**

- Neonates often have mild metabolic acidosis. Infants younger than 1 month have a reduced ability to excrete a large acid load; their kidneys are less able to reabsorb bicarbonate, they produce less ammonia, and urinary buffers are limited in quantity. These factors increase the risk of metabolic acidosis from acid accumulation.
- Adolescents with eating disorders may develop metabolic alkalosis from repeated emesis and hypokalemia or metabolic acidosis from starvation and laxative-induced chronic diarrhea.

Primary acid-base imbalances arise when the normal regulatory mechanisms for acid-base homeostasis become impaired or are overwhelmed by a large acid or alkaline load. Pediatric and geriatric considerations are summarized in the boxes below. Primary metabolic acidosis arises when the kidneys are unable to excrete enough metabolic acid, or bicarbonate is lost from the body. The compensatory response to metabolic acidosis is hyperventilation. Primary respiratory acidosis arises when the lungs are unable to excrete enough carbonic acid. The compensatory response to respiratory acidosis is increased renal excretion of metabolic acid.

Primary metabolic alkalosis arises when the kidneys excrete too much metabolic acid or there is a gain of bicarbonate. The compensatory response to metabolic alkalosis is hypoventilation. Primary respiratory alkalosis arises when the lungs excrete too much carbonic acid. The compensatory response to sustained respiratory alkalosis is decreased renal excretion of metabolic acid. The  $P_{aCO_2}$  reflects the respiratory component of an acid-base imbalance; the plasma bicarbonate concentration reflects the metabolic (renal) component of an acid-base imbalance.

A mixed acid-base imbalance occurs when two primary imbalances exist at the same time. The two primary imbalances may drive the pH to an extremely abnormal value or may nearly cancel each other's effect on the pH, although the  $P_{aCO_2}$  and plasma bicarbonate concentration may still be very abnormal.

## GERIATRIC CONSIDERATIONS

**Acid-Base Imbalance**

- The chemoreceptor response to increased  $P_{aCO_2}$  (hyperventilation) is delayed in older adults, which may delay their ability to correct respiratory acidosis.
- Older adults are at increased risk of respiratory depression (and thus respiratory acidosis) from barbiturates because of increased drug half-life.
- Older adults' kidneys are less able to excrete a large acid load, which increases the risk for metabolic acidosis from acid accumulation.
- Diarrhea from chronic laxative overuse may contribute to metabolic acidosis.

The kidneys are responsible for maintaining fluid and electrolyte homeostasis and ridding the body of water-soluble wastes. To accomplish these functions, the kidneys filter more than 7 L of fluid per hour, then reabsorb about 99%, producing a small amount of urine containing a high concentration of wastes.<sup>1</sup> The kidneys can alter the amount and composition of urine to keep blood volume and electrolyte composition within normal limits. In addition, the kidneys perform two important endocrine functions: production of erythropoietin, which is a regulator of red blood cell quantity, and activation of vitamin D, which is a cofactor for intestinal calcium absorption.

Most individuals have two kidneys, each containing approximately one million **nephrons**, which provide a large renal reserve. The nephron is the functional unit of the kidney, performing all filtration, reabsorption, and secretory functions. Removal of 50% of a person's nephrons, as occurs with kidney donation, results in no significant impairment of renal function, although renal reserve is reduced.<sup>2,3</sup> Serious renal impairment generally does not occur until between 75% and 90% of the total nephrons have been damaged. Thus, clinical findings may not be evident until late in the course of chronic kidney disease. A number of laboratory and diagnostic tests are used to assess renal structure and function and to identify disease processes. These are briefly described at the end of this chapter. Kidney diseases, renal failure, and abnormalities of the bladder are discussed in Chapters 27, 28, and 29, respectively. A discussion of fluid and electrolyte imbalances and acid-base disturbances can be found in Chapters 24 and 25, respectively. The essentials of kidney structure and nephron function are presented in this chapter.

## RENAL ANATOMY

The urinary system consists of the kidneys, ureters, urinary bladder, and urethra (Figure 26-1). The kidneys are located in the **retroperitoneal** space in the posterior abdomen. One kidney is on each side of the vertebral column between the level of the twelfth thoracic and third lumbar vertebrae. The costovertebral angle (CVA), the point at which the bottom of the rib cage meets the spine, is commonly used as an external landmark for finding kidney position during physical examination.<sup>4</sup> The right kidney is located beneath the liver and is placed slightly lower than the left kidney.

The kidneys are protected and surrounded by strong back and flank muscles, fascia, and fat. The kidneys are somewhat mobile and can be injured by high-impact activities, such as bouncing along on horseback or on a mountain bike, or by direct trauma, as might occur from falls or blunt trauma. Kidney hemorrhage results in bleeding into the retroperitoneal space but not into the peritoneal cavity.

The kidneys drain urine into the ureters by gravity flow and the ureters provide peristaltic action to move urine along to the bladder where it is stored. The two principal parts of the bladder are the body and the neck. The body stores urine and is made up of smooth muscle known as detrusor muscle. Detrusor muscle extends in all directions throughout the bladder and contracts as a unit in response to initiation of action potentials. The urinary bladder collects 300 to 500 ml before stretch receptors signal a need for bladder emptying. Urine is drained from the bladder by the urethra when the internal and external sphincters are relaxed. Innervation and control of bladder function are discussed in detail in Chapter 29.

An adult kidney weighs approximately 115 to 170 g; is 11 cm long, 6 cm wide, and 3 cm thick; and is shaped like a red kidney bean, with the concave portion, termed the **hilum**, facing the vertebral column.<sup>5</sup> A thin, fibrous capsule covers each kidney and encloses blood vessels, lymphatic vessels, and nerve fibers, including pain receptors. Lymphatic vessels, blood vessels, and nerves enter and exit the kidney through the hilum.

**FIGURE 26-1** Structure of the urinary tract. The kidneys are located in the retroperitoneal space in the posterior abdominal cavity, in contact with the diaphragm and covered on the upper portions by ribs.

## Renal Parenchyma

On cross-section, the kidney is seen to contain three principal areas: the pelvis, the medulla, and the cortex (Figure 26-2). The renal pelvis is a large collecting area for the urine that drains from the many collecting ducts of the nephrons. The minor (smaller) calices collect urine as it drains from the papilla of the renal pyramids. The normal kidney has 8 to 18 minor calices and 2 to 3 major calices.<sup>1</sup> The major calices are large collecting spaces located between the minor calices and the upper part of the ureter.

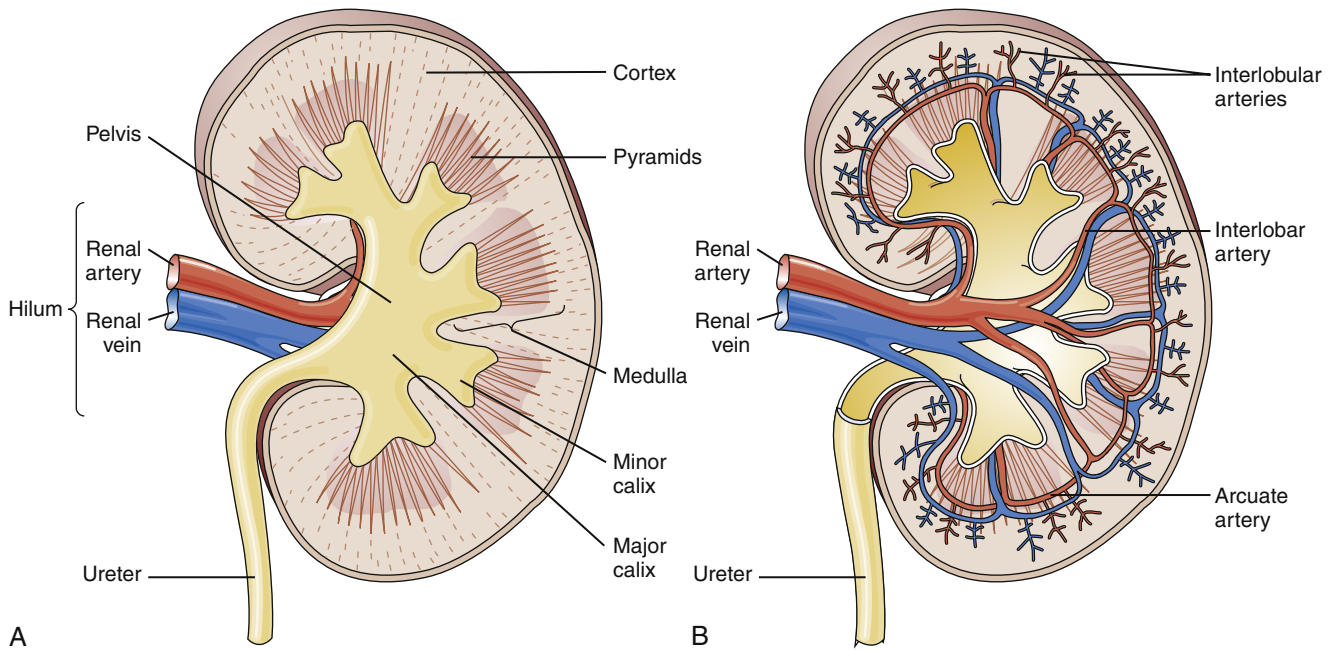

The medulla contains 8 to 18 renal pyramids, the bases of which are adjacent to the outer cortex, whereas the apices open into the minor calices. The pyramids consist of collecting tubules, collecting ducts, long loops of Henle, and vasa recta. The papillae are the openings at the tips of the renal pyramids through which urine exits the collecting ducts.

The renal cortex, which is the outer rim of the kidney, is about 1 cm thick. The cortex contains all of the glomeruli as well as 85% of the nephron tubules. Fifteen percent of nephrons send their loops of Henle deep into the medulla and are called **juxtamedullary nephrons**. Columns of cortical tissue are found between the medullary pyramids and provide the passageway for the interlobar arteries.

## Renal Lymphatics and Innervation

There are two lymphatic systems in the kidney. One system is composed of vessels that are located both in the renal capsule and immediately under the capsule in the outer cortex. The other lymphatic system is composed of vessels that accompany and wrap around the arterial blood vessels. All the lymphatic vessels, as well as blood vessels and

**FIGURE 26-2** **A**, Cross-section of the kidney showing the renal pelvis, medullary pyramids, and cortex. Normal kidneys have 8 to 18 renal pyramids and a corresponding number of minor calices. The major calices drain urine into the ureter. Blood vessels, lymphatic vessels, and nerves enter and exit through the hilum. **B**, The arterial blood supply to the kidney is derived from the renal arteries, which branch from the abdominal aorta and enter the kidney through the hilum. The renal artery branches to form several interlobular arteries, which travel toward the cortex in the renal columns. The interlobular arteries branch to form the arcuate arteries, which divide further to form the interlobular arteries. Interlobular arteries branch multiple times to provide the afferent arterioles for each of the kidney's million nephrons.

nerves, exit the kidney through the hilum, and lymph drains into the paraaortic lymph nodes.

The kidneys are innervated by the sympathetic division of the autonomic nervous system. The lesser splanchnic nerves come from the renal plexuses, which are located next to the renal arteries. These nerve fibers travel with the renal arterial blood vessels and terminate in smooth muscle of the afferent and efferent arterioles, proximal and distal tubules, and the renin-secreting juxtaglomerular cells.<sup>1,5</sup> Stimulation of the sympathetic nervous system results in renal vasoconstriction and renin release. The renal capsule and all structures between the renal pelvis and urinary meatus are innervated with pain receptors (see Chapter 27).

### Renal Blood Supply

Approximately 25% of the cardiac output is delivered to the kidneys, the majority of which circulates through the cortex, while only 1% to 2% perfuses the medulla.<sup>5</sup> Total renal blood flow in both kidneys is approximately 1250 ml/min. Blood flows to the kidneys from the abdominal aorta through the renal arteries, which then divide into several interlobular arteries.<sup>5</sup> The interlobular arteries travel in the renal columns adjacent to the pyramids (see Figure 26-2). When the interlobular arteries reach the border of the medulla and the cortex, they branch into the arcuate arteries. The arcuate arteries then travel along the cortical medullary border parallel to the renal capsule. The arcuate arteries branch further to form small interlobular arteries, which penetrate the cortex and branch extensively to form the afferent arterioles. The afferent arterioles divide to form glomerular capillaries, which coalesce to form the efferent arterioles (Figure 26-3). The efferent arterioles branch again to form a second capillary bed. The peritubular capillaries wrap around the proximal and distal convoluted tubules (Figure 26-4). Some capillaries, called *vasa recta*, dip down into the medulla to surround the loops of Henle and collecting ducts. The

**FIGURE 26-3** Scanning electron micrograph showing branching of an interlobular artery into two afferent arterioles (*af*), with associated glomerular tufts and efferent arterioles (*ef*). (From Kimura K et al: Effects of atrial natriuretic peptide on renal arterioles: morphometric analysis using microvascular casts, *Am J Physiol* 259:F936, 1990. Used with permission.)

*vasa recta* have a specialized loop structure that enables them to pick up interstitial fluid without excessive removal of interstitial solutes. Solutes and water move into and out of the *vasa recta* passively such that the descending limb gains solute as it dips into the highly concentrated medulla, but then most of the solute is lost as the ascending loop makes its way back up to the cortex.

**FIGURE 26-4** The nephron tubule is covered by peritubular capillaries and vasa recta, which pick up the fluid and solutes that have been reabsorbed by the tubular epithelium and return them to the general circulation.

The capillaries of the peritubular system and the vasa recta join together and drain into interlobular venules. The veins that drain blood from the kidney run parallel to the arteries and are similarly named (Figure 26-5).

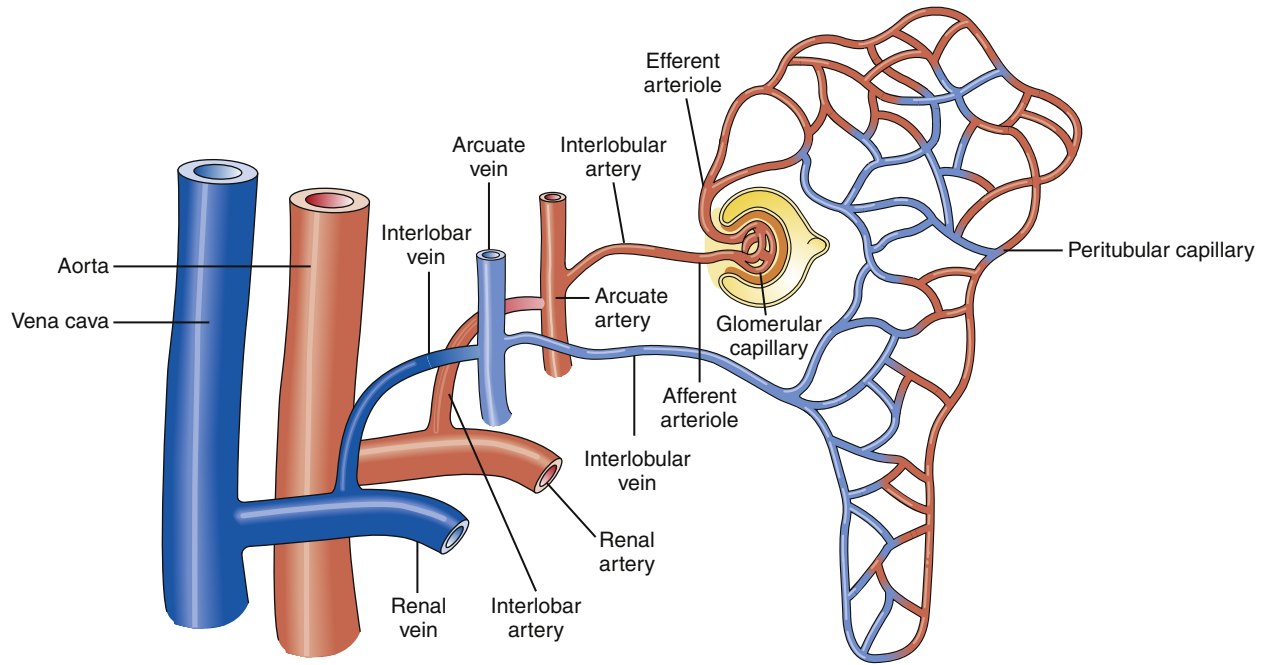

#### KEY POINTS

- The kidneys are located in the retroperitoneal space, just under the diaphragm. The right kidney is slightly lower than the left. The costovertebral angle is an external landmark useful for locating the kidneys.
- The kidney can be divided into three principal anatomic sections: the pelvis, the medulla, and the cortex. The pelvis is composed of urinary collecting structures, called *calices*. The medulla is the middle portion and contains the renal pyramids. The cortex is the outer portion and contains glomeruli and nephron tubules.
- The kidneys are supplied with lymphatics to drain excess interstitial fluid and proteins and with sympathetic neurons to regulate blood supply and renin release.
- Blood is supplied to the kidneys by the renal artery, which divides several times to form the interlobar, arcuate, and interlobular arteries. The interlobular arteries branch multiple times to form afferent arterioles for each of the millions of kidney glomeruli.
- Each nephron has its own afferent arteriole, capillary network or tuft, and efferent arteriole. Efferent arterioles continue on to form peritubular capillaries, or vasa recta, which wrap around nephron structures and eventually drain into the renal veins. The loop structure of the vasa recta enables them to pick up interstitial fluid without removing excessive solute.

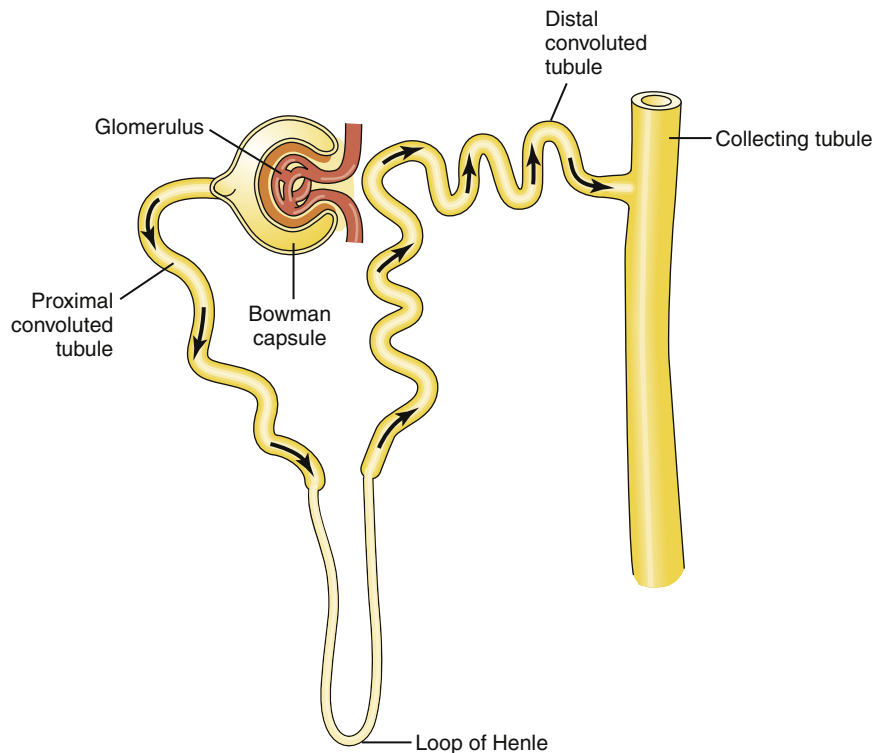

## OVERVIEW OF NEPHRON STRUCTURE AND FUNCTION

Most of the physiologic functioning of the kidney can be understood by examining the function of an individual nephron. Thus, the nephron is said to be the functional unit of the kidney. Nephrons are organized in parallel such that each must accomplish all the necessary processing before releasing urine into the collecting ducts. Complex autoregulatory mechanisms ensure that the workload is evenly distributed among the kidneys' many nephrons.

As the unit of kidney function, a nephron must accomplish three major functions: (1) filtration of water-soluble substances from the blood; (2) reabsorption of filtered nutrients, water, and electrolytes; and (3) secretion of wastes or excess substances into the filtrate. Different segments of the nephron are specialized to accomplish each of these processes. Each nephron is composed of a glomerulus, which includes the capillary tuft and Bowman capsule, and a tubule, which includes the proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting tubule (Figure 26-6). The nephron tubule is composed of a single layer of epithelial cells with an apical side facing the lumen and a basolateral side facing the interstitial space and capillaries (Figure 26-7). The epithelial cells in each segment of the tubule are specialized for certain functions (Table 26-1). Nearly all cells in the nephron have a single cilium that protrudes from the apical surface into the lumen of the tubule. These cilia are mechanoreceptors and chemoreceptors that sense flow rate and composition of the tubular filtrate. Stimulation of the cilium triggers signaling cascades within

**FIGURE 26-5** The venous vessels of the kidney parallel the arterial vessels and are similarly named.

**FIGURE 26-6** The nephron is composed of a glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting tubule. Filtration occurs at the glomerulus, and the remaining tubule segments perform reabsorption and secretion functions.

the tubule cells that regulate cell proliferation, differentiation, and apoptosis. Abnormalities in cilia signaling function have been found in patients with polycystic kidney disease, associated with mutations in genes (*polycystin*, *PKD1*, *PKD2*) that code for cilia membrane proteins (see Chapter 27).

### Glomerulus

The glomerulus is the site of fluid filtration from the blood to the nephron tubule. It is formed by a capillary tuft, which lies between the afferent and efferent arterioles, and by the surrounding epithelial cells of Bowman capsule. The outer layer of the glomerular capsule

**FIGURE 26-7** Each segment of the nephron is specialized for certain functions, which is reflected in the type of epithelial cells that compose the tubules.

**TABLE 26-1 FUNCTIONS OF THE NEPHRON SEGMENTS**

NEPHRON SEGMENT	FUNCTIONS
Glomerulus	Filters fluid from blood into Bowman capsule; prevents passage of blood cells and proteins
Proximal convoluted tubule	Transports two thirds of filtered water and electrolytes and all of the filtered bicarbonate, glucose, amino acids, and vitamins from filtrate to interstitium
Descending loop of Henle	Transports water; delivers a concentrated filtrate to ascending loop of Henle
Ascending loop of Henle	Actively transports $\text{Na}^+$ , $\text{K}^+$ , $\text{Cl}^-$ to produce a hypoosmotic filtrate and a high interstitial osmolality
Distal convoluted tubule	Transports $\text{Na}^+$ , $\text{Cl}^-$ , water, and urea; responsive to aldosterone; site of macula densa regulation of GFR; secretes $\text{H}^+$ and $\text{K}^+$
Collecting tubule	Passively transports water under influence of ADH; secretes $\text{H}^+$ and $\text{K}^+$

ADH, Antidiuretic hormone; GFR, glomerular filtration rate.

**FIGURE 26-8** Structure of the glomerulus, including the afferent and efferent arterioles, capillary tuft, and surrounding epithelial membrane of Bowman capsule. The enlargement shows the glomerular membrane to be composed of the endothelial cells of the capillary, the podocytes of Bowman capsule, and the basement membrane between them.

is called the *parietal layer* and consists of a single thickness of epithelial cells resting on a layer of basement membrane (Figure 26-8). The inner (visceral) layer of the capsule is composed of specialized epithelial cells called *podocytes*. Podocytes have foot processes (pedicels) that surround the glomerular capillary walls (Figure 26-9). Between the podocyte and the capillary endothelium is a layer of extracellular matrix called the *basement membrane* (see Figure 26-8).

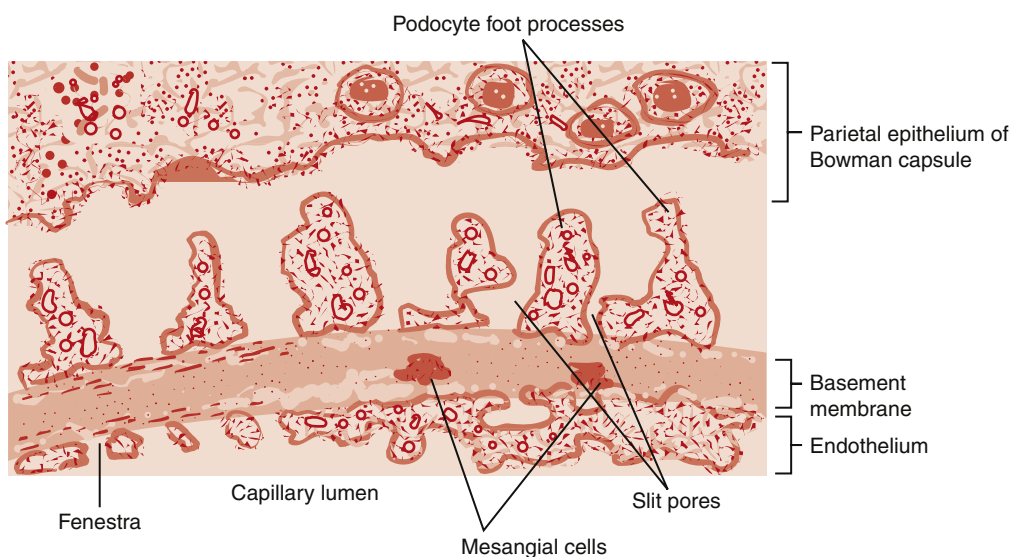

Spaces between the endothelial cells are called *fenestra*, and spaces between the podocyte foot processes are called *slit pores*. These intercellular spaces provide the surface area for glomerular filtration and make the glomeruli considerably more permeable than other capillaries in the body (Figure 26-10). The basement membrane is an important selectivity barrier of the glomerulus, preventing plasma proteins, erythrocytes, leukocytes, and platelets from passing through. Cells are too large to pass through pores, and plasma proteins are negatively charged and repelled to some extent by the basement membrane. Slit pores have a thin diaphragm of extracellular proteins

that restricts the filtration of plasma proteins that make it through the basement membrane.<sup>5</sup> *Nephrin*, podocin, NEPH1, CD2AP, and others are important proteins in the slit pores as demonstrated by the proteinuria (protein in urine) that occurs when they are genetically mutated (Figure 26-11).<sup>5</sup> Proteins and blood cells are not usually present in the urine. If the glomerulus is injured, blood cells and proteins may filter through and be found in urine. Proteinuria is an important sign of basement membrane dysfunction. Except for the lack of proteins and cells, the glomerular filtrate is very similar in composition to plasma.

Another important component of the glomerulus is the mesangium, which includes mesangial cells and mesangial matrix. Mesangial cells have a number of functions including provision of structural support for glomerular capillaries, secretion of matrix proteins, phagocytosis, and regulation of the **glomerular filtration rate (GFR)**. By contracting and relaxing, mesangial cells can alter the available surface area for filtration and affect GFR. The GFR averages about 125 ml/min.

**FIGURE 26-9** Electron micrograph showing a close-up view of podocyte foot processes of the glomerular capillary. Note the spaces between the podocyte foot processes that contribute to a highly permeable glomerular membrane. *CB*, Podocyte cell body; *PB*, primary branch; *SB*, secondary branch; *TB*, tertiary branch; *Pe*, pedicle; *FS*, filtration slits (slit pores). **FIGURE 26-10** Section of the glomerular membrane showing the large spaces between the endothelial cells and podocyte foot processes. Filtration occurs through the fenestra and slit pores. The basement membrane provides the principal selectivity barrier of the glomerulus.

### Proximal Convoluted Tubule

The Bowman capsule drains the glomerular filtrate directly into the proximal tubule segment, where two thirds of the water and electrolytes are rapidly transported from the filtrate to the interstitium for reabsorption by peritubular capillaries<sup>6</sup> (Figure 26-12). Nutrients, vitamins, and small proteins normally are reabsorbed completely in the early proximal tubule. The early proximal tubule is the site of most bicarbonate ion reabsorption, whereas chloride ion is reabsorbed in the late proximal tubule. The proximal tubule consists of cuboidal epithelium that is convoluted to provide a greater surface area for reabsorption. The epithelial cells in this segment have microvilli that form a brush border next to the filtrate and substantially increase the apical surface area. Proximal tubule cells have high adenosine triphosphate

(ATP) requirements because most reabsorption utilizes active transport mechanisms that are dependent on  $\text{Na}^+\text{-K}^+$  ion pumps in the basolateral membrane. Details of some of these transport mechanisms are discussed in subsequent sections. Water is reabsorbed passively through paracellular transport between the tubular cells and through water channels in the tubule cell membranes made of proteins called *aquaporin 1*. Reabsorption of solutes creates the osmotic force for passive water reabsorption.

### Loop of Henle

The loop of Henle is divided into the descending and ascending limbs, which differ significantly in structure and function. The descending limb receives filtrate from the proximal convoluted tubule and delivers it to the ascending limb. The thin descending limb is permeable to

**FIGURE 26-11** Diagram of the major proteins that constitute the matrix in the slit pore between renal podocyte foot processes.

water, but the thin and thick ascending part of the loop is not.<sup>6</sup> The thick ascending segment contains powerful membrane pumps that cotransport ions ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $2\text{Cl}^-$ ) from the filtrate and deposit them in the interstitial fluid surrounding the loops of Henle and collecting ducts (Figure 26-13). About 15% of nephrons have extra-long loops of Henle that dip down into the medulla (juxtamedullary nephrons). These nephrons are vital for creating concentrated urine.

The loop formation of the loop of Henle creates a countercurrent mechanism, which allows the ascending loop of Henle to create a high interstitial gradient in the medulla of the kidney (Figure 26-14). Because the ascending loop is impermeable to water, water cannot follow the  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$  ions that are pumped into the interstitium. The descending loop is permeable to water, and water will be drawn out by the extra ions that were pumped into the interstitium by the ascending limb. Thus, the filtrate that reaches the ascending limb will be more concentrated than the original filtrate. Delivery of a more concentrated filtrate to the ascending limb allows the  $\text{Na}^+-\text{K}^+-2\text{Cl}^-$  cotransporter to pump out a greater number of ions and reach an even higher interstitial gradient (Figure 26-15). This countercurrent mechanism creates a maximal osmolarity of about 600 mOsm/L at the tip of the loop of Henle as compared with the usual extracellular osmolarity of 280 to 300 mOsm/L at the cortex. Another 600 mOsm/L is contributed by the accumulation of urea particles in the interstitium.<sup>6</sup> Urea moves passively from the filtrate into the interstitium down its concentration gradient. Urea becomes concentrated in the tubule filtrate when electrolytes and water are removed in the proximal tubule and loop of Henle. An overall interstitial osmolarity is generated that begins in the cortex at about 300 mOsm/L and increases progressively to about 1200 mOsm/L at a point deep in the medulla. This high interstitial osmolarity provides a gradient for water reabsorption from the collecting ducts as they pass through the medulla on their way to the renal pelvis. The maximal interstitial gradient attained is dependent on the length of the loops of Henle. In some animals that survive in dry climates, such as the desert mouse, very long loops of Henle create a much higher interstitial osmolarity, which allows formation of extremely concentrated

urine. Fluid that is reabsorbed from collecting tubules into the medullary interstitium is picked up by the specialized capillary network called the vasa recta and returned to the venous circulation. Like other capillaries, the vasa recta passively exchange ions according to concentration gradients and passively reabsorb fluid by filtration forces. The loop structure of the vasa recta allows the capillary to passively leak accumulated solute back into the interstitium as the capillary makes its way back to the cortex from the medulla. This process minimizes the washout of the interstitial osmolality and has been called the *countercurrent exchange mechanism*.

### Distal Convoluted Tubule

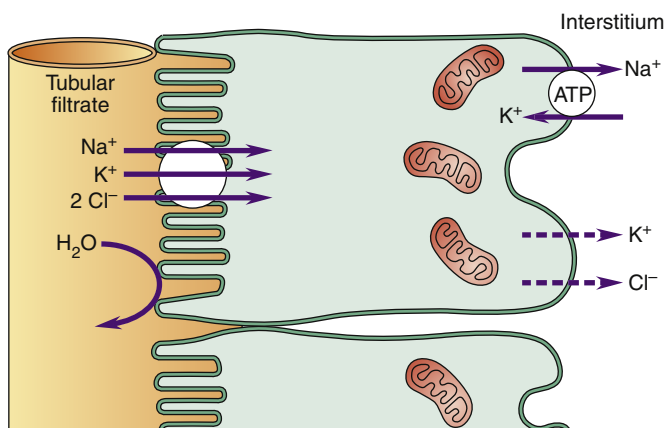

The filtrate that reaches the distal tubule is normally hypoosmotic (100 mOsm/L) in comparison with plasma (280 mOsm/L) because electrolytes have been removed by the pumps in the ascending loop of Henle.<sup>7</sup> At this point in the nephron, only 10% of the original glomerular filtrate volume remains, and further reabsorption in the distal tubule is largely under hormonal control. Aldosterone and angiotensin II (AII) stimulate the tubule cells to reabsorb sodium and water, whereas atrial natriuretic peptide (ANP) and urodilatin inhibit reabsorption.

### Collecting Duct

The distal tubules of several nephrons empty into a single collecting tubule, which then merges into progressively larger and fewer collecting ducts that run parallel to the loops of Henle. Eventually the collecting ducts form the medullary pyramids, which empty into the minor calices through the papilla. The collecting ducts travel through the high interstitial gradient of the medulla on their way to the renal pelvis. The collecting ducts have two cell types called *principle cells* (*P cells*) and *intercalated cells* (*I cells*). The majority of cells are the P type that responds to antidiuretic hormone. In the presence of antidiuretic hormone (ADH), more than 99% of the original filtrate is reabsorbed by the time it reaches the renal pelvis, creating 30 to 60 ml of concentrated urine per hour. The I cells participate in acid-base balance by regulating the secretion of acid.

**FIGURE 26-12** The proximal convoluted tubule has numerous membrane transporters that function to reabsorb filtered glucose, amino acids, water, and electrolytes. The early proximal tubule reabsorbs nearly all of the filtered bicarbonate ions, whereas the late proximal tubule reabsorbs chloride ions.

**FIGURE 26-13** The epithelial cells of the thick ascending loop of Henle possess powerful ion pumps that cotransport Na<sup>+</sup>, K<sup>+</sup>, and 2Cl<sup>-</sup> ions from the filtrate into the cell. The Na<sup>+</sup> is then pumped out of the basolateral membrane and into the interstitium. The loop of Henle ion cotransporter is responsible for creating a highly concentrated medullary interstitium.

## REGULATION OF GLOMERULAR FILTRATION

The GFR is determined by the filtration pressure in the glomeruli and by the permeable surface area of the glomerular membrane ( $K_f$ ). Filtration pressure varies considerably from the afferent end of the glomerulus to the efferent end and is difficult to measure directly. The average net filtration pressure for the capillary as a whole is about 10 mm Hg, and the permeability constant  $K_f$  is about 12.5 ml/min per mm Hg. GFR is the product of filtration pressure and  $K_f$  (10 mm Hg  $\times$  12.5 ml/min per mm Hg = 125 ml/min).<sup>1,5</sup> The GFR is determined by the physical principles of filtration across a capillary membrane (Figure 26-16). These values are not easily measured in patients, so a global assessment of GFR is used clinically to assess renal function (see Tests of Renal Structure and Function); however, understanding the principles that underlie the global clinical measurement is essential to anticipation and prevention of impaired GFR.

### Physics of Filtration

Filtration rate is affected by factors that alter hydrostatic and oncotic pressure on either side of the glomerular membrane, as shown by the following filtration equation:

$$\text{GFR} = K_f [(P_{GC} + \pi_{BC}) - (P_{BC} + \pi_{GC})]$$

**FIGURE 26-14** Mechanism of countercurrent multiplication. Ion pumps in the ascending loop of Henle create an interstitial gradient in the medulla of the kidney. The separation of solute from water in the ascending loop of Henle also produces a dilute tubular fluid allowing the excretion of excess water by making a dilute urine in the absence of antidiuretic hormone (ADH). NaCl accumulation in the interstitium contributes about half of the total osmolality. Urea particles in the interstitium contribute the other half of the particles that produce the normal interstitial gradient in the medulla. As water is removed from the collecting duct (in the presence of ADH), urea becomes more concentrated and moves passively down its gradient into the interstitium. The specialized loop structure of the vasa recta allows it to pick up interstitial water from the medulla without significant solute removal. Although solutes are acquired in the descending segment of the vasa recta, they passively diffuse back out as the ascending segment reaches the cortex. This process is called *countercurrent exchange*.

where  $P_{GC}$  is glomerular capillary hydrostatic pressure (mm Hg);  $\pi_{bc}$  is oncotic pressure in the Bowman capsule (mm Hg);  $P_{bc}$  is Bowman capsule hydrostatic pressure (mm Hg); and  $\pi_{gc}$  is oncotic pressure in the glomerular capillary (mm Hg). The following is an illustrative example resulting in a normal GFR of 125 ml/min:

$$GFR = 12.5[(60 + 0) - (18 + 32)]$$

$$GFR = 125 \text{ ml/min}$$

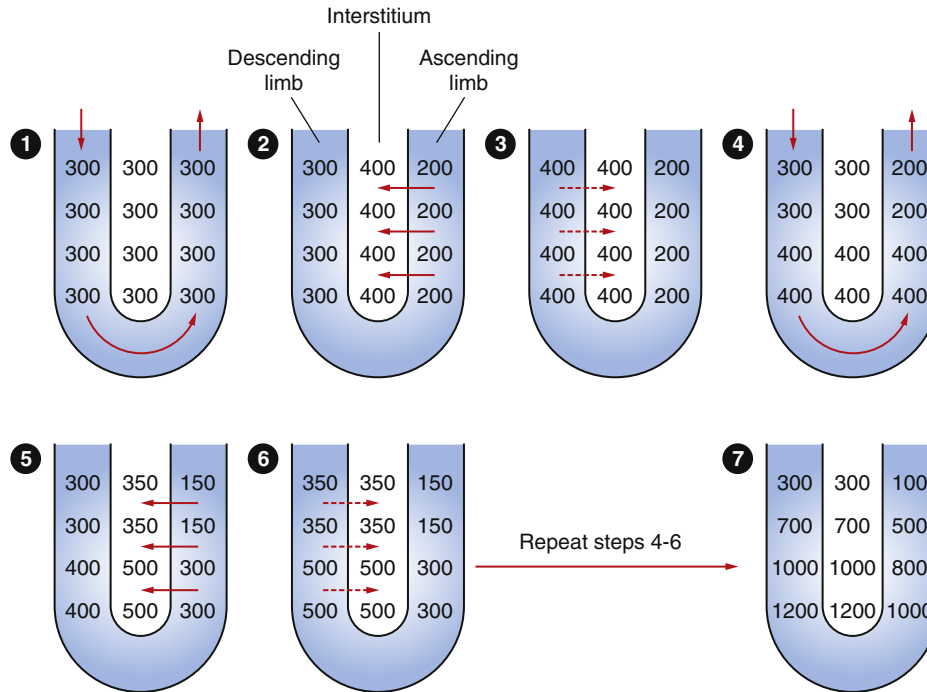

The main driving force for filtration is hydrostatic pressure in the glomerular capillaries. The glomerular capillary hydrostatic pressure exerts a force against the glomerular capillary walls. As blood circulates through the capillaries, the hydrostatic pressure pushes blood against the walls, and fluid is filtered out. The hydrostatic pressure remains fairly constant along the length of the capillary and exerts an average force of approximately 60 mm Hg.<sup>1</sup>

The glomerular capillary oncotic (colloid osmotic) pressure exists because proteins are present in the blood. Plasma proteins are negatively charged and attract positive ions, which subsequently attract water. Because ions and water are attracted to the proteins and are not pushed against the capillary wall, the glomerular capillary colloidal osmotic

pressure opposes filtration by holding water and ions in the capillaries. The glomerular oncotic pressure is lower at the afferent end and becomes progressively higher along the length of the capillary (see Figure 26-16).

The hydrostatic pressure in Bowman capsule is determined by the volume of filtrate present in the capsule. This pressure exerts a force against the walls of Bowman capsule and the glomerular capillaries and opposes filtration. The normal Bowman capsule hydrostatic pressure is about 18 mm Hg. Normally plasma proteins do not filter into Bowman capsule. If they did filter, then they would create Bowman capsule oncotic pressure. This pressure would enhance glomerular filtration because proteins attract cations and water. In a healthy kidney, this pressure is negligible.

In summary, the net filtration pressure across the glomerular membrane is approximately 18 mm Hg. The filtration pressure is higher at the afferent arteriole side of the capillary and diminishes as the blood reaches the efferent end. This occurs because the capillary oncotic pressure is lower at the afferent end. As blood passes through the capillaries, continued filtration leaves a greater concentration of proteins in the capillaries, which raises the oncotic pressure. As blood reaches the efferent arterioles, filtration may cease.

**FIGURE 26-15** Sequence of events in development of the interstitial gradient by countercurrent multiplication. The  $\text{Na}^+\text{-K}^+\text{-2Cl}^-$  cotransporters in the thick ascending loop of Henle can produce a gradient across the tubule wall of about 200 mOsm/L. The overall interstitial solute gradient is higher than these pumps could accomplish without the loop structure of the tubule. Countercurrent multiplication occurs because the descending loop is permeable to water and equilibrates with the rising interstitial solute concentration. Thus the filtrate reaching the ascending loop is increasingly concentrated with each step (1-7), allowing the ascending loop to further increase the osmolality of the interstitial fluid.

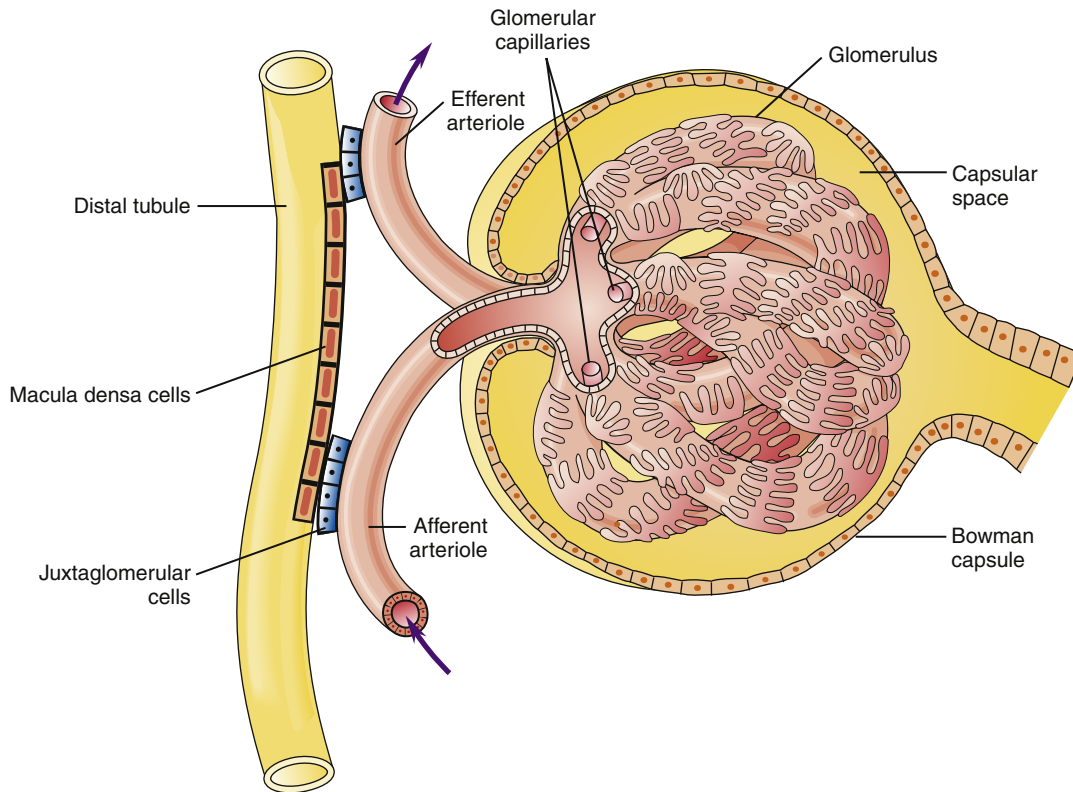

**FIGURE 26-16** Net filtration is higher at the afferent end of the glomerular capillary because the hydrostatic blood pressure in the capillary exceeds the pressure in Bowman capsule and the oncotic pressure in the capillary. Toward the efferent end of the capillary, the filtration pressure is low because the oncotic pressure of the blood is high and offsets the hydrostatic blood pressure. Capillary oncotic pressure gets progressively higher along the capillary because fluid is filtering out of the blood into Bowman capsule and leaving the proteins behind so they become more concentrated and exert a greater oncotic pressure. *FP*, Filtration pressure;  $\pi$ , oncotic pressure; *P*, hydrostatic pressure.

### Factors Affecting Filtration Pressure

One of the most important physiologic regulators of GFR is blood volume.<sup>1</sup> When blood volume increases because of fluid intake, the blood pressure rises slightly and causes glomerular hydrostatic pressure to increase. GFR increases, and the extra fluid is pushed into the filtrate to be excreted from the body. The opposite also occurs: when blood volume is decreased, capillary hydrostatic pressure falls, resulting in a lower GFR, and fluid is conserved. The glomerular capillary is protected from large swings in blood pressure by autoregulation. Autoregulation adjusts the arteriolar resistance to maintain a relatively steady rate of blood flow despite changes in perfusion pressure. Autoregulation is effective when arterial blood pressure varies between 75 and 160 mm Hg.<sup>1</sup> Autoregulation of renal blood flow is achieved in part by a stretch response in the vascular smooth muscle of the afferent arterioles. When blood pressure increases, the vascular smooth muscle cells reflexively constrict to keep blood flow at about the same rate. This mechanism is called *myogenic autoregulation*.

Other factors can affect GFR by altering the pressure within Bowman capsule or affecting plasma oncotic pressure. Obstruction in the tubules or collecting ducts can significantly elevate the pressure in Bowman capsule. According to the filtration equation, GFR would fall because filtration pressure would be reduced. Because plasma oncotic pressure is determined primarily by the concentration of plasma proteins, a low serum albumin concentration would increase GFR.

Although  $K_f$  is called a constant, it is subject to change for physiologic and pathologic reasons. Specialized mesangial cells located in the glomerulus are thought to be important regulators of  $K_f$ . These

**FIGURE 26-17** The juxtaglomerular apparatus is composed of the macula densa cells of the distal tubule, the afferent and efferent arterioles, and the renin-secreting juxtaglomerular cells. Macula densa cells sample the distal filtrate for NaCl content and send signals to the glomerulus to adjust glomerular filtration rate.

cells contract and relax in response to various stimuli and alter the surface area for filtration.<sup>8</sup> Contraction squeezes the capillary cells together and reduces GFR, whereas relaxation allows the permeable surface area to expand. Disease processes that damage the glomerular membrane also can affect permeability. Sclerotic processes reduce  $K_f$ , whereas some inflammatory injuries may increase it.

### Tubuloglomerular Feedback

Each nephron is able to regulate its own individual GFR through a process termed *tubuloglomerular feedback*. A specialized group of cells forms the regulatory structure, called the **juxtaglomerular apparatus**. The juxtaglomerular apparatus is composed of the glomerulus, the macula densa, and specialized juxtaglomerular cells, which are located around the glomerular arterioles (Figure 26-17). The macula densa cells are located near the end of the thick ascending loop of Henle, which loops up to come in contact with the glomerulus and juxtaglomerular cells.

Macula densa cells sense changes in the amount of NaCl delivered to the tubule. When glomerular filtration is increased, a higher load of NaCl is delivered to the distal tubule. The mechanism whereby macula densa cells sense GFR is not completely understood, but NaCl delivery to the macula densa cells is a critical part of the process. Macula densa cells possess the same Na-Cl-K transporters as other cells in the thick ascending limb and when NaCl delivery is high, more is transported into the cells through this transporter (Figure 26-18). The macula densa cells increase the activity of the Na-K pump in the basal membrane, which stimulates production of adenosine and ATP. Adenosine stimulates contraction of afferent arterioles and relaxation of efferent arterioles, thus decreasing filtration at the glomerulus.<sup>5</sup>

Tubuloglomerular feedback helps to distribute GFR evenly among the kidneys' 2 million nephrons.

The juxtaglomerular cells that surround the afferent arteriole are also thought to be mediators of tubuloglomerular feedback. The juxtaglomerular cells produce and release **renin**, an enzyme that converts angiotensinogen to angiotensin I (AI). Angiotensin I is then converted to angiotensin II (AII) by endothelial cells in the glomerular capillary, which possesses angiotensin-converting enzyme (ACE) activity. AII is a potent vasoconstrictor that constricts both afferent and efferent arterioles.<sup>9</sup> The signals that pass from the macula densa to the glomerulus to regulate tubuloglomerular feedback are not completely known; however, in addition to roles for adenosine and ATP, release of prostaglandins and nitric oxide has been demonstrated.<sup>10</sup> Some prostaglandins have vasodilating activities, whereas others are vasoconstrictors.

The importance of prostaglandins and AII in regulating GFR is supported by the observation that drugs that inhibit their activity interfere with tubuloglomerular feedback in some persons. For example, ACE inhibitors block AII production and may interfere with constriction of the efferent arteriole. This can be particularly detrimental to renal function in patients who require high filtration pressures, such as those with polycystic kidney disease or collecting system obstructions. Drugs that inhibit cyclooxygenase, such as aspirin and nonsteroidal antiinflammatory drugs, interfere with prostaglandin production and may precipitate excessive renovascular constriction in some patients.<sup>11</sup>

### Effects of Glucose and Amino Acids

The amount of glucose and amino acids filtered into the tubular fluid may alter GFR through the tubuloglomerular feedback mechanism.

**FIGURE 26-18** Mechanism of NaCl sensing by macula densa cells in tubuloglomerular feedback. Entry of ions through the apical Na-K-Cl transporter stimulates activity of the Na-K-ATPase pump on the basal side and stimulates production of ATP and adenosine. Receptors on vascular smooth muscle cells (VSM) of the afferent arterioles bind to ATP and adenosine and cause vasoconstriction. Renin release from the juxtaglomerular cells is also inhibited, thus reducing the amount of angiotensin II that reaches the efferent arteriole. The efferent arteriole becomes less constricted. Afferent constriction and efferent dilation reduce the filtration pressure in the glomerulus, and reduce the delivery of NaCl to the macula densa. *ADO*, Adenosine; *A<sub>1</sub>*, adenosine-1 receptor; *P2X*, purinoreceptor (ATP receptor).

Both glucose and amino acids are filtered freely through the glomerular membrane and then are reabsorbed by active transport processes in the proximal tubule. Reabsorption occurs through transporters that use sodium ion entry into the cell to actively cotransport glucose and amino acids. The greater the load of tubular glucose and amino acids, the greater the amount of sodium reabsorbed by the proximal tubule. Fewer sodium ions are transported to the macula densa cells in the distal tubule, and the macula densa perceives this as a need to increase GFR.<sup>5</sup> In addition, chronically high serum glucose concentrations, as occurs in poorly controlled diabetes mellitus, may induce excessive nitric oxide production, producing hyperfiltration, excessive GFR, and damage to the glomerulus.

### Role of Mesangial Cells

Mesangial cells are located around the glomerular capillaries and are thought to regulate the surface area available for glomerular filtration.<sup>9</sup> Contraction of the mesangial cells reduces surface area, and relaxation increases it. Mesangial cells are responsive to glomerular stretch and are stimulated to contract when more blood enters the glomerulus. This response provides a negative feedback that decreases surface area when filtration pressure is increased. In addition, mesangial cells respond to a number of chemical mediators, including AII and endothelin (peptides that favor mesangial contraction) and ANP and nitric oxide (substances that favor relaxation). Mesangial cells thus may regulate GFR by altering the filtration constant  $K_f$ .

### KEY POINTS

- GFR is determined by the permeable surface area ( $K_f$ ) and by capillary hydrostatic pressure and Bowman capsule oncotic pressure, which favor filtration, and by plasma oncotic pressure and Bowman capsule hydrostatic pressure, which oppose filtration. Normal GFR is about 125 ml/min.
- The filtration rate in an individual nephron is regulated by tubuloglomerular feedback in which macula densa cells sample the NaCl content (or other constituents) in the distal tubule and signal the juxtaglomerular apparatus to make appropriate adjustments in GFR.
- Afferent constriction and efferent dilation decrease GFR, whereas afferent dilation and efferent constriction increase GFR. Adenosine, AII, nitric oxide, and prostaglandins are important chemical mediators of arteriolar resistance.
- Excessive filtration of glucose and amino acids can result in increased GFR because their reabsorption in the proximal tubule requires cotransport of sodium ions. Fewer sodium ions are delivered to the macula densa, and GFR is increased.
- Mesangial cells respond to glomerular capillary stretch by contracting to reduce the surface area for filtration. Mesangial cells also respond to chemical signals that induce them to contract and relax, which alters GFR accordingly.

## TRANSPORT ACROSS RENAL TUBULES

Reabsorption and secretion of substances across the nephron tubule are accomplished by two routes: the *transcellular* and the *paracellular* routes. Transcellular transport uses specific transporter proteins in the membranes of the tubular epithelial cells to move substances between

**FIGURE 26-19** Summary of nutrient and electrolyte composition of the filtrate in each segment of the nephron. Two thirds of the filtrate is reabsorbed in the proximal tubule. (Adapted from Hall JE, editor: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 334.)

the tubular filtrate and the interstitial fluid. Most of these transport processes are dependent on  $\text{Na}^+$  reabsorption and made possible by the  $\text{Na}^+$ - $\text{K}^+$  pump in the basolateral membrane. Paracellular transport refers to movement of substances through the tight junctions that hold the tubular epithelial cells together. Substances using the paracellular route therefore do not traverse the cell membrane and instead move passively through the spaces between cells. *Reabsorption* is the process of transporting a substance from the filtrate into the renal capillaries and requires several transport steps. First, the substance is moved from the filtrate into the tubular cell through transporters on the apical surface of the cell; then it passes through another transporter on the basolateral side of the tubular cell and into the interstitium. From the interstitium, it moves passively by diffusion or filtration into the capillary. In general, the reabsorption of cations, especially sodium, provides an electrical gradient to pull anions across the tubule and into the interstitium. Reabsorption of ions and solutes creates an osmotic force to pull water passively across the renal epithelium. A summary of transport in the various tubule segments is shown in Figure 26-19. The details of glucose, bicarbonate,  $\text{H}^+$ , and  $\text{K}^+$  transport are described as important representative examples.

### Reabsorption of Glucose

Glucose is filtered freely across the glomerular membrane such that the tubular load (in milligrams per minute) is determined by the product of serum glucose concentration (in milligrams per milliliter) and GFR (in milliliters per minute). Normally, all of the filtered glucose is reabsorbed in the proximal tubule by a sodium-dependent cotransporter called SGLT 2 (Figure 26-20). The transport proteins have a maximal rate of transport that can be exceeded if the tubular load of glucose is too

great. The transport maximum for normal kidneys is about 375 mg/min.<sup>6</sup> A tubular load of glucose in excess of this amount results in glycosuria. In fact, some spillage of glucose begins at a much lower tubular load because of the uneven distribution of GFR to individual nephrons or differences in the number of transporters in different nephrons. Some nephrons with higher GFR or fewer transporters may exceed their transport maximum, whereas other nephrons are working below capacity. The point at which glucose begins to spill into the urine is called the *renal threshold*. In normal kidneys with a GFR of 125 ml/min, the renal threshold will be reached when serum glucose concentration approaches 180 mg/dl, but significant glycosuria will not occur until the transport maximum is reached at a serum glucose level of about 300 mg/dl. Persons with low GFR associated with renal disease may not experience spillage of glucose until the serum glucose level is much higher, and glycosuria is not a reliable indicator of serum glucose level in these individuals. For example, a patient with a GFR of 50 ml/min and a serum glucose concentration of 300 mg/dl will have a tubular glucose load of only 150 mg/min, which is well below the normal renal threshold. No glycosuria would occur despite the high serum glucose level.

### Regulation of Acid-Base Balance

The kidney tubules have an important role in maintaining the pH of the blood. In addition to excreting excess  $\text{H}^+$ , the kidneys also regulate the concentration of bicarbonate ( $\text{HCO}_3^-$ ) in the blood. The pH of the blood normally ranges between 7.35 and 7.45 and is determined by the ratio of acid ( $\text{H}_2\text{CO}_3$ ) to base ( $\text{HCO}_3^-$ ). The lungs and kidneys work together to maintain this balance. Metabolic processes create an excess of acid, which is excreted by the lungs in the form of  $\text{CO}_2$  and by the kidneys in the form of  $\text{H}^+$ . In addition,  $\text{HCO}_3^-$  is filtered freely through the glomerulus and must be efficiently reabsorbed to maintain acid-base balance. Most  $\text{HCO}_3^-$  is reabsorbed in the proximal tubule; however, the distal segment also participates in regulating  $\text{HCO}_3^-$  and  $\text{H}^+$  transport.

Reabsorption of  $\text{HCO}_3^-$  is complex because it is not directly transported across the apical membrane; rather, it is combined with  $\text{H}^+$  in the tubule to form  $\text{H}_2\text{CO}_3$ , which dissociates into  $\text{CO}_2$  and water (Figure 26-21). The  $\text{H}^+$  for this reaction is secreted into the filtrate in exchange for  $\text{Na}^+$ . Carbonic anhydrase present in the brush border of the proximal tubule cell catalyzes the reaction. Carbon dioxide is lipid soluble and diffuses passively into the tubular cell. Once inside, intracellular carbonic anhydrase catalyzes the reverse reaction to once again form  $\text{HCO}_3^-$  and  $\text{H}^+$ . The  $\text{HCO}_3^-$  is transported out through the basolateral membrane, whereas the  $\text{H}^+$  is recycled to the tubular fluid to bind with another  $\text{HCO}_3^-$ . The energy to power this reabsorptive process is provided by the  $\text{Na}^+$ - $\text{K}^+$  pump, which keeps intracellular  $\text{Na}^+$  concentration low so that the sodium gradient can continue to move  $\text{H}^+$  into the tubule lumen through the  $\text{Na}^+$ - $\text{H}^+$  exchanger.

Normally, all of the filtered  $\text{HCO}_3^-$  is reabsorbed by this mechanism to help maintain acid-base balance.<sup>12</sup> Excess  $\text{H}^+$  ions that find no  $\text{HCO}_3^-$  in the filtrate with which to bind are excreted in the urine, and urine is normally acidic. The number of  $\text{H}^+$  ions that can be excreted in urine is limited to a pH of about 4.0. However, urine buffers, including  $\text{HPO}_4^{2-}$  and  $\text{NH}_3$ , are secreted into the filtrate and bind with excess  $\text{H}^+$ , greatly increasing the ability of the kidney to excrete an acid load (see Figure 26-21). Ammonia ( $\text{NH}_3$ ) is produced by the renal epithelium via metabolism of amino acids. Ammonia binds to  $\text{H}^+$  to form ammonium ion ( $\text{NH}_4^+$ ), whereas  $\text{HPO}_4^{2-}$  binds to  $\text{H}^+$  to form  $\text{H}_2\text{PO}_4^-$ . The amino acid glutamine can also be metabolized to generate new  $\text{HCO}_3^-$  with the concurrent production of  $\text{NH}_4^+$  that must be excreted in the urine.

### Renal Compensation Process

In some cases, the kidneys are called on to compensate for an abnormality in lung function. The lungs normally regulate the amount of carbon

**FIGURE 26-20** The glucose transporter in the proximal tubule (*SGLT 2*) is dependent on sodium reabsorption from the filtrate. The  $\text{Na}^+\text{-K}^+$  pump in the basolateral membrane keeps the intracellular sodium level low and maintains a gradient for sodium and glucose reabsorption. Glucose diffuses out of the tubule cell and back into the interstitial fluid through passive carrier proteins (*GLUT 2*). *ATP*, Adenosine triphosphate.

dioxide in the blood ( $\text{Paco}_2$ ). When  $\text{Paco}_2$  is high, more carbonic acid is formed, and the blood pH becomes acidic. The kidneys compensate by excreting more  $\text{H}^+$  and by creating new  $\text{HCO}_3^-$  to enhance the buffering capacity of the blood. These  $\text{HCO}_3^-$  ions are additional to those already being reabsorbed from the filtrate and are, thus, new. First, excess circulating  $\text{CO}_2$  from respiratory acidosis diffuses into the renal cell and is converted to  $\text{HCO}_3^-$  and  $\text{H}^+$  by the enzyme carbonic anhydrase. The new  $\text{HCO}_3^-$  is sent back to the bloodstream, and the new  $\text{H}^+$  is secreted into the urine filtrate, where it binds with a renal buffer and is excreted. As mentioned previously, new  $\text{HCO}_3^-$  also can be formed by the metabolism of glutamine, and the new  $\text{HCO}_3^-$  is sent back to the bloodstream (see Figure 26-21). Gradually, the creation of new  $\text{HCO}_3^-$  in this way increases the serum  $\text{HCO}_3^-$  concentration and restores the pH toward normal. This process may take hours to days.

The kidneys are also able to compensate for respiratory alkalosis by excreting some of the filtered  $\text{HCO}_3^-$ . Alkalosis reduces the number of  $\text{H}^+$  ions available for transport into the filtrate. Some of the filtered  $\text{HCO}_3^-$  escapes the proximal tubule without being converted to  $\text{CO}_2$  and is excreted in the urine.

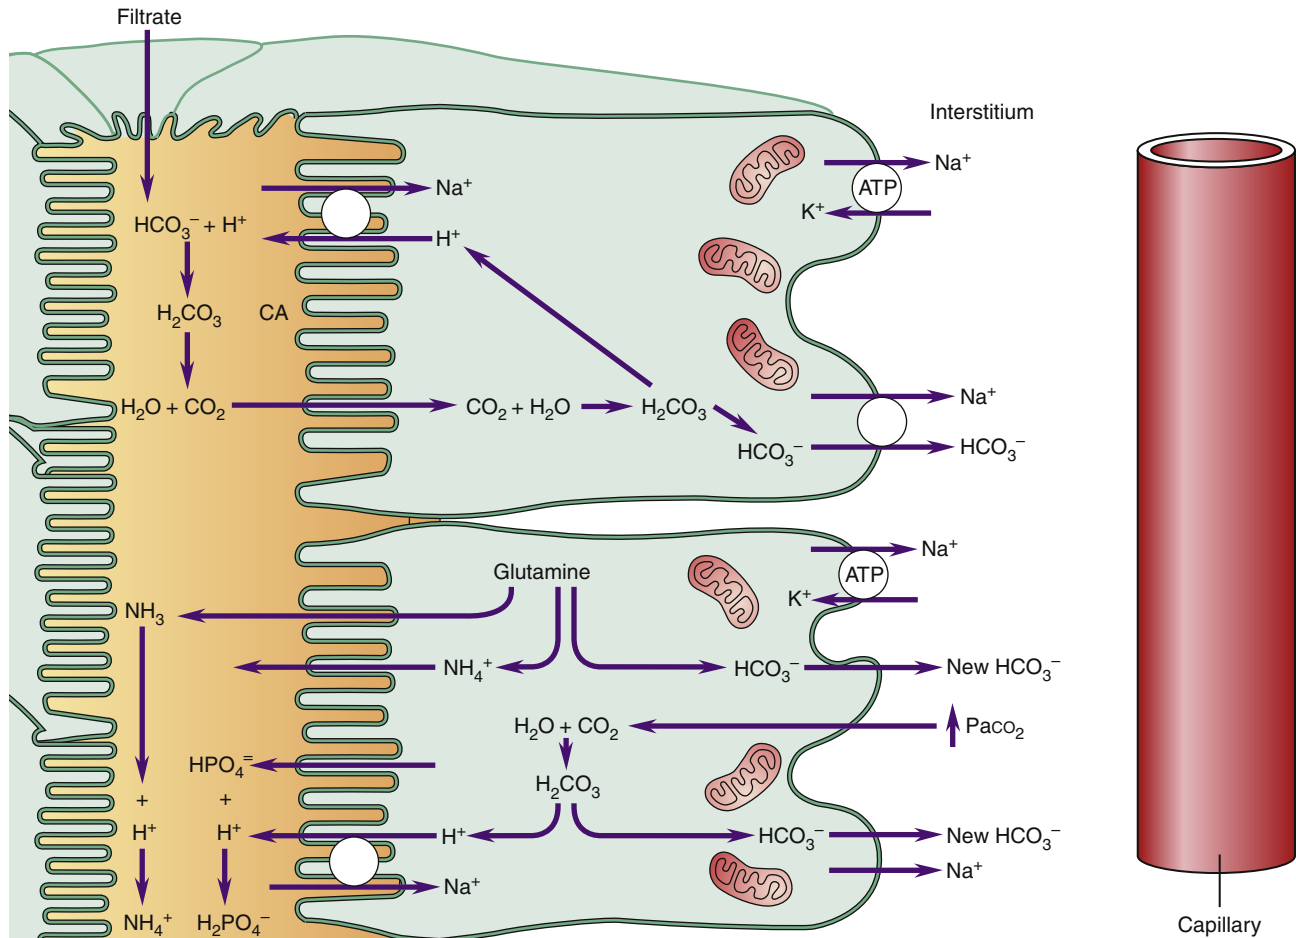

### Secretion of Potassium

There is normally a net excess of potassium from dietary sources that must be excreted by the kidneys. The primary transporter responsible for this process is the  $\text{Na}^+\text{-K}^+$  pump in the basolateral cell membrane. The  $\text{Na}^+\text{-K}^+$  pump moves  $\text{K}^+$  into the tubular cell and increases the gradient for diffusion of  $\text{K}^+$  through the apical membrane and into the filtrate (Figure 26-22). Principle cells in the distal tubule and collecting duct are the site of potassium excretion. The activity of  $\text{Na}^+\text{-K}^+$  pumps

in these segments is sensitive to aldosterone, a steroid hormone secreted by the adrenal cortex. Aldosterone increases reabsorption of  $\text{Na}^+$  and water and excretion of  $\text{K}^+$ . Potassium excretion also is affected by the activity of the  $\text{K}^+\text{-H}^+$  exchanger and by the plasma  $\text{K}^+$  concentration.

### KEY POINTS

- Reabsorption across the tubular epithelium occurs by transcellular and paracellular routes. The transcellular route utilizes transporters in the apical and basolateral membranes of tubular cells to move substances from the filtrate, through the cell, to the interstitium. The paracellular route allows passive transport of substances between the tubular cells. Renal capillaries passing through the interstitium passively take up substances through filtration and diffusion and return them to the venous circulation.
- Reabsorption of glucose is accomplished by proximal tubule cell sodium-dependent transporters. These transporters have transport maxima that can be overwhelmed by excessive tubular loads of glucose, in which case glycosuria results.
- The kidneys participate in acid-base regulation through secretion of excess  $\text{H}^+$  and reabsorption and creation of  $\text{HCO}_3^-$ . Urine buffers  $\text{HPO}_4^{2-}$  and  $\text{NH}_3$  bind excess  $\text{H}^+$  and increase the ability of the kidney to excrete an acid load.
- $\text{HCO}_3^-$  is not directly reabsorbed across the renal epithelium; it is first converted to  $\text{CO}_2$  by the enzyme carbonic anhydrase. The  $\text{H}^+$  ions needed for this reaction are provided by  $\text{Na}^+\text{-H}^+$  pumps on the apical cell membrane.
- Secretion of potassium ions is promoted by activity of the  $\text{Na}^+\text{-K}^+$  pump on the basolateral cell membrane. In the distal tubule, these pumps are regulated by aldosterone, which increases potassium excretion.

**FIGURE 26-21** Bicarbonate ion reabsorption across the renal tubule. Filtered HCO<sub>3</sub><sup>-</sup> is combined with secreted H<sup>+</sup> to form carbonic acid, which dissociates into water and carbon dioxide. Carbon dioxide is lipid soluble and diffuses into the cells, where the reverse reaction converts it back to HCO<sub>3</sub><sup>-</sup> and H<sup>+</sup>. The bicarbonate ion moves out of the basolateral membrane and returns to the bloodstream, whereas the H<sup>+</sup> is returned to the lumen to bind with another HCO<sub>3</sub><sup>-</sup> ion. Excess H<sup>+</sup> ions are excreted in the urine in combination with phosphate and ammonia buffers. The kidney is able to create new bicarbonate as needed to maintain pH balance. *ATP*, Adenosine triphosphate; *CA*, carbonic anhydrase.

## REGULATION OF BLOOD VOLUME AND OSMOLALITY

The kidneys play a vital role in maintaining normal blood volume and osmolality. As previously discussed, changes in blood volume alter the pressure in the glomerulus and affect GFR. An increase in blood volume results in a pressure diuresis, whereas a fall in blood volume reduces urine output. The kidney tubules are responsive to a number of hormonal signals that fine-tune tubular reabsorption (Table 26-2). These hormones include ADH, aldosterone, AII, ANP, urodilatin, uroguanylin, and guanylin. Antidiuretic hormone is the principal regulator of osmolality, and the others regulate extracellular volume by increasing or decreasing NaCl and water reabsorption.

### Antidiuretic Hormone

ADH (also called vasopressin) is secreted from the posterior pituitary when osmoreceptors located in the hypothalamus detect a high osmolality of the extracellular fluid. Principle cells in the collecting tubules respond to ADH by translocating water pores called *aquaporin 2* to the apical membrane (Figure 26-23). These pores make the

tubule permeable to water and allow water to be reabsorbed from the urinary filtrate. The high interstitial gradient of the medulla provides the osmotic force for water reabsorption. Recall that this gradient was formed by the action of powerful ion pumps in the thick ascending limb of the loop of Henle.

As water is reabsorbed into the medullary interstitium, it creates a high tissue pressure that pushes fluid into the vasa recta. The vasa recta return the reabsorbed water to the general circulation. The reabsorbed water dilutes the blood and reduces osmolality. Osmoreceptors in the brain detect the reduced osmolality and inhibit further production of ADH. When blood osmolality is too low, ADH secretion is completely inhibited, and the collecting tubules become impermeable to water. Water is not reabsorbed from the filtrate, and a large quantity of dilute urine is produced. Loss of water in excess of solute returns the blood osmolality toward normal.

An insufficiency of ADH secondary to pituitary damage results in the condition of *diabetes insipidus* in which large volumes of dilute urine are excreted, leading to severe fluid imbalances. A similar problem occurs when the collecting tubules are unresponsive to ADH. This condition is called *nephrogenic diabetes insipidus* and usually

**FIGURE 26-22** Tubular secretion of potassium ion. Increased serum potassium concentration and aldosterone increase the activity of the  $\text{Na}^+\text{-K}^+$  pump and enhance  $\text{K}^+$  secretion into the filtrate. The  $\text{H}^+\text{-K}^+$  exchanger also regulates the secretion of  $\text{K}^+$  ions. *ATP*, Adenosine triphosphate.

**TABLE 26-2 HORMONES THAT REGULATE  $\text{NaCl}$  AND WATER REABSORPTION**

HORMONE	MAJOR STIMULUS	NEPHRON SITE OF ACTION	EFFECTS ON TRANSPORT
Angiotensin II	$\uparrow$ Renin	PT, TAL, DT/CD	$\uparrow$ $\text{NaCl}$ and $\text{H}_2\text{O}$ reabsorption
Aldosterone	$\uparrow$ Angiotensin II, $\uparrow$ $[\text{K}^+]_p$	TAL, DT/CD	$\uparrow$ $\text{NaCl}$ and $\text{H}_2\text{O}$ reabsorption*
ANP, BNP, urodilatin	$\uparrow$ ECFV	CD	$\downarrow$ $\text{H}_2\text{O}$ and $\text{NaCl}$ reabsorption
Uroguanylin, guanylin	Oral ingestion of $\text{NaCl}$	PT, CD	$\downarrow$ $\text{H}_2\text{O}$ and $\text{NaCl}$ reabsorption
Sympathetic nerves	$\downarrow$ ECFV	PT, TAL, DT/CD	$\uparrow$ $\text{NaCl}$ and $\text{H}_2\text{O}$ reabsorption*
Dopamine	$\uparrow$ ECFV	PT	$\downarrow$ $\text{H}_2\text{O}$ and $\text{NaCl}$ reabsorption
ADH	$\uparrow$ $P_{\text{osm}}$ , $\downarrow$ ECFV	DT/CD	$\uparrow$ $\text{H}_2\text{O}$ reabsorption*

Data from Koeppen B, Stanton B: *Berne & Levy physiology*, ed 6, Philadelphia, 2010, Mosby, p. 610.

results from genetic defects in either the ADH receptor ( $\text{V}_2$ ) or the aquaporin 2 genes.<sup>5</sup>

### Aldosterone, Angiotensin II, Natriuretic Peptides, Urodilatin, Uroguanylin, and Guanylin

Aldosterone, AII, ANP, urodilatin, uroguanylin, and guanylin alter blood volume without affecting its concentration. Aldosterone and AII increase reabsorption of  $\text{Na}^+$ , which provides a gradient for water reabsorption. Because salt and water are reabsorbed together, the osmolality of the reabsorbed fluid is isosmotic with plasma.

AII and aldosterone are produced when the juxtaglomerular cells in the kidney are stimulated to release renin. Renin is released in response to (1) decreased blood flow to the kidney, (2) reduced serum sodium levels, and (3) activation of sympathetic nerves to the juxtaglomerular cells.<sup>5</sup> Renin begins a cascade of reactions that result in the production of AII and aldosterone. When AII and aldosterone restore blood volume and blood pressure to normal, the

stimuli for renin release are removed and the concentrations of AII and aldosterone fall.

ANP is released from atrial cells in the heart when the chamber is overstretched by excessive blood volume. ANP inhibits all of the actions of AII and results in loss of sodium and water in the urine. Thus, ANP reduces extracellular volume, but the fluid losses are isosmotic with plasma, and blood osmolality remains unchanged. Urodilatin is a peptide that is secreted by distal and collecting tubule cells in response to increased circulating volume.<sup>6</sup> It is very similar in structure and function to ANP and inhibits  $\text{Na}^+$  and water reabsorption by the collecting duct.

Uroguanylin and guanylin are peptide hormones produced by neuroendocrine cells in the intestine in response to  $\text{NaCl}$  ingestion. The targets for these hormones are guanylyl cyclase receptors located on cells in the proximal tubule and collecting duct. Binding to these receptors generates cGMP, which inhibits  $\text{Na}^+$ ,  $\text{Cl}^-$ , and water reabsorption and produces an effect similar to that of natriuretic peptides and urodilatin.

**FIGURE 26-23** Antidiuretic hormone (ADH) action on the collecting tubule epithelium. ADH binds to receptors on the basolateral cell membrane, resulting in translocation of water pores (aquaporin 2) to the apical surface. Increased water permeability results in reabsorption of water from the filtrate and into the interstitium. *cAMP*, Cyclic adenosine monophosphate; V<sub>2</sub>, vasopressin-2 receptor.

### Diuretic Agents

The ability of the kidneys to reabsorb fluid can be inhibited by drugs that block sodium and water reabsorption. These agents are called *diuretics* and include osmotic diuretics, ACE inhibitors, loop diuretics, thiazide-like diuretics, and inhibitors of aldosterone activity (Table 26-3).<sup>13</sup> Diuretics work by altering osmotic gradients in the kidney tubules so that reabsorption of water is inhibited. Recall that water always moves passively according to an osmotic gradient. When the solute content of the filtrate is elevated, reabsorption of water is inhibited, resulting in a larger output of urine.

Osmotic diuretics (e.g., mannitol) are filtered through the glomerulus and are not reabsorbed by the tubules. The osmolality of the filtrate is increased by the presence of the solute, and more water remains in the

tubule and is excreted in the urine. ACE inhibitors (e.g., captopril) inhibit the formation of AII and aldosterone, which normally stimulate the kidney tubules to reabsorb Na<sup>+</sup>. In the absence of these hormones, more Na<sup>+</sup> stays in the urinary filtrate, resulting in less reabsorption of water.

Loop diuretics (e.g., furosemide) block the Na<sup>+</sup>-K<sup>+</sup>-2Cl<sup>-</sup> pumps in the ascending loop of Henle. The ions that would normally have been pumped into the interstitium stay in the filtrate and hold water with them. In addition, the maintenance of the high interstitial gradient in the medulla may be impaired. Washout of the gradient reduces the force for water reabsorption from the collecting ducts.

Thiazide-like diuretics (e.g., hydrochlorothiazide) block Na<sup>+</sup> reabsorption in the distal tubule. Sodium ions remain in the filtrate and oppose the action of the interstitial osmotic gradient.

All of these agents also increase the excretion of K<sup>+</sup> and are called *potassium-wasting diuretics*. Patients receiving chronic diuretic therapy with these agents usually require potassium replacement therapy.

In contrast, the aldosterone-blocking agents (e.g., spironolactone) are potassium sparing. Recall that aldosterone increases activity of the Na<sup>+</sup>-K<sup>+</sup> pumps on the basolateral membrane of the distal tubule cells. These pumps promote Na<sup>+</sup> and water reabsorption and potassium secretion. Blockage of aldosterone reduces the activity of these pumps and results in less sodium and water reabsorption as well as less potassium excretion. Significant elevations in serum K<sup>+</sup> concentration can occur with these agents.

Diuretics are used primarily in the management of high blood pressure (see Chapter 16) and congestive heart failure (see Chapter 19), but

**TABLE 26-3 COMMONLY USED DIURETICS**

DIURETIC	ACTION
Osmotic diuretics	Increase solute load in tubule
ACE inhibitors	Block production of AII and aldosterone
Loop diuretics	Block Na <sup>+</sup> -K <sup>+</sup> -2Cl <sup>-</sup> transporter in ascending loop of Henle
Thiazide-like diuretics	Block Na <sup>+</sup> reabsorption in distal tubule
Aldosterone inhibitors	Block action of aldosterone on distal tubule Na <sup>+</sup> -K <sup>+</sup> transporters

they also may be used in the diagnostic phase of acute renal failure or to manage potassium overload.

#### KEY POINTS

- The kidneys regulate blood volume and osmolality by altering GFR and reabsorption from the urinary filtrate.
- Changes in blood volume alter the filtration pressure in the glomerulus, resulting in a pressure diuresis when blood volume is high and in reduced filtration and fluid conservation when blood volume is low.
- The kidney tubules are responsive to hormones that alter their reabsorptive properties. ADH increases the permeability of the collecting tubule to water, resulting in increased reabsorption and reduced blood osmolality.
- Aldosterone, All, ANP, and urodilatin alter blood volume without affecting blood osmolality. Aldosterone and All increase sodium and water reabsorption, whereas ANP and urodilatin inhibit their reabsorption.
- Diuretics alter the osmolality of the urinary filtrate and oppose the reabsorption of water, resulting in an increase in urine volume.

## ENDOCRINE FUNCTIONS

The kidney is the source of two important endocrine hormones: erythropoietin and active vitamin D. Secretion of these hormones is impaired in chronic kidney disease and contributes to the anemia and osteodystrophy found in this disorder (see Chapter 28).

### Erythropoietin

Erythropoietin is a peptide growth factor that stimulates erythrocyte development in the bone marrow. The regulation of erythropoietin secretion is not completely understood; however, hypoxemia and decreased circulating red cell mass are known to increase its release (see Chapter 13). Erythropoietin is commercially available in a recombinant form that can be given parenterally. The anemia of chronic kidney disease usually responds well to erythropoietin replacement therapy.

### Vitamin D

Synthesis of active vitamin D is an interdependent function of the skin, liver, and kidney. The precursors to active vitamin D can be formed in the skin in response to the ultraviolet rays in sunlight, or they can be ingested in fortified food products. These precursors (cholecalciferol) then must undergo a series of two hydroxylations to become active. The first occurs in the liver, resulting in the formation of 25-hydroxycholecalciferol. The kidney performs the second hydroxylation to form 1,25-dihydroxycholecalciferol, which is the active form of vitamin D. Vitamin D is a necessary cofactor for calcium absorption from the intestine. It may also facilitate calcium reabsorption in the kidney tubules.

In chronic kidney disease, the production of active vitamin D is impaired, resulting in poor calcium absorption from the intestine and low serum calcium levels. A low serum calcium level is the stimulus for parathyroid hormone release, resulting in removal of calcium and phosphate from the bones. Eventually excessive parathyroid hormone activity leads to the condition of osteodystrophy and predisposes to skeletal fractures (see Chapter 28).

#### KEY POINTS

- The kidney secretes two important endocrine hormones: erythropoietin, a growth factor for red blood cells, and active vitamin D, a necessary cofactor for calcium absorption from the intestine.
- In chronic kidney disease, impaired production of these hormones results in anemia and osteodystrophy.

## AGE-RELATED CHANGES IN RENAL FUNCTION

### Infant

In the early postnatal period, the GFR is less than half the adult rate. Owing to an immature ability of the infant kidneys to regulate urine osmolality, infants are predisposed to volume depletion during fluid losses, such as those that occur with diarrhea, fever, fluid restrictions, or decreased intake. Volume regulation improves as the kidney matures. In addition, the glomerular and tubular basement membranes thicken, the glomeruli become increasingly permeable, and the loops of Henle lengthen. Systemic changes, such as increased cardiac output and increased levels of plasma proteins, also influence the improvement in renal function. Between the first and second years of life, renal function essentially reaches maturity. Thereafter the kidney grows in proportion to overall body growth, reaching maximal size between 35 and 40 years of age. Renal function in infants is described in the Pediatrics Considerations box.

### Adult and Elderly

As part of the normal aging process, the kidney begins to diminish in size and function after the fourth decade and more significantly by the middle of the sixth decade. The effects of aging on renal function are described in Geriatric Considerations: Changes in the Renal System. After age 40 years, the number of glomeruli begins to decrease, and by age 70 years it is estimated that as many as 30% to 50% of the glomeruli have been lost. Renal blood flow decreases after the fourth decade at an approximate rate of 10% per decade because of vascular changes, especially in the cortical blood vessels.

As the number of functional nephrons decreases with aging, there is less renal reserve. Under normal conditions, the kidney functions adequately; however, elderly people are much more susceptible to fluid and electrolyte imbalances and renal damage. The elderly are also very susceptible to kidney damage from drugs and medications, including contrast media. Consequently, it is essential that renal function be evaluated before, during, and after they receive these agents or substances.

#### KEY POINTS

- Renal function is impaired at both ends of the life span. Infants have reduced ability to make concentrated urine because of kidney immaturity. Aged individuals have reduced numbers of functioning nephrons, reduced renal blood flow and GFR, and decreased ability to conserve salt and water.
- The very young and very old are at increased risk for fluid and electrolyte imbalances and drug toxicity.

## TESTS OF RENAL STRUCTURE AND FUNCTION

Urinalysis, serum **creatinine level**, blood urea nitrogen (BUN) levels, and tests of GFR are most helpful in evaluating kidney function, whereas other diagnostic tests are best for evaluating kidney structure.

### Urine and Blood Studies

Routine assessment of urine is commonly performed to screen for a variety of kidney and metabolic disorders. Serum creatinine and BUN levels are used to monitor the progression of renal disease or to screen for occult renal insufficiency.

### Urinalysis

Most often urinalysis is done on a single voided sample; however, longer collections may be done for quantitative analysis. Urinalysis assesses urine color, clarity, odor, specific gravity, pH, and concentrations of glucose, ketones, protein, and sediment (including cells,

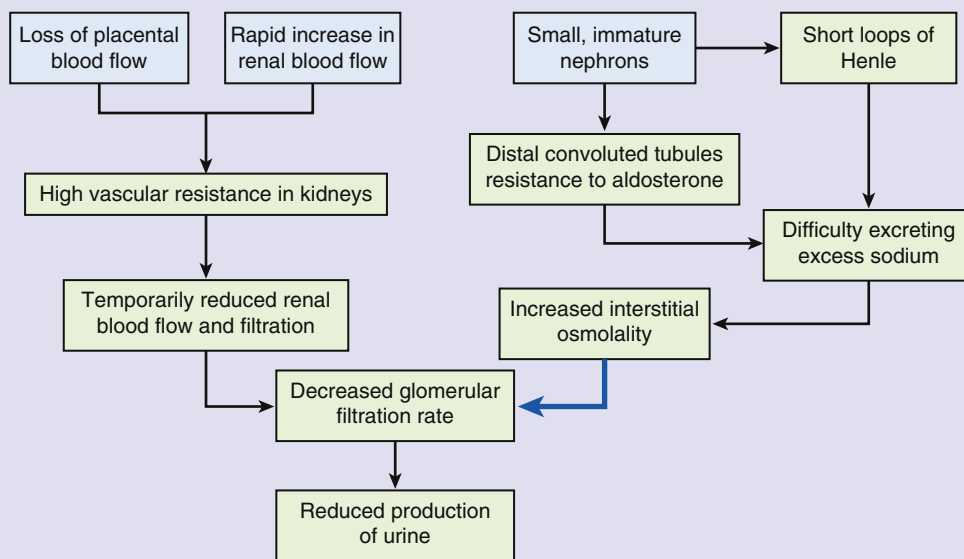

## PEDIATRIC CONSIDERATIONS

### Changes in the Kidneys in Infants

At birth, the loss of placental blood flow and the rapid increase in renal blood flow lead to high vascular resistance in the kidneys. The immature kidneys respond by temporarily reducing renal blood flow and filtration to compensate. The filtration capacity of the glomeruli is reduced. The kidneys cannot adequately concentrate urine to conserve body water. This makes the child susceptible to water loss. In the first 24 hours of life, the newborn will have decreased urine output. Ninety-five percent of infants will pass urine in the first 24 hours of life, although the amount is small (about 20 ml) (Hockenberry & Wilson, 2011). As the infant increases the number and volume of feedings in the first few weeks of life, the capillary resistance is reduced and filtration is increased by the glomeruli.

The kidneys have small immature nephrons. The nephrons are lined with cuboid epithelium, which limits the function of the nephrons. The cuboid epithelium is

not replaced by pavement epithelium and fully functioning until after the first year of life (MacGregor, 2008). The immaturity of the nephrons also makes the distal convoluted tubules resistant to aldosterone. The immature nephrons also have short loops of Henle, where water and sodium levels are normally adjusted. The short loops of Henle and the resistance to aldosterone make it difficult for an infant to excrete excess sodium. The presence of excess sodium increases the interstitial osmolality, which will decrease the glomerular filtration rate in the infant. The decreased glomerular filtration rate contributes to the reduced production of urine that is seen with the infant. As the child grows and the kidney matures, the glomerular filtration rate will increase. The glomerular filtration rate triples by 9 months of age and reaches 30% of adult values by 2 years of age (MacGregor, 2008).

Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby. MacGregor J: *Introduction to the anatomy and physiology of children: a guide for students of nursing, child care and health*, ed 2, New York, 2008, Routledge.

crystals, **casts**, and bacteria or other organisms). The first urine voided in the morning is the most concentrated, due to overnight fasting, and therefore is the best specimen to use for a routine or baseline urinalysis, especially to assess pH, osmolality, and sediment (Table 26-4).

A 24-hour urine collection measures the total quantity of a substance or substances excreted in a day. This is helpful for evaluating substances that are excreted in varying concentrations throughout the day, such as hormones, creatinine, protein, urea, and glucose.

Urine microscopy and culture and sensitivity tests assess the urine for the presence of microorganisms and accompanying cells and to determine the medications or drugs to which the organisms are most sensitive. For these tests, a few milliliters of urine is collected by the clean-catch method and placed into a sterile container.

Urine is approximately 95% water and contains varying amounts of water-soluble waste products. Freshly voided urine has a slight odor attributable to the breakdown of urea to ammonia. If urine stands for a period of time or has a large bacteria population, it will have a strong ammonia smell. The ingestion and excretion of certain foods, such as asparagus, or of certain medications, such as vitamins, may cause urine to have a different odor.

The pale yellow to amber color of urine is due to the presence of urochrome pigments. Urine color can change because of the presence

of cells or because of an increased urine concentration. The presence of red blood cells (RBCs), or hematuria, can cause urine color to range from brown to bright red. White blood cells (WBCs) can make urine look cloudy. Concentrated urine is usually dark yellow to orange. Certain foods and drugs can change urine color. For instance, if beets have been eaten, the urine may be burgundy, and if the individual has taken phenazopyridine (Pyridium), the urine may be orange.

Normally, urine is clear and slightly acidic, although the pH range is 4.5 to 8.0. Urine allowed to stand undisturbed will become cloudy and alkaline because of the breakdown of urea to ammonia, which increases the pH. Cloudiness can result from the presence of cells, bacteria, crystals, casts, or fat substances.

Urine specific gravity and urine osmolality are measures of the concentration of solute in the urine. Urine specific gravity varies with the amount of solids in the urine, such as cells, casts, and microorganisms, but urine osmolality is not affected by these substances. Thus, urine osmolality is a more accurate measure of the kidneys' ability to concentrate and dilute the urine. The range for specific gravity is 1.003 to 1.030, with the higher number indicating a more concentrated urine. Usually urine osmolality and specific gravity vary throughout the day and from day to day. Results that remain fixed over consecutive voidings and days could be an indicator of renal disease.

## GERIATRIC CONSIDERATIONS

## Changes in the Renal System

In the aging individual, there is a 30% to 50% decrease in the number, size, weight, and function of the nephrons, with an accompanying reduction in the size and weight of the kidney. There is increasing interstitial fibrosis of the renal afferent arterioles. Loss of nephrons and diminished renal blood flow contribute to a decrease in the glomerular filtration rate (GFR).

There is also a decrease in the length and the excretory and reabsorptive capabilities of the tubules. The tubule changes affect the countercurrent mechanism, leading to significant changes in urine concentration, excretion, and absorption. Specifically, the changes include reduced urine concentration,

decreased sodium retention, diminished drug and metabolite excretion, decreased hydrogen ion ( $H^+$ ) secretion, and increased renal threshold for glucose. With aging, the kidney does not respond quickly to correct pH or sodium imbalances.

With aging, urinary muscles weaken, and sphincter tone and bladder capacity decrease. This increased muscular weakness can lead to a rise in the residual volume in the bladder and difficulty in starting the urinary stream. The length of the urethra decreases. There is also less bladder innervation and a reduced sensation of filling. A loss of the diurnal excretory pattern induces nocturia.

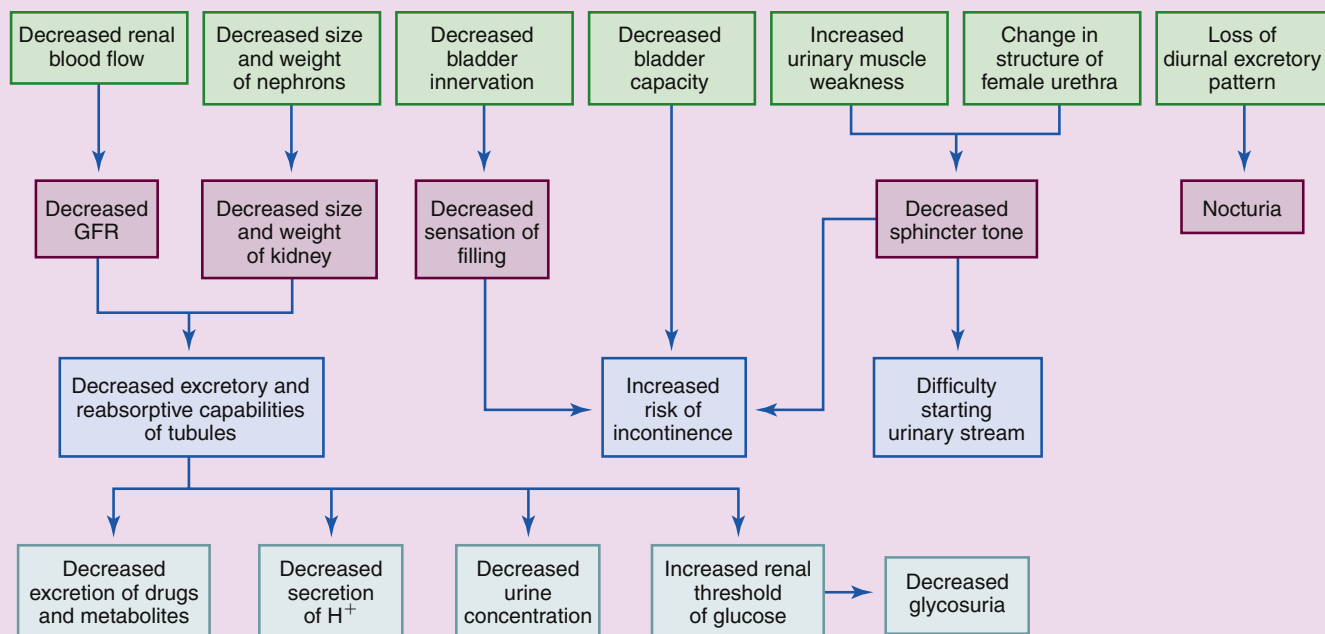

TABLE 26-4 NORMAL COMPOSITION OF URINE

CHARACTERISTICS	NORMAL VALUE
Color	Light yellow to amber
pH	Acidic
Specific gravity	1.003-1.030
Red blood cells	<5/HPF
White blood cells	<5/HPF
Protein	Negative
Glucose	Negative
Ketones	Negative
Nitrites	Negative
Casts	None
Crystals	None

HPF, High-powered field.

Normal urine contains little or no protein. A small amount of protein in the urine is insignificant, but excretion of more than 150 mg per 24 hours should be investigated, because it could indicate glomerular capillary disease. Proteinuria can cause urine to be foamy.

Glycosuria, or glucose in the urine, is abnormal and usually indicates hyperglycemia (elevated blood glucose level), which can occur with diabetes mellitus or following an excessive ingestion of sugar. Rarely does glycosuria indicate renal disease.

A few epithelial cells, erythrocytes, leukocytes, and bacteria are normally found in urine. Fewer than 5 RBCs or WBCs per high-powered field is considered to be within normal limits. An excess of any of these cells may indicate a pathologic process; however, collection technique and presence of menstrual blood may be confounding factors.

Crystals and stones are not usually found in the urine. Either can originate anywhere along the urinary tract. If found in the urine, their composition should be identified and the urinary tract assessed for more crystals and stones (see Chapter 27).

When urinary casts are present, they provide important clues for differentiating renal diseases. Casts are formed in the nephron tubule and are composed of a protein meshwork with entrapped cells or cell fragments. Cells in the thick ascending loop of Henle produce and secrete small amounts of a glycoprotein, called *Tamm-Horsfall* protein (also called *uromodulin*), into the tubular lumen. This protein forms the meshwork that entraps cells in the tubule to form casts and is found in normal urine. Normal protein casts that do not have cells in them are called agranular casts. There are many types of abnormal casts, each associated with certain renal pathologic conditions. For example, WBC casts are associated with renal infections (pyelonephritis); RBC

casts indicate inflammation of the glomerulus (glomerulonephritis); and epithelial cell casts indicate sloughing of tubular cells (acute tubular necrosis).

### Serum Creatinine and Blood Urea Nitrogen

Creatinine is an end product of muscle metabolism that is excreted exclusively by the kidney. The serum creatinine level averages approximately 0.7 to 1.5 mg/dl and is relatively constant throughout the day and from day to day. Creatinine levels are slightly higher in men than in women because of men's larger muscle mass.

Serum creatinine level is a fairly reliable indicator of renal function because it is affected by only two factors: (1) the rate of creatinine produced from muscle, which is relatively constant in the absence of muscle breakdown; and (2) the rate of creatinine excreted by the kidney, which is determined primarily by the GFR. Therefore, the GFR is reflected in the serum creatinine level. For instance, when the GFR decreases by half, the concentration of creatinine in the serum doubles. A rise in serum creatinine level indicates a decrease in renal function.

Urea is an end product of protein metabolism. It is excreted primarily by the kidney and measured in the blood as **blood urea nitrogen (BUN)**. The BUN averages approximately 10 to 20 mg/dl and rises with a decrease in renal function, a decrease in fluid volume, and an increase in catabolism and dietary protein intake. When a change in renal function occurs, the BUN measurement tends to change more rapidly than the creatinine level; however, the BUN value is less specific. Often BUN and creatinine are measured together, and the ratio is determined. Acute changes in GFR are reflected in a higher BUN-to-creatinine ratio, usually greater than 20:1.

### Measures of Glomerular Filtration Rate

GFR is an important parameter in the assessment of renal function. GFR is commonly measured by evaluating the clearance of a filterable substance from the plasma. Creatinine clearance is frequently used to assess GFR, but it is not completely accurate because some secretion and reabsorption occurs in the nephron tubules. At low GFR, creatinine clearance is quite unreliable. The accuracy of creatinine clearance tests can be improved by administration of cimetidine, a drug that blocks the tubular secretion of creatinine.<sup>14</sup>

A more accurate measurement of GFR is obtained by using inulin, an inert substance that is filtered freely at the glomerulus and is completely unaffected by tubular secretion and reabsorption. The use of inulin is more expensive and cumbersome than creatinine clearance because it must be injected. The formula for measuring clearance is the same regardless of the marker substance used. Creatinine clearance is used in the following example, but the corresponding values for inulin can be substituted in the equation.

Creatinine clearance estimates the GFR by measuring the amount of blood that is cleared of creatinine each minute. Usually a 24-hour urine specimen and a blood specimen at the midpoint of the urine collection are used to determine creatinine clearance; however, shorter intervals can be used. The measured values are calculated in the following formula:

$$\text{Clearance} = \frac{\text{Urine volume (ml/min)} \times \text{urinary creatinine (mg/dl)}}{\text{Plasma creatinine (mg/dl)}}$$

An estimate of GFR called the *Modification of Diet in Renal Disease study equation* (MDRD) can be made using only patient demographics and serum creatinine value ( $S_{cr}$ ).<sup>15</sup> This estimate is based on an average body surface area for an adult of 1.73 m<sup>2</sup>. It does not require urine collection, making it simple compared to other measures of clearance:

$$\text{GFR (ml/min/1.73 m}^2\text{)} = 186 \times (S_{cr})^{-1.154} \times (\text{Age})^{-0.203} \\ \times (0.742 \text{ if female}) \times (1.210 \text{ if African American})$$

### Diagnostic Tests

Although studies of urine and blood are good indicators of renal function, they often are not adequate to determine the underlying pathologic process. Diagnostic tests are helpful in assessing structural abnormalities, such as tumors or obstructions, congenital anomalies, perfusion defects, and histologic abnormalities. Sometimes a combination of diagnostic tests is necessary.

#### Kidney, Ureter, and Bladder Roentgenography

A kidney, ureter, and bladder (KUB) roentgenography is a plain radiograph (x-ray) taken of the abdomen to visualize the kidneys, ureters, and bladder. A KUB study shows the position, shape, size, and number of macroscopic or gross renal, ureteral, and bladder structures and surrounding bones. In addition, foreign bodies, radiopaque objects, stones, and neoplasms can be seen on KUB. The KUB may serve as a screening examination to inform further diagnostic testing.

#### Intravenous Urography/Pyelography

During intravenous urography, also called intravenous pyelography (IVP), an iodine-containing radiopaque dye is injected into a vein; it circulates through the kidney and is excreted in the urine. A rapid series of radiographs is made as the dye is being excreted. This test shows the size, shape, and location of urinary tract structures and can be used to evaluate renal excretory function. The dye is **nephrotoxic**, meaning poisonous to the kidney, and allergenic to some people. A state of hydration helps the dye to pass through the kidney and prevents renal damage. Because fecal matter and gas in the intestinal tract will interfere with visualization of the kidneys and ureters on the radiographs, a laxative or enema may be indicated before IVP.

#### Radionuclide Studies

Renograms and renal scans are diagnostic studies that use radioactive isotopes to assess kidney structure and function. In general, the renogram is more useful for assessing function, whereas the renal scan is better at detecting structural anomalies. During a renogram procedure, a small amount of filterable radioactive material is administered intravenously. It circulates through the kidney and is excreted in the urine. While the radionuclide circulates through the renal vessels and nephrons, a radiation detection probe counts the activity of the radioactive substance and simultaneously creates a graphic record of the activity. This test assesses renal function by measuring renal blood flow, glomerular filtration, and tubular secretion.

The renal scan uses a radionuclide that tends to accumulate in areas that are well perfused by blood. The renal scan images depict the concentration of the radionuclide in the kidney and provide anatomic and some physiologic information. In the presence of tumors or nonfunctioning areas, the radioactive material will not be detected by the scan.

A more dynamic assessment of renal physiology can be obtained using positron emission tomography (PET) or single-photon emission computed tomography (SPECT). These modalities use scintigraphic imaging to view the kidney and can pick up subtle, dynamic changes. Regional differences in GFR, for example, can be detected by PET scan.

#### Ultrasonography

Ultrasonography is a noninvasive, painless procedure that uses high-frequency sound waves to image renal structures. The sound waves are at a frequency above the limit of human hearing. Ultrasound is used because its short wavelength produces a more detailed picture or image

than other types of sound waves. A probe with a transducer inside is held against the back and emits ultrasound waves that travel through tissue to the kidney and reflect off the kidney, back to the probe. Ultrasonography demonstrates gross renal anatomy, true kidney depth, structural abnormalities, and perirenal masses, and it can be used to distinguish between a fluid-filled cyst and a solid tumor.

### Computed Tomography

Computed tomography (CT) combines roentgenography with computer technology and is a noninvasive, painless procedure. Instead of using broad x-ray beams, CT uses thin x-ray beams, each about 10 degrees apart. The information obtained during scanning is transmitted to a computer, which constructs a tomograph and calculates its density. Because the kidneys are located deep within the abdominal cavity, they opacify better after an IV injection of a contrast agent. CT shows more detail than ultrasonography. CT can demonstrate perirenal and renal masses, renal vascular disorders, and filling defects of the collecting system.

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a painless, noninvasive procedure that does not use x-rays or radioactive markers. The imager applies a strong magnetic field that causes protons to align themselves with the magnetic field. Pulses of radio waves are emitted that cause the magnetic fields to rotate or resonate. The rotating fields induce electrical signals that the computer analyzes and uses to create images or pictures on a screen. The renal images are available in all planes and show more detail than the images achievable with CT. Newer methods of MRI have been developed to obtain dynamic images using the movement of contrast dye through the kidney. Sequential fast-pulse imaging (functional MRI) allows assessment of obstructions, vascular disorders, and renal insufficiency.

## SUMMARY

The kidneys have a vital role in excreting water-soluble waste products and maintaining fluid, electrolyte, and acid-base homeostasis. To perform these functions, the kidneys must have a sufficient GFR. Most waste products are removed by filtration rather than by secretion; thus, a reduced GFR results in accumulation of wastes in the blood. The kidney has a large renal reserve and accomplishes its functions well until more than 75% of the nephron mass is dysfunctional.

The nephron is the structural and functional unit of the kidney. It performs three essential functions: filtration, secretion, and reabsorption. Filtration occurs at the glomerulus at a rate of about 125 ml/min. The composition of filtrate is similar to that of blood except that proteins and blood cells are absent. Normally 99% of the filtrate

### Renal Biopsy

The purpose of a kidney biopsy is to obtain renal tissue that may be studied to determine the nature and extent of renal disease for diagnosis, management, and prognosis. The renal tissue is studied histologically by light and electron microscopy and immunofluorescence. Some indications for a kidney biopsy are persistent proteinuria, hematuria originating from the kidney, unexplained acute renal failure, glomerular disease, renal mass, rejection of a transplanted kidney, and renal involvement in systemic disease.

#### KEY POINTS

- Urinalysis provides important information about kidney function. Normal urine is clear, pale yellow to amber, and slightly acidic, and it may contain a few cells. Urine osmolality and specific gravity normally vary over the course of the day, depending on fluid intake. Urine is abnormal if it is cloudy or malodorous or contains protein, RBCs, crystals, stones, or casts. A fixed osmolality or specific gravity may indicate renal impairment.
- Serum creatinine and BUN measurements are useful indicators of renal function. Serum creatinine level is a more reliable indicator of renal function than BUN measurement. In conditions of reduced GFR, serum creatinine and BUN levels increase.
- GFR can be estimated by measuring the clearance of a filterable substance from the urine. Creatinine clearance is frequently used for this purpose, but it is not completely accurate because of some tubular processing. Inulin clearance provides a more accurate measurement of GFR. The MDRD is a simple calculated method of estimating GFR using serum creatinine values.
- Diagnostic studies used to evaluate kidney structure and function include plain radiography, pyelography, radionuclide studies, ultrasound, CT, and MRI. Renal biopsy may be performed to obtain tissue for histologic examination.

is reabsorbed along the nephron tubules, resulting in the elimination of 30 to 60 ml/hr of concentrated urine. Each nephron regulates its own GFR through tubuloglomerular feedback to prevent overloading its reabsorptive capacities.

The kidneys are responsive to a number of endocrine hormones that regulate blood osmolality and volume, including ADH, aldosterone, AII, ANP, urodilatin, uroguanylin, and guanylin. In addition, the kidneys produce two important endocrine hormones: erythropoietin and vitamin D. Urinalysis, serum creatinine and BUN levels, and tests of GFR are important indicators of renal function. Structural abnormalities can be assessed by a variety of imaging techniques.

Functional kidneys are necessary for the removal of waste products from the blood and the maintenance of fluid, electrolyte, and acid-base balance despite wide variations in intake and losses. Systemic disorders that alter the delivery of blood flow to the kidney may adversely affect the kidney's ability to perform its filtering and homeostatic functions. In addition, many disorders occur primarily within the kidney and have the potential to result in chronic kidney disease or end-stage renal disease (ESRD). In general, these disorders can be categorized as (1) congenital, (2) neoplastic, (3) infectious, (4) obstructive, and (5) glomerular.

## COMMON MANIFESTATIONS OF KIDNEY DISEASE

### Pain

Thorough pain assessment is an essential component of the history and physical examination of any patient. The results can be useful in localizing the etiology of the pain, but assessment is also challenging because pain perceived as coming from the abdomen can originate from many varied organs and tissues within the abdomen or extraabdominally (see Chapter 47). Pain associated with the urinary tract may originate from the lower urinary tract (ureters, bladder, or urethra) or the kidney itself. Renal or kidney pain is also referred to as nephralgia (-algia is from the Greek *algos*, meaning pain). Extensive damage to a kidney can occur without nephralgia because most of the kidney lacks pain receptors. However, the renal capsule is innervated by nociceptors, and when a disease process causes it to be distended, inflamed, or punctured, a dull to sharp pain is felt. Distention or inflammation produces a dull, constant pain. This may be the result of intrarenal fluid accumulation such as occurs with inflammation, infected or bleeding cysts, hemorrhage from blunt trauma, or neoplastic expansion. In addition, whenever the renal capsule is penetrated (e.g., during biopsy or trauma), a dull pain or intense pressure may be felt. The renal pelvis and the rest of the

urinary tract are innervated by many pain receptors. Obstruction of the intrarenal collecting system causes pain if the obstruction leads to distention of the renal pelvis or capsule. Large calculi, however, can develop insidiously in the renal pelvis or calices and may be painless until they start to move into the ureteral junction. Ischemia caused by the occlusion of renal blood vessels (e.g., from an embolus, atherosclerotic disease, or neoplasm) results in a constant dull or sharp pain.

Pain associated with intrarenal disorders affecting the capsule is classically assessed by palpation or light percussion over the costovertebral angle posteriorly and is recorded as **CVA tenderness** or **flank pain**. Sympathetic nerves transmit information from renal and ureteral nociceptors to the spinal cord between the T10 and L1 levels. Because these sympathetic nerves enter the spinal cord at this level, the pain can be felt throughout the corresponding T10-L1 dermatomes. A **dermatome** is an area of skin innervated by a specific spinal cord segment (Figure 27-1). Visceral and cutaneous afferent fibers enter the spinal cord in close proximity and converge on some of the same neurons at the spinal, thalamic, and cortical levels of the central nervous system. When visceral pain fibers are stimulated, concurrent stimulation of cutaneous fibers occurs and the visceral pain is perceived as though it had originated in the skin. Nerve fibers from the renal plexus communicate with the spermatic plexus, and because of this association, scrotal pain in males and labial pain in females may accompany renal pain.

### Abnormal Urinalysis Findings

Urinalysis is an essential laboratory test for all suspected problems of the genitourinary system<sup>1</sup> (see Chapter 26). After history taking and a physical examination, urinalysis generally serves as a starting point for the differential diagnosis. First, urine is examined grossly, encompassing both the solvent and the solutes. The color, odor, and turbidity of the urine offer the first clues. Dark, strong-smelling urine may be an

**FIGURE 27-1** Dermatomes T10 (thoracic) to L1 (lumbar) correspond to areas that innervate the renal structures.

**TABLE 27-1 URINE DIPSTICK FINDINGS ASSOCIATED WITH KIDNEY DISORDERS**

URINE DIPSTICK FINDING	ASSOCIATED KIDNEY DISORDERS
<b>Specific Gravity</b>	
Decreased	Chronic kidney disease (decreased concentrating ability) Diabetes insipidus
Increased	Diabetes mellitus Syndrome of inappropriate secretion of antidiuretic hormone
<b>pH</b>	
Increased (6.5-8.0)	>7.5 Urinary tract infection with urea-splitting bacteria (e.g., <i>Proteus</i> ) Renal tubular acidosis Calcium or struvite calculi
Decreased (4.5-5.5)	Uric acid or cystine calculi
<b>Hematuria</b>	Renal cell carcinoma Tubulointerstitial renal disease Urinary tract infection Trauma Glomerulonephritis Obstructive processes (e.g., calculi, neoplasms)
<b>Proteinuria</b>	Diabetic nephropathy Renal hypertension Glomerulopathies Nephrotic syndrome Renal arterial or venous obstruction
<b>Glycosuria and Ketones</b>	Diabetes mellitus Protein-energy malnutrition
<b>White Blood Cells/Leukocyte Esterase</b>	Urinary tract infection
<b>Nitrites</b>	Urinary tract infection (especially with gram-negative bacteria)

Data derived from Gerber GS, Brendler CB: Evaluation of the urologic patient: history, physical examination, and urinalysis. In Wein JA et al, editors: *Campbell-Walsh urology*, ed 9, Philadelphia, 2007, Saunders, pp 97-105.

indicator of decreased renal function. Cloudy, pungent urine generally indicates an infectious process, the turbidity being a result of leukocytes in the urine. Dipstick tests and microscopic analysis provide a great deal of additional information. Microscopic examination entails the assessment of the urine sediment, the portion that remains after the urine specimen is centrifuged.<sup>1</sup> Table 27-1 lists major kidney disorders that are associated with abnormalities identified by urine dipstick testing. Table 27-2 provides abnormal microscopic urinalysis results indicative of kidney disorders.

### Other Diagnostic Tests

Many of the diagnostic tests presented in Chapter 26 are applicable to intrarenal disorders. The simple kidney, ureter, and bladder (KUB) radiograph identifies gross abnormalities of the kidney related to position, size, and shape as well as renal calculi that are radiopaque.<sup>1</sup> Renal vasculature can be examined by renogram or renal scan; renal scans will also identify neoplasms in the kidney. Ultrasonography differentiates the solid mass of a neoplasm from fluid-filled cysts. Computerized

**TABLE 27-2 MICROSCOPIC URINALYSIS FINDINGS AND ASSOCIATED KIDNEY DISORDERS**

MICROSCOPIC URINALYSIS FINDING	ASSOCIATED KIDNEY DISORDERS
<b>Cells</b>	
RBCs (circular shaped)	Urinary tract infection Trauma Obstructive disorders (e.g., calculi, neoplasm)
RBCs (irregularly shaped)	Glomerulopathies
WBCs (>1-2/HPF)	Infection or inflammation (e.g., urinary tract infection, neoplasm, calculi)
Irregular transitional epithelial cells	Malignancy
<b>Casts</b>	
Hyaline	Usually no pathologic significance Chronic kidney disease Pyelonephritis
Fatty	Nephrotic syndrome Nephrosis
RBC	Glomerulonephritis
WBC	Acute glomerulonephritis Acute pyelonephritis Acute tubulointerstitial nephritis
Waxy	Chronic kidney disease Diabetic nephropathy Glomerulonephritis
<b>Crystals</b>	
Cystine	Cystinuria Acidic urine
Uric acid	Uric acid calculi Acidic urine
Calcium oxalate	Calcium calculi Acidic urine
Calcium phosphate	Calcium calculi Alkaline urine
Triple phosphate/struvite	Struvite calculi Alkaline urine
Bacteria $\geq 5$ /HPF	Bacterial urinary tract infection
Yeast	Yeast urinary tract infection
Parasites (e.g., <i>Trichomonas vaginalis</i> )	Vaginitis in women Urethritis in men

HPF, High-power field; RBC, red blood cell; WBC, white blood cell.

tomography (CT) and magnetic resonance imaging (MRI) provide detailed information regarding multiple pathologies including thrombi or other vascular occlusions, masses, and obstructions involving the kidney. In situations in which these diagnostic tests are insufficient and actual tissue examination is necessary (e.g., neoplasm assessment), a renal biopsy may be required.<sup>1</sup>

**KEY POINTS**

- Renal pain is generally perceived at the costovertebral angle. Pain is transmitted to the spinal cord between T10 and L1 by sympathetic afferent neurons. Pain may be felt throughout the dermatomes corresponding to T10-L1. Renal pain is usually due to distention and inflammation of the renal capsule and has a dull, constant character.
- Urinalysis provides a foundation for the differential diagnosis of renal dysfunction. Dipstick and microscopic urinalysis results provide clues to intrarenal pathologies.
- Other diagnostic tests provide information related to abnormal kidney anatomy and function.

**CONGENITAL ABNORMALITIES**

A wide variety of anomalies in the development of the kidneys have been documented in the literature. One or both kidneys may be involved. In some cases, findings are associated with other abnormalities, whereas in others the renal abnormalities are isolated. Congenital kidney abnormalities may be exceptionally rare or may occur with considerable frequency. They may be identified prenatally during ultrasound assessment of the developing fetus, noted at birth, or manifest only in later life. Discussion here will focus on the more common congenital anomalies because a complete discussion of all these pathologies is beyond the scope of this text.

**Renal Agenesis and Hypoplasia**

**Renal agenesis** means a failure of one or both kidneys to embryonically develop at all.<sup>2,3</sup> On the other hand, **renal hypoplasia** describes a condition in which some fetal development of the kidneys has occurred. They both can be found as a single entity or in combination with other congenital malformations.

Bilateral renal agenesis (BRA) results from failure of the metanephros (renal buds) to develop in the fetus.<sup>2</sup> It is incompatible with extrauterine life and results in stillbirth or death shortly thereafter.<sup>2,4</sup> It is usually found in Potter syndrome, where severely inadequate quantities of amniotic fluid result in compression of the fetus within the uterus.<sup>2</sup> This pathology is characterized by a collection of associated anomalies that includes wide-spaced eyes with epicanthal folds, low-set ears with insufficient cartilage, a beaked nose, and a receding chin.<sup>4</sup>

Unilateral renal agenesis (URA) is more common than bilateral renal agenesis.<sup>3</sup> URA is often associated with concurrent urologic or nonurologic congenital anomalies. Nonurologic anomalies are usually cardiac or gastrointestinal in nature. Sometimes renal agenesis has been found to be familial and inherited as a dominant trait; screening by ultrasound of parents and siblings has been recommended when infants with agenesis or dysgenesis are involved. Poorly controlled diabetes and exposure to certain drugs (e.g., those affecting angiotensin II) and chemicals have been implicated as teratogens. In URA, the remaining kidney usually enlarges as a compensatory mechanism. Lifelong monitoring of renal function is recommended.<sup>3</sup>

Congenital renal hypoplasia is estimated to cause 40% to 60% of the pediatric cases of ESRD. Gene mutation is likely responsible for the incomplete development of the kidney. Hypoplasia may be insufficient for extrauterine life if both kidneys are involved or may not impact renal functioning until later in life.<sup>2,4</sup> When renal hypoplasia has been identified, lifelong monitoring is recommended.<sup>2</sup>

**Cystic Kidney Diseases**

Cystic disease of the kidneys incorporates a wide range of hereditary, developmental, and acquired conditions.<sup>5-10</sup> Depending on the classification, these fluid-filled craters may be present at birth or only visible later in life. They may involve one or both kidneys and be accompanied

**TABLE 27-3 COMPARISON OF AUTOSOMAL RECESSIVE AND AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE**

FEATURE	AUTOSOMAL RECESSIVE	AUTOSOMAL DOMINANT
Gene defect	Chromosome 6p	Gene <i>PKD1</i> on chromosome 16, or gene <i>PKD2</i> on chromosome 4, or gene <i>PDK3</i> location unknown
Incidence	1:20,000	1-2:1000
Age at diagnosis	Usually neonate to childhood	Usually fourth to fifth decade
Imaging findings	Symmetrically enlarged kidneys	Enlarged kidneys, often asymmetric
Histologic findings	Cysts derived from epithelial cells of collecting ducts	Entire nephron involved
Liver involvement	Abnormal portal ducts progressing to fibrosis	Multiple cysts
Other systemic findings	Usually none	Cysts in other abdominal organs, aneurysms, abnormal cardiac valves, hernias, and diverticuli

by other anomalies, or they may be the only pathology present.<sup>8</sup> More commonly found in men, and increasing in prevalence with aging, renal cysts have been reportedly identified in more than half of patients over the age of 50.<sup>6</sup> Cysts may be found in other organs, or limited to the kidneys, depending on the disorder. Within the kidney, cysts may be diffuse or confined to one anatomic area.<sup>8</sup> Renal cysts of significant size produce flank pain and hemorrhage.<sup>6</sup>

The two most common forms of cystic kidney disease are the autosomal recessive and autosomal dominant polycystic diseases.<sup>5,8,9</sup> Autosomal recessive polycystic kidney disease (ARPKD) is usually diagnosed in infants and young children, whereas autosomal dominant polycystic kidney disease (ADPKD) is generally diagnosed in adulthood.<sup>8,9</sup> Although the pathogenesis is similar, the ARPKD and ADPKD forms of the disease are genetically different, and their clinical courses are usually distinct (Table 27-3).

**Autosomal Recessive Polycystic Kidney Disease**

ARPKD is often identified in the neonatal period, and when accompanied by pulmonary hypoplasia, it may result in death.<sup>9</sup> In ARPKD, the kidneys retain their shape but are uniformly enlarged, and collecting ducts are dilated from the medulla to the cortex. Abnormal portal ducts are found in neonates, and portal fibrosis is noted in older patients.<sup>9</sup> The most common clinical signs in the neonatal period are respiratory distress or palpable kidneys on physical examination. Systemic hypertension is frequently most severe in infancy.<sup>9</sup> Those who live to reach adulthood typically retain some renal function, but experience a progressive decline in liver function.<sup>9</sup> There has been no documented evidence of ARPKD being linked with renal neoplasia.<sup>11</sup> A recessive pattern of inheritance within the family and pathology on liver biopsy are the best diagnostic data because both the clinical presentation and the results of ultrasounds, CT, or MRI can be similar to those of the autosomal dominant form of polycystic kidney disease.<sup>10</sup>

### Autosomal Dominant Polycystic Kidney Disease

ADPKD is the most common of all the hereditary cystic kidney diseases.<sup>5,7,10</sup> Typically, both kidneys are involved, but in 17% of the cases, kidney disease is unilateral and these are most likely to be the pediatric cases. The other kidney is often affected by the time the child reaches adulthood.<sup>5</sup> For 5% of the end-stage kidney disease patients receiving hemodialysis in the United States, the etiology of their disease is ADPKD.<sup>10</sup> The disease affects both genders and has no racial preference.<sup>7,11</sup> Although prenatal and neonatal cases have been reported and ADPKD can present at any age, it usually manifests in patients who are 40 to 59 years old.<sup>10,11</sup> In less than 1% of cases, ADPKD is identified in the neonate or in utero.<sup>7</sup> ADPKD is marked by a great deal of variability in the rate of decline in renal function.<sup>9,11</sup> The disease process appears to advance more rapidly in men than in women.<sup>7</sup> The incidence of renal cell carcinoma is no greater in ADPKD than in the general population, but it does occur at an earlier age.<sup>7</sup>

There are two genetically distinct but phenotypically similar forms of ADPKD: *PKD1* and *PKD2*. Distribution of these genotypes is such that 85% of the cases are associated with *PDK1* and just less than 15% with *PDK2*.<sup>5,7,11</sup> Mutations of these genes add further complexity to ADPKD.<sup>7</sup> Approximately 10% of the cases of ADPKD are not familial in origin and appear sporadically.<sup>5</sup> Because of significant variability in clinical presentation within families, environmental modifying factors have been suggested, though not yet documented.<sup>7</sup> It does seem that the specific gene is responsible for the initiation of cystic development, but not necessarily for cyst expansion.<sup>7</sup>

While the cysts multiply and expand, the overall size of the kidneys increases and there is a progressive decline in glomerular filtration rate (GFR) as the amount of normally functioning tissue is slowly reduced.<sup>7</sup> Figure 27-2 provides a comparison of normal and polycystic kidneys. Renal perfusion decreases, and significant remodeling occurs in the renal circulation.<sup>7</sup> Expansion of the cysts compacts and distorts the vascular system, and the resulting local ischemia activates the intrarenal renin-angiotensin system. The progressive reduction in renal function appears to be primarily associated with an increase in the size of the kidney and the overall volume of the cysts.<sup>7</sup>

In contrast to its recessive form, ADPKD is associated with pathologies in other body systems.<sup>5,9,11</sup> The most common extrarenal presentation is in the liver. Additional extrarenal sites include the spleen, pancreas, lung, seminal vesicles, circle of Willis, skin, and heart.<sup>5,7,11</sup>

Involvement of these other organs and tissues results in additional clinical manifestations, each requiring attention by health care providers.<sup>7</sup> In the early phases of the disease, the ability to concentrate urine is decreased.<sup>7</sup> Hypertension is often diagnosed late in the disease process and increases the likelihood of escalated loss of renal function, proteinuria, and hematuria.<sup>7</sup> In 60% of adult patients with ADPKD, pain is the most frequent complaint.<sup>7</sup> Pain may be due to bleeding within the kidney, movement of kidney stones, or the development of urinary tract infections. Kidney stones develop in 20% of the cases and are usually uric acid-based or calcium oxalate-based. Urinary tract infections are most often attributable to *Enterobacter* organisms. Infection of the cysts themselves may also develop; these infections are more difficult to treat, and patients with this condition may require months of antimicrobial therapy. When it occurs, hemorrhage of cysts is usually self-limited.<sup>7</sup>

Diagnosis is based on genetic history and imaging techniques, most often ultrasonography.<sup>7,9,11</sup> When there is no family history of ADPKD, a presumption of the disease is made if imaging either identifies cysts and bilaterally enlarged kidneys or shows cysts in the liver and both kidneys. Genetic testing is then performed to substantiate the diagnosis.<sup>7,10</sup>

Treatment of ADPKD is primarily supportive, emphasizing the control of blood pressure and the management of any associated pathologic conditions.<sup>7</sup> Once ESRD is reached, dialysis or kidney transplantation is required.<sup>7</sup>

**FIGURE 27-2** Comparison of normal and polycystic kidneys. (From Brundage DJ: *Renal disorders*, St Louis, 1992, Mosby.)

#### KEY POINTS

- Renal agenesis is relatively rare, and its presence is often associated with other congenital malformations. Bilateral renal agenesis is not compatible with life. Unilateral renal agenesis results in compensatory hypertrophy of the functional kidney. A single normal kidney is sufficient to maintain normal renal function.
- Polycystic kidney diseases are genetically transmitted kidney disorders. Autosomal recessive forms are evident at birth. In the autosomal dominant type, symptoms generally occur later in life. Expanding cysts disrupt urine formation and flow. The inevitability of renal failure necessitates dialysis or transplantation.

### NEOPLASMS

Neoplasms found in the kidney may be benign or malignant primary tumors, or result from metastases from extrarenal sites. Because the kidney is encased in a tough, fibrous capsule, growing renal neoplasms will distort the architecture of the kidney and ultimately hinder kidney function. Malignant renal neoplasms also carry the threat of metastasis to distant sites.

#### Benign Renal Neoplasms

Several benign neoplasms may be found in the kidney, developing from the renal cortex, medulla, or capsule, but they are less common than malignant neoplasms.<sup>6</sup> Contrary to most benign neoplasms, those in the kidney are not truly encapsulated.<sup>6</sup> Table 27-4 summarizes the etiology and pathogenesis of some of these benign neoplasms.

**Diagnosis and treatment.** Renal neoplasms are typically detected incidentally during abdominal imaging for other reasons.<sup>35</sup> The neoplasm may attain sufficient size to be detected with abdominal palpation, produce flank pain, and cause hematuria. Generally, benign renal neoplasms are treated by removal of the kidney (**nephrectomy**) because they are space-occupying lesions and because of their propensity to undergo malignant changes.<sup>6</sup> More recently, laparoscopic and tissue-sparing approaches have been developed, allowing the retention of more functioning renal tissue.<sup>14</sup>

#### Renal Cell Carcinoma

The vast majority of renal cancer is due to renal cell carcinoma (RCC) (85% to 90%).<sup>13,15,18</sup> The remaining 10% to 15% of cases are primarily

TABLE 27-4 SUMMARY OF BENIGN RENAL NEOPLASMS

BENIGN NEOPLASM	ETIOLOGY AND PATHOGENESIS
Renal cortical adenomas	Small, solid growths that develop from cortical tissue; incidences of less than 1% up to 23%; typically <1 cm; patient is asymptomatic
Metanephric adenoma	Histologically related to Wilms tumor
Oncocytoma	Most difficult to differentiate from renal cell carcinoma; light brown to tan in color with well-defined borders
Angiomyolipoma	Composed of adipose, smooth muscle tissue, and blood vessels; believed to be hormone dependent because it is primarily found in postpubescent women
Nephroma	Cystic neoplasm not reliably differentiated from renal cell carcinoma in adults or nephroblastoma in children
Mixed epithelial stromal neoplasm	Most often found in perimenopausal women, most of whom are taking estrogen replacement therapy
Leiomyomas	Evolve from renal capsule, pelvis, or renal vein
Hemangiomas, fibromas, lipomas, lymphangiomas, and reninomas	Rare benign neoplasms

From Campbell SC, Novick AC, Bukowski RM: Neoplasms of the upper urinary tract. In Wein JA et al, editors: *Campbell-Walsh urology*, ed 9, Philadelphia, 2007, Saunders, pp 1575-1582.

**FIGURE 27-3** Cross-sectional view of renal cell carcinoma. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 965.)

transitional cell cancers of the pelvis. Figure 27-3 illustrates a cross-sectional view of RCC. In the United States in 2011, the number of new cases of renal cell and renal pelvis cancers combined was estimated to be 60,920, with 13,120 fatalities.<sup>17</sup> Approximately 57,760 new cases of RCC were diagnosed in 2009,<sup>16</sup> with about 14,000 deaths.<sup>15</sup> This represents only 2% of all adult malignancies.<sup>15</sup> Since the early 1970s, the incidence has progressively risen in the United States and most of Europe,<sup>13,15</sup> occurring two to three times

BOX 27-1 RISK FACTORS FOR RENAL CELL CARCINOMA

- Cigarette smoking
- Obesity
- Hypertension
- Diabetes mellitus
- Asbestos exposure
- Multiparous women
- Long-term renal dialysis
- Kidney transplantation

more frequently in men than in women.<sup>6,13,15</sup> Incident rates among African Americans are 20% higher<sup>6</sup> and continue to increase more rapidly than the incidence in Caucasians.<sup>18</sup> Rates among Hispanics are also rising.<sup>18</sup> Taken as a whole, these trends are gradually altering the overall distribution of the disease. Age at diagnosis averages the early sixties.<sup>13,15</sup>

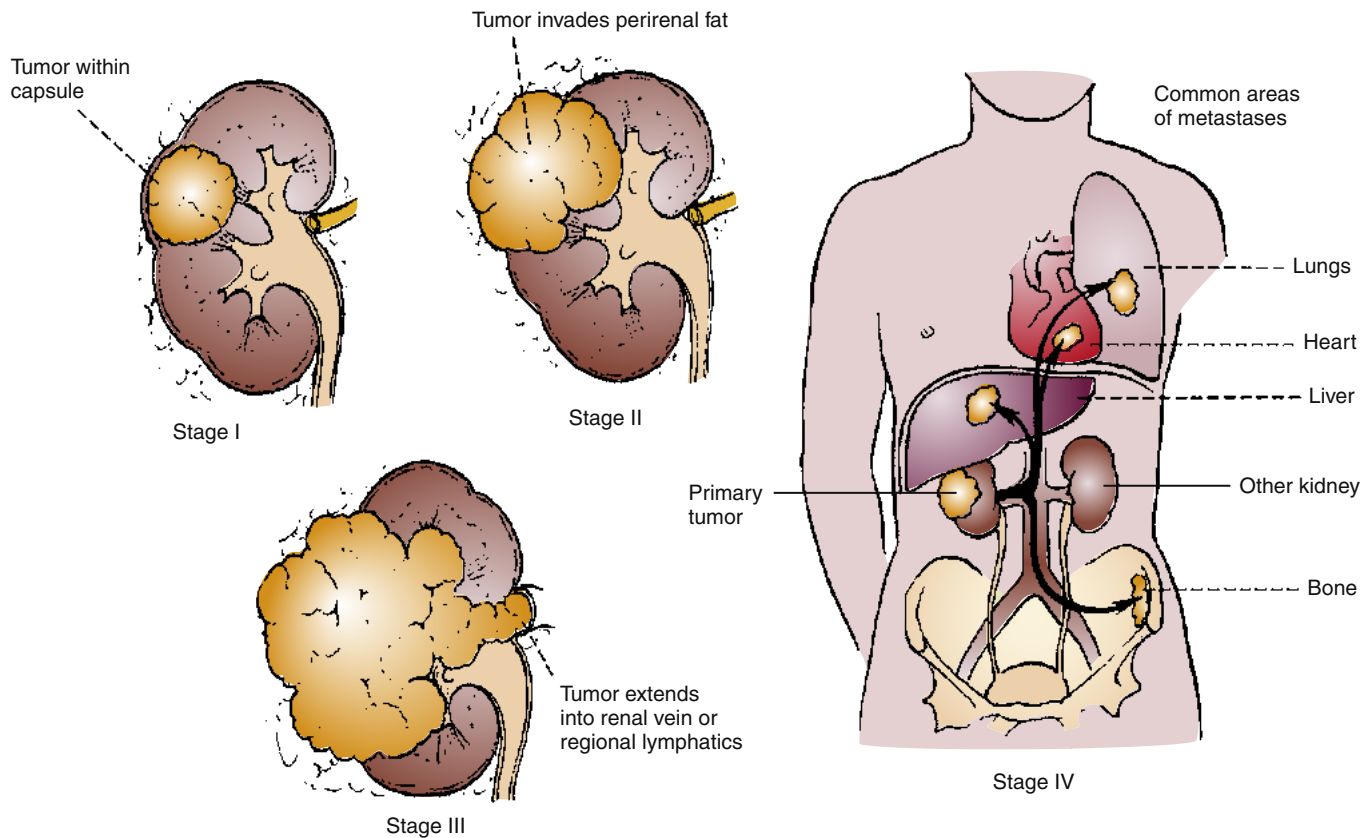

**Etiology and pathogenesis.** Although only a small portion of the cases of RCC are attributed to genetic factors, the risk of its development is greater than twofold when there is a first-degree relative with the disease. These hereditary kidney cancers have been the source of most of the knowledge regarding RCC. Several specific genes have been identified in these cases and are associated with specific subtypes.<sup>13,15,16,19</sup>

The identification of risk factors has been derived from pooled data from a large number of studies worldwide<sup>18</sup> and these are listed in Box 27-1. The primary risk factors are obesity, cigarette smoking, and hypertension with risk reduction documented with weight loss, smoking cessation, and decreased blood pressure. Evidence linking trichloroethylene to renal cell cancer risk is accumulating.<sup>18</sup> Low fruit/vegetable intake has not been adequately substantiated.<sup>18</sup>

Renal cell carcinoma encompasses several subtypes, histologically differentiated from one another. This variability in histology complicates diagnosis. The World Health Organization (WHO) has established a system of terminology and differentiation of these subtypes.<sup>15</sup> The most common of these (approximately 85%) is **clear cell RCC**.<sup>12,13</sup> These tumors originate in the renal cortex from cells of the proximal tubule and are usually unilateral and random in occurrence with rare cases of familial patterns of inheritance.<sup>12</sup> Clear cell RCC is most frequently associated with metastatic disease.<sup>15</sup> Next in frequency is **papillary RCC**, representing 10% to 15% of all renal cell carcinomas.<sup>12,16</sup> Papillary RCC evolves from cells of the distal tubule. This type of RCC may also be sporadic or hereditary, and two subtypes of familial papillary RCC have been identified.<sup>12,16</sup> When compared to clear cell RCC, papillary RCC is less likely to metastasize and therefore has a better prognosis; however, if it does metastasize, the prognosis is poorer than that of clear cell RCC.<sup>12</sup> **Chromophobe RCC** represents 4% to 6% of all RCC cases.<sup>12,16</sup> This subtype originates from the renal parenchyma.<sup>12</sup> Because of slow growth and infrequent metastasis, 5-year survival rates exceed 90%.<sup>12</sup> Cell membranes are prominent. Finally, **medullary and collecting duct carcinomas** are the least common, representing less than 1% of all RCC cases.<sup>12</sup> Unfortunately, they occur in younger patients, develop rapidly, and carry only a 30% 5-year survival rate.<sup>12</sup> Medullary RCC has been found to be associated with the sickle cell trait.

**Clinical manifestations.** RCC is often asymptomatic until it is quite advanced. When it does present with signs and symptoms, the most common are CVA tenderness, hematuria, and a palpable abdominal mass. Dyspnea, cough, and bone pain develop secondary to metastasis.

**Diagnosis and treatment.** Renal ultrasound and CT of the abdomen may be of value. If cysts accompany RCC, renal ultrasound is 98% accurate in discerning them. Figure 27-4 illustrates the staging system used with RCC. When RCC is localized, it can be surgically removed in a nephrectomy, and this is the standard of treatment.<sup>12,13</sup> Unfortunately, metastasis occurs in more than one third of cases,<sup>12,14</sup> and metastatic RCC has been found to be unresponsive to cytotoxic

**FIGURE 27-4** Staging system for renal cell carcinoma. (From Black JM, Matassarini-Jacobs E: *Medical-surgical nursing: clinical management for continuity of care*, ed 8, Philadelphia, 2009, Saunders, p 923.)

chemotherapy.<sup>14,16</sup> The standard nephrectomy is a major surgery, necessitating a large lateral incision. Other less radical approaches include nephron-sparing interventions and laparoscopic nephrectomy. In metastatic disease, spontaneous regression of metastases following nephrectomy occurs in less than 1% of cases. Conventional chemotherapeutic interventions have been found to elicit a poor response in advanced RCC. Interferon- $\alpha$  and interleukin-2 (IL-2) are cytokines used as tissue-specific therapies in these situations with clear cell RCC, with 6% to 27% response rates.<sup>13,14</sup> More targeted therapies, specifically angiogenic inhibitors and tyrosine kinase inhibitors, have been studied in clinical trials or are now available for selected patient situations.<sup>13,14,20</sup>

### Nephroblastoma (Wilms Tumor)

Nephroblastoma is the fifth most frequently occurring pediatric malignancy and the most common childhood kidney cancer, affecting 8 out of 1 million children in the United States less than 15 years old.<sup>23</sup> Seventy-five percent of the cases occur in children less than 5 years old, with a peak incidence at 2 to 3 years of age.<sup>23</sup> Wilms tumor is very rarely found in children older than 15 years of age.<sup>22</sup> Incidence is equally distributed between genders,<sup>21</sup> it is primarily unilateral and sporadic, and only 1% to 2% of patients diagnosed with Wilms tumor have a relative who has been diagnosed with the disease.<sup>22</sup> In 5% to 10% of cases, the tumor presents bilaterally or multifocally.<sup>21,22</sup> Bilateral presentation is often associated with cysts in combination with the tumor.

**Etiology and pathogenesis.** Nephroblastomas develop from embryonic pluripotent kidney precursor cells.<sup>21</sup> Precursor lesions called *nephrogenic rests*, persistent clusters of embryonic cells, are notable histologic findings.<sup>22</sup> The first gene found to be associated with Wilms tumor was *WT1*, located on the short arm of chromosome 11.<sup>21</sup>

Nephroblastomas are typically large, well-encapsulated tumors that grow rapidly. They undergo hemorrhage and cystic changes; necrosis

that occurs because of hemorrhaging is responsible for the development of cysts. As the malignant cells proliferate, the normal architecture of the kidney is altered. The renal pelvis becomes compressed, and locally the tumor infiltrates into the renal veins and hilar nodes. Metastasis is typically via the bloodstream to the brain, liver, adrenal glands, and bone.

**Clinical manifestations.** A palpable abdominal mass is evident in about 80% of cases. Abdominal pain, hypertension, and hematuria are also common local manifestations. Nephroblastoma may produce a tumor thrombus in the inferior vena cava, which can lead to decreased venous return and lower extremity edema. Additional signs or symptoms may be noted reflective of the sites of metastasis.

**Diagnosis and treatment.** Most often the tumor is identified by the parents or during a routine physical examination. Renal ultrasound and/or CT scan will usually identify anatomic abnormalities associated with the tumor. Over the past 20 years, treatment protocols have improved to the point that this previously lethal disease now has a cure rate of more than 90%.<sup>23</sup> Key to treatment is the removal of the involved kidney (nephrectomy). Radiation and chemotherapy are routine following surgery. Radiation therapy may also be administered preoperatively to shrink tumors and reduce their vascularity.

### KEY POINTS

- A number of benign and malignant primary neoplasms may develop in the kidney. Symptoms depend on the size of the neoplasm and the presence of metastasis. Neoplasms may be asymptomatic until quite large. At that time, a palpable abdominal mass, hematuria, and flank pain may be noted.

- Neoplasms are usually detected with renal ultrasound and/or CT scan. Nephrectomy remains the initial treatment of choice for both benign and malignant renal neoplasms. Nephron-sparing approaches are increasingly utilized.
- RCC is particularly resistant to radiation, immunotherapy, and chemotherapy. This resistance combined with the typical advanced stage at diagnosis makes the prognosis for late-stage disease and recurrent cancer quite poor. Recent advances based upon gene pathways hold future promise.
- Nephroblastoma, or Wilms tumor, is the most common kidney cancer in children. Nephrectomy, radiation therapy, and chemotherapy are used in the management of nephroblastomas. Cure rates are excellent.

## INFECTION

Normally, a number of host defense mechanisms serve to protect the renal system from infection. Chemically, the acidic pH and the presence of urea in the urine produce a relatively hostile environment for bacterial growth. Bacteriostatic prostatic secretions in men also act as a protective mechanism against bacterial invasion. In women, glands in the distal urethra secrete mucus that captures bacteria, preventing progression to the bladder. Small numbers of bacteria that may enter the system are washed out by micturition. Normal unidirectional flow prevents **reflux** of urine from the bladder to the kidney via the ureter by contraction of the vesicoureteral junction that occurs with bladder filling. In children, urinary tract infections may be associated with vesicoureteral reflux or other anatomic malformations of the urinary tract<sup>24</sup> (see discussion of vesicoureteral reflux in Chapter 29). Epithelial cells of the urinary tract provide a physical barrier to infectious organisms, and indigenous proteins trap bacteria or block their adhesion to epithelial cells.<sup>26</sup> The inflammatory response to bacterial attachment encourages their destruction and removal. As is so often the case with the inflammatory response, it is the secondary injury associated with this response that is ultimately responsible for subsequent damage to urinary structures.<sup>40</sup>

Infection of the kidney is known as **pyelonephritis** or upper urinary tract infection and affects the renal parenchyma, pelvis, and calices. Although infectious organisms responsible for upper urinary tract infections may be delivered to the kidney via the bloodstream or lymphatic system, they most commonly reach the kidneys as an ascending infection from the lower urinary tract (urethra, bladder, and ureters)<sup>26</sup> (Figure 27-5). Infection of the lower urinary tract is discussed in Chapter 29.

The most common causative agents of renal system infection are serogroups of *Escherichia coli*, whereas *Enterobacter*, *Enterococcus*, *Proteus mirabilis*, and strains of *Klebsiella* are responsible for most of the other infections.<sup>25,28,29</sup> Most often, infections with these other organisms are linked to calculi or to anatomic abnormalities of the urinary tract. In certain populations, *Staphylococcus saprophyticus* and group B *Streptococcus* have been identified. Fungal infections, mycoplasmas, and other anaerobic bacteria are occasionally responsible. Infections attributable to *Neisseria gonorrhoeae* or *Chlamydia trachomatis* are associated with sexually transmitted diseases and are typically limited to the urethra.<sup>25</sup> Uropathogenic bacteria possess a substance that allows the bacteria to bind to epithelial cells of the urinary tract.<sup>25-27</sup> Some bacteria secrete proteins that aid in protection from phagocytosis by cells of the immune system.<sup>25</sup> At the same time, the bacteria responsible for urinary tract infections undergo continuous mutation in an effort to overcome both host defenses and antimicrobials used in their treatment.<sup>28</sup>

Risk factors for urinary tract infections are listed in Box 27-2. One of the most significant preventive interventions is the early removal of urinary catheters. Anatomically, women are at increased risk because of their shortened urethras, but the resulting infections are most often confined to the lower urinary tract.<sup>25</sup> In 2005, 1.8 million patients in emergency departments were diagnosed with urinary tract infections.<sup>28</sup>

**FIGURE 27-5** Pathways of renal infection. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 940.)

### BOX 27-2 RISK FACTORS FOR URINARY TRACT INFECTIONS

- Increasing age
- Vesicoureteral reflux
- Congenital anatomic anomalies of the urinary tract
- Female gender
- Pregnancy
- Diaphragms with spermicidal agents for contraception
- Neurogenic bladder
- Instrumentation of the urinary tract (catheterization, cystoscopy)
- Urinary obstruction (calculi, benign prostatic hyperplasia)
- Glucocorticoids, radiation, or cytotoxic chemotherapy
- Immunodeficiency conditions such as AIDS
- Diabetes mellitus
- Obesity
- Sickle cell trait

**FIGURE 27-6** Acute pyelonephritis. Cortical surface shows grayish white areas of inflammation and abscess formation. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Mosby, p 941.)

More than 50% of women will have at least one urinary tract infection in their lifetime.<sup>28</sup> As many as 2% to 3% of boys and 8% to 11% of girls are reported to have urinary tract infections during childhood.<sup>32</sup> The majority of these occur in the first 12 months. Male children who are uncircumcised experience these infections more frequently than those who are circumcised.<sup>24</sup>

### Acute Pyelonephritis

**Etiology and pathogenesis.** It is estimated that acute pyelonephritis accounts for approximately 250,000 physician office visits and 200,000 hospital admissions each year in the United States.<sup>29</sup> Recent research results suggest that there is an inherited susceptibility to acute pyelonephritis.<sup>30</sup> Pregnancy is the major risk factor for acute pyelonephritis in women because of the physiologic alterations that occur in the urinary tract.<sup>25</sup> In nonpregnant women, men, and children, the most common risk factors for acute pyelonephritis are diabetes mellitus, anatomic abnormalities of the urinary tract (especially vesicoureteral reflux in children<sup>24</sup>), and obstructive causes.<sup>25</sup> The populations with the highest incidence were young women, infants, and the elderly. *E. coli* is the causative organism in 80% of acute pyelonephritis cases involving women and 70% of those involving men.<sup>31</sup> Pyelonephritis is usually unilateral, involving the right kidney (>50%); 25% of the cases involve the left kidney, and pyelonephritis is bilateral 25% of the time.<sup>24,25</sup> Acute infection of the kidney usually originates as an ascending infection but may arrive at the kidney via the bloodstream. Once in the kidney, bacteria bind to epithelial cell receptors, initiating an inflammatory response. Inflammatory mediators and bacterial toxins are responsible for the parenchymal damage to the kidney.

**Clinical manifestations.** The onset of acute pyelonephritis is sudden; patients are acutely ill and present with fever, chills, and CVA tenderness, as well as symptoms of lower urinary tract infection (dysuria, urgency, and frequency).<sup>25</sup> Nausea, vomiting, and anorexia are frequent accompaniments, increasing the fever-induced dehydration.<sup>25,28</sup>

Complications of acute pyelonephritis include abscesses, septic shock, acute respiratory distress syndrome, recurrent/chronic pyelonephritis, and chronic kidney disease attributable to scarring produced by recurrent infections.<sup>25,28</sup> Renal scarring and the subsequent development of chronic kidney disease are more likely when there are pre-existing anatomic or functional urinary tract abnormalities.<sup>32</sup> Chronic

kidney disease has been found to progress more rapidly following acute pyelonephritis. Preexisting chronic kidney disease can also increase the severity of an infection. Overall, however, the risk of decreased renal function subsequent to acute pyelonephritis is low, occurring in only 3% to 4% of cases. The term **urosepsis** describes organisms in the bloodstream originating from a urinary tract infection. Urinary tract infections are the cause of 20% to 30% of all septic patients.<sup>33</sup> Figure 27-6 illustrates acute pyelonephritis complicated by abscess formation.

**Diagnosis and treatment.** In addition to the clinical manifestations, diagnosis of acute pyelonephritis is confirmed by urinalysis results illustrating the presence of significant amounts of bacteria.<sup>25</sup> Elevated levels of white and red blood cells and leukocyte esterase are also noted. The urinalysis dipstick may be positive for nitrites, especially if gram-negative organisms are involved. White blood cell casts are common findings.<sup>25</sup> Barring complications, patients are treated with empirical antimicrobial therapy on an outpatient basis for 7 to 10 days.<sup>25,28,29</sup> If improvement is not noted within 48 to 72 hours or the patient's condition deteriorates, urine is cultured to allow targeted therapy and the patient may be further assessed for such problems as urinary obstruction or an extraurinary focus of infection. In cases of complicated acute pyelonephritis, such as septicemia, patients are hospitalized and treated with intravenous antimicrobials and fluids.<sup>25,28,29</sup>

### Chronic Pyelonephritis

Chronic pyelonephritis is characterized by small atrophied kidneys with diffuse scarring and blunting of the calices secondary to persistent or recurrent infection of the kidney.

**Etiology and pathogenesis.** Reflux of infected urine into the renal pelvis is the typical cause of chronic pyelonephritis. The kidneys are usually smaller than normal with caliceal deformity, chronic inflammation, and parenchymal scarring.<sup>34,35</sup> Chronic pyelonephritis causes about 2% to 3% of the cases of end-stage renal disease.<sup>35</sup> Individuals at risk for developing chronic pyelonephritis have bacteriuria associated with obstructive disorders such as renal calculi, neurogenic bladder, vesicoureteral reflux, or underlying intrarenal disease. Chronic or recurrent pyelonephritis is one potential cause of chronic kidney disease (see Chapter 28).

**Clinical manifestations.** The symptoms of chronic pyelonephritis may be vague, inconsistent, or similar to those of acute pyelonephritis.<sup>35</sup> Patients may have flank or abdominal pain, fever, malaise or anorexia.<sup>35</sup> It is often diagnosed incidentally during the diagnostic evaluation.<sup>35</sup>

**Diagnosis and treatment.** Urinalysis results typically parallel the findings of acute pyelonephritis, but may not be as profound. Diagnostic testing includes renal ultrasound and other imaging tests that show one or both kidneys to be smaller than normal with distorted architecture and significant scarring. Renal tubules may be dilated or atrophied. Other diagnostic tests may be performed to determine underlying pathologies such as vesicoureteral reflux or obstruction caused by renal calculi. Treatment is based on the correction of these underlying causes, administration of antimicrobial therapy that may continue for several months, and support of compromised renal function, if it exists.

#### KEY POINTS

- Pyelonephritis is an infection of the renal pelvis and parenchyma that is usually due to an ascending urinary tract infection. Costovertebral angle tenderness is the classic symptom. It is frequently accompanied by fever, chills, nausea, vomiting, and anorexia. Urinalysis generally shows evidence of an infective process. The presence of WBC casts is specifically indicative of an upper urinary tract infection as opposed to a lower urinary tract infection. When managed promptly and effectively, acute pyelonephritis does not generally result in decreased renal function.

**FIGURE 27-7** Obstructions of the urinary tract. (From Cotran RS et al: *Robbins pathologic basis of disease*, ed 6, Philadelphia, 1999, Saunders, p 988.)

- Chronic pyelonephritis can potentially result in chronic kidney disease. It is usually associated with vesicoureteral reflux or obstructive processes leading to persistent urine stasis. Ongoing inflammation causes fibrosis and scarring and loss of functional nephrons. The diagnosis is confirmed by renal imaging. Urinalysis results mirror those of acute pyelonephritis, but may not be as significant. Treatment includes correction of the underlying processes and often extended antimicrobial therapy.

## OBSTRUCTION

Obstructive disorders of the urinary tract interfere with the flow of urine. Obstruction can occur at any point in the system from the renal pelvis to the urethral meatus (Figure 27-7). In general, it causes dilation of the tract proximal to the obstruction. Stasis of urine occurs and predisposes to urinary tract infection and structural damage. Prolonged obstruction results in postrenal acute kidney injury and can ultimately lead to acute tubular necrosis (intrarenal acute kidney injury) (Chapter 28).

Disorders resulting in urinary tract obstruction may be congenital or acquired. In children, urinary tract obstruction is usually due to anatomic abnormalities such as with ureteral valves, strictures of the urethral meatus, and stenosis at the ureterovesical or ureteropelvic junction. Obstruction in adults predominantly occurs as a result of acquired disorders and may be either intraluminal (e.g., renal calculi)

TYPE OF OBSTRUCTION	CAUSE
Intraluminal	Calculi, clot Tumor: bladder, urethra, kidney Papillary necrosis
Extrinsic	Prostatic hypertrophy Retroperitoneal fibrosis Tumor: pelvic, retroperitoneal
Acquired	Neurogenic bladder Ureteral stricture Urethral stricture

or secondary to extrinsic compression (e.g., tumors). Acquired obstructions are due to anatomic anomalies of the urinary tract (Table 27-5). Complications of urinary obstruction include infection, sepsis, acute kidney injury, and, potentially, chronic kidney disease.

Changes that occur within the urinary tract as a result of obstruction are dependent on (1) location and degree of obstruction (i.e., partial or complete, unilateral or bilateral) and (2) the duration and timing (acute onset or chronic) of the obstruction. Initially, in complete or significant partial obstruction, hydrostatic pressure increases proximal to the obstruction as a consequence of continued glomerular filtration and simultaneous obstruction to the flow of urine. Other structures proximal to the obstruction then begin to dilate. The more distal to the kidney the obstruction is located, the less dilation is seen because the pressure is distributed over a greater surface area. Complete obstruction of a ureter results in its dilation (**hydroureter**). The renal pelvis and tubules enlarge with the increased pressure, and the renal papillae flatten. The enlarged kidney is called **hydronephrosis**. Glomerular filtration rate (GFR) and renal perfusion decline, and eventually portions of the kidney become ischemic. Over the course of several weeks, if the obstruction is not corrected, tubular atrophy and destruction of the medulla result in scar tissue and nonfunctioning or poorly functioning glomeruli. Hydronephrosis is found at postmortem examination in 2% to 4% of patients.<sup>35</sup> Postrenal acute kidney injury is discussed in detail in Chapter 28.

Partial obstruction is much more common. In this situation, the renal pelvis may become very dilated but the structural or functional disruption of the kidney may be minimal. If the obstruction is bilateral, however, clinical manifestations of fluid retention will be present. Patients often complain of symptoms such as weight gain, nausea, anorexia, malaise, headaches, increased abdominal girth, and ankle edema. Functionally, partial obstruction can produce a slight to moderate decrease in blood flow and GFR and an inability to concentrate urine or secrete potassium and hydrogen ions. Compensatory hypertrophy occurs in the unaffected kidney. Renal calculi are the most common cause of urinary tract obstruction.<sup>31</sup>

### Renal Calculi (Nephrolithiasis)

**Renal calculi**, or lithiasis, are crystal aggregates composed of organic and inorganic materials located within the urinary tract. These calculi are thought to form within the kidney, in the tubules or the collecting system, and may then migrate to more distal structures. Occasionally, terminology is used to identify where these calculi are found (e.g., *ureterolithiasis*, located in the ureters), but more commonly, the terms *renal calculi* or **nephrolithiasis** are used to describe the formation and passage of calculi anywhere within the urinary tract.<sup>38</sup> The Greek term *lithiasis* means *stone*, so renal calculi are also referred to as *kidney stones*.

### BOX 27-3 GENERAL CONTRIBUTING FACTORS TO NEPHROLITHIASIS

- Hyperparathyroidism
- Gout
- Certain medications
- Hypertension
- Urinary tract infections
- Chronic inflammatory bowel disease; irritable bowel disease; chronic diarrhea
- Excess dietary meat
- Excess dietary sodium
- Excess dietary oxalate
- Past medical history or family history of nephrolithiasis
- Obesity
- Insulin resistance/type 2 diabetes mellitus
- Dehydration
- Prolonged immobility
- Congenital kidney defects/anatomic alterations (e.g., abnormal kidney shape)
- Vesicoureteral reflux

Nephrolithiasis affects individuals throughout the world<sup>36,37</sup> and has been traced back as far as Egyptian mummies.<sup>37</sup> Worldwide prevalence is estimated to be between 2% and 20%, with the highest lifetime risk in the United Arab Emirates and Saudi Arabia.<sup>41</sup> It is estimated that 10% to 15% of Americans will experience a kidney stone during their lifetime.<sup>39</sup> Historically, kidney stones have been more common in men than women,<sup>36</sup> but rates in women are increasing.<sup>41</sup> Examining incidence according to race/ethnicity, the risk of stone disease is significantly lower among non-Hispanic African Americans and Mexican Americans than among non-Hispanic Caucasians for both genders.<sup>38</sup> Although little is currently known about genetic predisposition, it is clearly a factor given the ethnic distribution and the increased risk associated with family history,<sup>41</sup> and the fact that some stones are associated with congenital metabolic abnormalities. There seems to be an increased prevalence of calculi in areas of the United States characterized by mountains, desert, or tropical climates. Prevalence increases moving from the North to the South and from West to East; the Southeastern United States, therefore, has the highest rates in the country.<sup>37,38,41</sup> It has been postulated that this is due to increased fluid loss through perspiration resulting in decreased urine volume.<sup>37,38</sup> Occupations where there is increased exposure to high temperatures or sedentary levels of activity are also associated with an increased incidence of stone formation. Nephrolithiasis has been found to be uncommon before age 20.<sup>37</sup> Although the exact rates are unknown, the incidence of nephrolithiasis in childhood is believed to be approximately 10% of that in adults.<sup>42</sup> Approximately 40% of children with urolithiasis have a positive family history of kidney stones and most of the children have a metabolic background of stone disease.<sup>42</sup>

**Etiology and pathogenesis.** Crystallization and stone formation occurs with many solutes found in urine and may be promoted or inhibited by a number of factors.<sup>38,41,43</sup> Some of these factors are inherent to the urinary tract and the characteristics of urine, whereas others are unique to the individual and the type of renal calculi formed. Box 27-3 identifies general factors that contribute to the formation of renal calculi. The general process of stone formation, however, is a physiologic constant.

The pathogenesis of nephrolithiasis begins with urine becoming supersaturated with the specific solute.<sup>36-38</sup> Urine is a solution of solvent (water) and solutes (particles). Certain of these solutes have a tendency to form crystals if their concentration within the urine becomes

### TABLE 27-6 TYPES OF NEPHROLITHIASIS, RELATIVE INCIDENCE, AND SPECIFIC RISK FACTORS

CONSTITUENT OF STONE	INCIDENCE	SPECIFIC RISKS
Calcium oxalate (primarily)	75%	Genetic predisposition; idiopathic; hypercalcemia and/or hypercalciuria (hyperparathyroidism, prolonged immobility, increased gastrointestinal absorption, impaired renal reabsorption); hyperuricosuria (see risks below); hyperoxaluria
Struvite	7-10%	Urinary tract infection with urea-splitting bacteria (e.g., <i>Proteus</i> , <i>Klebsiella</i> , <i>Pseudomonas</i> )
Uric acid	7-10%	Genetic predisposition; hyperuricosuria associated with gout, acute leukemia, glycogen storage disease, malignancy; excessive intake of meat, fish, poultry; obesity; type 2 diabetes; urine pH <5.5
Cystine	1-3%	Genetic defect in renal cystine reabsorption
Ephedrine, guaifenesin, indinavir, xanthine	All <1%	Secondary to specific medications

great enough; this is the meaning of *supersaturation*.<sup>36</sup> Urinary supersaturation is an essential requirement for stone formation.<sup>36-38</sup> These crystals begin their development somewhere in the nephron's loop of Henle, distal tubule, or collecting duct.<sup>41</sup> Crystallization is enhanced when a person is dehydrated (decreased solvent).<sup>36,38,41</sup> Crystals are unable to aggregate into a calculus of sufficient size to obstruct the urinary tract if urine is moving freely through the system.<sup>41</sup> Adequate fluid intake is therefore an inhibitor to stone formation, and because urine flows by gravity, urinary stasis, as may occur with immobility and a sedentary lifestyle, facilitates calculus formation.<sup>43</sup>

In addition to a crystalline component, nephrolithiasis also consists of a noncrystalline, organic component termed the calculus *matrix*.<sup>37</sup> Matrix itself consists of protein, sugar, glucosamine, bound water, and organic ash.<sup>37</sup> The matrix represents approximately 2.5% of the overall weight of the calculus. For some stones, the matrix is the dominant component; this is primarily true for stones that form with chronic urinary tract infections, where 65% of the stone is matrix. The specific role matrix plays in genesis of calculi is unclear.<sup>37</sup>

The types of renal calculi are shown in Table 27-6, along with their relative incidence in adults, and primary risk factors. Calcium oxalate-based stones are by far the most common in both children and adults.<sup>36-38</sup> Calcium-based nephrolithiasis is primarily idiopathic in etiology (unknown cause), but a genetic component is implicated.<sup>41</sup> Primary risk factors for calcium-based calculi are hypercalciuria and/or hypercalcemia, hyperoxaluria, and hyperuricosuria.<sup>35,36</sup> Hypercalciuria and/or hypercalcemia is commonly due to increased gastrointestinal absorption, impaired renal tubular reabsorption, and primary hyperparathyroidism, and less often to prolonged immobility, metastatic bone cancer, multiple myeloma, prolonged metabolic acidosis, hypocalcemia, and excessive amounts of vitamin D.<sup>35,36,43</sup> Hyperoxaluria can

increase the urinary saturation of calcium oxalate.<sup>36</sup> It may be due to a genetic defect that increases urinary oxalate excretion, a defect in liver metabolism, or increased gastrointestinal absorption of an oxalate-rich diet (rhubarb, spinach, chocolate, nuts, beer, coffee, tea, cocoa, or excessive vitamin C).<sup>36,41</sup> Hyperuricosuria facilitates precipitation of calcium oxalate stones or may produce uric acid stones.<sup>35-37</sup> There is a genetic predisposition for hyperuricosuria, which may be found in association with gouty arthritis or secondary purine excess attributable to overproduction in myeloproliferative disorders, excess ingestion of purine-rich foods, or errors of purine metabolism.<sup>35,36</sup> Foods high in purine include organ meats such as liver and kidney, sardines, anchovies, salmon, and foods high in yeast such as beer and bread. Uric acid and struvite calculi are the second most frequently occurring stones, following calcium oxalate stones. In addition to the risk factors previously identified for hyperuricosuria, an increased body mass index and glucose intolerance or type 2 diabetes are frequently associated with uric acid stones.<sup>36</sup> Calculi are uric acid–based in patients with diabetes 30% to 40% of the time compared with 10% or less in the nondiabetic population.<sup>36</sup> The basis of struvite stones is not metabolic, but rather the changes that occur within the urinary tract with some infectious processes, and often assisted by some underlying anatomic or functional abnormalities that facilitate urinary stasis.<sup>36,38</sup> Struvite stones are composed of magnesium, ammonium, and phosphate. Urinary tract infections with certain bacterial species capable of splitting urea into two ammonium ions and one bicarbonate ion neutralize the urine and support bacterial proliferation as well as stone formation. Struvite stones form around a bacterial nucleus, producing an antimicrobial barrier. They grow rapidly and assume a jagged formation known as *staghorn*.<sup>36,38</sup> Other types of nephrolithiasis are less common and are associated with familial defects in renal transport,<sup>41</sup> or are produced as adverse effects of certain drugs (e.g., indinavir, triamterene, and xanthine).<sup>43</sup>

**Clinical manifestations.** Signs and symptoms of renal calculi differ with their size and location and may mimic any number of other causes of abdominal pain.<sup>39,43</sup> Pain may be vague or, more commonly, acute renal colic or flank pain.<sup>39,43</sup> Stones within the kidney are responsible for flank pain that may be dull and localized. While the stone moves to the ureteropelvic junction and down into the ureter, spasmodic, intermittent sharp pain known as renal colic develops. The pain may radiate into the ipsilateral groin area, testicle, or labia. The pain induced by nephrolithiasis makes the patient acutely uncomfortable and is often accompanied by nausea and vomiting, diaphoresis, tachycardia, and tachypnea. When the stone reaches the bladder, there is often a noticeable reduction in the pain. If the stone results in a partial obstruction at the urethra, dysuria, urgency, and frequency are common findings. These findings may present earlier if there is a concomitant urinary tract infection.<sup>43</sup> Renal calculi may develop as a result of a urinary tract infection (struvite stones), or increase the risk of its development.<sup>43</sup> If the infection reaches the kidney itself (pyelonephritis), the patient will become acutely ill (see Acute Pyelonephritis section). Prolonged or repeated nephrolithiasis may result in scarring of the kidney and, if bilateral, chronic kidney disease.

**Diagnosis and treatment.** In addition to the clinical manifestations, a thorough family history should be obtained, risk factors for nephrolithiasis should be assessed, and any anatomic or functional urinary tract anomalies should be identified.<sup>41</sup> Urinalysis permits the identification of a concomitant infection, levels of specific stone-forming constituents (e.g., hypercalciuria), and urinary pH, which affects crystallization. Hematuria (gross or microscopic) may be present persistently or intermittently with or without other manifestations.<sup>43</sup> If a stone has been passed and is available, it is sent for analysis of its composition. Determination of a complete blood count; measurement of levels of serum electrolytes, serum creatinine, and BUN; and

### BOX 27-4 GENERAL INTERVENTIONS FOR NEPHROLITHIASIS

- Narcotic analgesics for pain management
- Increased fluid intake (>2 L/day; oral and/or IV)
- Antimicrobials for urinary tract infection
- Shock-wave lithotripsy, ureteral stenting, ureteroscopy for removal of large stones unable to pass spontaneously
- Dietary modifications unique to stone composition
- Medications unique to stone composition (e.g., allopurinol for uric acid stones)

### BOX 27-5 DIETARY MODIFICATIONS FOR NEPHROLITHIASIS

- Increase water intake (minimum of 2 L/day).
- Ensure adequate dietary calcium intake.
- Avoid calcium supplementation.
- Avoid foods with additional vitamin D (and vitamin C, if recommended).
- Avoid calcium-based antacids.
- Limit intake of coffee, tea, or colas to ≤2 per day.
- Reduce protein intake from meat, fish, and poultry.
- Limit dietary sodium and oxalate intake.
- Avoid high-purine foods for uric acid stones (and if recommended, for calcium).

assessment of parathormone level provide information related to risk factors and renal function.

The traditional gold standard for the assessment of renal calculi has been intravenous pyelogram (IVP), but it has been effectively replaced by computerized tomography (CT scans).<sup>39,43</sup> Basic abdominal x-rays identify only those stones that are radiopaque.<sup>41,43</sup> Ultrasonography is considered as effective as IVP, but provides limited data relative to renal function. It is second in choice for diagnosis to the CT scan.<sup>41,43</sup> CT scanning can identify renal calculi, other potential sources of flank pain, and anatomic anomalies.<sup>41,43</sup>

Treatment of nephrolithiasis may be medical or surgical and is determined by the size, position, and composition of the calculus; the presence or absence of urinary tract infection; and the involvement of one or both kidneys. Interventions are generally summarized in Box 27-4, and dietary changes are listed in Box 27-5. The goal is not only treatment of existing stones but also prevention of their recurrence.<sup>35,43</sup> Acute pain requires intervention with opiates. Morphine is especially useful because it reduces renal colic as well as affecting both transmission and perception of painful stimuli. With increased fluid intake, most stones pass out of the urinary tract spontaneously in both children and adults.<sup>35,41</sup> Stones less than 5 mm in diameter have a high chance of being passed, whereas those 5 to 7 mm in diameter have a 50% chance, and those >7 mm almost always require urologic intervention.<sup>38</sup> Other interventions that may be required include extracorporeal shock-wave lithotripsy, where the stone is broken into smaller pieces for passage, or percutaneous approaches to stone removal by endoscopy with basket retrieval or ultrasonic or laser lithotripsy.<sup>41</sup> Open surgical approaches are required when no other intervention is successful, but are usually avoidable and therefore uncommon. Unfortunately, depending upon the type of renal calculus, 30% to 50% of adults can expect a recurrence within 5 to 10 years.<sup>35,43</sup> Dietary modifications can decrease this risk.<sup>41</sup> Recommendations are designed for each individual patient, based upon the type of stone and specific risk factors.<sup>41</sup>

**KEY POINTS**

- Obstructive processes result in urine stasis, which predisposes to infection and structural damage. Common causes of obstruction include stones, tumors, prostatic hypertrophy, and strictures of the ureters or urethra. Of all potential causes, renal stones are the most common.
- Complete obstruction results in hydronephrosis, decreased GFR, and ischemic kidney damage because of increased intraluminal pressure. Prolonged postrenal acute kidney injury resulting from the obstruction may result in acute tubular necrosis (intrarenal acute kidney injury) and chronic kidney disease.
- Stones tend to form in the urinary tract under conditions of solute supersaturation, low urine volume, and abnormal urine pH. Certain factors increase the risk of stone formation, whereas others act as inhibitors.
- Most stones are composed of calcium crystals. Other forms include uric acid, struvite, cystine, and stones that form in association with certain medications.
- Stationary stones in the renal pelvis are generally asymptomatic. When the stone migrates to the junction with the ureters and beyond, intense renal colic pain ensues. Pain is usually abrupt in onset and may radiate. Additional signs and symptoms include nausea, vomiting, and diaphoresis.
- Most stones pass spontaneously, but other interventions may be necessary including lithotripsy or endoscopic approaches. Stones tend to recur, and prevention is enhanced by a high fluid intake to dilute the urine and dietary changes based upon the type of stone.

**GLOMERULAR DISORDERS (GLOMERULOPATHIES)**

Glomerular disorders result from alterations in the structure and function of the glomerular capillary circulation and are broadly delineated as **glomerulopathies**. The membranes of glomerular capillaries have three layers: endothelium, basement membrane, and a layer of specialized epithelial cells with footlike projections (podocytes) that encircle the basement membrane<sup>40</sup> (Figure 27-8). Together, this triple layer comprises the filtration barrier of the glomerulus. The glomerular filtrate passes through gaps (slit pores) between these podocytes, enters the space in Bowman capsule, and progresses into the proximal tubule. Glomerulopathies are responsible for 90% of the cases of end-stage renal disease.<sup>44</sup>

Pathologic changes to nephron glomeruli may occur insidiously, altering function over the course of months or years, or they may have an acute onset, with rapidly developing impairment. In some cases, there are no apparent signs or symptoms and glomerular dysfunction is identified serendipitously during routine physical examination or evaluation of some other health concern. The specific etiologies of glomerulopathies are often unknown. Hereditary and environmental factors are implicated; metabolic, infectious, hemodynamic, toxic, immune, genetic, and other mechanisms of injury are involved.<sup>44</sup> Immune or inflammatory processes are most often implicated.<sup>44</sup>

The challenge in any discussion of glomerulopathies lies in the often confusing range of clinical and pathologic approaches to their classification. One approach is to classify glomerular disorders according to primary and secondary etiologies.<sup>35,45</sup> *Primary glomerulopathies* are disease states in which the kidney is the only or the predominant organ involved, and *secondary glomerulopathies* result from drug exposure, infection, or glomerular injury in the setting of multisystem or vascular abnormalities. Goodpasture syndrome is an example of a secondary glomerulopathy, affecting the basement membranes of both the glomeruli of the kidney and the alveoli of the lung.<sup>35</sup> Systemic lupus erythematosus also causes a secondary glomerulopathy.<sup>46</sup> Diabetic nephropathy and renal damage attributable to undiagnosed or inadequately managed hypertension are also examples of secondary glomerulopathies.

The specific location and features of glomerular injury is another method of classification that has been used. Glomerular involvement

may be characterized as *diffuse* (all glomeruli) or *focal* (some but not all glomeruli).<sup>45-47</sup> Within the affected glomeruli, lesions may be *global*, affecting all parts of the glomerulus, or present as patches (*segmental*) when only specific parts of the glomerulus are involved.<sup>44,47,48</sup> If thickening of glomerular capillary walls is present, the glomerulopathy is *membranous*. Membranous changes involve the basement membrane and are usually due to accumulated deposition of immunoglobulins (IgG) and complement components (C5).<sup>35,45</sup> *Sclerotic* changes refer to scarring attributable to persistent or recurrent injury and may occur within the capillaries, in the capillary space, or at the point of initiation of the proximal tubule. The site of deposition of noncellular materials as part of the glomerulopathic process may be described specifically as *mesangial*, *subendothelial*, or *subepithelial*.<sup>45</sup> Efforts to specify the glomerulopathy often result in combinations of terminology, such as *focal segmental*<sup>47,48</sup> or *membranoproliferative*.<sup>35</sup> Various glomerulopathies may be linked to more than one type of injury, however; so this lack of specificity makes absolute classification by this criterion less beneficial. Its primary value rests in providing a common vocabulary for the description of glomerulopathic lesions. Renal biopsy and histologic examination are required for this level of specificity. More recently, a method of classification according to the degree and type of dysfunction, injury, or loss of the glomerular podocytes has been proposed.<sup>44</sup>

Glomerulopathies may result in proteinuria, hematuria, abnormal urinary casts, decreased GFR, and hypertension; however, these manifestations may not all be present in a single pathology and/or they may present along a continuum of degree. Proteinuria is classically the clinical manifestation associated with glomerulopathy; other urinary or systemic conditions may present with hematuria, urinary casts, reduced GFR, or hypertension. Damage to the glomerulus will result in protein loss from the bloodstream into the urine.<sup>1</sup> Under normal circumstances, protein molecules are too large to pass through the slit pores of the glomerulus, so they are retained in the bloodstream. The very small Bence Jones protein associated with multiple myeloma is easily filtered and will appear in the urine in that condition. Transient proteinuria may be seen with diets high in protein, or as a result of excessive exercise or emotional stress. Normally, protein lost in the urine amounts to 50 to 80 mg in 24 hours (at rest).<sup>1</sup> Glomerulopathies may be classified according to the degree of proteinuria.<sup>45</sup> **Nephrotic syndrome** is specifically characterized by protein loss  $\geq 3$  to 3.5 g in 24 hours<sup>1</sup> and is most commonly associated with minimal change disease/lipoid nephrosis, focal segmental glomerulosclerosis, and membranous nephropathy, but can occur with any glomerulopathy if the injury is sufficient to allow significant protein loss.<sup>51</sup> **Nephritic syndrome** is also a reflection of glomerular inflammation. In this case, hematuria is seen on gross urinalysis, and red blood cell (RBC) casts are present in the sediment. Mild to moderate proteinuria, edema, hypertension, oliguria, and decreased GFR producing an elevation in serum creatinine level may also be noted.<sup>1,35,51</sup>

The most common types of glomerular disease are acute postinfectious glomerulonephritis, IgA nephropathy, rapidly progressive/crescentic glomerulonephritis, nephrotic syndrome (includes membranous glomerulonephritis, focal segmental glomerulosclerosis, minimal change disease/lipoid nephrosis), and chronic glomerulonephritis. By far the most common secondary glomerulopathies are diabetic nephropathy and glomerulopathy resulting from hypertension. These are addressed in Chapters 41 and 16, respectively.

**Glomerulonephritis**

Glomerulonephritis includes an assortment of immune-mediated conditions that produce inflammation of glomeruli and other areas of the kidney.<sup>45</sup> It may have a primary etiology, which is commonly believed to be autoimmune, or a secondary one, in which it is associated with a number of autoimmune, metabolic, malignant, or infectious systemic disorders.

**FIGURE 27-8** Schematic illustration of the lobe of a glomerulus. Note the foot processes of the podocytes, basement membrane, and endothelium of the glomerular capillary. (From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 543.)

Although there is some variation, for the most part glomerulonephritis is more common among men than women.<sup>45</sup> More than 20 years ago, glomerulonephritis was believed to be the leading cause of the end-stage of chronic renal disease.<sup>40</sup> Although worldwide it remains the second most common cause,<sup>45</sup> in the United States the glomerulopathies associated with diabetes mellitus and hypertension hold that distinction.<sup>40,45</sup>

### Acute Glomerulonephritis

The term *acute glomerulonephritis* encompasses a constellation of inflammatory glomerulopathies that are characterized by the abrupt onset of varying degrees of hematuria, proteinuria, oliguria and azotemia, edema,

and hypertension.<sup>45</sup> A wide variety of triggers may initiate the process (Box 27-6). The pathophysiologic process is summarized in Figure 27-9.

*Postinfectious acute glomerulonephritis* is historically most well-known to follow skin (impetigo) and throat infections with specific strains of group A  $\beta$ -hemolytic streptococci.<sup>35,45,51</sup> This etiology is common today only among children in impoverished areas of developed countries and developing countries,<sup>45,51</sup> where it is the basis of 4.6% to 51.6% of pediatric acute kidney injury admissions.<sup>51</sup> The reduction in incidence of this etiology elsewhere is most likely due to early diagnosis and treatment of streptococcal infections.<sup>51</sup> The infectious organism acts as the antigen, initiating an antibody-antigen reaction. The onset of glomerular

inflammation varies; in the case of a streptococcal etiology, damage to the glomerulus is initiated 1 to 3 weeks following the initial infection.<sup>35</sup>

As with most other forms of glomerulonephritis, antibody deposition leading to inflammation is the key pathologic event.<sup>45</sup> In this case,

Irradiation for Wilms tumor

IgG is the immunoglobulin involved.<sup>51</sup> Proliferation of mesangial cells is initiated following immune complex deposition<sup>40</sup> resulting in characteristic proliferative lesions. Autoimmune mechanisms in poststreptococcal glomerulonephritis have also been suggested.<sup>35,51</sup> Complement is activated, primarily by the alternate pathway.<sup>51</sup> It is deposited within the glomerulus; this is a major aspect of most forms of glomerulonephritis.<sup>45</sup> In response to complement, chemotactic factors, macrophages, neutrophils, and T helper cells infiltrate the glomerular capillary walls.<sup>51</sup> Elevated levels of IL-6, IL-8, and tumor necrosis factor- $\alpha$  are noted in the serum. Lysosomal enzymes are released and attack glomerular walls. The resulting changes in the structure of the glomerular wall result in a decrease in the surface area available for filtration and allow substances that were previously restricted to enter the glomerular space. Locally-acting vasoactive compounds such as angiotensin and leukotrienes contract mesangial cells and reduce perfusion to glomerular capillaries, decreasing the GFR.<sup>51</sup> In severe cases, the coagulation cascade is activated and fibrin is deposited within capillaries, further impairing perfusion.<sup>45</sup>

Clinical manifestations of postinfectious acute glomerulonephritis vary in severity.<sup>51</sup> Smoky or coffee-colored urine attributable to hematuria and red cell casts (nephritic syndrome) are the most common findings. White cell casts may also be present. The degree of proteinuria is variable, and may reach nephrotic syndrome level. Reduced GFR presents as increased circulating volume, producing edema, hypertension, and oliguria with increasing serum levels of creatinine and nitrogenous wastes (BUN).<sup>35,51</sup>

Diagnosis is based on the patient's history, clinical manifestations, and urinalysis results. Renal function is evaluated by BUN and creatinine levels. A renal biopsy may be indicated. Care is supportive and symptomatic. Dialysis may be needed to support renal function. Especially in children, resolution of the inflammatory process may occur within about 2 weeks (poststreptococcal) with no sequelae or

**FIGURE 27-9** Summary of the pathophysiologic process of acute glomerulonephritis and associated clinical manifestations.

complications, or the deterioration of renal function may continue, resulting in chronic glomerulonephritis, nephrotic syndrome (glomerulosclerosis), and chronic kidney disease.<sup>35,40</sup>

*IgA nephropathy (Berger disease)* is the most commonly diagnosed type of primary glomerulonephritis worldwide.<sup>35,50</sup> It is more common in the adult population than among pediatric patients.<sup>45</sup> Upper respiratory tract or gastrointestinal viral infections appear to be the triggers, initiating the deposition of IgA in the glomerular mesangium.<sup>35</sup> Increased abnormal IgA<sub>1</sub> production and formation of IgA<sub>1</sub> complexes cause mesangial injury, leading to renal failure.<sup>35,50</sup> Hematuria is usually apparent within 1 to 2 days, but the proteinuria, edema, and hypertension common with other glomerulopathies are generally not evident. Prognosis is variable; as many as half the patients develop glomerulosclerosis and end-stage renal disease.<sup>35,50</sup>

### Crescentic Glomerulonephritis/Rapidly Progressive Glomerulonephritis (RPGN)

The condition previously known as *rapidly progressive glomerulonephritis* is now more often called *crescentic glomerulonephritis* because of its characteristic lesions.<sup>45</sup> The lesions are proliferative in nature and composed of crescent-shaped depositions of accumulated epithelial cells, fibrin, and macrophages that are found in Bowman space.<sup>45</sup> Podocytes that are progressively losing their markers of differentiation are also a part of the process.<sup>44</sup> This form of glomerulonephritis may have an acute onset, with hematuria, proteinuria, and red cell casts followed by a swift decline in renal function within 6 months.<sup>35</sup> It occurs predominantly in patients 20 to 50 years old.<sup>35</sup> When not idiopathic, causes of crescentic glomerulonephritis fall into four general categories: (1) complication of an acute or subacute infection; (2) complication of a multisystem disease; (3) drug exposure; and (4) a primary disorder in the absence of other systemic disease. The most common infections associated with this disorder are poststreptococcal glomerulonephritis and infective endocarditis. Multisystem diseases associated with it are systemic lupus erythematosus, Henoch-Schönlein purpura, systemic necrotizing vasculitis, and Goodpasture syndrome. Examples of drugs identified as causative are penicillamine, hydralazine, allopurinol in the presence of vasculitis, and rifampin.<sup>45</sup>

*Goodpasture syndrome* is an autoimmune disorder that results from the combination of glomerulonephritis with alveolar hemorrhage and the presence of anti-glomerular basement membrane (anti-GBM) antibodies. It most often develops in genetically susceptible people who smoke cigarettes. Men are affected more than women.<sup>35</sup> Patients suffer with the clinical manifestations of glomerulonephritis and also shortness of breath and hemoptysis because of pulmonary involvement. Manifestations of pulmonary involvement may appear before those associated with glomerulonephritis. Prognosis is good when treatment is begun before onset of respiratory or renal failure.<sup>35</sup> Treatment is based on system support; plasmapheresis (therapeutic plasma exchange to decrease circulating antibodies), corticosteroids, and immunosuppression are the most common interventions.<sup>35</sup>

### Chronic Glomerulonephritis

Glomerular diseases that assume a progressive course ultimately develop into chronic kidney disease.<sup>45</sup> These patients present with persistent proteinuria, with or without hematuria, and slowly declining renal function. In many cases, patients appear to have recovered from the initial insult. Proteinuria and hypertension are both capable of advancing renal damage. The pathophysiology is an extension of that seen in acute glomerulonephritis. Proliferative and membranous lesions are present but sclerotic injury dominates, resulting in ongoing fibrotic changes. Tubulointerstitial damage contributes to the reduction in renal function. Nephrons atrophy and ultimately the kidneys

become small, scarred, and nonfunctional. While the chronic kidney disease progresses, supportive interventions may retard the process (see Chapter 28), but the patient ultimately reaches end-stage renal disease and dialysis or transplantation is required.<sup>45</sup>

### Nephrotic Syndrome

Nephrotic syndrome is a glomerulopathy in which there is a urinary elimination of >3 to 3.5 grams of protein per day due to glomerular damage.<sup>52,53</sup> Ultimately, most patients will develop the full constellation of nephrotic syndrome manifestations: hypoalbuminemia, hyperlipidemia, edema, and a propensity for thrombus formation. The most common primary causes are minimal change disease (lipoid nephrosis), idiopathic focal segmental glomerulosclerosis, and membranous nephropathy. Several systemic diseases, such as systemic lupus erythematosus and Henoch-Schönlein purpura, as well as infections, malignancies, and vasculitis have been found to be associated with nephrotic syndrome, but the most common cause in adults is diabetes mellitus.<sup>52,53</sup>

The pathophysiology of nephrotic syndrome is shown in [Figure 27-10](#). The increased permeability of the glomerular membrane allows large quantities of protein to leave the bloodstream and exit the body in the urine. This produces hypoalbuminemia and proteinuria. The low serum albumin concentration serves to stimulate the liver to increase production of cholesterol and lipoproteins, producing hyperlipidemia.<sup>52-54</sup> The actual mechanism has not been fully elucidated but is clearly multifactorial and complex.<sup>52-54</sup> Levels of cholesterol and low-density lipoproteins (LDLs) are elevated; cholesterol levels are consistently greater than 300 mg/dl.<sup>53</sup> Lipid casts or fat droplets may appear in the urine.<sup>1</sup> Oval fat bodies, epithelial cells from the tubules, may also be sloughed.<sup>1</sup> There is an increased risk of thrombotic events in nephrotic syndrome.<sup>52,53</sup> This complication has many possible etiologies, but most likely the proteins required for hemostasis are lost in the urine, stimulating hepatic synthesis of clotting factors.<sup>52,53</sup> Edema is the most common clinical manifestation of nephrotic syndrome.<sup>52,53</sup> Two theories have been proposed to explain its development.<sup>53</sup> As the serum albumin is lost, the oncotic pressure within the blood vessels declines and the hydrostatic pressure is relatively increased, forcing fluid into the interstitial spaces. Reduction in circulating volume results in the activation of the renin-angiotensin-aldosterone system, causing sodium and then water retention and promoting more protein loss and edema. The second theory claims that the kidneys' intrinsic sodium-retaining mechanism is activated before the loss of protein, expanding circulating volume, and increasing capillary filtration and edema formation. A vicious cycle of protein loss, fluid retention, and edema is initiated.

Treatment of nephrotic syndrome, regardless of causation, includes gradual removal of fluid with diuretics to treat edema.<sup>52,53</sup> Elevated lipid levels are routinely treated with lipid-lowering therapy, if rapid recovery from nephrotic syndrome is not anticipated.<sup>52,53</sup> Hypertension is treated with angiotensin II receptor blockers and/or angiotensin-converting enzyme inhibition, as is recommended for chronic kidney disease. Treatment with immunosuppression or immunomodulation is standard for most primary etiologies, although response is variable.<sup>52,53</sup>

### Membranous Nephropathy (MN)

MN accounts for about one third of the cases of adult-onset nephrotic syndrome.<sup>49,55</sup> Twenty percent of these cases have secondary causes such as infections, autoimmune diseases, and malignancies. For lack of any concrete evidence, the remaining 80% are said to be idiopathic.<sup>49,55</sup> [Figure 27-11](#) illustrates the histologic findings with MN and the pathologic changes in the glomerulus. Immune deposits and as-yet unidentified antigens collect in the subepithelium of the distal portion of the basement membrane and produce a membranous thickening.<sup>35,49,55</sup> Spontaneous remission occurs in approximately 25% of cases, 25%

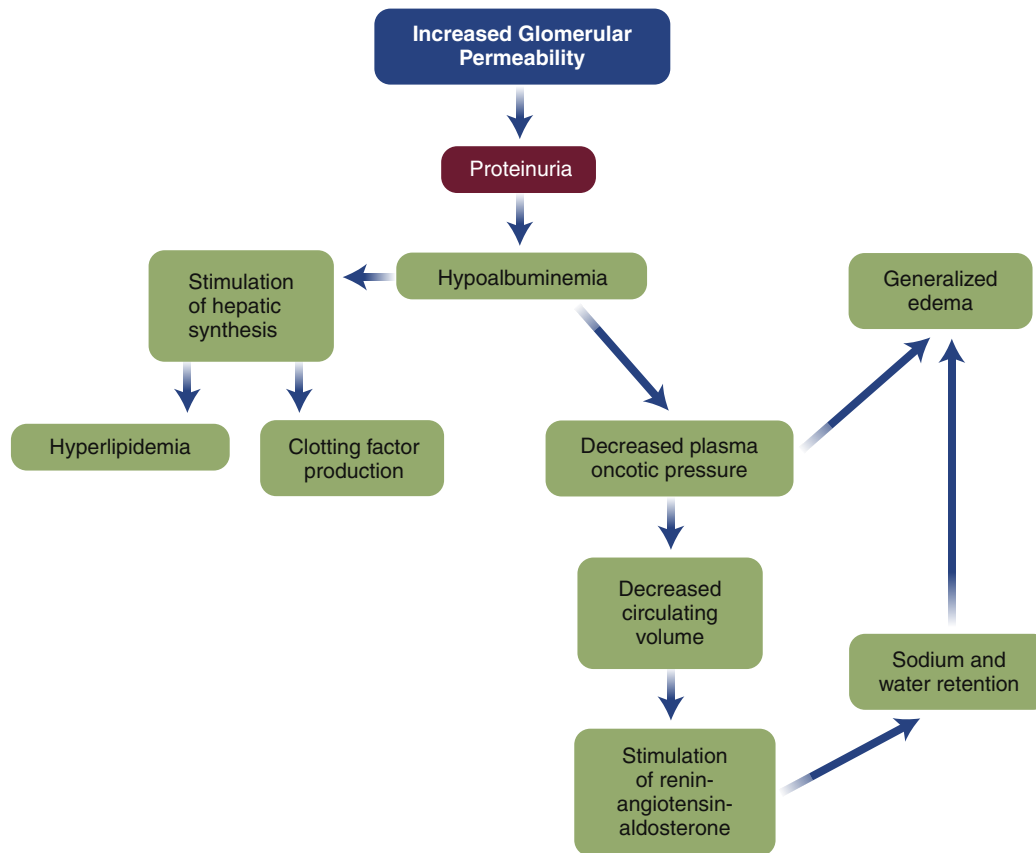

FIGURE 27-10 Pathophysiologic process of nephrotic syndrome.

develop persistent nonnephrotic-range proteinuria, 25% develop persistent nephrotic syndrome, and 25% of the individuals with MN progress to end-stage renal disease.<sup>35</sup>

### Focal Segmental Glomerulosclerosis (FSGS)

FSGS is now the most common cause of idiopathic (or primary) nephrotic syndrome among adults in the United States.<sup>35</sup> It may develop secondarily to a number of immunologic, metabolic, interstitial, hemodynamic, or other conditions. Only a portion of the glomeruli are affected (segmental), and glomeruli within the kidney are not uniformly impacted (focal). This is a disease of glomeruli podocytes that over time progresses to scarred lesions. Epithelial injury and endothelial cellular injury initiate the protein loss across the glomerular membrane. In addition to proteinuria, patients can develop mild hematuria, hypertension, and azotemia.<sup>35</sup> Only 5% of patients will experience complete remission. Once proteinuria reaches nephrotic syndrome levels, 50% of those with FSGS will reach ESRD within 6 to 8 years.<sup>48</sup> Disproportionately, more blacks than other ethnic groups develop FSGS.<sup>35</sup>

### Minimal Change Disease (MCD)

Previously called *lipoid nephrosis*, MCD is the primary cause of idiopathic nephrotic syndrome in children, accounting for 77% of nephrotic syndrome diagnoses by biopsy in children and adolescents.<sup>56</sup> It is usually initiated by an allergic or immune condition, including lymphomas. The result of the altered structure of the podocytes is a less effective glomerular filtration and the loss of copious amounts of albumin in the urine. Onset of edema, heavy levels of proteinuria, and hypoalbuminemia is sudden.<sup>35</sup> Although a longer course is usually needed in children, MCD responds well to treatment with corticosteroids.<sup>35</sup> Fewer patients progress to ESRD with MCD than the other common forms of nephrotic syndrome.

### KEY POINTS

- Glomerulopathies alter glomerular capillary structure and function. Damage is mediated by immune processes. The glomerular damage may result in some combination of hematuria, proteinuria, abnormal casts, decreased GFR, edema, and hypertension.
- Glomerulonephritis is due to an immune response to a variety of potential triggers and may have a primary or secondary etiology. Attraction of immune cells to the area of inflammation results in lysosomal degradation of the basement membrane. The GFR may fall, in part because of contraction of mesangial cells resulting in decreased surface area for filtration.
- Glomerulonephritis may be classified as acute, crescentic, or chronic. Acute forms are usually triggered by infection. The cause of the crescentic form is often unknown, but it may be secondary to other disease processes such as Goodpasture syndrome. Chronic forms are those that progress to chronic kidney disease.
- Treatment of glomerulonephritis may include steroids, plasmapheresis, and supportive measures such as dietary and fluid management and management of systemic and renal hypertension. End-stage renal disease is a common outcome of chronic glomerulonephritis, necessitating dialysis or kidney transplantation.
- Nephrotic syndrome occurs because of increased glomerular permeability to proteins, which results in a urinary loss of 3 to 3.5 g of protein or more per day. Proteinuria leads to hypoalbuminemia and generalized edema as a result of decreased blood colloid osmotic pressure. Hyperlipidemia and hypercoagulability are thought to occur because of a generalized increase in liver activity stimulated by hypoalbuminemia.
- Treatment of nephrotic syndrome is conservative, consisting of management of symptoms and the underlying process that initiated the syndrome, when possible. Although many cases resolve spontaneously, others progress to end-stage renal disease.

## SUMMARY

Many diseases can cause damage to the kidney. Any process that disrupts the normal architecture of the kidney will cause altered function, whether in the glomeruli, the vascular tree, or the collecting/drainage system. Despite the kidney’s resiliency and capacity to respond to treatment, ultimately any abnormality in the system has the potential to progress to chronic kidney disease.

## KEY QUESTIONS

- How do the prerenal, intrinsic, and postrenal types of acute kidney injury differ in etiology, prognosis, clinical manifestations, and management?
- What are the characteristic clinical and laboratory findings in each of the three stages of acute tubular necrosis (acute intrarenal renal failure)?
- What is the relationship between the degree of nephron loss, reductions in glomerular filtration rate, and the stages of chronic kidney disease?
- What are the similarities and differences between acute kidney injury and end-stage chronic kidney disease?
- What are the characteristic findings of uremic syndrome?
- How can acute kidney injury be prevented, and how is it treated?
- How is the progression of chronic kidney disease retarded?
- How is end-stage renal disease treated?

The kidneys have a number of regulatory roles within the body.<sup>1</sup> These key functions include the regulation of body fluid volume and osmolality, electrolyte balance, and acid-base balance. Additionally, the kidneys produce and secrete hormones, and excrete metabolic waste products and foreign materials.<sup>1</sup> When the kidneys are unable to carry out these functions on a temporary or permanent basis, the ramifications are significant to each body system.

## ACUTE KIDNEY INJURY

Acute kidney injury (AKI), formerly known as acute renal failure (ARF), represents a broad spectrum of kidney diseases ranging from minor changes in renal function to complete renal failure requiring renal replacement therapy.<sup>2-5</sup> Acute kidney injury is the sudden reduction of kidney function causing disruptions in fluid, electrolyte, and acid-base balances; retention of nitrogenous waste products; increased serum creatinine level; and decreased glomerular filtration rate (GFR).<sup>2-4</sup> Classification criteria for AKI have been developed to identify kidney injury and improve patient outcomes. The 5-point system is known as the RIFLE classification system (R = Risk of injury, I = Injury, F = Failure, L = Loss of function, and E = End-stage kidney disease)<sup>2,3</sup> (Table 28-1). The first three stages indicate severity of kidney injury and the last two stages represent patient outcomes. Subsequent to the development of the RIFLE classification, The Acute Kidney Injury Network (AKIN) proposed modifications to the RIFLE criteria, namely, the addition of an absolute increase in serum creatinine concentration of  $\geq 0.3$  mg/dl and the specification that the reduction in kidney function occur within a 48-hour period.<sup>2</sup>

The incidence of AKI in hospitalized patients ranges from 2% to 7%, with higher rates in elderly patients.<sup>2,3</sup> Despite improvements in treatments, mortality rates range from 40% to 90%.<sup>3</sup> In critical care units, the incidence of AKI reportedly ranges from 1% to 25% with mortality rates between 15% and 60%.<sup>6</sup>

### Etiology and Pathophysiology

The risk of developing acute kidney injury is increased by certain pre-existing conditions. These comorbidities include preexisting kidney impairment, cardiovascular and peripheral vascular disease, hypertension, diabetes mellitus, heart failure, malignancies, and benign prostatic hypertrophy.<sup>2</sup> Not only are the elderly more likely to have one or more of these conditions, but also aging itself results in changes within the kidney that make it more susceptible to damage. Renal blood flow may drop by 50% between the ages of 20 and 80 and the GFR by about 8 ml/min/1.73 m<sup>2</sup> per decade after the age of 30.<sup>2,8</sup> These alterations in function increase the risk of AKI and can negatively impact overall prognosis. The aging kidney is less capable of concentrating and diluting urine, conserving sodium, producing prostaglandin, and maintaining renin and aldosterone levels.<sup>2,8</sup> See Chapter 26 for a discussion of the effects of aging on renal function.

Acute loss of renal function is attributed to conditions that affect renal perfusion (prerenal), factors that obstruct urine flow distal to the kidney (postrenal), or circumstances within the kidney blood vessels, tubules, glomeruli, or interstitium (intrinsic).<sup>2,7</sup> These anatomic delineations are broadly seen as the types or causes of AKI, but the specific etiology must also be identified. Determination of the specific etiology as well as the type of AKI is essential for effective management. Box 28-1 shows the types of AKI and some of their etiologies.

### Prerenal Kidney Injury

When acute kidney injury develops because of diminished perfusion of the kidney, it is termed *prerenal* kidney injury because the etiology occurs before the kidney itself.<sup>10</sup> As seen in Box 28-1, this can be due to an

**TABLE 28-1 RIFLE CLASSIFICATION FOR STAGING ACUTE KIDNEY INJURY**

STAGE	GFR CRITERIA	URINE OUTPUT CRITERIA
<b>Risk</b>	Serum creatinine increased $\times 1.5$ or GFR decreased by 25%	Urine output $< 0.5$ ml/kg/hr for 6 hr
<b>Injury</b>	Serum creatinine increased $\times 2$ or GFR decreased by 50%	Urine output $< 0.5$ ml/kg/hr for 12 hr
<b>Failure</b>	Serum creatinine increased $\times 3$ or GFR decreased by 75% or serum creatinine $> 4$ mg/dl with acute rise $\geq 0.5$ mg/dl	Urine output $< 0.3$ ml/kg/hr for 24 hr (oliguria) or anuria for 12 hr
<b>Loss</b>	Persistent acute kidney failure; complete loss of kidney function $> 4$ wk	
<b>End-stage kidney disease</b>	Complete loss of kidney function $> 3$ mo

absolute or relative decrease in circulating volume, or abnormalities of renal hemodynamics. Actual or relative depletion of volume are the most common etiologies.<sup>27</sup> Fever, vomiting, diarrhea, burns, hemorrhage, and overuse of diuretic therapy produce fluid volume deficits that can lead to prerenal kidney injury. Decreased renal perfusion also results if large volumes of fluid collect in extravascular spaces as in edema (interstitial space) or ascites (peritoneal space). Any number of conditions reduces the ability of the heart to generate a cardiac output sufficient to meet the needs of body organ systems. Even though the kidney receives 20% to 25% of the cardiac output,<sup>7</sup> that volume may be inadequate when the cardiac output is markedly decreased by cardiogenic shock, heart failure, or lethal ventricular dysrhythmias.

Although most patients who develop prerenal kidney injury have an episode of decreased blood pressure that results in decreased perfusion to the kidney, in some cases perfusion drops without the blood pressure falling below normal.<sup>9</sup> These “normotensive” cases of prerenal kidney injury arise in susceptible individuals with very modest reductions in blood pressure who have preexisting impairments in renal autoregulation. Use of nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors (ACEIs), and angiotensin II (AII) receptor blockers is known to interfere with renal vascular autoregulation and can precipitate prerenal kidney injury in certain populations of patients. This includes those who are older than 60 years of age with atherosclerotic cardiovascular disease or have preexisting renal insufficiency (elevated serum creatinine level), heart failure, advanced liver disease, or nephrotic syndrome.<sup>2,9</sup> These drugs cause either vasoconstriction of afferent arterioles (NSAIDs) or vasodilation of efferent arterioles (ACE inhibitors and AII blockers); either of these actions results in a decrease in glomerular perfusion pressure.<sup>2,9</sup> Thrombus, embolus, dissection, or stenosis of the renal arteries will also result in prerenal kidney injury,<sup>2,9</sup> and the risk increases significantly if ACE inhibitors or AII blockers are being used.<sup>2,9</sup>

Prerenal oliguria is the kidney’s normal physiologic response to a decrease in perfusion,<sup>7,9</sup> and at least for a time the renal tissue is unharmed. Neurohumoral mechanisms of local autoregulation are activated as the kidneys attempt to autoregulate perfusion and maintain GFR, and systemic mechanisms such as the renin-angiotensin-aldosterone system (RAAS) act to increase the total

**BOX 28-1 TYPES OF ACUTE KIDNEY INJURY****Prerenal**

- Absolute decrease in circulating volume
  - Hemorrhage
  - Dehydration
  - Burns
- Relative decrease in circulating volume
  - Distributive shock (neurogenic, anaphylactic, septic)
  - Third-spacing and edema
  - Decreased cardiac output

  - Acute allergic interstitial nephritis
  - Acute pyelonephritis
- Vascular
  - Vasculitis
  - Emboli
  - Nephrosclerosis (due to primary hypertension, hypertensive emergencies, and urgency)

\*Use of ACE inhibitors or All receptor blockers increases the risk.

†Preexisting chronic renal insufficiency, cirrhosis, heart failure, or elderly persons (>60 years) with atherosclerotic cardiovascular disease, hypotension, diuretic use, or nephritic syndrome.<sup>11</sup>

circulating volume.<sup>2,7</sup> The sensed decrease in renal blood flow results in a decrease in GFR and urine output. Because of the kidney's ability to tolerate significant reduction in perfusion (as long as it is not greater than 20% to 25% of normal), and as long as the hypoperfusion etiology is identified and corrected, prerenal oliguria will not affect the parenchyma of the kidney.<sup>2,7</sup> Efforts to restore adequate perfusion should be fully effective in restoring normal renal function within 1 to 2 days.<sup>9</sup> In the case of normotensive patients who have impaired perfusion, by far the smallest subset of prerenal kidney injury cases, interventions must be targeted to the specific etiology.<sup>9</sup> Regardless of the etiology, persistent prerenal kidney injury will result in hypoxic renal cells. If hypoxia continues and ischemia lasts more than a few hours, prerenal kidney injury will progress to acute tubular necrosis (intrinsic kidney injury).<sup>7,8</sup>

**Postrenal Kidney Injury**

Obstruction of the normal outflow of urine from the kidneys can result in postrenal kidney injury.<sup>2,7,8</sup> Box 28-1 lists the most common etiologies of this type of AKI. If only one kidney is affected, the activity of the remaining kidney will increase to maintain fluid and electrolyte balance.<sup>2,7</sup> Obstruction of the renal pelvis or ureters of both kidneys, of the bladder outlet, or of the urethra will result in discernible postrenal kidney disease. This type of AKI is the least common and the most amenable to intervention. Normalization of renal function depends on the length of time the obstruction persists.<sup>7</sup> Should obstruction persist, the increasing retrograde pressure of urine will result in acute tubular necrosis (intrinsic AKI), and if the obstruction continues over several days or weeks, irreversible damage to the kidney will result.<sup>7,8</sup>

**Intrinsic/Intrarenal Kidney Injury**

AKI intrinsic to the kidney itself is further classified by the specific anatomic area involved: vascular, interstitial, glomerular, or tubular<sup>2</sup>

(see Box 28-1). Some references incorporate the vascular and tubular classifications together because damage to one ultimately leads to damage of the other.<sup>7</sup> All of these etiologies are capable of producing the potentially reversible rapid decline in renal function that is AKI. When the small vessels within the kidney are inflamed, obstructed, or damaged by an acute hypertensive episode, the injury may be sufficient to impair nephron functioning. Acute glomerulonephritis is due to an abnormal immune reaction, whereby immune complexes are deposited in the basement membrane of the glomerulus, thereby damaging the glomeruli.<sup>7</sup> Normal renal function is disrupted to some degree during this acute inflammatory process, usually lasting about 2 weeks. Acute glomerulonephritis is discussed in detail in Chapter 27. Inflammation of interstitial tissues may be sufficient to result in intrinsic kidney injury. This is usually due to an infection of the kidney (pyelonephritis), an allergic reaction to medications, or an autoimmune disease.<sup>2,5</sup> Long-standing pyelonephritis causes damage to the renal medulla and progressive loss of functional renal tissue.<sup>7</sup>

By far the most common cause of intrinsic kidney injury is acute tubular necrosis (ATN), which itself has many potential etiologies.<sup>2,7</sup> Acute tubular necrosis is the result of tubular cell injury, primarily attributable to ischemia or exposure to nephrotoxic substances. Acute tubular necrosis accounts for nearly half of all cases of AKI in hospitalized patients. Sepsis is the most common cause of ischemic ATN and may develop in about 50% of critically ill patients. It causes vasodilation leading to hypoperfusion within the kidney.<sup>10</sup> In the elderly, about 30% of ischemic cases are due to sepsis and another third are due to surgical interventions.<sup>2</sup> Prolonged prerenal kidney injury, perioperative and postoperative hypotension, hemorrhage, gastrointestinal drainage, and preoperative cardiac complications also contribute to many case of ATN.<sup>2</sup>

The list of medications and chemicals toxic to the kidney is expansive,<sup>2,7</sup> each one inducing a specific toxic reaction in the tubular

cells and causing the death of many of them.<sup>7</sup> Of all of these nephrotoxins, contrast medium is the most common offending agent.<sup>2,7</sup> Contrast-induced AKI (also known as contrast-induced nephropathy) is a major cause of AKI in hospitalized elderly patients, and can develop within 12 to 24 hours of contrast administration.<sup>10</sup> Risk factors for developing contrast-induced AKI are underlying kidney insufficiency, age greater than 70, volume depletion, repeated exposures to contrast media in a short time, and coexisting heart failure or diabetes mellitus.<sup>10</sup> Prevention is aimed at avoidance of unnecessary contrast administration to high-risk patients, avoidance of multiple procedures over a 24- to 48-hour period, and adequate administration of hypotonic and isotonic intravenous (IV) fluids before and after contrast administration.<sup>2,10</sup> ATN caused by contrast media results in prolonged hospitalization, increased health care costs, and an increased risk of death.<sup>37</sup> Other nephrotoxic agents include commonly used medications such as aminoglycosides, NSAIDs, amphotericin B, cisplatin, and tetracycline.<sup>2,7,10</sup>

In ATN, there are two pathophysiologic processes that result in the rapid decrease in glomerular filtration rate: a vascular process and a tubular process.<sup>11</sup> The two processes are interrelated, and the severity of one contributes to the severity of the other. Renal blood flow is decreased by 30% to 50% in ATN, and blood is shunted from the medulla to the cortex, further compromising the medullary cells.<sup>11,12</sup> Local vasoconstrictors such as prostaglandins and leukotrienes are released, and the effects of sympathetic nervous system (SNS) stimulation contribute further to the vasoconstriction.<sup>12</sup> Hypoxia or direct tubular damage, attributable to toxins, initiates an inflammatory response, activating the cascade of inflammatory mediators. When perfusion is restored, more inflammatory cells are enlisted and reperfusion injury perpetuates damage in some areas. Cells in part of the proximal tubule and outer cortex begin the repair process when perfusion is returned, but endothelial cells and those in the ascending limb continue to be injured, become necrosed, and commit apoptosis, resulting in a further decline in GFR.<sup>11,12</sup>

The pathogenesis of the tubular process is a reflection of the ischemia<sup>11</sup> and the inflammatory process (Figure 28-1). Damaged

tubular epithelial cells, both viable and nonviable, are shed from the basement membrane and accumulate in the tubular filtrate, where they obstruct filtrate flow.<sup>7,11</sup> These cells combine with inflammatory cells and debris to form casts that contribute further to the urinary obstruction.<sup>11</sup> Obstructed urinary flow produces an increased pressure within the nephron that is communicated backwards to the glomerulus, further reducing the GFR. The increasing pressure generated by the tubular obstruction forces filtrate through the partially denuded tubular basement membrane into the interstitial space and even into the bloodstream, a process known as *tubular backleak*.<sup>10</sup> Half of the already limited quantity of glomerular filtrate may be lost to the interstitium by this process.

Recovery following ATN is highly dependent on the extent of injury and slower than in the other two types of AKI.<sup>7,12</sup> If sufficient destruction of the basement membrane occurs, there may be no recovery and the patient develops end-stage renal disease, the final stage of chronic kidney disease. But the tubules can repair themselves within 10 to 20 days when the basement membrane is intact and new epithelial cells are produced on that surface.<sup>7</sup> As with the other types of renal failure, the clinical presentation of ATN is primarily a reflection of the loss of the normal functions performed by the kidney.

### Clinical Presentation of Acute Tubular Necrosis

Prerenal kidney injury can be reversed if treated before perfusion drops to below 20% of normal and ischemia occurs.<sup>7</sup> It is at this point that ATN develops. Prerenal or postrenal kidney injury will ultimately progress to intrinsic kidney injury if not corrected within a few hours.<sup>7</sup> The course of ATN is roughly divided into three phases, and the clinical presentation varies with the phase<sup>16</sup> (Figure 28-2). The laboratory findings that differentiate prerenal from intrinsic kidney injury are shown in Table 28-2. Table 28-3 provides the laboratory profile associated with renal failure; some of these findings are more likely to be noted in end-stage renal disease than in AKI. Though serum creatinine

## CHAPTER 28 Acute Kidney Injury and Chronic Kidney Disease

**TABLE 28-2 LABORATORY VALUE DIFFERENCES IN PRERENAL AND INTRINSIC AKI**

LABORATORY TEST	PRERENAL FINDINGS	INTRARENAL FINDINGS
FENa %	<1	>2
Proteinuria	Absent	Possible
Urine specific gravity	>1.020	1.010-1.020
Urine osmolality (mOsm/kg)	>500	300-500
BUN/creatinine ratio	>20:1	10-20:1
Urine sodium concentration (mmol/L)	<10	>20
Urinary sediment	Few hyaline casts	Tubular, RBC, and WBC casts

**TABLE 28-3 LABORATORY PROFILE FOR RENAL DISEASE**

TEST	NORMAL RANGE FOR ADULTS	VALUES IN RENAL DISEASE	COMMENTS
<b>Test to Evaluate Removal of Nitrogenous Wastes</b>			
Serum creatinine	Male: 0.6-1.2 mg/dl Female: 0.5-1.1 mg/dl Older adults: Decreased	<b>In Chronic Kidney Disease</b> May increase by 0.5-1.0 mg/dl every 1-2 yr May be as high as 15-30 mg/dl before symptoms of CKD are present <b>In Acute Kidney Injury</b> Gradual increase of 1-2 mg/dl every 24-48 hr May increase 1-6 mg/dl in 1 wk or less	Consistently elevated levels indicate decreased renal function. Serum creatinine levels are used to evaluate effectiveness of dialysis treatments.
Blood urea nitrogen	10-20 mg/dl Older adults: May be slightly increased	<b>In Chronic Kidney Disease</b> May reach 180-200 mg/dl before symptoms develop <b>In Acute Kidney Injury</b> Often increases by 1-20 mg/dl at same pace as serum creatinine level May reach 80-100 mg/dl within 1 wk	Increases depend on protein intake and other factors. Rate of increase is controlled by limiting protein intake. This intervention is believed to decrease the rate of onset of systemic symptoms, such as anorexia, nausea, and vomiting. Elevations have multiple causes, including diminished renal function, excessive protein intake, sepsis, GI bleeding, dehydration, and tissue catabolism.
<b>Electrolyte Studies</b>			
Serum sodium	136-145 mEq/L; 136-145 mmol/L (SI units)	Normal or decreased	Clients with renal disease retain sodium. With associated water retention, serum sodium levels seem normal. With excessive water retention, serum sodium levels seem decreased owing to hemodilution. Assess client for evidence of fluid volume excess: edema, weight increase, or elevation of diastolic blood pressure. Limit fluid intake as directed. Avoid excessive sodium intake. Monitor for signs of hypernatremia: dry skin, excessive thirst, dry mucous membranes, elevated body temperature, and flushed skin. Client may need diuretics or dialysis.
Serum potassium	3.5-5.0 mmol/L (SI units)	Increased	Advise client to avoid salt substitutes and to limit potassium-containing foods. Monitor for rapidly increasing serum potassium levels in AKI. ECG changes occur with serum potassium levels $\geq 6.5$ . Monitor for signs of hyperkalemia: dizziness, weakness, cardiac irregularities, muscle cramps, diarrhea, and nausea. May require administration of sodium polystyrene sulfonate (Kayexalate) or other treatment.

*Continued*

TABLE 28-3 LABORATORY PROFILE FOR RENAL DISEASE—cont'd

TEST	NORMAL RANGE FOR ADULTS	VALUES IN RENAL DISEASE	COMMENTS
Serum phosphorus (phosphate)	3.0-4.5 mg/dl, 0.97-1.45 mmol/L (SI units) <i>Older adults:</i> May be slightly decreased	Increased	Short-term increases have potential to cause rapid decrease in serum calcium level and cardiac rhythm disturbances. Long-term increases demineralize bones of calcium and enhance fracture potential. Phosphate-binding medications help control hyperphosphatemia and prevent calcium depletion from bones.
Serum calcium	Total calcium: 9.0-10.5 mg/dl; 2.25-2.75 mmol/L (SI units) Ionized calcium: 4.5-5.6 mg/dl; 1.05-1.3 mmol/L (SI units) <i>Older adults:</i> Slightly decreased	Decreased	Decreases in AKI may necessitate replacement. Decreases in CRF may only be slight and may or may not necessitate replacement. As serum phosphate level increases, serum calcium level decreases. Chronic calcium deficiency leads to renal osteodystrophy. Control of phosphate excess is usually essential before calcium replacement is initiated. Monitor for manifestations of hypocalcemia: abdominal cramps, hyperactive reflexes, tingling fingertips, and spasms in feet and wrists.
Serum magnesium	1.3-2.1 mEq/L; 0.65-1.05 mmol/L (SI units)	Increased	Advise patient to avoid compounds containing magnesium (e.g., laxatives).
Serum bicarbonate	23-30 mEq/L (venous); 23-30 mmol/L (SI units)	Decreased	Replace bicarbonate. Monitor respiratory rate and depth. Monitor for decreased orientation.
Arterial blood pH	7.35-7.45	Decreased (in metabolic acidosis) or normal	Respiratory system attempts to compensate by hyperventilation (increased rate and depth of respiration). Values are within normal range if blood buffers and lungs can compensate. Monitor breathing rate and depth. Monitor level of consciousness.
Arterial blood bicarbonate (HCO <sub>3</sub> <sup>-</sup> )	21-38 mEq/L	Decreased	Provide replacement oral, IV, or by hemodialysis or peritoneal dialysis.
Arterial blood (Paco) <sub>2</sub>	35-45 mm Hg	Decreased	Monitor for respiratory fatigue (client breathes more rapidly and deeply to "blow off" carbon dioxide).
<b>Other Blood Studies</b>			
Hemoglobin	<i>Female:</i> 12-16 g/dl, 7.4-9.9 mmol/L (SI units) <i>Male:</i> 14-18 g/dl, 8.7-11.2 mmol/L (SI units) <i>Older adults:</i> Slightly decreased	Decreased	Decreased levels indicate anemia. Monitor for pallor, weakness, lethargy, dizziness, possible shortness of breath, and activity intolerance.
Hematocrit	<i>Female:</i> 37-47% <i>Male:</i> 42-52% <i>Older adults:</i> May be slightly decreased	Decreased to 20%	Same as for hemoglobin. With erythropoietin therapy, may be able to obtain levels as high as 36%.
<b>Urinalysis*</b>			
Specific gravity	Usually 1.010-1.025 Possible range: 1.005-1.030	Usually decreased and fixed	Reflects inability of tubules to produce concentrated or diluted urine in response to changes in plasma osmolarity. Monitor for fluid volume deficit or excess.
pH	Average: 5.5-6 Possible range: 4.6-8	May be fixed; pH does not change with dietary changes	Collect a freshly voided specimen for testing.
Glucose	None or <15 mg/dl Usually detectable in urine of nondiabetic clients when blood level is 160-180 mg/dl	Increased	Renal threshold is often increased; therefore blood glucose level may be >160-180 mg/dl before glucose is detectable in urine. Monitor <i>blood</i> glucose levels.

TABLE 28-3 LABORATORY PROFILE FOR RENAL DISEASE—cont'd

TEST	NORMAL RANGE FOR ADULTS	VALUES IN RENAL DISEASE	COMMENTS
Protein	0-8 mg/dl	Increased when there is glomerular damage or disease	Increases may be an incidental and benign finding. Transient increases occur with extreme exercise, fever, stress, or infection. Persistent proteinuria requires 24-hr collection for determination of total quantity excreted. Persistent proteinuria may indicate a serious renal problem. Instruct client about need for follow-up. Instruct client in correct procedure for collection of 24-hr specimen.
Occult blood	No RBCs or occasionally 2 or 3 RBCs per HPF No hemoglobin	More than 2 or 3 RBCs per HPF Detectable hemoglobin	Hemoglobin is detectable when hemolysis of RBCs has occurred. Intact RBCs are detectable only with microscopic examination. Collect a freshly voided specimen for testing. Often indicates need for urine culture.
WBCs	0-5 per HPF	Increased in urinary tract infection	
Bacteria	Fewer than 1000 colonies/ml	Increased in presence of infection, with or without an increase in WBCs	Obtain urine culture.
Casts	None or a few; composed of RBCs, WBCs, protein, or tubular cell casts such as hyaline	Casts present	Casts may be a benign occurrence or may signify that some renal injury or disease is present. Collect a freshly voided specimen for direct microscopic examination.
Creatinine clearance	Male: 107-109 ml/min Female: 87-107 ml/min Older adults: Progressively decreased with advancing age	Decreased	Change reflects decreases in GFR. Creatinine clearance is determined from a 24-hr urine collection and a serum creatinine value.

\*Urine may become cloudy with heavy sediment. Urine output and appearance vary, depending on remaining renal function.

levels begin to increase within 12 hours to 2 days after injury,<sup>3</sup> new biomarkers are being investigated to detect AKI earlier than the rise in serum creatinine level, with the promise of leading to earlier detection and treatment. Examples of these new biomarkers currently being tested are interleukin-18, neutrophil gelatinase-associated lipocalin, and kidney injury molecule-1.<sup>3,17</sup> As with other aspects of the clinical presentation, laboratory findings are affected by the phase of ATN. Although the naming of the phases of AKI varies among resources, the clinical progression of ATN is consistent.

**Prodromal Phase**

Patients during this phase will typically have a normal or declining urine output. Serum blood urea nitrogen (BUN) and creatinine levels begin to rise.<sup>10</sup> The insult to the kidney has occurred and the duration of this phase will vary depending on the cause of the injury, the amount of the toxin ingested, or the duration and severity of the hypotension.<sup>16</sup>

**Oliguric Phase**

Most patients with ATN develop oliguria, though some will remain nonoliguric.<sup>16</sup> Those with severe injury often become anuric.<sup>7,11,13</sup> Renal function is monitored according to fluctuations in the serum creatinine level and the calculated GFR that is derived from it.<sup>15</sup> As urine output drops, metabolic waste products are retained and fluid and

electrolyte balance is disrupted.<sup>7</sup> These alterations are reflected in the physical assessment and laboratory data. Because it cannot be excreted, body water is retained. This hypervolemia results in the development of edema and hypertension.<sup>7</sup> Other signs and symptoms of fluid volume overload include distended neck veins (jugular venous distention [JVD]), weight gain, crackles, and possibly additional manifestations of heart failure.<sup>16</sup> Normally, as renal perfusion is reduced, the kidney responds by increasing the reabsorption of sodium and reducing its elimination. In ATN, this mechanism is impaired and sodium is lost in the reduced volume of urine that is produced.<sup>16</sup> Tubular casts are present in the urine, and white blood cells, red blood cells, and protein are also likely to appear.<sup>8</sup> Other electrolytes are typically retained in the blood (potassium, magnesium, and phosphorus) and their levels in the urine are decreased (see Table 28-3). Of all the potential electrolyte problems, hyperkalemia is of greatest concern because the normal range is narrow (3.5 to 5 mEq/L) and levels of less than double the normal values can be fatal.<sup>7</sup> Metabolic acidosis develops as a result of the kidney's decreased ability to excrete hydrogen ions (acid load).<sup>7</sup> The hydrogen ions shift into the cells in exchange for intracellular potassium. Thus hyperkalemia and metabolic acidosis often occur together. Changes in the levels of other electrolytes may not be seen unless the oliguric phase is prolonged. Anorexia, nausea, vomiting, weakness, seizures, acidosis, confusion, and coma are also possible.<sup>16</sup> Although these

TABLE 28-4 PATHOPHYSIOLOGY OF MANIFESTATIONS OF UREMIC SYNDROME

SYSTEM	MANIFESTATION	PATHOPHYSIOLOGIC BASIS
Central nervous system	Uremic encephalopathy <ul style="list-style-type: none"> <li>• Disorientation</li> <li>• Lethargy</li> <li>• Coma</li> </ul>	Brain cells shrink because of osmotic gradient

Cardiovascular system	Bleeding Anemia Decreased cardiac output Ischemic syndromes Pericarditis*	Decreased platelet function and coagulation factor production Decreased RBC life span; blood loss Negative inotropic effect Escalated coronary heart disease Uremic crystals deposited in pericardium
Immune system	Infections	Decreased immune cell production and immune response
Gastrointestinal system	Anorexia Nausea and vomiting	Direct effect of toxins
Integumentary system	Impaired healing* Pruritus; dermatitis* Uremic frost*	Decreased collagen production Deposition of uremic crystals on skin
Acid-base balance	Metabolic acidosis	Accumulation of acidic metabolic wastes

\*More likely to occur with chronic kidney injury.

manifestations are classically much more severe in end-stage renal disease, there is no identifiable point at which uremia presents, so some symptoms may be present in AKI. A GFR that is only slightly less than 50% of the normal for age may produce mild manifestations.<sup>14</sup>

As the GFR drops, organic metabolic waste products are retained. Urea represents the largest amount of these wastes. Other uremic solutes involved have been found to be responsible for many of the signs and symptoms that collectively are called uremic syndrome<sup>14</sup> (Table 28-4). This phase typically lasts 10 to 14 days, but can range from 1 day to 8 weeks. Development of uremia in AKI necessitates temporarily replacing renal function with dialysis. Nonoliguric patients have lower mortality and morbidity and less need for dialysis.<sup>16</sup>

### Postoliguric Phase

Termination of the oliguric phase is marked by the beginning of renal recovery. The urine output gradually returns to normal.<sup>16</sup> Unfortunately, not all patients recover. In about 5% of cases, AKI is not reversible.<sup>11</sup> In the elderly, 31% of those with AKI may not regain renal function.<sup>2</sup> Tubular dysfunction may continue and is manifested by polyuria and sodium wasting, as well as depletion of electrolytes (especially potassium) previously retained.<sup>16</sup> Typically, urine output is more than 1 L per day, and may be as much as 4 to 5 L, causing a fluid volume deficit if fluids are not rapidly replaced. The elevated BUN level contributes to an osmotic diuresis, as the large molecules are filtered and draw more water into the tubules. Renal perfusion begins to increase, slowly advancing filtration ability and tubular function.

If full recovery of renal function does occur, it may take only 1 week but more often requires as much as 1 year. Full recovery is indicated when the serum creatinine level returns to within the normal range. This variation in recovery time is due to the diversity of ATN causes and degree of damage as well as the quality of interventions provided and patients' concomitant conditions. Even after recovery, progressive loss of renal function following AKI is a frequent finding, especially in pediatric cases. The loss of renal function following AKI in childhood has been found to result in progressive deterioration by adolescence or early adulthood.<sup>11</sup>

### KEY POINTS

- AKI is an abrupt reduction in renal function producing an accumulation of waste materials in the blood. Oliguria is usually present. AKI is classified into three types according to the site of disruption: prerenal, postrenal, and intrinsic. Distinction between the types of AKI is necessary to determine appropriate therapy.
- Prerenal kidney injury is due to conditions that impair renal blood flow, such as hypovolemia, hypotension, cardiac failure, and renal artery obstruction. It is characterized by clinical manifestations of a low GFR, usually including oliguria, high urine specific gravity and osmolality, and low urinary sodium concentration. Signs and symptoms of fluid volume overload are present. Prolonged prerenal kidney injury results in intrinsic kidney injury.
- Postrenal kidney injury is due to obstruction within the urinary collecting system distal to the kidney. Obstruction results in elevated pressure in Bowman capsule, which impedes glomerular filtration. Clinical findings vary, based on the duration of the obstruction. Prolonged postrenal kidney injury results in intrinsic kidney injury.
- Intrinsic failure is due to a primary dysfunction of the nephrons. Although it may be due to glomerular, vascular, or interstitial etiologies, most often the problem is within the renal tubules, resulting in ATN. ATN may occur with nephrotoxic or ischemic insults. Clinical manifestations depend upon the phase of ATN.
- ATN has three characteristic phases. The first phase, prodromal, is characterized by normal or declining urine output and varies in duration depending on the causative factors. The oliguric phase may last up to 8 weeks with a usual urine output of 50 to 400 ml/day. Retention of nitrogenous wastes and certain electrolytes is likely. Fluid volume excess is expected. During the postoliguric phase, diuresis occurs, tubular function remains impaired, and azotemia continues. Fluid volume deficit is characteristic until the kidneys gradually recover. Recovery can last up to 12 months, and is characterized by gradual normalization of serum creatinine and BUN levels. Often a degree of renal insufficiency persists.
- AKI results in characteristic alterations in laboratory tests of the blood and urine. Renal function is monitored by serum creatinine level and calculated GFR. The retention of metabolic wastes (azotemia/uremia), which is monitored by the BUN level, produces widespread systemic effects (uremic syndrome).

**BOX 28-2 RISK FACTORS FOR CHRONIC KIDNEY DISEASE**

- Acute tubular necrosis (not progressing beyond the oliguric stage)
- Developmental/congenital conditions
  - Renal agenesis
  - Aplastic kidneys
  - Renal hypoplasia
  - Ectopic/displaced kidneys
  - Fused kidneys
- Cystic disorders
  - Polycystic kidney disease
  - Medullary cystic disease
- Neoplasms
  - Benign tumors of the kidney
  - Malignant tumors of the kidney (including Wilms tumor)
- Infections
  - Recurrent pyelonephritis
  - Renal tuberculosis
- Glomerulonephritis
- Systemic conditions
  - Diabetes mellitus\*
  - Diabetes insipidus
  - Hypertension\*
  - Hyperparathyroidism
  - Liver failure/cirrhosis
  - Gout
  - Amyloidosis
  - Scleroderma
  - Goodpasture syndrome
  - Systemic lupus erythematosus (produces glomerulonephritis)
- Other
  - Genetics
  - Increasing age
  - Race (blacks)
  - Overweight/obesity
  - Dyslipidemia
  - Family history of cardiovascular disease
  - Smoking

\*Most common risk factors.

## CHRONIC KIDNEY DISEASE

Chronic renal failure is the outcome of the progressive and irrevocable loss of nephrons.<sup>7,16</sup> The normal resiliency of the kidney means that more than 75% of the total number of nephrons must be lost before clinical manifestations appear.<sup>7</sup> What is termed *chronic renal failure* is the final outcome of chronic kidney disease (CKD). More commonly, this point is called *end-stage renal disease* (ESRD) in acknowledgment of the progressive process of deterioration of renal function. At some point in the CKD process, renal disease will proceed to ESRD progressively, irreversibly, and to the point where renal dialysis or transplantation is required for survival.<sup>17-24</sup>

Chronic kidney disease is a global health problem. Historically, the majority of the overall morbidity and mortality throughout the world was due to infectious disease. Today, chronic diseases are responsible for most of the world's illness and death.<sup>23</sup> More than 4 million people throughout the world have ESRD<sup>23</sup> and depend on dialysis. Many of them await renal transplantations that may not be available in time to save their lives. Every year, this number increases by nearly 250,000.<sup>23</sup> The highest incidence of untreated ESRD is found in North America, Japan, and Europe.<sup>23</sup> More than 20 million people ages 20 years and older in the United States have CKD, whereas another 547,982 people are being treated for ESRD.<sup>18,19,21</sup> Because of the rapidly escalating incidence of the two primary risk factors, diabetes and hypertension, the number of people afflicted with CKD is likely to increase in the years to come.<sup>7,19</sup>

### Risk Factors

Chronic kidney disease is defined as either decreased kidney function or kidney damage of 3 months' or more duration based on blood tests, urinalysis, and imaging studies.<sup>20,25</sup> Alternatively, it may be defined as a glomerular filtration rate (GFR) <60 ml/min/1.73 m<sup>2</sup> for 3 months with or without indication of damage to the kidney.<sup>25,26</sup> CKD is a syndrome in that it can occur as a complication of many other conditions, such as diabetes and hypertension. This means that the etiologies and/or risk factors of these conditions are also risk factors for the development of CKD. Although some of the conditions and risk factors have been identified for many years, new research findings have added to the list and altered perceptions of their relative importance (Box 28-2).

In 2008 diabetes and hypertension accounted for more than 50% of the individuals in the United States with ESRD, followed by glomerulonephritis and cystic kidney disease.<sup>19</sup> Type 2 diabetes is projected to double in incidence worldwide within the next 25 years. Diabetic nephropathy is a major complication of that disease. Of those who develop diabetic nephropathy, about 30% ultimately progress to ESRD whereas the remainder most often die from cardiovascular disease before reaching that point.<sup>20</sup>

Hypertension is another major risk factor for CKD, and it also develops as a complication of it.<sup>25</sup> The majority of patients (70% to 80%) with CKD have hypertension, climbing to 90% in those treated with dialysis.<sup>27,28</sup> The aging of the population in the United States is predicted to escalate the incidence of systolic hypertension and resulting renal disease.<sup>22,25</sup> Some of the risk factors for CKD are not amenable to modification. These include a family history of CKD, a history of exposure to toxins (heavy metals, tobacco smoke, radiopaque dyes), age greater than 65 years, and ethnicity (non-Hispanic black, non-Hispanic white, and Mexican American).<sup>26</sup> It has been recommended that high-risk groups be screened for CKD (those with family histories, diabetes mellitus, hypertension, recurrent urinary tract infections, urinary obstructions, or other systemic conditions affecting the kidney) and that screening be extended to those without any other identified risks other than being older than age 65.<sup>7,29</sup> Research is under way to identify genes associated with CKD and diabetic nephropathy as well as biomarkers to assess for risk and likelihood of a positive response to treatment.<sup>30</sup>

### Pathophysiology of Progression of Chronic Kidney Disease

Regardless of the origin of CKD, the decline in renal function is progressive and irreversible. The damaged nephrons are unable to function properly. The remaining nephrons initially compensate by enlarging and increasing their clearance capacity. Through this process, renal function remains relatively normal until 75% to 80% of the nephrons are damaged and nonfunctional. Over the course of several years, these compensatory changes may cause further injury to the remaining nephrons. Although the cause of this additional injury is unknown, some investigators believe that the increased workload of the remaining glomeruli and small arterioles may cause sclerosis of these vessels

**TABLE 28-5 STAGES OF CHRONIC KIDNEY DISEASE ACCORDING TO NEPHRON LOSS AND CLINICAL PRESENTATION**

STAGE	% NEPHRON LOSS	CLINICAL PRESENTATION
Decreased renal reserve	<75%	No signs or symptoms BUN and creatinine normal May not be diagnosed
Renal insufficiency	75-90%	Polyuria, nocturia Slight elevation in BUN and creatinine May be controlled by diet and medication
End-stage renal disease	>90%	Azotemia/uremia Fluid and electrolyte abnormalities Osteodystrophy Anemia Dialysis or transplantation essential

leading to further decline in kidney function and ultimately ESRD.<sup>7</sup> Progression of CKD is monitored by measuring changes in GFR, determining the presence and degree of proteinuria, examining urinary sediment for white or red blood cells, measuring serum creatinine levels, and performing imaging studies with renal ultrasonography to document kidney size.<sup>25</sup>

### Stages of Chronic Kidney Disease

The progression of CKD is determined by monitoring GFRs. A five-stage system depicts severity of disease, with decreasing GFRs reflecting a higher stage of progression. The recommendation is that diagnosis of CKD not be based on a specific pathology (e.g., diabetes mellitus), but rather on the presence of damage to the kidney and the level of function according to the GFR measurement as shown in Table 28-5.<sup>25</sup> Screening for the complications of CKD is recommended to begin in stage 3.<sup>31</sup>

In stage 1 of the GFR staging system shown in Table 28-5, patients' blood pressures and laboratory values are usually normal and they are asymptomatic, though they have some form of kidney disease.<sup>31</sup> An initial reduction in GFR with or without documented kidney damage depicts stage 2. This would include, for example, a diabetic patient with proteinuria or an older person with the predictable age-related diminishment of renal function. Again, patients may be asymptomatic without laboratory value changes. The aims in stages 1 and 2 are to identify individuals at risk for progressive renal disease, and reduce those associated risks.

Beginning with stage 3, patients are classified as having chronic kidney disease, according to GFR, regardless of the existence of kidney damage. Although they may be otherwise asymptomatic in stage 3, hypertension is nearly always noted. At stage 4, diagnosis is made because manifestations are usually very apparent with the significant decline in renal function. Planning for ESRD should occur. By stage 5, manifestations of ESRD are present and renal function is so impaired that dialysis or transplantation is required.<sup>31</sup>

The staging system shown in Table 28-6 is useful because the terms *renal insufficiency* and *decreased renal reserve* are commonly used in clinical practice. Decreased renal reserve is not associated with signs or symptoms of renal failure, largely because the remaining nephrons

**TABLE 28-6 STAGES OF CHRONIC KIDNEY DISEASE ACCORDING TO GLOMERULAR FILTRATION RATE\***

STAGE	DESCRIPTION
Stage 1	Kidney damage with normal or increased GFR GFR >90 ml/min/1.73 m <sup>2</sup>
Stage 2	Mildly decreased GFR GFR 60-89 ml/min/1.73 m <sup>2</sup>
Stage 3	Moderately decreased GFR GFR 30-59 ml/min/1.73 m <sup>2</sup>
Stage 4	Severely decreased GFR GFR 15-29 ml/min/1.73 m <sup>2</sup>
Stage 5	End-stage kidney disease GFR <15 ml/min/1.73 m <sup>2</sup> (or dialysis)

\*From National Kidney Foundation: *Kidney disease outcomes quality initiative*, 2002.

GFR, Glomerular filtration rate.

accommodate the additional workload. Electrolyte and fluid levels are maintained within normal limits.<sup>7</sup> Although not abnormally elevated, creatinine levels are usually at the high end of the normal range—a common finding in the elderly population. Interventions for those at risk for CKD (see Box 28-2) should be initiated to help slow disease progression. At this point, kidney function is already impaired and significant deterioration is possible if the kidney is stressed. There may be small amounts of protein in the urine. The stage of renal insufficiency is reached with further nephron damage. Although electrolyte levels remain within normal limits with the GFR decline, the metabolic wastes (creatinine and urea) are retained at levels proportional to nephron loss.<sup>7</sup> Impairment of the kidney's ability to concentrate the filtrate often results in increased urinary output (polyuria), often leading to nocturia. ESRD develops when more than 90% of the kidneys' nephrons have been destroyed. At this point, the patient typically demonstrates the sequelae and complications of renal failure, seen as laboratory alterations and signs and symptoms associated with the inability of the kidneys to fulfill their multiple roles within the body. Without interventions, when the remaining nephrons number less than 5% to 10% of normal, death is inevitable.<sup>7</sup>

### Complications of Chronic Kidney Disease

The consequences of CKD are affected by the intake of food and water and the degree to which renal function is impaired.<sup>7</sup> Some of the complications of CKD begin to appear when the GFR falls below 60 ml/min/1.73 m<sup>2</sup> (stage 3 of the GFR-based classification).<sup>25</sup> Because of the widespread impact of the kidneys on nearly every part of the body, the effects of their failure are seen in every body organ system.<sup>7</sup> Complications impact the gastrointestinal, neurologic, musculoskeletal, dermatologic, cardiovascular, and endocrine systems. Immune function, acid-base regulation, and the coagulation cascade are affected as well. In many cases, complications are interrelated, one contributing to or exacerbating the development of others. Laboratory alterations become significant as CKD progresses; typical values are shown in Table 28-3. Major complications of CKD are discussed in the following sections.

#### Hypertension and Cardiovascular Disease

Cardiovascular disease and CKD have many risk factors in common: increasing age, black race, hypertension, diabetes mellitus, smoking,

decreased GFR, proteinuria, obesity, and RAAS overactivity.<sup>7,32,35</sup> If hypertension was not a precursor to CKD, it inevitably develops with decreasing renal function,<sup>27,28,32</sup> appearing in stage 2 or 3.<sup>31</sup> The excess fluid volume and escalated atherosclerotic process along with heightened RAAS activity and evidence of increased SNS activity are all involved in the development of hypertension in CKD.<sup>32,35</sup> Most people with CKD do not die from kidney failure, but rather from the results of cardiovascular disease, which is both a risk factor for and a complication of CKD.<sup>33,35</sup> The incidence of cardiovascular morbidity and mortality is markedly increased in CKD.<sup>34</sup> In the elderly, death from cardiovascular disease is more common than progression to renal replacement therapy.<sup>34</sup> Although the risk of cardiovascular disease is greatest for those with end-stage disease, it has been found to be an issue at all stages of CKD.<sup>34,35</sup> A clear link exists between deterioration of kidney function and development of cardiovascular disease.<sup>35</sup> Multiple factors have been identified that are conducive to this, including, but not limited to, dyslipidemias, anemia, electrolyte-induced dysrhythmias, hypertension, endothelial dysfunction (including inflammation, alterations in nitric oxide activity, oxidative stress), proteinuria, premature atherosclerosis, activity limitations, and volume overload.<sup>27,35</sup>

### Uremic Syndrome

As renal function declines, retention of metabolic wastes increases, creating a toxic environment within the body. Uremia produces signs and symptoms in many body systems (see Table 28-4). Compared to the presentation in AKI, uremic syndrome in CKD is far more severe and its effects are more widespread even though the serum levels often must be much higher for manifestations to be apparent.

### Metabolic Acidosis

Normally, the human body produces 50 to 80 more millimoles of acids than bases during daily metabolism.<sup>7</sup> Metabolic acidosis occurs with the retention of acidic waste products of metabolism as part of uremia. It is also produced in association with hyperkalemia, when potassium ions in the blood are exchanged for intracellular hydrogen ions, lowering the pH of the blood (see Chapter 25). The kidneys lose their ability to secrete hydrogen ions or to produce bicarbonate, and with the limited capacity of the other buffers, pH can fall precipitously; coma develops and death will occur if the pH drops below 6.8.<sup>7</sup> Metabolic acidosis depresses cardiac as well as central nervous system function. The respiratory system attempts to compensate for metabolic acidosis by increasing the rate and depth of respirations.

### Electrolyte Imbalances

The loss of renal mechanisms involved in electrolyte balance result in the retention of potassium, phosphorus, and magnesium in the blood. Each of these imbalances is associated with specific manifestations (see Chapter 24). Hyperkalemia is of special concern, as discussed with AKI, because it can be responsible for fatal cardiac dysrhythmias. The inability to eliminate phosphorus and the loss of the renal mechanisms involved in maintaining calcium balance result in mineral and bone disorders, which are discussed next.

### Mineral and Bone Disorders

The inability of the kidney to excrete phosphorus in CKD results in elevated phosphorous levels in the blood. Because phosphorus and calcium maintain a reciprocal relationship in the body, as hyperphosphatemia develops in CKD, hypocalcemia likewise develops. The body's system of maintaining calcium balance is sophisticated, and involves the activation of parathyroid hormone (PTH) when the calcium level is low. When this occurs because of CKD, the result

is secondary hyperparathyroidism.<sup>36</sup> The normal response to PTH release is the increase in serum calcium levels by (1) increasing reabsorption by the kidney, (2) increasing absorption of dietary calcium, in the presence of vitamin D, which must be activated by the kidney, and (3) mobilizing calcium release from bone.<sup>7,36</sup> Vascular and soft-tissue calcifications as well as osteoporosis are the end results of the prolonged elevation of PTH level and altered bone and mineral metabolism.<sup>36</sup> The resulting bone pain, deformities, and fractures are significant long-term complications of CKD.<sup>24,27,36</sup> Additionally, abnormal PTH, calcium, and phosphorous levels are reported to have been identified as independent risk factors of cardiac-caused mortality during dialysis.<sup>36</sup>

### Malnutrition

Protein-energy wasting (PEW) is the loss of muscle and visceral protein stores and is a common finding in advanced CKD.<sup>36</sup> Decreased nutrient intake is due to the anorexia of uremic syndrome, changes in taste sensation, and the depression of chronic illness, as well as the dietary limitations imposed by disease. Additionally, a negative-nitrogen balance exists because of escalated protein catabolism and decreased protein synthesis. Medications and concomitant diseases such as diabetes may cause nausea, vomiting, and slowed gastric emptying. The best serum marker of PEW is albumin level. Hypoalbuminemia in dialysis patients has a strong association with increased mortality and morbidity. However, caution must be used in interpreting these levels, because the serum level may be affected by the inflammatory response. Malnutrition has a negative impact on CKD prognosis.<sup>36</sup>

### Anemia

The development of anemia is an anticipated problem as CKD progresses. The production of red blood cells by the bone marrow depends on numerous cofactors; perhaps the most significant of these is erythropoietin, which is produced by the kidneys.<sup>7</sup> Erythropoiesis, with all essential ingredients, requires about 5 days.<sup>39</sup> Lacking erythropoietin, fewer red blood cells are produced and anemia is a persistent problem. The problem is often further escalated by malnutrition, due to nutritional deficits of iron, folate, and vitamin B<sub>12</sub>. Chronic inflammation and elevations of PTH level suppress bone marrow. At the same time, the uremia associated with CKD produces a toxic environment for red blood cells, reducing their normal life expectancy of 120 days. Blacks appear to have both a greater prevalence of anemia as well as more severe reductions in RBC counts and hemoglobin concentrations. By stage 5 and the initiation of dialysis, approximately 66% of patients have hemoglobin levels <11 g/dl.<sup>39</sup> The cardiovascular compensatory efforts for the chronic anemia of CKD can lead to myocardial dilatation, left ventricular hypertrophy, and remodeling.<sup>27,39</sup> The combination of worsening CKD, anemia, and heart failure is referred to as *cardiorenal anemia syndrome* and becomes a chain of escalating pathologies.<sup>39</sup>

### Pain

The causes of pain in kidney disease are multifactorial. Surgery may be needed to create access for dialysis or to biopsy a kidney. Dialysis itself can be a painful experience with frequent needle sticks and accumulation of uremic toxins. The primary cause of kidney disease, such as cystic kidney or diabetes (due to neuropathies or ulcerations), may result in pain. Finally, comorbidities such as gout, bone disease, and peripheral vascular disease may also contribute to pain in the person with CKD.<sup>24</sup> The challenge lies in finding a balance between pain relief and the right analgesic and dose to avoid toxicity and drug-induced nephropathy.<sup>24</sup>

## Depression

The prevalence of depression in patients with CKD is reported to be between 20% and 30%.<sup>38</sup> Reasons for depression stem from comorbid conditions as well as the process of kidney disease itself. Many patients with renal disease experience a high rate of cardiovascular events, which are also associated with higher rates of depression. In addition, the disruption of social interactions and relationships, possibly attributable to dialysis and fatigue, contributes to depressive symptoms. In patients with CKD, as in the general population, depression may lead to a decrease in quality of life, functional impairment, and sexual dysfunction.<sup>38</sup>

### KEY POINTS

- CKD is characterized by a gradual, irreversible loss of functional nephrons. The two most common causes are diabetes mellitus and hypertension, followed by recurrent pyelonephritis, glomerulonephritis, and polycystic kidney disease.
- Progression of CKD is monitored by a staging system based on increasing severity of disease. There are five stages of CKD progression and with each higher stage, the GFR and kidney function decline. In stage 1, kidney function may be normal, though some disease exists. The patient is asymptomatic. The focus in stages 1 and 2 is minimizing risk factors. By stage 3 symptoms may be starting to appear and treatment may be needed. In stage 4, planning for dialysis or transplant should begin, and in stage 5 renal replacement therapy is needed or death will ensue. Complications of CKD include hypertension and increased cardiovascular risks, uremic syndrome, metabolic acidosis, electrolyte disturbances, bone and mineral disorders, malnutrition, anemia, pain, and depression.

## CLINICAL MANAGEMENT

Clinical management of AKI and CKD requires a multidisciplinary approach. Collaboration among the nurse, physician, clinical pharmacist, and dietitian is essential to attain optimal patient outcomes. Prevention of the development of AKI is the goal. With CKD, prevention of the myriad of causes is certainly desirable; however, prevention also focuses on retarding the inevitable progression of the disease and reducing cardiovascular risk factors.

### Acute Kidney Injury

AKI is often entirely preventable.<sup>13</sup> Prevention is highly dependent on recognizing patients who are at risk for the development of AKI and establishing prophylactic interventions to decrease this risk.

Etiologies and risk factors for prerenal kidney injury should be identified and, whenever possible, treated swiftly.<sup>9</sup> Early consultation with a nephrologist is recommended. Hypotension attributable to hypovolemia should be addressed; medications that might be contributing (antihypertensives, opioids) should be decreased or discontinued. Nutrition should be supported, and indwelling catheters and other invasive equipment should be removed as soon as possible to decrease the risk of infection. Development of infection should be monitored, and treated if it develops.<sup>9</sup> Maintaining adequate circulating volumes and supporting cardiac function, especially in those at risk for prerenal kidney injury, are the primary foci for prevention.

Should prerenal oliguria develop, efforts should be initiated to enhance renal perfusion before ATN can occur. Two interventions that were previously staples of treatment of prerenal oliguria have been deemed to be harmful, or at the very least ineffective.<sup>40</sup> Dopamine in the low-dosage range was previously believed to enhance

## BOX 28-3 SELECTED CHEMICALS TOXIC TO THE KIDNEYS

Acetaminophen  
 Acyclovir (Zovirax)  
 Allopurinol  
 Aminoglycosides  
 Amphotericin B (Fungizone)  
 Angiotensin-converting enzyme inhibitors  
 Certain cytotoxic chemotherapeutic agents  
 Cocaine  
 Cyclosporine (Sandimmune)  
 Foscarnet (Foscavir)  
 Heavy metals  
 Hemoglobin; myoglobin  
 Heroin  
 Lithium  
 Nonsteroidal antiinflammatory drugs  
 Pentamidine (Pentam 300 and others)  
 Radiocontrast media\*  
 Uric acid  
 Vasopressors (norepinephrine, high-dose dopamine)

Derived from McKenry L, Tessier E, Hogan M: *Mosby's pharmacology in nursing*, ed 22, St Louis, 2006, Mosby; Needham E: Management of acute renal failure, *Am Fam Physician* 72(9):1739-1746, 2005.

\*Most common.

renal perfusion; evidence now indicates that use of this medication produces no difference from placebo therapy in the progression of AKI, the need for dialysis, or death. Again, compared to placebo therapy, loop diuretics made no difference in the recovery of renal function.<sup>40</sup> Aggressive management of conditions such as glomerulonephritis can prevent progression to intrinsic kidney injury.<sup>13</sup> Prevention of intrinsic kidney injury caused by chemicals begins with an awareness of the most likely harmful agents; these are listed in Box 28-3. Whenever possible their use should be limited, and if these agents must be prescribed, their serum levels may need to be monitored.<sup>13</sup> Single doses of aminoglycosides, rather than multiple doses, and liquid formulations of amphotericin B appear to be less nephrotoxic.<sup>40</sup> Of all the chemicals listed in Box 28-3, the most common culprit is radiocontrast media.

Prevention of contrast-induced AKI is aimed at initiating intravenous volume expansion with saline both before and after the contrast administration, administering the antioxidant *N*-acetylcysteine (Mucomyst) to patients at risk, measuring the serum creatinine concentration of patients with suspected renal dysfunction, and using either low-osmolar or iso-osmolar contrast media for all patients with renal insufficiency.<sup>37</sup> It is important to note that the evidence to support the effectiveness of Mucomyst in preventing contrast-induced AKI has demonstrated mixed results.<sup>10,37</sup> More research is needed. Postrenal etiologies should be avoided whenever possible, but if they occur they should be rapidly identified and corrected.<sup>13</sup> Postrenal kidney injury is the least common and most readily identifiable; promptly addressing it will prevent the progression to ATN.

### Chronic Kidney Disease

Clinical management of CKD is complex and requires a multidisciplinary approach. Treatment is directed at slowing the progression to ESRD and managing the complications that are inevitable. This means that patient education regarding the trajectory of the illness, management of modifiable risk factors, and clinical management of

**BOX 28-4 THERAPEUTIC GOALS IN CHRONIC KIDNEY DISEASE**

- Maintain volume status.
- Prevent and treat acid-base and electrolyte disturbances.
- Prevent and treat uremia.
- Support nutritional needs.
- Prevent and treat infection.
- Prevent and treat anemia.
- Improve quality of life.
- Lower mortality and morbidity rates.
- Control pain.

the disease are essential. Because death is often due to cardiovascular pathologies, management of these risk factors assumes significant importance. At a community level, screening for hypertension, diabetes, and CKD is essential to stem the tide of these interrelated chronic diseases.<sup>23</sup> Underdiagnosis and undertreatment mediate the problem, and lack of awareness is the enemy of early diagnosis and treatment.

The speed with which CKD progresses varies significantly among individuals. Complications are typically evident by stage 3 or 4 and attention is directed to therapeutic interventions designed to minimize and treat these complications. Therapeutic and pharmacologic interventions are presented within the context of each complication listed in the following paragraphs. An in-depth presentation is beyond the scope of this text; discussion is simply an overview. Goals of therapeutic interventions for CKD are summarized in Box 28-4.

**Hypertension and Cardiovascular Disease**

Evaluation of risk factors for cardiovascular disease is an important part of intervention, because the risk of morbidity and mortality rises with the decline of GFR. Hypertension is associated with a more rapid progression of CKD; therefore control of blood pressure (BP) is critical. Lowering BP reduces the risk of proteinuria and prevents the development of cardiovascular and cerebrovascular events.<sup>27</sup> The BP goal with CKD patients is <130/80 mm Hg. An ACEI or an AII receptor blocker is considered the treatment of choice to delay progression, followed by a thiazide or loop diuretic.<sup>27</sup> ACEIs and AIIIs have an additional benefit of reducing proteinuria by 40% to 45%.<sup>27</sup> However, it should be noted that effectively lowering BP does not necessarily improve survival.<sup>28</sup>

The benefits of using statins to treat dyslipidemia in patients with CKD have not been clearly established and remain controversial. Although a reduction in total and low-density lipoprotein (LDL) cholesterol levels occurs, and may be effective in decreasing cardiovascular events, there is no improvement in the GFR or the rate of CKD progression.<sup>27,28</sup> There is some evidence to indicate that there is a benefit from use of statins in stages 1 to 3, but not once patients start dialysis.<sup>27</sup> This is an area of ongoing research.

**Metabolic Acidosis**

Mild acidosis with a pH of 7.30 to 7.35 requires no therapy. Patients with chronic metabolic acidosis (<7.30) may be prescribed sodium bicarbonate.<sup>16</sup> In a single-center randomized trial, 134 adult patients with stage 4 CKD were treated with bicarbonate supplements. After 2 years of treatment, 6.5% of patients in the sodium bicarbonate group required dialysis compared to 33% in the control group.<sup>27</sup> Replication of this study is needed.

**TABLE 28-7 TARGET RANGES FOR CALCIUM AND PHOSPHORUS IN CKD**

STAGE	CALCIUM	PHOSPHORUS
3	8.4-9.5 mg/dl	2.7-4.6 mg/dl
4	8.4-9.5 mg/dl	2.7-4.6 mg/dl
5	8.4-9.5 mg/dl	3.5-5.5 mg/dl

Data from Legg V: Complications of chronic kidney disease: a close look at renal osteodystrophy, nutritional disturbances, and inflammation, *Am J Nurs* 105(6):40-49, 2005.

**Fluid and Electrolyte Imbalances**

Fluid restrictions are implemented when the sodium level drops below 135 mmol/L. Patients with edema, heart failure, or hypertension may need a 2 g/day sodium restriction.<sup>16</sup> Mild hyperkalemia (<6 mmol/L) can be treated by reducing potassium intake and correcting metabolic acidosis. Potassium levels >6 mmol/L require more urgent treatment, such as an IV infusion of calcium gluconate, 5% dextrose in water (D<sub>5</sub>W), and insulin, or oral or rectal administration of sodium polystyrene sulfonate.<sup>16</sup>

**Bone and Mineral Disorders**

Hyperphosphatemia is addressed nutritionally, and later through drug management. Serum levels of parathyroid hormone (PTH), calcium, and phosphorus should be monitored in patients with a GFR less than 60 ml/min/1.73 m<sup>2</sup>.<sup>36</sup> Calcium carbonate and calcium acetate effectively bind phosphorus, correct hypocalcemia, and are inexpensive,<sup>27</sup> though they are associated with hypercalcemia and vascular calcifications.<sup>36</sup> Lanthanum carbonate has potent phosphorus-binding ability and is generally well-tolerated.<sup>36</sup> Vitamin D therapies such as calcitriol, paricalcitol, and ergocalciferol are indicated for use in vitamin D deficiencies and to suppress PTH levels.<sup>36</sup> Calcimimetics, such as cinacalcet, have also been shown to decrease secretion of PTH. Target ranges for both calcium and phosphorus levels are shown in Table 28-7.

**Malnutrition**

Nutrition plays a large role in the treatment of CKD. Advanced CKD produces gastrointestinal manifestations, anorexia, nausea, and changes in the sense of taste, which further complicate the necessary modifications in diet.<sup>16</sup> Caloric requirements are increased. Sufficient carbohydrate and fat are needed to meet energy requirements.<sup>16</sup> Aspects of nutritional management of CKD include limiting intake of dietary phosphorus, protein, sodium, potassium, and water depending on lab values and other clinical manifestations. Avoiding malnutrition, preventing anemia, and countering disease- and drug-induced constipation are other aspects of nutritional management. Lists of foods high in sodium, potassium, and protein should be provided; patients can then be encouraged to identify their favorite foods and choose smaller portions or eat them less often. Additionally, diet-related risk factors for cardiovascular disease must be considered. This can all seem overwhelming to patients, so involvement of a dietitian and thorough education considering concomitant conditions, personal likes and dislikes, eating habits, and financial resources is essential.

**Anemia**

Erythropoiesis-stimulating agents, such as epoetin alfa and darbepoetin alfa, have dramatically improved the quality of life for patients

with CKD, but have had little effect in reducing overall cardiovascular mortality or the rate of GFR loss.<sup>27,28</sup> Target hemoglobin (Hgb) levels have been the subject of much debate.<sup>27,28</sup> The National Kidney Foundation's *Kidney Disease Outcome Quality Initiative (KDOQI) Guidelines* recommend Hgb levels between 11 and 12 g/dl.<sup>27,28</sup> In addition to pharmacologic interventions, strategies for reducing fatigue, such as balancing rest and activity throughout the day, should be employed.

### Pain

Pain in patients with CKD may be acute or chronic. Choice of medication and dosage needs to consider the patient's age, comorbidities, and degree of kidney failure; the pathway of elimination of the medication (i.e., through the liver, kidney, or dialysis); and the risk of drug-induced nephropathy.<sup>24</sup> Nonpharmacologic methods of pain relief should also be explored.

### Depression

Studies have explored the use of pharmacologic and nonpharmacologic approaches to treat depressive symptoms in patients with CKD.<sup>38</sup> The safety of antidepressants in patients with decreased renal function is a significant concern. Psychotherapy, exercise therapy, cognitive behavioral therapy, and music therapy all have demonstrated varying degrees of success.<sup>38</sup>

### Acute-on-Chronic Kidney Disease

Acute-on-chronic kidney disease describes a scenario in which acute kidney injury occurs in someone with preexisting chronic kidney disease. Incidence varies from 10% to greater than 30%, depending on the study population. Preexisting CKD is a strong risk factor for development of AKI.<sup>50</sup> The most common causes of AKI in someone with CKD include systemic infections, medications, dehydration, and urinary tract obstruction.<sup>51</sup> Management is directed towards identifying and treating the underlying cause of the acute deterioration, in order to prevent a possible irreversible drop in kidney function.<sup>50,51</sup>

### Dialysis

The procedures, advantages, disadvantages, and expected outcomes of dialysis should begin to be discussed when the patient is in stage 4 of CKD.<sup>31</sup> When patients with CKD reach stage 5, dialysis is indicated.<sup>45</sup> The primary reason for the initiation of dialysis is the development of uremia.<sup>14</sup> Approximately two thirds of the total body urea content is removed by each dialysis treatment.<sup>14</sup> Dialysis may also be required if severe hyperkalemia is unresponsive to other interventions<sup>13</sup> or in cases of severe volume overload. If these conditions develop during the oliguric phase of ATN, dialysis may be required temporarily. Dialysis supports all the treatment goals in **Box 28-4** and is the only therapeutic option for those with ESRD who are unable to obtain a transplant. Dialysis may be accomplished by hemodialysis, peritoneal dialysis, or continuous renal replacement therapy (CRRT).

Hemodialysis was first carried out on humans in 1924; before that time, patients with ESRD simply died. In 1972 the national ESRD program was signed into law, giving all Americans the right to treatment; ESRD is the sole recipient of this status.<sup>45</sup> In hemodialysis, an artificial kidney serves as the dialyzing semipermeable membrane. The patient's blood passes through a bundle of hollow capillary tubules and dialyzing fluid bathes these tubules.<sup>7</sup> Solutes that are present in high concentration in the uremic blood (i.e., phosphate, urea, creatinine, potassium) diffuse across the dialyzing tubule membrane into the dialyzing fluid and are discarded.<sup>7</sup>

Excess water in the uremic blood is eliminated through osmosis across the membrane. Preferred access for hemodialysis is established by creating an arteriovenous (AV) fistula, most commonly in the arm. AV grafts and specialized central venous catheters are other means of access. Most patients with ESRD go through hemodialysis treatments three times per week,<sup>45</sup> each treatment lasting about 4 hours. Although a life-saving intervention, dialysis treatments have complications, some of which are life-threatening, and long-term morbidity remains quite high.<sup>45</sup> Despite dialysis, cardiovascular disease remains the most common cause of death in ESRD patients.<sup>41</sup>

In peritoneal dialysis (PD), the peritoneum serves as the dialyzing membrane. A dialysis catheter is surgically placed in the abdomen for access. During the treatment, the peritoneal cavity is slowly filled with dialysate through the catheter. Extra fluid and waste products are drawn out of the uremic blood and into the dialysate.<sup>42</sup> There are two major types of PD: continuous ambulatory peritoneal dialysis (CAPD) and continuous cycling peritoneal dialysis (CCPD).

CAPD is carried out in the patient's home and without the use of machines. The patient instills about 2 quarts of dialysate into the peritoneum through the catheter. The dialysate remains there for 4 to 5 hours or longer, before it is drained and discarded. This is called an exchange.<sup>42</sup> While the dialysate resides in the peritoneal cavity, the patient has more freedom to continue his or her usual activities at work, at school, or at home.<sup>42</sup> Peritonitis is a potentially serious complication.

CCPD can also be performed at home, but uses a special machine called a cycler. This is similar to CAPD except that a number of cycles (exchanges) occur. Each cycle usually lasts 1½ hours and exchanges are done throughout the night while the patient sleeps.<sup>42</sup>

CRRT is limited to in-hospital acute kidney injury patients. Continuous hemofiltration and hemodialysis procedures filter and dialyze the blood without interruption. CRRT removes fluid and wastes from patients who are not hemodynamically stable enough (e.g., shock, multiple organ system failure) to tolerate the larger quantity of blood removed from the body during typical hemodialysis. This "gentler" continuous removal of wastes and blood helps avoid the hypotensive episodes caused by intermittent hemodialysis and its intermittent removal of large volumes of fluid.<sup>16</sup>

### Kidney Transplant

Kidney transplantation is an alternative to dialysis for patients with ESRD. As with other conditions in which transplantation is indicated, the primary limiting factor is the availability of organs. Kidneys are obtained from deceased and living donors. For most of those who choose it, transplantation allows for increased independence, return to normal activities of daily living, and resumption of normal renal function. Thousands of patients receive kidney transplants each year in the United States, with a remarkable rise in transplant recipients over the last decade.<sup>43,44</sup> The 5-year patient survival rate (2003-2008) was estimated to be about 82% for a deceased donor and about 91% for a living donor transplant.<sup>44</sup> Given the number of transplant recipients and the improving patient survival rates, many patients need follow-up health care outside of transplant centers. This means that general health care providers will be caring for transplant recipients and the chronic medical conditions that accompany transplantation surgery. Common medical complications include cardiovascular disease, obesity, hypertension, dyslipidemia, diabetes, cerebrovascular disease, anemia, gout, depression, bone disease, malignancies, and infections.<sup>43</sup> Even with the best possible tissue matching, antirejection drug therapy is required and the adverse effects of these medications

may have a significant impact on health and quality of life. Transplant recipients will be prescribed a combination of immunosuppressants, usually tacrolimus or cyclosporine, mycophenolate, and prednisone.<sup>43</sup>

### Chronic Kidney Disease in Older Adults

A decline in kidney function as one ages is well understood. What is less clear is whether the CKD that develops in older adults is a manifestation of the aging kidney or the associated cardiovascular disease and life exposure to vascular risk factors such as hypertension, diabetes, and smoking.<sup>46,48</sup> The majority of patients diagnosed with CKD are older adults,<sup>30,48</sup> and the rates of treated ESRD among the elderly (>80 years) have risen by more than 50% in the last decade.<sup>49</sup> Although progression of CKD to ESRD is costly and incurs significant health problems, it appears less frequently in older adults compared with cardiovascular mortality.<sup>30</sup> The majority will die as a result of cardiovascular disease.<sup>30,48</sup>

In the past 5 decades, increased numbers of older patients have initiated dialysis worldwide. Results from some studies indicate that elderly adults choosing peritoneal dialysis have higher mortality rates than those receiving hemodialysis.<sup>49</sup> With increased numbers of older adults on dialysis comes not only increased survival but also increased morbidity. Elderly patients who are on dialysis seem to have a higher burden of age-related problems, such as frailty, falls, and cognitive impairment. There is also emerging evidence that dialysis initiation may be associated with accelerated rates of functional and/or cognitive decline.<sup>47,48</sup> Primary care providers will be challenged with the complex care required of this population.

### KEY POINTS

- Prevention of AKI includes early identification of those at risk, maintenance of fluid volume status and cardiac output, avoidance of exposure to nephrotoxic chemicals as well as subsequent treatment if necessary, and avoidance and aggressive treatment of infections. Prerenal and postrenal kidney injuries are treated by addressing their specific etiologies. Intrinsic kidney injury (ATN) is treated with many of the same interventions used to support renal function in CKD.
- Slowing the progression of CKD is the focus of interventions until stages 4 to 5. Appropriate management of ATN, blood glucose control in patients with diabetes, use of ACE inhibitors or AII blockers to reduce proteinuria, and aggressive management of hypertension are the primary foci. Because cardiovascular disease both is a risk factor for CKD and accelerates progression, interventions are also included to retard it.
- Nutritional needs for patients in renal failure include increased caloric intake as well as calcium and vitamin supplementation. Intake of fluids, phosphorus, potassium, sodium, and protein is usually restricted, depending on the underlying pathologic process and stage of the disease.
- Drug therapy in CKD is used to control hypertension, anemia, and some of the electrolyte and acid-base imbalances.
- Dialysis is used for some patients with ATN and for patients with CKD in stage 5 in order to remove metabolic wastes and correct fluid and electrolyte abnormalities.
- Kidney transplantation is a potential option for patients with ESRD. Kidney transplantation has been associated with a high degree of success.
- CKD is very prevalent in older adults. While many are initiating dialysis in ESRD, most will die of cardiovascular disease before reaching stage 5. The many comorbid conditions of this population require complex care.

## SUMMARY

Renal failure can occur at any age. AKI has multiple causes that can be classified into one of three categories according to the physical location of the problem: prerenal, postrenal, or intrinsic. Each category has unique pathologic features and some variation in laboratory values. Intrinsic failure (ATN) is divided into three phases: prodromal, oliguric, and postoliguric. Interventions differ for each phase.

CKD is a progressive, irreversible process. It is characterized by stages of declining GFR producing increasing impairment in the ability of the kidney to maintain homeostasis. The clinical manifestations

of CKD are determined by the degree of impairment of the kidneys' normal functions.

Key aspects of care include pharmacologic management of fluid overload, electrolyte abnormalities, and metabolic wastes; nutritional management; dialysis; and renal transplantation.

A clear understanding of the pathophysiology related to renal dysfunction is essential for any health care professional caring for patients in renal failure. Older adults with AKI, CKD, and ESRD add an additional layer of complexity to patient care. The impact that renal failure has on all other body systems presents many challenges.

*Ureterolithiasis, 621*

*Bladder (Vesical) Urolithiasis, 621*

The lower urinary tract encompasses several structures that together are responsible for the transport and elimination of urine from the body. These structures include the ureters, bladder, urethra, and associated urinary sphincters. The male prostate gland is anatomically located in this area, but is functionally involved in male reproduction; the role and disorders of the prostate gland are presented in Chapters 30 and 31, respectively.

Ureters collect the urine formed in the kidneys from the renal pelvises and transport it to the bladder. The bladder is a hollow, muscular reservoir for urine that expands to store it and then contracts to

expel urine through the urethra. Urine storage depends on intact spinal reflexes. The process of micturition (voiding) involves both reflex and voluntary mechanisms, mediated by the micturition center in the pons. Voiding is a result of coordinated function of bladder mechanoreceptors, neurologic impulse transmission, bladder muscle contraction, and urethral sphincter relaxation.<sup>1</sup>

In addition to voiding dysfunction, disorders of the lower urinary tract can generally be classified as congenital, neoplastic, infective, inflammatory, or obstructive. These disorders are often interrelated. For instance, stasis of urine, which occurs with a variety of disorders,

often leads to urinary tract infection (UTI). Infection of the kidney, pyelonephritis (see Chapter 27), and acute postrenal kidney injury (see Chapter 28) can be caused by any number of pathologies affecting the lower urinary tract. Lower urinary tract disorders can result in significant health problems that have tremendous physical, psychosocial, and economic ramifications on patients and their families.<sup>2-5</sup>

## LOWER URINARY TRACT

The role of the lower urinary tract is to transport urine formed by the kidneys and allow its appropriate removal from the body. The anatomy of the lower urinary tract is presented in Chapter 26. Urine movement from the kidneys to the bladder is due to the effect of gravity facilitated by peristaltic movement of the ureters. The bladder stores the urine until it is released through the urethra, ultimately by conscious decision. Anatomic integrity of the ureters and bladder, competent urethral sphincters, and an appropriately functioning nervous system are required for the lower urinary system to properly carry out its role.

### Diagnostic Tests

Several of the procedures presented in Chapter 26 are used to diagnose urologic disorders discussed in this chapter. Other, more specialized diagnostic tests are often even more appropriate. A urinalysis (U/A) is the simplest and least costly test that can provide a wealth of information. For the lower urinary tract, it is primarily used in the diagnosis of infection.

Although the abdominal radiograph known as a KUB (kidneys, ureters, and bladder) provides information regarding anatomy and may detect neoplasms or urinary stones, it is not the most frequently used procedure for this purpose. Ultrasonography, which is painless, does not involve radiation, and provides excellent visualization of the urinary system, is the most common initial screening study for infants and children with urinary problems. Cystography may be required to yield more specific information about the bladder than can be obtained by ultrasound.<sup>6</sup> Voiding cystourethrography (VCUG) involves placing a catheter in the bladder and then filling it with sterile, iodinated, dilute contrast material. The catheter is then removed and the patient voids. Images of the bladder are taken before voiding to detect a ureterocele or tumor, and images taken during voiding can identify reflux or urethral abnormalities. Radionuclide voiding cystography also requires catheterization but involves the use of a small amount of radioactive material. A technetium-99m-labeled radiopharmaceutical is instilled in the bladder through the catheter, followed by sterile normal saline to fill the bladder. Once the catheter is removed, images are taken with the bladder full and during voiding, but this procedure does not allow visualization of the urethra.

The term *urodynamic testing* is used for procedures associated with diagnosing voiding dysfunction.<sup>6</sup> There are multiple urodynamic tests and procedures and the choice of tests is based on clinical presentation and begins with the least invasive of the desired tests. The most common tests are cystometry (measurement of intrabladder pressure during filling); urethral pressure profilometry (measurement of intraluminal pressure along the length of the urethra); uroflowmetry (noninvasive method of measuring characteristics of urine flow); and pressure-flow micturition studies (invasive method of measuring characteristics of urine flow). Electrophysiologic testing may also be done to determine pathologic processes underlying voiding dysfunction. Neurophysiologic tests provide information about the coordination between the bladder and the external sphincter. Neurophysiologic tests are much more involved and are completed only in very specialized laboratories.

### Physiology of Micturition

Micturition is often taken for granted by health care providers and patients, but is a complicated process. Understanding of the process

begins with a review of the significant role the nervous system plays in controlling the functions of the lower urinary tract structures.

### Nervous System Innervation of the Lower Urinary Tract

The central, autonomic, and peripheral nervous systems are all involved in urinary elimination. The pontine micturition center coordinates relaxation of the internal sphincter and contraction of the bladder to enable urination, whereas the cerebral cortex primarily inhibits the process through conscious control of the external sphincter.<sup>1</sup> Any disease process affecting these areas can interfere with urination. This includes such pathologies as Parkinson disease, multiple sclerosis, traumatic brain injury, spinal cord injury, or stroke.

The smooth muscle of the bladder is innervated by both the sympathetic and parasympathetic branches of the autonomic nervous system (Figure 29-1). This innervation controls the detrusor muscle in the bladder wall and the bladder neck, ultimately controlling filling and emptying of the bladder. In other words, the bladder itself does not respond to voluntary control, but rather to neurologic reflexes. The nerves responsible for these reflexes have both autonomic efferent motor and afferent sensory roles; efferent nerves control bladder smooth muscle, and afferent fibers transmit sensations of bladder stretch—distention and fullness—and pain. Injury or disease of the spinal cord in this region profoundly affects lower urinary tract function.

Sympathetic outflow of the autonomic nervous system to the bladder originates from the spinal cord region of L1-L2; the release of norepinephrine causes relaxation of the bladder and contraction of the bladder neck, allowing the storage of urine. Parasympathetic innervation of the urinary tract is supplied via the pelvic nerves, which exit the spinal cord at S2-S4. Their stimulation causes contraction of the detrusor muscle and relaxation of the internal sphincter (bladder neck). Parasympathetic signals from the posterior urethra in response to stretch of the bladder lining (urothelium) and bladder musculature are primarily responsible for initiating bladder emptying.

The somatic nerve fibers of the peripheral nervous system control the voluntary skeletal muscle of the external bladder sphincter via the pudendal nerve. The peripheral nervous system is primarily responsible for muscle function at the pelvic floor.

### Mechanism of Micturition

The softness, pliability, mucosal secretions, and submucosal cushioning of the urethra are responsible for the maintenance of a water-tight seal or “compression” of the urethra. The *internal sphincter* is located at the proximal portion of the urethra, where the convergence of the detrusor muscle fibers provides pressure to keep it closed. When the internal sphincter has normal tone, the bladder is prevented from emptying until the pressure in the body of the bladder rises above a specific threshold. The sequence of urination begins with the bladder filling with urine until a first sensation of fullness is felt. This causes the internal bladder pressure to trigger stretch receptors in the bladder wall. Activation of these receptors results in afferent communication to the nervous system to cause contraction of the bladder detrusor muscle. The internal sphincter simultaneously relaxes, taking on a funnel shape.

The very noticeable urge to urinate causes an individual to consciously tighten the external sphincter. The *external sphincter* is located at the distal end of the urethra, surrounded by a ring of skeletal muscle from the pelvic floor. This musculature provides the necessary tension needed to maintain continence at normal resting bladder pressures. The external sphincter allows voluntary emptying of the bladder or the prevention of urination. Usually, enough pressure to hold the urine in the bladder can be voluntarily generated until about 350 to 400 ml of urine has collected in the bladder. At this point an urgent sensation to void

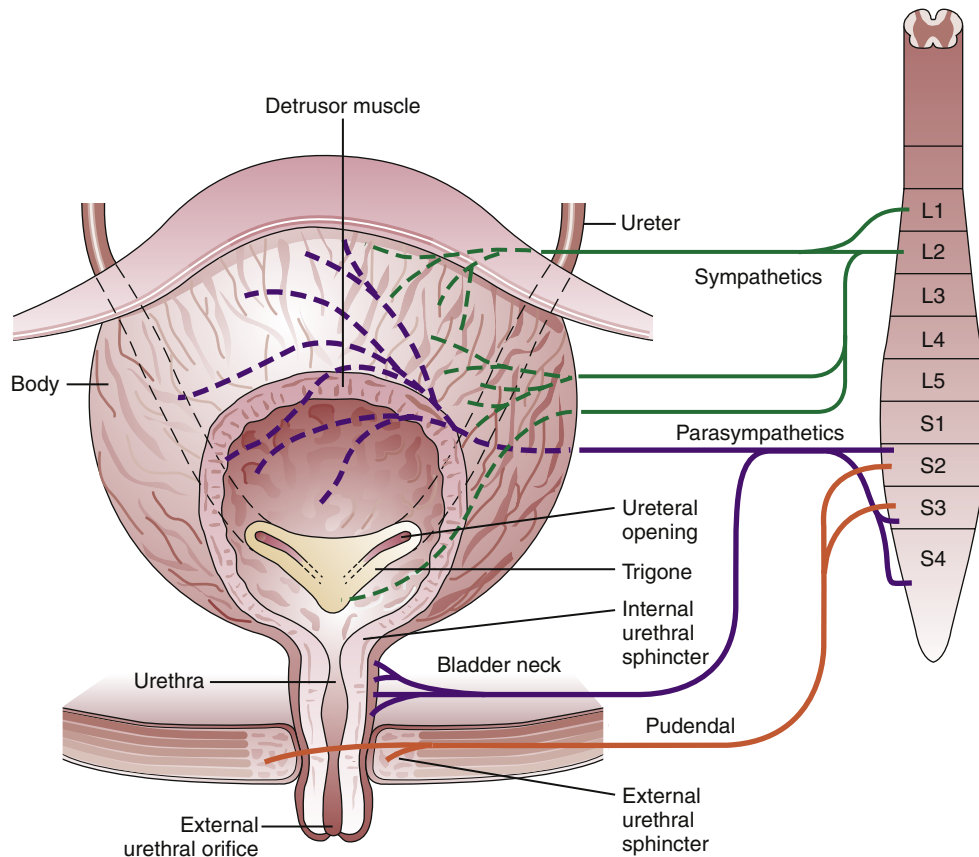

FIGURE 29-1 Bladder structure and innervation.

occurs and the resulting activation of the voiding centers in the brain (central nervous system) also helps inhibit the bladder from emptying. At the appropriate time, a coordinated nerve response allows the detrusor muscle to contract and both urethral sphincters to relax, and voiding occurs. If an individual is able to coordinate urination at a suitable location and desired time, we consider the individual to be **continent**.

Normal adult bladder capacity is 300 to 500 ml; the urge to void usually develops when 150 to 250 ml are present.<sup>2</sup> With an average fluid intake, this typically results in a voiding pattern of every 4 to 5 hours, with no need to awaken at night in order to void. With aging, bladder capacity declines to 200 to 350 ml; urination becomes more frequent (every 3 to 4 hours), and awakening at night to urinate is common. Under normal circumstances, the adult bladder contains less than 50 to 100 ml following voiding.<sup>2</sup> This volume of postvoiding urine is called **residual urine**. Certain pathologies are associated with incomplete bladder emptying, and increased residual urine volumes.

#### KEY POINTS

- The lower urinary tract transports urine from the kidneys and facilitates its removal from the body. A variety of laboratory tests are used in the diagnosis of lower urinary tract disorders.
- Bladder innervation is supplied by sympathetic nerves that exit the spinal cord at L1 and L2 and allow relaxation and filling. Stimulation of parasympathetic nerves from S1 to S4 results in bladder contraction and relaxation of the internal sphincter. The somatic pudendal nerve innervates the external bladder sphincter.
- Micturition requires central, autonomic, and peripheral nervous system functioning. It is a result of parasympathetic and voluntary motor control.

## VOIDING DYSFUNCTION

Voiding dysfunction can be associated with pathologies affecting the central, autonomic, and peripheral nervous systems. However, voiding dysfunctions may also be associated with other factors affecting control of micturition, including medications and access to toileting facilities. Disorders of the lower urinary tract, such as infection, can cause secondary problems with voiding. Voiding dysfunction encompasses several types of incontinence, and enuresis.

### Incontinence

The International Continence Society defines the symptom of urinary incontinence as the report of any involuntary urine loss.<sup>7</sup> Issues of urinary incontinence in adults are two times more common among women than men until age 80; after that point rates are equal.<sup>2</sup> The prevalence of urinary incontinence increases across women's lifetimes: 12% to 42% of middle-aged and younger women report urge incontinence, with these values increasing to 17% to 55% in older women.<sup>7</sup> However, incontinence is not normal under any circumstances and is not a normal part of aging. In 2000 the overall cost of incontinence in the United States was nearly \$20 billion.<sup>8</sup> Itemization of these costs illustrates the complexity of the problem: 3% for diagnostic testing, 9% for routine care, 32% for treatments, and 56% for the indirect costs of nursing home admissions and loss of productivity.<sup>8</sup> The personal financial cost is high as well; median weekly out-of-pocket costs for women with severe incontinence have been estimated at more than \$10 in 2005 terms.<sup>9</sup>

**Pathogenesis.** Continence requires both physiologic and cognitive capabilities. Physiologic requirements include an appropriately functional nervous system, and intact bladder and urethral function.

### BOX 29-1 RISK FACTORS FOR INCONTINENCE

<b>Risk Factors</b>	Childhood nocturnal enuresis
Immobility	Pregnancy, vaginal delivery, or episiotomy
Impaired cognition	
Medications (e.g., diuretics)	
Morbid obesity	<b>Pathologies</b>
Smoking	Urinary tract infection
Fecal impaction	Diabetes mellitus
Delirium	Diabetes insipidus
Environmental barriers to toileting	Stroke
High-impact physical activities	Multiple sclerosis
Estrogen depletion	Parkinson disease
Low fluid intake	Spinal cord injury
Pelvic muscle weakness	Spinal cord defects

Cognitively, individuals must have the ability to react to bladder urges and be motivated to be continent. Any disruption in these capabilities can result in an inability to attain or maintain continence. Risk factors associated with acute and chronic urinary incontinence are listed in Box 29-1.

Urinary incontinence is not a part of normal aging, but it may be a result of disorders that are more common in the elderly or medications that induce urinary changes (e.g., diuretics). Age-related changes in the function or structure of the lower urinary tract and the possible limitations in the mobility and independence of the elderly predispose them to incontinence.<sup>8</sup>

Acute incontinence has a sudden onset and is due to potentially reversible, more easily treatable conditions. Examples of such conditions include urinary tract infections and constipation or fecal impactions.<sup>2</sup> Chronic urinary incontinence is usually classified by type, based on the specific characteristics of presentation. These types are urge, stress, mixed, overflow, and functional incontinence. The etiologies and treatments vary, so identification of the type of incontinence is clinically important.

*Stress incontinence*, the most prevalent type of chronic incontinence, occurs when urine is involuntarily lost with increases in intraabdominal pressure.<sup>2,10</sup> It is precipitated by effort or exertion, such as by lifting heavy objects, or by coughing or sneezing. Stress incontinence is thought to occur as a result of loss of pelvic muscle and/or fascial support of the bladder and urethra. Without this support, whenever there is an increase in intraabdominal pressure the normal angle between the bladder and posterior urethra is disrupted, forces that support urethral closure are reduced, and urine is lost.<sup>2,10</sup> Decreased estrogen availability with menopause also contributes by reducing urethral closing pressure.<sup>11</sup> Age-related loss of pelvic floor muscle fibers decreases muscular support. Other factors that favor the development of stress incontinence include obesity, childbirth-related trauma, urologic or retropubic surgery, pelvic radiotherapy, and the presence of conditions such as diabetes or degenerative neurologic diseases that impair nerves innervating the structures involved in micturition.<sup>2,10</sup>

*Urge (urgency) incontinence* involves the involuntary leakage of urine suddenly along with or immediately following the sensation of a need to urinate (urgency).<sup>7,12</sup> This condition is most often due to an overactive detrusor muscle that suddenly contracts without the patient's desire for it to do so.<sup>2</sup> Aging is known to increase the frequency of spontaneous involuntary detrusor contractions.<sup>10</sup> Contributing factors may include bladder infections that irritate the bladder lining and bladder outlet obstruction attributable to prostate enlargement. Urge incontinence is the most common type of incontinence

experienced by older men.<sup>2</sup> Additionally, urge incontinence may result from central nervous system conditions such as stroke, Parkinson disease, and multiple sclerosis in which damage to inhibitory pathways occurs. Finally, drugs that increase urine flow, such as diuretics and alcohol, can aggravate urge incontinence.<sup>10</sup> In cases in which a specific cause is not determined, urge incontinence is said to be *idiopathic*. When urgency is associated with increased daytime frequency and **nocturia** (a need to get up at night to void), though not necessarily with incontinence, it is termed *overactive bladder syndrome*.<sup>12</sup>

*Mixed incontinence* is a combination of both stress and urge incontinence.<sup>7</sup> It is common for these two types of incontinence to occur together, especially in older women. The self-report of mixed incontinence, as well as urge incontinence, has been associated with a greater impact on quality of life than the self-report of stress incontinence alone.<sup>5</sup>

*Neurogenic bladder* is a broad classification of voiding dysfunction in which the specific cause is a pathology that disrupts the nervous communication governing micturition. Patients with neurogenic bladder include those with central nervous system disorders (e.g., stroke, Parkinson disease, multiple sclerosis) and those with disorders affecting the autonomic innervation of the bladder (e.g., spinal cord injury, spinal cord anomalies such as meningocele). Depending upon the nature of the neurologic deficit, the result may be detrusor overactivity (spasticity) or hypotonia (flaccidity) of the bladder. Those affected may exhibit overflow incontinence, urge incontinence, uncoordinated detrusor contraction and urethral relaxation, or urinary retention.<sup>10</sup> The phenomenon termed *overflow incontinence* occurs when the bladder becomes so full that it leaks urine, or “overflows.”<sup>8</sup> This can also happen when an obstructed urethra prevents the bladder from emptying normally, such as with an enlarged prostate, urethral stricture, cystocele, or prolapsed uterus.

Some experts describe *functional incontinence* as incontinence related to physical or environmental limitations resulting in an inability to access a toilet in time.<sup>8</sup> The urinary system may work well, but inaccessible toilets, mobility disorders, cognitive dysfunction, or mental disabilities prevent normal toilet usage. Health care workers can be critical in manipulating the environment to facilitate the patient's timely access to the toilet to maintain “dependent continence.”<sup>12</sup>

**Diagnosis.** Patients should be assessed for reversible issues affecting the function of the lower urinary tract. These include potential drug-induced effects, UTIs or obstructions, fecal impaction, overuse of alcohol or caffeine, and excess intake of fluid. Impaired cognitive function may be due to chronic illness, depression, or delirium. All disorders associated with cognitive or neurologic function (e.g., stroke, Parkinson disease) should be identified. Circumstances or conditions affecting mobility should also be acknowledged.<sup>13</sup>

Patients may be asked to keep a bladder diary, recording the time, frequency, and volume of micturition as well as incidents of incontinence.<sup>7</sup> In addition to the physical examination, such diagnostic tests as residual urine measurement, filling cystometry studies, and pressure flow studies during voiding may be used to establish the diagnosis of incontinence.<sup>6,7</sup>

**Treatment.** Management of incontinence begins by addressing reversible contributing factors. Lifestyle changes such as losing weight, reducing caffeine intake, and avoiding constipation may be useful. Additional treatment may include behavioral, pharmacologic, and surgical interventions, depending on the cause of incontinence. Pelvic floor muscle training (PFMT), a behavioral intervention, is recommended for urge incontinence in both men and women. PFMT may be as simple as the performance of exercises to strengthen pelvic muscles, or more complex to include techniques with vaginal weights, pelvic floor electrical stimulation, and biofeedback. Bladder training

incorporates education, scheduled voiding with systematic delay of voiding to conform with the schedule, and positive reinforcement.

Pharmacologic agents may be used to promote or inhibit physiologic activities associated with micturition, depending on the cause of incontinence. This may include anticholinergic agents (e.g., oxybutynin), vaginal or oral estrogen, and  $\alpha$ -adrenergic blockers (e.g., prazosin, tamsulosin) or 5 $\alpha$ -reductase inhibitors (e.g., finasteride) for men with bladder outlet obstruction.<sup>14,15</sup> The addition of drug therapy often increases the effectiveness of behavioral interventions. Injections with botulinum toxin are being used for detrusor overactivity. Surgical procedures for incontinence, used if nonsurgical interventions are ineffective, vary depending on the underlying anatomic or physiologic problems. Several surgical options are available to treat urge incontinence in women. The anterior colporrhaphy involves the repair of a weakened anterior vaginal wall that has allowed the bladder to prolapse into the vagina. A colposuspension is performed by using sutures to tighten the muscles of the pelvic floor that support the uterus and bladder; the procedure may be performed via laparoscope. Sling procedures involve implanting strips of synthetic or natural material around the bladder neck and urethra to support urethral closure. Surgical options for men may include artificial urinary sphincter implantation for sphincter incompetence and placement of a perineal compression sling for post-prostatectomy incontinence.<sup>16</sup>

Incontinence that is not resolved by behavioral, pharmacologic, or surgical treatment occasionally may be managed by supportive approaches such as intermittent catheterization, indwelling catheterization, or use of incontinence undergarments.<sup>2</sup> Each of these devices creates the potential for further complications. UTIs are more likely with stasis of urine in the bladder and, in the case of catheterization, with continuous or intermittent introduction of a foreign object into the normally sterile bladder. Catheterization is never an appropriate solution solely for caregiver convenience. Stasis of urine also increases the risk for bladder and renal calculi. Management of incontinence with incontinence undergarments predisposes patients to skin breakdown.

## Enuresis

**Enuresis** as defined by the International Children's Continence Society means intermittent incontinence while asleep.<sup>17</sup> Nocturnal enuresis is a common childhood condition, more common in boys than girls. One study, conducted using a strict definition of enuresis as incontinence twice a week for a minimum of 3 consecutive months, estimated a prevalence of 4.45% in children in the United States ages 8 to 11.<sup>18</sup> *Primary nocturnal enuresis* describes a child who has never achieved continence, whereas *secondary enuresis* refers to enuresis that develops after a period of at least 6 months of dryness.<sup>17</sup> In *monosymptomatic nocturnal enuresis*, the child has nocturnal incontinence but no other signs of lower urinary tract malfunction such as urgency, postvoid dribbling, and daytime incontinence. *Nonmonosymptomatic nocturnal enuresis* is diagnosed when the child has symptoms of urgency, frequency, or daytime incontinence in addition to nighttime enuresis.

**Pathogenesis.** Primary *monosymptomatic nocturnal enuresis* is thought to be present in less than half of the cases of nocturnal enuresis.<sup>19</sup> Three main mechanisms are considered to contribute to the condition. Some children exhibit nocturnal polyuria, linked in many cases to a deficiency in vasopressin (antidiuretic hormone [ADH]). Other children exhibit nocturnal overactivity of the detrusor muscle, which contributes to incontinence. Finally, immature or abnormal arousal mechanisms may explain why the child does not awaken.<sup>19,20</sup>

The fact that parents and siblings of children with nocturnal enuresis also report a history of the problem has led to the establishment of a genetic contribution.<sup>21</sup> Enuresis is associated with such conditions as

constipation, attention-deficit hyperactivity disorder, and sleep-disordered breathing.<sup>19,22,23</sup>

**Diagnosis.** Clinical workup for enuresis includes a thorough history of elimination patterns via a bladder diary and a physical examination to identify gross anatomic abnormalities. Children with monosymptomatic nocturnal enuresis (MNE) should also be tested for diabetes mellitus.<sup>19</sup> Additional diagnostic tests, including flow cytometry and urinary tract imaging, are warranted for children who present with nonmonosymptomatic nocturnal enuresis (NMNE).<sup>24</sup>

**Treatment.** Treatment for MNE, not recommended before age 6, begins with education about appropriate daytime and bedtime voiding patterns.<sup>24</sup> If constipation is present it is managed with fiber intake, physical activity, and stool softeners. Enuresis alarms, designed with a moisture sensor in the bed linen or nightclothes, arouse and/or condition children to contract pelvic muscles; alarm therapy is effective for approximately two thirds of children. A second course of alarm therapy may be required if there is relapse.<sup>19</sup> "Overlearning" is recommended as a technique to strengthen the child's response to a full bladder; after dryness is established the child is instructed to drink liquids an hour before bedtime.

Pharmacotherapy may be added if nonpharmacologic treatments are ineffective. Desmopressin, a vasopressin analogue, effects a full response in 30% of children and a partial response in 40%.<sup>19</sup> Imipramine, a tricyclic antidepressant, is effective in about half of the children but its risk of cardiotoxicity mandates careful use in selected children. Anticholinergics such as oxybutynin and tolterodine are sometimes used, in combination with desmopressin or alone, and are effective in about 40% of cases. Urinary retention and constipation are side effects of anticholinergics that are worrisome in the setting of enuresis.<sup>19</sup> In children who remain enuretic after many months of standard treatment, additional diagnostic testing such as ultrasound is recommended. Efforts to manage enuresis without treating an underlying pathology are likely to be unsuccessful.

## KEY POINTS

- Voiding dysfunction may be secondary to disorders of the lower urinary tract, attributable to pathologies affecting the central, autonomic, and peripheral nervous systems, or associated with a wide variety of factors affecting control of micturition, including medications and access to toilet-facilities.
- Urge incontinence may be idiopathic or attributable to bladder infections that irritate the bladder lining, radiation therapy, tumors or stones in the urinary tract, or central nervous system damage to inhibitory pathways (as would occur with stroke, dementia, Parkinson disease, and multiple sclerosis).
- Weakening of pelvic muscles or intrinsic urethral sphincter deficiency results in stress incontinence.
- Mixed incontinence is a combination of both stress and urge incontinence.
- Obstruction of the urethra, or an underactive or inactive detrusor muscle causes overflow incontinence.
- Functional incontinence is related to physical or environmental limitations in reaching a toilet in time to void.
- *Neurogenic bladder* is a broad classification of voiding dysfunction in which the specific cause is a pathology that produces a disruption of neurologic communication governing micturition.
- Treatment options for voiding dysfunction include behavioral, pharmaceutical, and surgical interventions.
- Enuresis is inappropriate wetting of clothing or bedding, with the term usually reserved for incontinence in children, particularly at night.
- Treatment for enuresis is usually behavioral modification with or without pharmacologic intervention.

## CONGENITAL DISORDERS

### Vesicoureteral Reflux

Reflux of urine from the bladder to the ureter and renal pelvis, known as **vesicoureteral reflux (VUR)**, is usually due to incompetence of the valvular mechanism at the ureter-bladder junction.

The incidence of vesicoureteral reflux in asymptomatic children (without a UTI) is low, estimated at 1%.<sup>25</sup> However, the incidence in infants and children with UTIs is much greater, between 30% and 40%. More common in females, a genetic component is also present.<sup>26</sup> In siblings of children in whom reflux had been diagnosed, the incidence is 27% to 51%. There is a 66% rate of VUR in the children of parents who have been diagnosed with reflux. The specific mode of inheritance has not yet been identified; a major, dominantly inherited allele, multifactorial or polygenic traits, and an X-linked pattern have all been postulated.<sup>27</sup>

**Pathogenesis.** VUR is usually due to incompetence of the valvular mechanism at the ureter-bladder (ureterovesical) junction. Normally, the ureters enter the bladder at an oblique angle and then continue for 1 to 2 cm under the bladder mucosa before exiting inside the bladder cavity. As the bladder fills, pressure within it increases against the muscle wall and closes the ureteral passageway. In the case of VUR, closure of the ureteral passage is unsuccessful, and the urine flows backward into the ureters, sometimes reaching the kidney.

Vesicoureteral reflux is classified as being of either a primary or a secondary etiology. Congenital abnormalities at the ureterovesical junction are a chief cause of primary reflux.<sup>28</sup> One such abnormality is a shortened ureteral tunnel through the bladder wall, which decreases the efficiency of the valvular mechanism. Impaired bladder dynamics may be a contributing factor; the prevalence reports of bladder dysfunction in children with primary VUR have ranged from 18% to 75%.<sup>28,29</sup> Primary reflux is also associated with other abnormalities of the urinary system, among them ureteral duplication, ureterocele with duplication, ureteral ectopia, and paraurethral diverticula. Secondary reflux can occur from increased pressure within the bladder (neurogenic bladder, bladder outlet obstruction), inflammatory processes, or surgical procedures at or near the ureterovesical junction. Reflux may be bilateral or unilateral; the extent of reflux is graded from I to V (Figure 29-2).

Reflux of urine may cause increased renal pelvis pressure; additionally, migration of bacteria from the bladder to the kidneys may result in pyelonephritis or renal scarring that may cause hypertension or renal insufficiency.<sup>26,30</sup> In the 1970s, in 50% of the cases of hypertension in children, VUR was documented as the specific etiology. At that time, up to 40% of the children treated at renal failure clinics had VUR. More recent data indicate that VUR is noted as the etiology of hypertension or renal insufficiency in only about 6% of the children. These differences may be due to changes in disease-coding procedures, and/or better diagnosis and treatment.<sup>30</sup>

**Diagnosis and clinical manifestations.** Reflux may be discovered prenatally, during ultrasonography, when hydronephrosis is identified.<sup>30</sup> The other most common time of diagnosis is during the screening of children with a family history of VUR.<sup>31</sup> It may also be identified during evaluation for recurrent UTI, voiding dysfunction, renal insufficiency, or hypertension in children. Diagnostic tests such as voiding cystourethrography (VCUG), intravenous pyelography (IVP), and computed tomography (CT) are performed to evaluate the status of the kidney and bladder system. Nuclear medicine scans of kidney function such as the technetium-99m-labeled dimercaptosuccinic acid (DMSA) renal scanning may be warranted.<sup>32</sup>

**Treatment.** In nearly 80% of cases, reflux resolves spontaneously as the child grows.<sup>33</sup> The factors predictive of spontaneous resolution are

younger age at diagnosis, classification as grade I or II reflux, higher bladder capacity at the onset of reflux manifestations, and a history of prenatal hydronephrosis. This information is helpful in determining when and how to treat patients, given questions about safety and efficacy of long-term prophylactic antimicrobial therapy and surgical interventions.<sup>33</sup>

For those with VUR most likely to resolve spontaneously, observation and medical management when necessary are recommended.<sup>32</sup> Continuous antibiotic prophylaxis is an appropriate option for children with a history of UTI. Observation with regular urinalysis and culture is an option for children without recurrent infection, with antibiotic therapy initiated for a diagnosed UTI.<sup>32</sup> Children who experience breakthrough UTI despite continuous antibiotic therapy are considered for surgical intervention; both endoscopic and open ureteral reimplantation procedures may be used.<sup>32</sup>

### Obstruction of the Ureteropelvic Junction

**Ureteropelvic junction obstruction (UPJO)** is defined as a blockage (partial or complete) in urinary flow from the renal pelvis at the entry point of one or both ureters.<sup>34</sup> It is diagnosed more often in males, and more frequently presents unilaterally at the left ureter.<sup>35</sup> Bilateral UPJO has an incidence of 10% to 40% and is usually diagnosed in infants under the age of 6 months.<sup>35</sup> It may be either congenital or acquired; acquired UPJO may be due to such conditions as urinary tract stones, postoperative or inflammatory strictures, or neoplasms of the ureters.<sup>34</sup> An autosomal dominant model of inheritance has been proposed but not verified.<sup>35</sup> An increased incidence in premature infants and twins has been noted, as well as an increased incidence of other urologic abnormalities in conjunction with UPJO.<sup>35</sup>

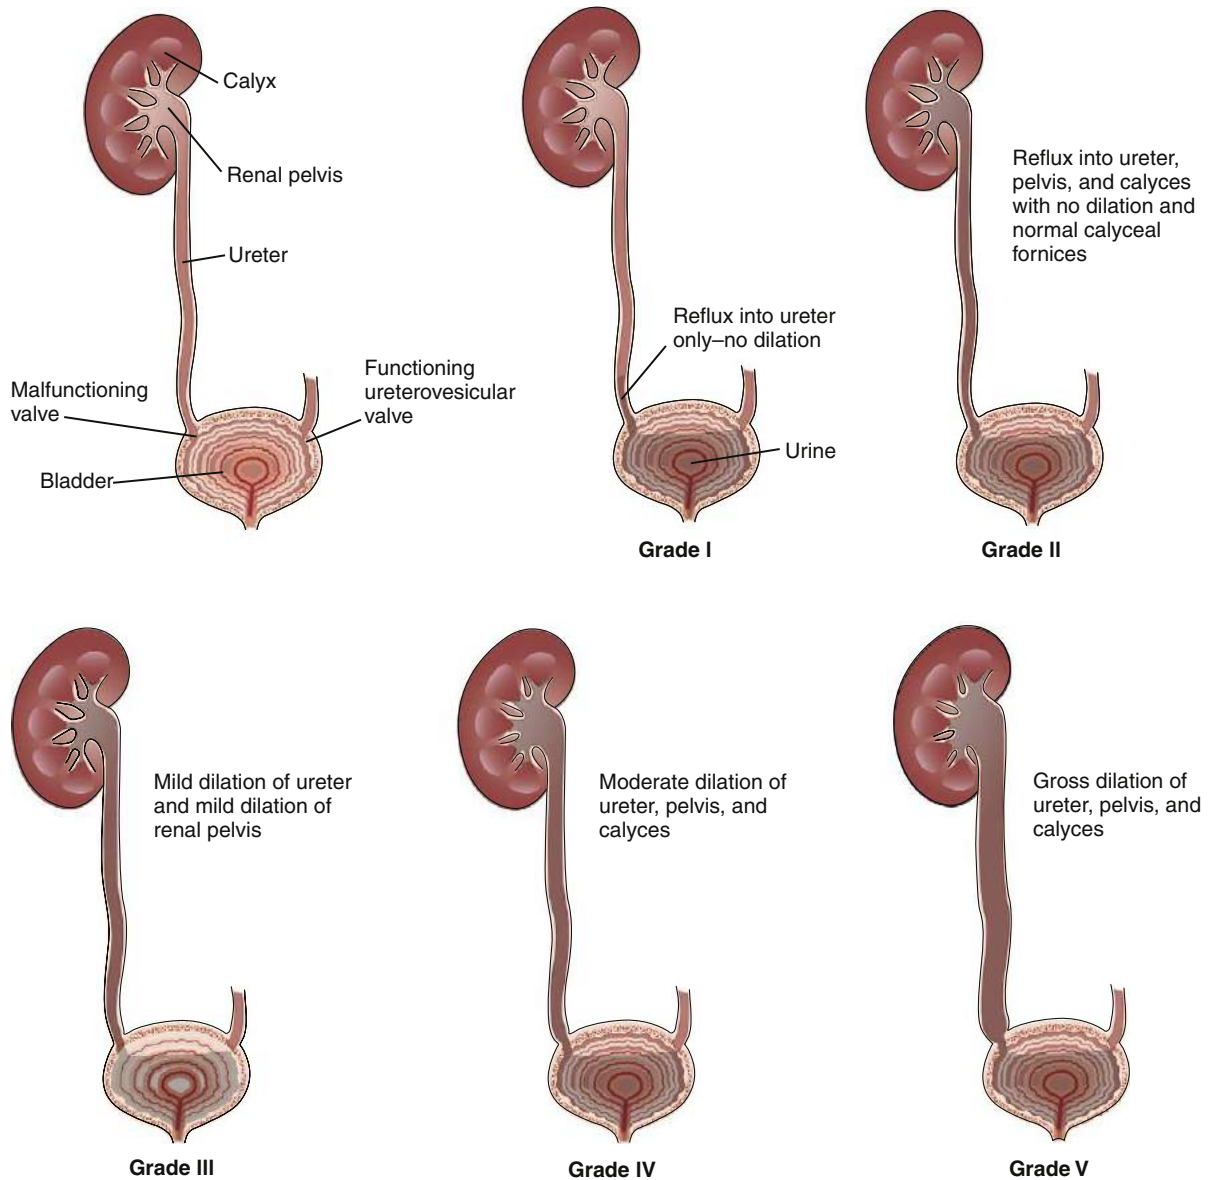

**Pathogenesis.** The exact etiology of UPJO remains unknown, but in the majority of cases, stenosis (narrowing) of the junction by either intrinsic or extrinsic factors is the cause of the obstruction. Excessive collagen in the muscle cells of the junction is a usual intrinsic source of UPJO, whereas compression from renal veins or arteries, "crossing vessels," is a possible external cause. Because uncrossing the vessels never solves the obstruction, it is likely that an intrinsic factor changes the structure of the renal pelvis producing these variations in the vasculature. The result of intrinsic and extrinsic UPJO is inefficient ureter drainage leading to progressive dilation of the renal pelvis and hydronephrosis. Eventually, structural damage to the renal parenchyma and kidney dysfunction will occur.

**Diagnosis and clinical manifestations.** The majority of UPJO diagnoses are made prenatally during maternal ultrasonography.<sup>34,35</sup> Neonates with hydronephrosis attributable to UPJO frequently have elevated serum creatinine levels and reduced urinary output, but it is not common for renal failure to be present in neonates with either unilateral or bilateral UPJO.<sup>35</sup> Other early signs and symptoms include a palpable flank mass in a newborn infant; abdominal, flank, or back pain; a UTI with fever; or hematuria without significant trauma. UPJO may also be asymptomatic and discovered incidentally on renal ultrasonography. A VCUG may be performed to rule out other conditions such as vesicoureteral reflux.

**Treatment.** Surgical intervention for UPJO has decreased in recent decades, in favor of more conservative approaches.<sup>34</sup> In the case of prenatally diagnosed UPJO, observation is considered most appropriate.<sup>34,36</sup> Conservative, observational management consists of frequent renal ultrasound to assess for hydronephrosis.

The intent of surgery is to relieve symptoms and/or maintain renal function, but for some asymptomatic cases, monitoring the patient has been found to be most appropriate.<sup>34</sup> The percentage of surgical interventions in children younger than 6 months of age has decreased from

**FIGURE 29-2** International classification of vesicoureteral reflux. (From James SR et al: *Nursing care of children: principles and practice*, ed 4, Philadelphia, 2013, Saunders, p 576.)

34.2% in an assessment from 1988 to 1991 to 25.2% in a similar review from 1997 to 2000.<sup>36</sup>

The timing of surgical intervention to correct UPJO is also controversial. Ultimately, it is a clinical decision based on the degree of obstruction, a careful analysis of kidney function, and the overall health of the infant or child. Early surgical repair is usually warranted if function of the affected kidney decreases, in cases of bilateral obstruction, and in cases of congenital single kidney with obstruction.

Pyeloplasty is the surgical reconstruction of the UPJ. It usually involves removal of the stenosed area of the junction and anastomosis of the ureter and renal pelvis. Endoscopic and laparoscopic techniques are being utilized widely in the United States.<sup>36,37</sup> An improvement in renal function is likely, although a small percentage of patients require a second surgical intervention because of the postoperative development of urine leakage or a return of the obstruction.<sup>37</sup> The use of a robotic endoscopic approach to surgery is increasingly popular in locations where it is available.<sup>38</sup>

### Ureteral Ectopy

An **ectopic ureter** is a single ureter implanted in an abnormal location or a duplicate ureter. Alternative or duplicate sites of ureter implantation predispose the patient to infection and a potential reduction in renal function.

**Pathogenesis.** Ureters may implant anywhere along the route of migration of the mesonephric duct during fetal development. Ectopic ureters are significantly more common in females than in males.<sup>39,40</sup> In males, the ectopy is usually unilateral and is most frequently found implanted in the urethra; the bladder neck, seminal vesicle, and vas deferens are also common sites. In females, ectopic ureters may be implanted in the urethra, vagina, cervix, ovarian tubes, or uterus.<sup>39,40</sup>

**Diagnosis and clinical manifestations.** An ectopic ureter is often found in conjunction with other genitourinary pathologies, including renal dysgenesis or agenesis, ectopic kidneys, abnormal ovaries or fallopian tubes, or abnormalities in the seminal vesicles.<sup>39,40</sup> The diagnosis of ureteral ectopy is frequently made during maternal ultrasonography.

Hydronephrosis secondary to obstruction is the typical sonographic finding. Postnatally, the condition is diagnosed with intravenous urography, renal ultrasonography, and endoscopy in symptomatic individuals. The clinical manifestations of ureteral ectopy vary depending on the site of implantation, and identification may not be made until significantly later, often by decades.<sup>39-42</sup> In females the most common symptom is incontinence; other symptoms experienced by male and female patients are continence with dribbling, UTIs, obstruction, and pain.<sup>39-41</sup> Epididymitis may be the initial problem in males.

**Treatment.** UTIs are treated appropriately. Surgical alternatives vary according to the site of ureteral ectopy, the function of the affected kidney(s), and the presence of any other pathology.<sup>39-42</sup> In the case of a single ectopic ureter, when the opposing kidney is normal, nephroureterectomy is the recommended course of treatment. If the involved kidney has adequate function, the ureter may be reimplanted in a more physiologically acceptable site. Heminephrectomy and ureteropyelostomy are not uncommon. Laparoscopic nephrectomy and heminephrectomy are increasingly used because of the reduced mortality and better visualization of the surgical field with laparoscopic procedures.<sup>39-42</sup> Antenatal sonography may lead to earlier diagnosis and an increase in kidney-sparing surgery.

### Ureterocele

A **ureterocele** is a congenital cystic dilation of the distal end of the ureter. These cystic dilations are called *intravesical* or *orthotopic* ureteroceles when they are entirely within the bladder itself and *extravesical* or *ectopic* when found in the neck of the bladder or in the urethra.<sup>43</sup> Ectopic ureteroceles are the more common form in the pediatric population. A ureterocele with a kidney that has just one ureter is called a *single system* ureterocele; *duplex system* ureteroceles are found with a kidney possessing two ureters.<sup>43</sup> Duplex system ureteroceles are more common. Ureteroceles occur more often in females than in males (6:1 ratio) and almost exclusively in Caucasians.

**Etiology and pathogenesis.** Ureteroceles are most often identified prenatally or in infants and children; however, they may not be found until adulthood.<sup>44</sup> It is most likely that the etiology of ureteroceles is complex rather than unified. Most certainly there are multiple points in embryogenesis when ureterocele formation could occur, often with concomitant anomalies of the kidney(s).<sup>43</sup> On histologic exam the microscopic structure of the muscle is abnormal, with smaller myocytes, decreased numbers of muscle bundles, and an absence of thick myofibrils.

Ureteroceles may be classified as simple structures when they are not associated with duplicate collecting systems, but the majority present as duplicate systems with ectopic implantation. They are infrequently bilateral. When identified in adults, they are typically intravesical, simple, and unilateral.<sup>44</sup> The small orifice of the ureter poses an obstruction in the collecting system and results in ureteral and renal calyx dilatation and often facilitates reflux and infection. If the ureterocele is large, obstruction of the bladder outlet may occur.<sup>45</sup>

**Diagnosis and clinical manifestations.** Ureteroceles are increasingly identified serendipitously during prenatal ultrasonography by the appearance of hydronephrosis and evidence of cystic dilatation.<sup>45</sup> After birth, confirmation with further assessment is necessary. UTIs are the most common manifestation in infants. In addition to the manifestations of UTI, patients with ureteroceles may present with either urinary retention or urinary incontinence if the bladder outlet is obstructed, ureteral calculus, hematuria, urosepsis, or a general failure to thrive. Ureteroceles discovered in adults are often asymptomatic.

Anatomically, ureteroceles present with significant variability, requiring a thorough history, physical examination, and diagnostic

testing. In addition to determining the precise presentation, diagnostic test results assist in determining the most appropriate surgical intervention. Ultrasonography is recommended for detection of the ureteral dilatation.<sup>46</sup> The structure and function of the urinary tract are also evaluated with VCUGs, magnetic resonance imaging (MRI), and nuclear renal scans.<sup>46</sup> These tests are most useful in guiding interventions, but are not necessary for ureterocele diagnosis. Prophylactic antibiotics are usually prescribed during diagnostic testing.

**Treatment.** Treatment goals for ureterocele include controlling infection, preserving urinary tract function, maintaining urinary continence, and removing obstruction.<sup>47</sup> Surgical interventions are often necessary to accomplish these goals, though there is recent discussion about using expectant management in select patients.<sup>48</sup> Surgical options range from endoscopic decompression to partial nephroureterotomy to a complete surgical reconstruction.<sup>46</sup> The evolution of endoscopic instruments that are small enough for neonates has increased the use of endoscopic surgery to accomplish the required procedures with less morbidity.<sup>45,47</sup> Immediate endoscopic ureterocele decompression by incision or puncture is recommended in the setting of infection or severe obstruction.<sup>46</sup> The choice of surgical procedure depends upon multiple factors including patient age and clinical condition, kidney function, and presence of obstruction or reflux.<sup>46</sup> Depending upon the anomalies found during diagnostic evaluation, the intervention may include transurethral incision of the defect, excision with reimplantation of the ureter, or partial nephrectomy and ureterectomy. In an acutely septic patient, a percutaneous nephrostomy to drain the upper collecting system may be needed.

#### KEY POINTS

- Congenital abnormalities of the bladder include misimplantation of ureters, strictures, an extra ureter, and ureterocele.
- These disorders cause problems by obstructing normal urine flow and predisposing to retrograde urine flow, urinary stasis, and secondary infection; they are usually treated with surgical interventions.

## NEOPLASMS

Primary cancers of the ureters or urethra are rare. Bladder cancer, however, is quite common.

### Bladder Cancer

The American Cancer Society estimated there would be approximately 69,250 new bladder cancer patients diagnosed in the United States in 2011—52,020 men and 17,230 women.<sup>49</sup> Bladder cancer is the fourth most common cancer diagnosed in men in the United States (following prostate, lung, and colon cancers) and the ninth most common cancer in U.S. women. The male/female ratio of incidence is 3:1.<sup>3</sup> The mortality rate for 2011 was estimated to be about 10,670 men and 4320 women.<sup>49</sup> The rates of both incidence and mortality attributable to bladder cancer have been quite stable across the last 20 years. Like most cancers, the risk of developing bladder cancer increases with age; median age at diagnosis for men is 69 years and for women is 71 years. From 2004 to 2008, the incidence in white males was nearly twice that in black males, and slightly lower in Hispanic males than in blacks.<sup>50</sup> Blacks, however, have more advanced stages of bladder cancer than whites at the time of diagnosis. At diagnosis, about half of bladder cancer patients have superficial cancers, and about 35% have bladder muscle-invasive cancer. In the remainder of patients, the cancer has spread outside the bladder, rarely to distant sites.<sup>49</sup>

There are four general types of bladder cancer, differentiated by their histologic appearance.<sup>49</sup> Some of these bladder cancer histologies are also found in malignancies of the renal pelvis, ureters, and/or urethra. More than 95% of all cases of bladder cancer are *urothelial (transitional cell)* carcinomas originating in the transitional epithelium, or urothelium, which is the lining found throughout the urinary tract. There are two subtypes of urothelial carcinomas (UCs); the majority exhibit a papillary appearance with the remainder having a flat appearance. Flat lesions tend to be more muscle-invasive and thus have a poorer prognosis.<sup>3</sup> *Squamous cell* carcinoma of the bladder represents only approximately 1% to 2% of the overall cases. This type of bladder cancer is microscopically very similar to skin cancer, and is quite invasive. About 1% of bladder cancers are *adenocarcinomas*. These tumors, arising from glandular tissue, are also invasive in nature. *Small cell* bladder cancers account for less than 1% of all bladder cancers; these cancers arise from neuroendocrine cells.<sup>49</sup> These diverse types of malignancies may respond differently to the interventions for bladder cancer. A very rare muscle cancer called *rhabdomyosarcoma* is not usually included in discussions of bladder cancer. It may originate in the bladder but more frequently involves other organs and tissues.

**Risk factors.** Bladder cancer risk usually is divided into environmental and inherited classifications. Environmental risk factors for bladder cancer are shown in Box 29-2. Smoking is the greatest risk factor, increasing risk by about threefold; smoking cessation has been shown to decrease bladder cancer risk.<sup>3</sup> Carcinogenic chemicals in cigarette smoke are inhaled, enter the bloodstream, and then are filtered and concentrated in the urinary tract. About 66% of deaths from bladder tumors in men and 30% in women are attributable to smoking.<sup>3</sup> Occupational exposure to carcinogens and smoking may increase bladder cancer risk synergistically.<sup>49</sup> People with occupational exposure to aniline (an aromatic amine) textile dyes, hair dyes (especially for greater than 10 years), paint and leather, carpet, rubber, and cement are at increased risk for bladder cancer.<sup>3</sup> Chronic inflammation of the bladder by UTIs is associated with an increased risk of bladder cancer, especially the invasive squamous cell type. Other causes of inflammation, such as stones, have also been associated with the disease. Certain chemotherapy agents (e.g., cyclophosphamide, ifosfamide) used in the treatment of other malignancies as well as radiation therapy to the pelvis increase the risk of bladder cancer. Low fluid intake is a risk factor for bladder cancer.<sup>3</sup> A family history of bladder cancer increases a person's risk, likely through inherited gene syndromes and/or shared exposure to environmental carcinogens. One heritable risk factor is a mutation of the retinoblastoma gene responsible for an infantile cancer of the eye that is associated with increased bladder cancer risk.<sup>49</sup>

### BOX 29-2 ENVIRONMENTAL RISK FACTORS FOR BLADDER CANCER

- Tobacco smoking (aromatic amines)
- Certain types of dyes, including hair, medical, and industrial dyes (aromatic amines)
- Certain chemicals used in rubber tire production
- Certain pesticides that contain aromatic amines
- Certain chemotherapeutic agents (e.g., cyclophosphamide)
- Diesel exhaust (polycyclic aromatic hydrocarbons)
- Arsenic in drinking water
- Low fluid intake
- Pelvic radiation therapy

In children, the congenital anomaly of exstrophy of the bladder (bladder outside the abdominal cavity) may predispose to the development of bladder tumors, particularly adenocarcinomas.<sup>3,49</sup> Parasitic infections from schistosomiasis, prevalent in the Middle East and Africa (especially Egypt), have been associated with squamous cell carcinoma as a result of urine-borne carcinogens formed during the infectious process and irritation by the parasitic ova.<sup>49</sup>

**Pathogenesis.** Bladder cancer metastasis occurs directly through the bladder wall to adjacent organs (e.g., prostate, bowel, vagina, uterus) or via lymph nodes in the pelvis and abdomen. Once treated, tumors can recur at the original site, or an entirely new tumor may develop at another site. The sites of metastasis most commonly include the lymph nodes, liver, lungs, and bone.<sup>3</sup> Specific details of the pathogenesis of cancer are found in Chapter 7.

**Clinical manifestations.** Painless hematuria is usually the initial symptom of bladder cancer.<sup>3</sup> However, in the early stages of bladder cancer, both gross and microscopic hematuria are often intermittent, and hematuria is associated with numerous urinary tract pathologies. Other manifestations related to bladder cancer include urinary frequency and urgency; dysuria is an uncommon finding. But again, all these symptoms are also seen with other conditions involving the urinary tract.<sup>3,49</sup> Because these signs and symptoms are so general, early diagnosis of bladder cancer requires a thorough workup by the health care provider, especially in persons more than 40 years of age.<sup>3</sup>

**Diagnosis.** In most cases, diagnostic evaluation for bladder cancer is initiated because of the development of one or more of the previously listed clinical manifestations. A thorough history may reveal risk factors for bladder cancer, or physical examination and diagnostic testing may indicate another etiology.

The recommended diagnostic test for suspected bladder cancer is cystoscopy, with biopsy of any questionable tissue and washings of free cells for cytologic examination.<sup>51</sup> White light cystoscopy allows direct visualization of tumors. Newer fluorescent cystoscopy uses a photosensitive substance such as 5-aminolevulinic acid (5-ALA) to enhance the ability to detect small high-grade urothelial lesions.<sup>52</sup> Urine specimens will be tested for the presence of tumor markers. The sensitivity and specificity of available tumor markers varies widely; at this time, no tumor marker is reliable enough to replace cystoscopy.<sup>3,51</sup> Tumor markers may also be used to monitor response to treatment.<sup>49</sup> Recommended imaging tests include intravenous pyelogram (IVP), computerized tomography (CT) scan, and transabdominal ultrasound.<sup>51</sup> Other tests such as bone scans may be performed to determine the presence of metastasis. The stage of the malignancy is an important contributor to treatment decisions, and also aids in the determination of prognosis. The TNM (tumor, node, metastasis) staging system is commonly used for bladder cancer.<sup>3</sup>

The examination of biopsied tissue, cells obtained during cystoscopy, and cells that might be found in the urine is essential to the determination of the specific type and grade of the tumor. (See Chapter 7 for a thorough discussion of staging and grading.) The World Health Organization grading system for non-muscle-invasive UC addresses risk for invasion and recurrence.<sup>51</sup> Examination of the biopsy also allows determination of the depth to which the tumor has penetrated the bladder wall and facilitates staging. All of this information is used to guide the selection of the specific treatment approach.

**Treatment.** Treatment protocols are based on the tumor's features: the type of bladder cancer and its grade and stage. The primary options are surgery, radiation therapy, chemotherapy, and immunotherapy. Treatment selection is evidence-based, with available information

continuously being updated.<sup>51,53</sup> Surgery as the single treatment, or with other adjuvants, is the intervention for the majority of bladder cancers. The specific approach to surgery varies with the stage of the tumor. For non–muscle-invasive carcinoma, endoscopic transurethral resection of bladder tumors (TURBT) with appropriate cystoscopic and cytologic follow-up is recommended.<sup>51</sup> Intravesical immunotherapy with *Bacillus Calmette–Guérin* (BCG) is also recommended, either as a single dose or as a course of doses over time, depending upon risk of recurrence and progression.<sup>51</sup> Adjuvant intravesical instillation of chemotherapeutic agents (e.g., mitomycin C, doxorubicin) has been shown to reduce recurrence.<sup>51</sup>

If the tumor is at high risk for progression, unresponsive to BCG, or muscle-invasive, more extensive surgical procedures are employed. Chemotherapy or radiation therapy may be performed preoperatively to reduce tumor size and improve survival.<sup>51,53</sup> Surgical removal of the bladder (cystectomy), either partial or total, may be performed; a total cystectomy requires urinary diversion to provide for storage and elimination of urine.<sup>49</sup> Urinary diversions typically involve the creation of a reservoir, using a portion of the intestine, into which the ureters are implanted. Urine is drained from the reservoir often through a stoma created through the abdominal wall; however, substitute bladder reservoir (neobladder) procedures involve connecting the urethra to the reservoir, allowing the patient to void normally. In cases where the tumor is large or there are multiple bladder tumors, a radical cystectomy is performed, in which the bladder and surrounding nodes are removed; in men the prostate gland is also removed, and in women the uterus, ovaries, fallopian tubes, and part of the vagina are also often removed.<sup>51,53</sup>

Therapies that preserve the bladder may be selected, even for muscle-invasive carcinomas, if the disease is bladder-localized. External beam radiation therapy may be an acceptable alternative for patients who are not sufficiently strong for radical surgical procedures. Systemic chemotherapy may be an option for people with metastatic bladder cancer.<sup>53</sup>

The prognosis for stage 0 (noninvasive papillary carcinoma or carcinoma in situ [CIS]) is excellent, with a relative 5-year survival rate of 98%.<sup>49</sup> As the tumor invades deeper into the bladder wall or metastasizes beyond the bladder, the survival rate begins to decline. The 5-year relative survival rate for muscle-invasive (stage II) bladder cancer is 63% and drops to 15% for metastatic (stage IV) cancer.<sup>49</sup> Risk of recurrence of bladder cancer is high, even for superficial malignancies; ongoing follow-up with periodic diagnostic tests is necessary.<sup>3</sup>

#### KEY POINTS

- Bladder cancer is the fourth most common cancer diagnosed in men in the United States and the ninth most common in women.
- Risk of developing bladder cancer increases with age; smoking and occupational exposure to carcinogenic chemicals are thought to be the main predisposing factors.
- There are four general types of bladder cancer, differentiated by their histologic appearance. About 95% of bladder tumors originate from the transitional epithelium (urothelium) lining the urinary tract.
- Bladder cancer is primarily manifested as hematuria. Frequency and urgency may also be present. Dysuria is not common.
- The most frequently used invasive test in the diagnosis of bladder cancer is cystoscopy, with biopsy of any questionable tissue and washings of free cells for cytologic examination.
- Treatment protocols are based on the tumor's features: the type of bladder cancer and its grade and stage. The primary options are surgery, radiation therapy, chemotherapy, and immunotherapy.

## INFLAMMATION AND INFECTION

Most inflammations of the lower urinary tract are due to infection. The normal defense mechanisms of the urinary tract are presented in detail in Chapter 27 with the discussion of pyelonephritis (infection of the kidney). Urinary tract infections (UTIs) are typically ascending in nature; they begin in the lower urinary tract and may progress to the kidney (upper urinary tract). By the time infection reaches the kidneys, the bladder and urethra are already infected. Involvement of the ureters does not seem to present with clinical manifestations.

### Urethritis

**Urethritis** is an inflammation of the urethra. Inflammation of the urethra may lead to pain, burning, and urinary incontinence, and if it is attributable to an infectious organism, it may progress to infective cystitis. Urethritis can be caused by infection, external irritants, or, in women, insufficient estrogen levels.

Infection of the urethra may be due to a wide variety of organisms, most often including *Neisseria gonorrhoeae* and *Chlamydia trachomatis*.<sup>4</sup> Urethritis is the most commonly occurring sexually transmitted infection (STI) in men.<sup>54</sup> Symptoms include dysuria, urgency, and frequency, often but not always accompanied by urethral discharge. Some people are asymptomatic; if the cause is an STI, they may not know they are infected until notified that their partner has an infection. The urethra is an estrogen-dependent structure, and postmenopausal women are at increased risk for irritation and inflammation of the urethra. Application of topical estrogen to the urethral opening helps maintain mucosal health.<sup>11</sup> If urethritis is due to a sexually transmitted organism, targeted pharmacologic therapy is indicated. Otherwise, urethritis attributable to infection is often asymptomatic until the organism progresses to the bladder, causing cystitis.

### Cystitis

**Cystitis**, or inflammation of the bladder lining, may result from bacterial, fungal, or parasitic infections, chemical irritants, foreign bodies (e.g., stones), or trauma. By far the most common cause of cystitis—and the focus of this discussion—is bacterial infection.

**Etiology and pathogenesis.** Normally, bacteria are cleared from the bladder by the flushing and dilutional effects of voiding. The high urea concentration and osmolarity and the low pH in urine act as natural barriers, killing invading bacteria in a normal bladder environment.

UTIs are highly prevalent, accounting for 8 million office and emergency department visits, about 100,000 hospital admissions, and over \$3 billion in treatment costs annually.<sup>4,55</sup> Incidence is higher in women but men tend to have more complicated infections. Risk factors are listed in detail in Box 29-3. In the pediatric population, uncircumcised male infants less than 6 months of age and females less than 12 months of age have the highest prevalence.<sup>56</sup> Recurrent UTIs are common in women.<sup>57</sup> A shorter urethra as well as a colonization route from both the rectum and the vagina to the urethra is thought to explain the increased rate of infections in women. They are common occurrences during pregnancy, and have been associated with an increased risk of premature delivery and low birth weight.<sup>4</sup> Use of spermicidal agents, with diaphragms or coated condoms, increases the risk of UTIs.<sup>4</sup> Prostatic secretions, which are antibacterial, inhibit cystitis in men younger than 50 years. *Escherichia coli* is responsible for 80% of cases of bacterial cystitis, with *Staphylococcus saprophyticus* as the next most common causative pathogen.<sup>57</sup> The microbial characteristics of *E. coli*

**BOX 29-3 RISK FACTORS FOR CYSTITIS****Factors Increasing Urinary Stasis**

Intrinsic obstruction (stone, tumor of urinary tract, urethral stricture, BPH)  
 Extrinsic obstruction (tumor, fibrosis compressing urinary tract)  
 Urinary retention (including neurogenic bladder and low bladder wall compliance)  
 Renal impairment

**Foreign Bodies**

Urinary tract calculi  
 Catheters (indwelling, external condom catheter, urethral stent, nephrostomy tube, intermittent catheterization)  
 Urinary tract instrumentation (cystoscopy, urodynamics)

**Anatomic Factors**

Congenital defects leading to obstruction or urinary stasis  
 Fistula (abnormal opening) exposing urinary stream to skin, vagina, or fecal stream  
 Shorter female urethra and colonization from normal vaginal flora  
 Obesity

**Factors Compromising Immune Response**

Aging  
 Human immunodeficiency virus infection  
 Diabetes mellitus

**Functional Disorders**

Constipation  
 Voiding dysfunction with detrusor sphincter dyssynergia

**Other Factors**

Pregnancy  
 Hypoestrogenic state  
 Multiple sex partners (women)  
 Use of spermicidal agents or contraceptive diaphragm (women)  
 Poor personal hygiene

From Lewis S et al: *Medical-surgical nursing: assessment and management of clinical problems*, ed 8, St Louis, 2011, Mosby. BPH, Benign prostatic hyperplasia.

promote its adherence to bladder mucosa and ability to evade the host's immune response.<sup>4</sup> Fungal infections, mycoplasmas, and other anaerobic bacteria are occasionally responsible. Infections attributable to *Neisseria gonorrhoeae* or *Chlamydia trachomatis* are associated with sexually transmitted diseases but are typically limited to the urethra.<sup>4</sup> Additional risk factors include sexual activity, diabetes mellitus, poor personal hygiene, any type of bladder dysfunction causing urine stasis, urinary catheterization and indwelling catheters, antimicrobial therapy in the previous month, postmenopausal status, and a family history of UTIs.<sup>4</sup>

**Clinical manifestations.** The majority of patients with cystitis experience an acute onset of frequency, urgency, dysuria, and pain, often in the suprapubic area.<sup>4,55</sup> The urine may appear pink because of hematuria or cloudy as a result of the infectious organism. Common symptoms of cystitis in children include fever, irritability, poor feeding, vomiting, diarrhea, and ill appearance.<sup>58,59</sup> Children who are able to talk may also indicate dysuria, suprapubic pain, or incontinence, but even older children sometimes have difficulty localizing signs and symptoms.<sup>58,59</sup> Untreated cystitis may lead to renal damage secondary to ascension of the infection to the upper urinary tract. Therefore, prompt intervention is essential.

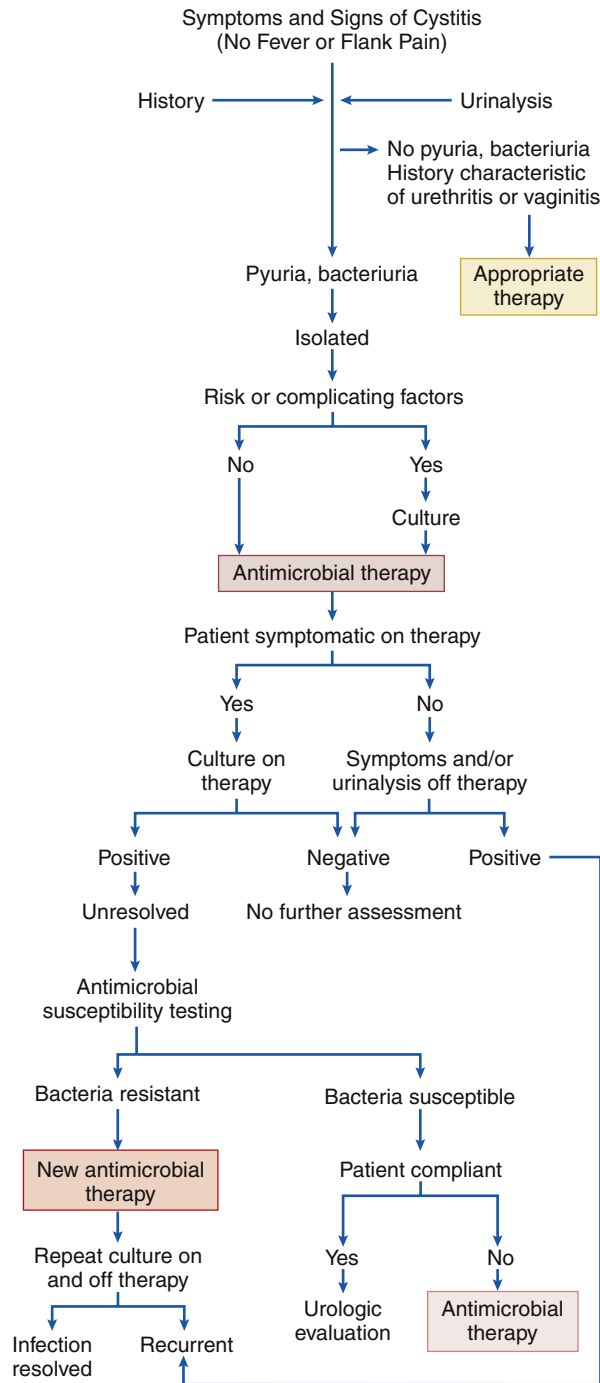

**Diagnosis and treatment.** Screening for suspected UTI is often performed using a clean-catch urine specimen and a simple nitrite and leukocyte esterase dipstick test.<sup>6</sup> Nitrites are present in UTI because many urinary pathogens produce enzymes that reduce nitrates to nitrites; the presence of leukocyte esterase is indicative of **pyuria** (white blood cells in the urine). The dipstick test is quite sensitive in detecting UTIs.<sup>6</sup> However, the sensitivity of dipstick urinalysis combined with visual appearance has been reported to be decreased in children; microscopic analysis is recommended.<sup>58,59</sup> A urine culture is not always necessary for the diagnosis of UTI. Uncomplicated infections, caused by common organisms, may be diagnosed on the basis of symptoms and a positive dipstick. Culture is recommended in situations in which the patient has manifestations suggesting pyelonephritis, fails to respond to empirical pharmacologic therapy, is pregnant, or has urinary calculi. A culture should be considered if the patient is immunosuppressed (because of the likelihood of atypical organisms) or has diabetes mellitus.<sup>56</sup> Under these circumstances, cultures precisely identify organisms and permit targeted pharmacologic therapy.

Men, children, and those women with recurrent infections, unresolved infections, atypical manifestations, or other problems previously identified have complicated UTIs and require physical examination and diagnostic testing.<sup>4,55</sup> *Recurrent UTIs* are repeated infections within a short period after verified resolution of the earlier infection. Recurrent UTIs are fairly common in women but rare in healthy adult men. Recurrent infections in men should trigger a urologic examination that may include endoscopy and a CT scan. *Unresolved infections* are those in which bacteriuria remains after the initial treatment.<sup>4</sup>

Treatment algorithms for acute cystitis and recurrent UTIs are shown in Figures 29-3 and 29-4, respectively. Acute, uncomplicated UTIs in women with no anatomic anomalies of the urinary tract, with no recent history of cystitis, and with no symptoms suggestive of either vaginitis or cervicitis may be treated empirically with a 3-day course of trimethoprim-sulfamethoxazole or a 5-day course of nitrofurantoin.<sup>4,60</sup>

Cystitis in healthy younger men is managed with a 7-day course of antibiotics.<sup>55</sup> In older men, a minimum of 14 and up to 28 days of antibiotic therapy is recommended. Unresolved infections are usually treated with targeted antimicrobials for 7 to 10 days. Urine culture and sensitivity are also necessary to ensure antibiotic effectiveness.<sup>56</sup> Some women with recurrent UTIs are treated with low-dose prophylactic antibiotics or given the option of a self-start antibiotic regimen in which the woman initiates antibiotic therapy with symptoms.<sup>57</sup> In elderly women, topical estrogen can be effective to prevent recurring infection because bacteria colonize in the urethra as a result of deestrogenization of the tissue attributable to menopause. In some women, recurrent infections are related to sexual intercourse, and a postcoital prophylactic antibiotic program is an effective treatment option.<sup>57</sup> Persistent bacterial infections are nearly always due to an anatomic abnormality or pathology in the urinary tract.<sup>57</sup> Such problems include calculi, prostatitis, foreign bodies, and duplicated or ectopic ureters.

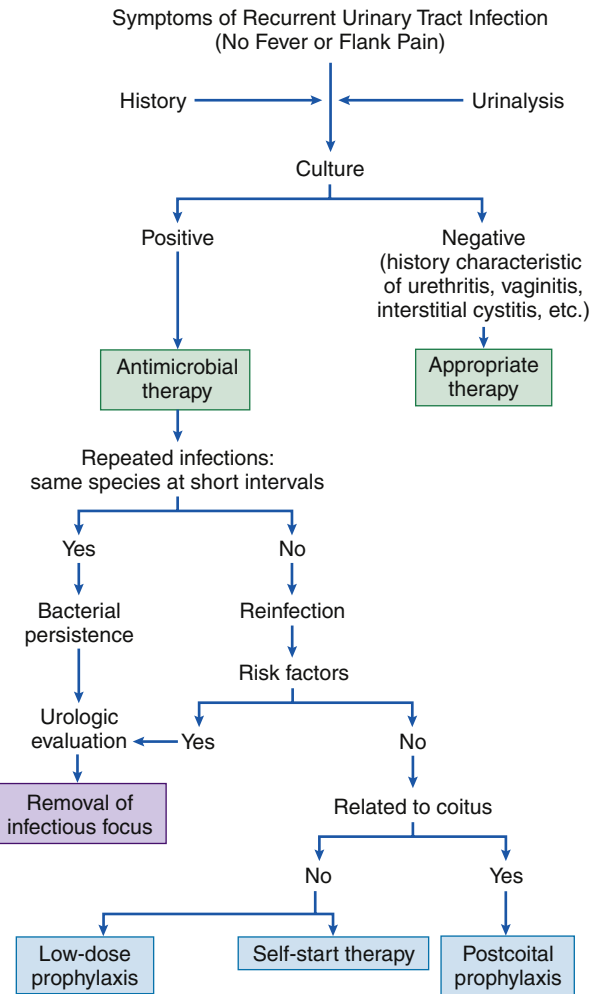

In children, administration of broad-spectrum antibiotics for 7 to 14 days is the treatment of choice.<sup>58</sup> The specific choice of therapy, including the initiation of parenteral fluids, is contingent on many factors including age, illness severity, illness duration, and ability to drink adequate fluids. However, children younger than 5 years should keep taking prophylactic doses of antibiotics until radiographic evaluation is completed. UTIs in children are often indicative of an underlying pathologic process (e.g., vesicoureteral reflux, ureteropelvic junction obstruction [UPJO]) and warrant prompt urologic evaluation.<sup>58</sup>

**FIGURE 29-3** Management of acute cystitis. (From Wein AJ et al, editors: *Campbell-Walsh urology*, ed 10, St Louis, 2012, Saunders.)

Pregnant women have the same prevalence of bacteriuria as non-pregnant women, but diagnosis and treatment are critical in pregnant women because of their greater propensity for pyelonephritis as a result of pregnancy-induced physiologic alterations.<sup>4</sup> Antibiotic therapy must be carefully chosen to avoid fetal harm.

Rates of bacteriuria significantly increase with age. Factors that predispose the elderly to cystitis include genitourinary abnormalities (e.g., calculi, benign prostatic hyperplasia, prostatitis), chronic illnesses (particularly diabetes mellitus and neurologic diseases), changes in urinary pH, decreased estrogen production in women, bowel incontinence, and greater prevalence of catheterization.<sup>4,55</sup> A 7- to 10-day course of

**FIGURE 29-4** Management of recurrent UTI. (From Wein AJ et al, editors: *Campbell-Walsh urology*, ed 10, St Louis, 2012, Saunders.)

antibiotic treatment and close monitoring for adverse effects are recommended for symptomatic UTIs. Symptoms associated with bacteriuria in the elderly may include anxiety, confusion, lethargy, and anorexia as opposed to dysuria and fever. The diagnosis is often one of exclusion, and urinalysis and culture are included in the diagnostic evaluation. Antibiotics are not recommended for asymptomatic bacteriuria in the elderly.

### Interstitial Cystitis/Bladder Pain Syndrome

**Interstitial cystitis/bladder pain syndrome (IC/BPS)** is a pain syndrome characterized by pelvic pain lasting longer than 6 months, perceived to be stemming from the bladder, and accompanied by other lower urinary tract symptoms such as frequency, urgency, dysuria, and dyspareunia.<sup>61,62</sup> The pain may worsen with a full bladder as well as with consumption of certain foods and drinks.<sup>61</sup> Pain is often relieved with voiding. The syndrome is more prevalent in women; an estimated 1.2 million U.S. women and 82,000 men suffer from IC/BPS.<sup>62</sup> This condition can have a serious impact on quality of life, interfering with work, daily activities, sleep, family life, and sexual activities.

The specific etiology is unknown and the pathophysiology is unclear, but a fundamental mechanism appears to be urothelial damage. Inflammation is activated and the damaged urothelium is less able to serve its protective functions, including production of mucus.<sup>62</sup> People with BPS are more likely to be diagnosed with other pain

syndromes such as fibromyalgia and with autoimmune conditions such as inflammatory bowel disease.<sup>61</sup>

Diagnosis of BPS is challenging because of the nonspecific nature of the syndrome. The diagnostic workup should include a history, physical exam, urinalysis, and possibly a urine culture and cytology to rule out subclinical infection and bladder cancer.<sup>63</sup> Pain is usually present in several locations, but physical exam is often negative. The foods and drinks most often associated with pain are alcohol, citrus fruits, coffee, carbonated beverages, tea, chocolate, and tomatoes. Hydrodistention of the bladder and instillations of potassium chloride will often reproduce the pain. Cystoscopy and urodynamic studies are unnecessary unless there is diagnostic uncertainty; IC/BPS is diagnosed as a symptom-based syndrome after eliminating other pathologies.<sup>63</sup> Treatment begins with lifestyle modifications such as avoiding known bladder irritants. Pelvic floor muscle training and bladder retraining may be helpful in moderating urgency.<sup>63</sup> Pentosan polysulfate sodium is approved for treating IC; the drug presumably coats and protects the urothelium. Amitriptyline and hydroxyzine are other drugs that have been prescribed for symptom management.<sup>62</sup> For people with intractable pain, major surgery such as cystectomy with urinary diversion may be performed as a last resort.<sup>63</sup>

#### KEY POINTS

- Urethritis is inflammation of the urethra. It is most often due to infection, either from the bladder or associated with a sexually transmitted disease. Sexually transmitted diseases are confined to the urethra; infections of other etiologies may ascend to the bladder before symptoms present. Urethritis may also be due to external factors such as frequent catheterizations or poor personal hygiene. Treatment depends on the cause.
- Cystitis is an inflammation of the bladder lining that may be due to infection, chemical irritants, stones, or trauma. Most cases have an infectious etiology and result from infection originating in the urethra.
- Factors predisposing to cystitis include female gender, increased age, catheterization, diabetes mellitus, bladder dysfunction, poor personal hygiene, and any disorder causing urinary stasis. Manifestations include frequency, urgency, dysuria, possible suprapubic pain, and cloudy urine, although the infection may be asymptomatic. Most female patients are treated based only on this information. More complicated situations, and cystitis in men and children, may require urine culture and/or further assessment.
- Symptoms of cystitis in older adults may be atypical and include lethargy, anorexia, confusion, and anxiety. Symptomatic cystitis in the elderly should be managed with close drug monitoring to avoid toxicity. Asymptomatic bacteriuria in the elderly should not be treated.
- Interstitial cystitis/painful bladder syndrome is a chronic condition consisting of bladder pain and often urgency, frequency, and nocturia, when no other etiology can be identified. It is diagnosed based on this information. Treatment is based on the identification of contributory lifestyle factors, such as some foods and beverages. Avoidance of these factors is the primary intervention; medication may be added to manage IC/BPS.

## OBSTRUCTION

Obstruction of the lower urinary tract develops when a stone obstructs urine transport. Stones in the lower urinary tract produce some manifestations that are similar to stones formed and lodged in the kidney.

### Lower Urinary Tract Urolithiasis

Stones, or calculi, usually form in the kidneys (*nephrolithiasis*). Nephrolithiasis is discussed in Chapter 27. The term **urolithiasis** is used for stones forming anywhere in the urinary tract, primarily in the kidney

or ureters, as well as those that form or travel into the ureters, bladder, or urethra. The manifestations of stones in the ureters and bladder vary somewhat from those associated with kidney stones, but the risk factors, stone composition, diagnostic tests, and treatment aspects are essentially the same. Refer to Chapter 27 for a detailed discussion of these topics. If diagnosis and treatment are not completed in a timely manner, the patient is at risk for the development of postrenal acute kidney injury (Chapter 28).

### Ureterolithiasis

Calculi in the ureters are usually those that were able to pass through the junction of the renal pelvis and ureters, as opposed to being formed there. In many cases, these stones are small, pass easily through the ureters, and cause no clinical manifestations. When a larger stone becomes wedged at the junction, manifestations are those characteristic of nephrolithiasis. Other stones enter the ureters and instigate an inflammatory process that increases prostaglandin synthesis. Prostaglandins increase renal blood flow, aggravating inflammation and edema.<sup>64</sup> Ureteral spasm contributes to pain that is termed ureteral colic. This is an acute, sharp, spasmodic pain, experienced in the flank area, possibly radiating into the umbilical region. Irritation of the ureters may result in hematuria. When the stone approaches the distal portion of the ureters, the pain may continue to be sharp in quality, but intermittent in nature. Or, instead of this presentation, the pain may increase, with radiation into the groin region, testicles, or labia. Manifestations associated with ureteral colic include tachycardia, tachypnea, diaphoresis, nausea, and vomiting.

Diagnostic approaches are the same as those used for nephrolithiasis, being sure to include the lower urinary tract region in scans. Ureteral calculi may be spontaneously expelled; the probability of and time to passage vary depending upon the size and location of the stone.<sup>64</sup> Stones  $\leq 2$  mm were reported as taking an average of 8.2 days to pass; stones 4 to 6 mm in size averaged 22.1 days.<sup>64</sup> Smaller stones warrant observation with pain management while waiting for spontaneous passage; however, failure of the stone to move or unrelenting pain is an indication for stone removal.<sup>65</sup> Medical expulsion therapy using  $\alpha$ -adrenergic blockers such as tamsulosin may facilitate passage of stones  $<10$  mm.<sup>64,66</sup> Larger stones ( $>10$  mm) may necessitate stone removal; shock-wave lithotripsy and ureteroscopy are first-line treatments for both adults and children. Either laparoscopic or open surgical removal of stones is recommended in cases of first-line treatment failure.<sup>65</sup> Therapeutic and preventive interventions are otherwise the same as those presented in Chapter 27. These interventions will affect stones formed anywhere in the urinary tract.

### Bladder (Vesical) Urolithiasis

Formation of stones in the bladder is rare in the developed world though more common in developing countries, including in children.<sup>67</sup> Ammonium acid urate is the main substance in bladder stones in the developing world.<sup>67</sup> Urinary stasis, infection, and foreign bodies in the bladder contribute to stone formation. Some patients are asymptomatic; those with symptoms may experience dysuria, suprapubic pain, and urinary hesitancy. A stone in the bladder may irritate the urothelium and result in hematuria; once the bladder neck or urethral orifice is reached, manifestations of obstruction may appear.

Diagnostic tests are similar to those for calculi in other segments of the urinary tract. Stone expulsion is often spontaneous; stones causing obstruction pose a risk for postrenal acute kidney injury and require prompt intervention. Stone removal procedures include transurethral lithotripsy for stones smaller than 1 cm, percutaneous cystolithotomy for stones up to 5 cm, and open cystolithotomy for stones  $\geq 5$  cm.<sup>67</sup>

**KEY POINTS**

- Urolithiasis is most often due to stones traveling to the ureters, bladder, or urethra from the kidney. They may also originate in the bladder or ureters. Manifestations are associated with tissue irritation and obstruction.
- Manifestations of ureterolithiasis include ureteral colic, hematuria, tachycardia, tachypnea, diaphoresis, nausea, and vomiting. Individuals with stones that approach the bladder may experience pain that is sharp in quality but intermittent in nature. Otherwise, the pain may increase and radiate into the groin region, testicles, or labia.
- Bladder urolithiasis is usually due to stones traveling from the ureters, but stones may form in the bladder, usually as a result of urinary stasis.
- Manifestations of bladder stones are often limited to dysuria and frequency; hematuria is possible. Obstructive signs and symptoms will present if stones obstruct the bladder neck or urethral orifice.
- Ureterolithiasis and bladder urolithiasis are similar to nephrolithiasis in terms of risk factors and stone characteristics. If infection is present, it is treated with appropriate antimicrobials, based on culture and sensitivity tests. Intervention for stones that do not pass spontaneously is endoscopic (transurethral) lithotripsy.

**SUMMARY**

Disorders involving the lower urinary tract are quite common. In adults, the most prevalent pathologic conditions are voiding dysfunction, malignancies, infections, and urinary stones. Incontinence as a result of bladder dysfunction affects millions of adults. The prevalence of incontinence increases with age and is more common in women than men. However, incontinence is not a result of the normal aging process, and patients should be urged to seek evaluation and treatment. Behavioral, pharmacologic, and surgical approaches may be used to manage voiding dysfunction. Interstitial cystitis/painful bladder syndrome is a chronic condition consisting of bladder pain and a variety of other manifestations typically associated with other bladder pathologies. However, these patients have no other identifiable pathology. Urgency, frequency, and nocturia are other common findings. In the United States, bladder cancer is the fourth most common type of cancer in men and the ninth most common type in women. The

primary clinical manifestation of bladder cancer is hematuria. Treatment is based on stage, grade, and type of cancer. Interventions include surgery, radiation, and chemotherapy.

Both childhood UTIs and enuresis should trigger more detailed urologic evaluation to rule out congenital disorders such as UPJO, ectopic ureters, ureterocele, and vesicoureteral reflux. Vesicoureteral reflux is the most prevalent congenital lower urinary tract disorder. It predisposes children to UTIs, which can result in kidney scarring and permanent renal impairment. Most cases of vesicoureteral reflux resolve spontaneously as the child ages. Before resolution, close medical management is necessary to prevent upper UTI and kidney damage.

Stones in the lower urinary tract usually arrive there after being formed in the kidney. Risk factors and treatment are much the same as those for nephrolithiasis; however, manifestations of urolithiasis in the ureters or bladder differ.

### KEY QUESTIONS

- What is the role of Sertoli cells in spermatogenesis?
- What is the function of Leydig cells?
- Which branch of the autonomic nervous system is responsible for penile erection? Ejaculation?
- Which genitourinary structures develop embryologically from the wolffian ductal system in males?
- How do the hypothalamic-pituitary gonadotropic hormones influence male reproductive function?
- How do the processes of capacitation and acrosome reaction affect the fertilization process?

### CHAPTER OUTLINE

This chapter provides a foundation for comprehending male genital and reproductive disorders, which are presented in Chapter 31. The anatomy and embryology of the male genitourinary tract—those organs involved in the processes of sexual reproduction and elimination of nitrogenous wastes—will be presented first. Because these

organs are derived from common embryologic structures, the anatomy and embryology of the male genitalia and urinary system will be emphasized, and the differences in embryologic development between males and females will be considered when pertinent. The remainder of this chapter will deal with the physiologic processes of male reproduction.

## ANATOMY

## Upper Genitourinary Tract

The upper genitourinary tract consists of the kidneys and ureters. The kidneys receive their blood from the renal arteries, which arise directly from the aorta. They are usually solitary but will at times be duplicated. The ureteral blood supply is derived from multiple sources. The renal pelvis and upper part of the ureter receive blood from branches of the renal artery. The arterial blood supply of the middle ureter segment comes from the internal spermatic artery (gonadal artery), and the lowermost ureter sections receive blood from the branches of the common iliac, internal iliac, and vesical arteries (Figure 30-1). The veins of the renal pelvis and ureter are usually paired with the arteries.

## Lower Genitourinary Tract

## Bladder

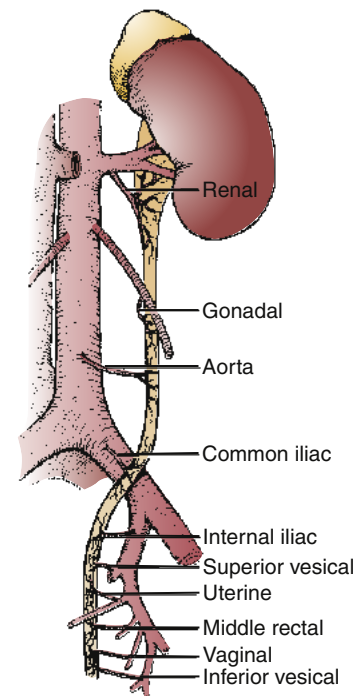

The bladder is a hollow muscular organ that serves as a reservoir for urine. The adult bladder normally has a capacity of 450 to 500 ml. When empty, the bladder lies behind the pubic symphysis and is mainly a pelvic organ. With overdistention or chronic urine retention, the abdomen may bulge, allowing easy palpation of the bladder in the suprapubic region.

The ureters enter the bladder posteroinferiorly. The ureteral orifices are situated on a crescent-shaped ridge and are approximately 2.5 cm apart. The triangular area demarcated by this interureteric ridge and bladder neck is called the *trigone* (Figure 30-2). As will be discussed later in the chapter, the **trigone** has a different embryologic origin from the rest of the bladder body, or fundus. The trigone is composed of mesoderm, and the fundus is composed of endoderm.

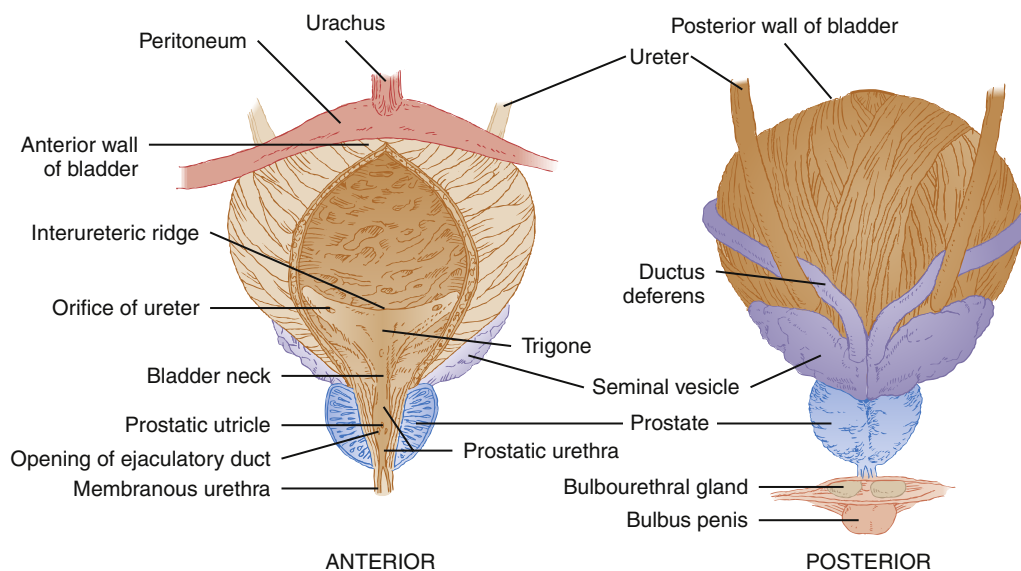

In males, the bladder lies anterior to the seminal vesicles, vasa deferentia, ureters, and rectum. The dome and part of the posterior bladder surfaces are covered by peritoneum and are thus in close proximity to the small bowel and the sigmoid colon. The neck of the bladder, which is the most inferior part, leads to the urethra. In males, the prostate lies between the bladder and the muscle layers of the pelvic floor that composes the urogenital diaphragm.

The arterial blood supply of the bladder comes from the superior, middle, and inferior vesical arteries, which originate from the anterior division of the hypogastric artery. Venous drainage occurs by a rich plexus of veins that surround the bladder and ultimately drain into the hypogastric veins.

The bladder and urethra receive their nerve supply from both the sympathetic and the parasympathetic divisions of the autonomic

**FIGURE 30-1** Sources of ureteral blood supply. (From Wein AJ et al, editors: *Campbell-Walsh urology*, ed 10, Philadelphia, 2012, Saunders.)

**FIGURE 30-2** Anterior and posterior views of the prostate gland and related structures. The triangular area demarcated by the interureteric ridge and the bladder neck is the trigone. (From Black JM et al: *Medical-surgical nursing: clinical management for positive outcomes*, ed 6, Philadelphia, 2001, Saunders, p 940.)

nervous system. The sympathetic fibers, originating mainly from the lower thoracic and upper lumbar segments (T11-T12 and L1-L2), innervate the bladder and urethra as the hypogastric nerves. These sympathetic fibers are distributed more densely in the bladder base and proximal end of the urethra than in the bladder dome. The sympathetic nerves facilitate storage of urine. Studies have revealed differences in the bladder muscle receptors, with cholinergic receptors concentrated in the fundus and adrenergic receptors present in the trigone and proximal end of the urethra (Figure 30-3).

The parasympathetic nerve supply originates from the sacral segments (S2-S4), which proceed to form a plexus surrounding the bladder. In the male, a separate segment will reach the prostate and form the prostatic plexus. From this plexus, nerves emerge to innervate the erectile tissue of the male penis and the clitoris of the female (see Figure 30-3).

Branches of the bladder plexus penetrate the muscular coat of the bladder and become distributed throughout the detrusor. Parasympathetic muscle receptors are cholinergic in nature, and parasympathetic stimulation induces a detrusor contraction that causes bladder emptying.

### Urethra

The male urethra, which extends from the bladder to the external opening (urethral meatus) at the tip of the penis, functions as a conduit for both urinary and genital systems. It is commonly divided into

three segments: the *prostatic*, the *membranous*, and the *penile* or *spongy urethra* (Figure 30-4).

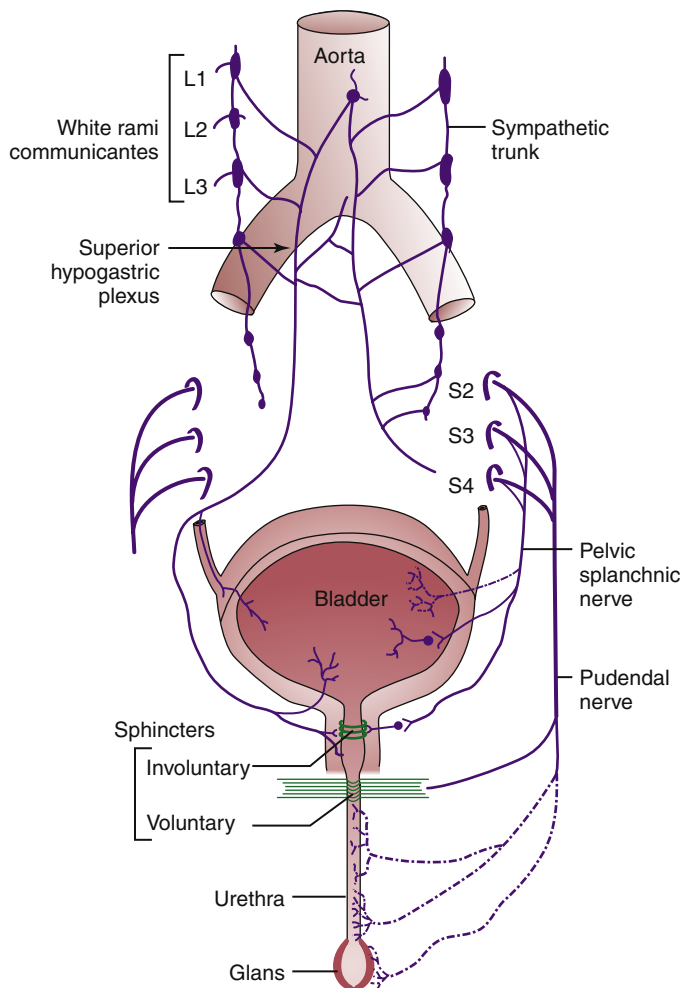

### Auxiliary Genital Glands

The auxiliary genital glands of the male consist of the *prostate*, the *seminal vesicles*, and the *bulbourethral glands*. These glands secrete products that contribute to the seminal fluid.

### Prostate

The **prostate** lies below the bladder and has both a muscular and a glandular component. The normal prostate weighs about 20 g and measures about 3.5 cm transversely and about 2.5 cm in its vertical and anteroposterior dimensions. The prostate is conical and is anterior to the rectum. Its base is continuous with the bladder neck, and the inferior aspect of the prostate gland, or apex, lies adjacent to the urogenital diaphragm (Figure 30-5).

The prostate consists of a thin fibrous capsule with internally circular smooth muscle fibers and collagenous tissue that surround the urethra. Deep in this layer of connective and elastic tissue lies the prostatic stroma, which contains the prostatic epithelial glands. These glands drain into excretory ducts, which open chiefly on the floor of the urethra between the verumontanum and the vesical neck. The prostate is primarily a reproductive organ. In conjunction with the seminal vesicles, the prostate produces the fluid that supports the sperm. In

**FIGURE 30-3** Diagram of nerve supply to bladder and urethra. (From Sauerland EK: *Grants dissector*, ed 10, Baltimore, 1991, Williams & Wilkins, p 66.)

**FIGURE 30-4** Cross-sectional view of the penis emphasizing the membranous urethra, the urogenital diaphragm, the bulbourethral or cowper gland, and the orifices of the bulbourethral glands. (From Applegate EJ: *The anatomy and physiology learning system: textbook*, ed 4, St Louis, 2011, Saunders.)

fact, the sperm constitute a small amount of the semen with the vast majority of the seminal fluid coming from the prostate and seminal vesicles. A further function of the prostate gland is to act as a valve for the bladder.

The main blood supply of the prostate is derived from the inferior vesical artery, a branch of the hypogastric artery. Besides the prostate, this artery also supplies the distal portion of the ureter, the seminal vesicles, and part of the bladder. A complex plexus situated between the prostate and overlying tissue freely communicates with the inferior hypogastric veins and provides venous drainage to the prostate.

### Seminal Vesicles

The **seminal vesicles** are paired organs that lie next to the prostate under the base of the bladder (see [Figure 30-5](#)). Their coiled pouches secrete a fluid important to the survival of spermatozoa.

### Bulbourethral Glands

The **bulbourethral** or **Cowper glands** are located on each side of the membranous urethra within the urogenital diaphragm. They add a mucoid secretion to the semen.

## External Genitalia

### Scrotum

The **scrotum** (see [Figure 30-5](#)) is a pouchlike sac that lies below the penis and pubic symphysis. A septum of connective tissue divides the sac into two compartments. Each compartment contains a male gonad, or testis, with its associated epididymis and the lower portion of

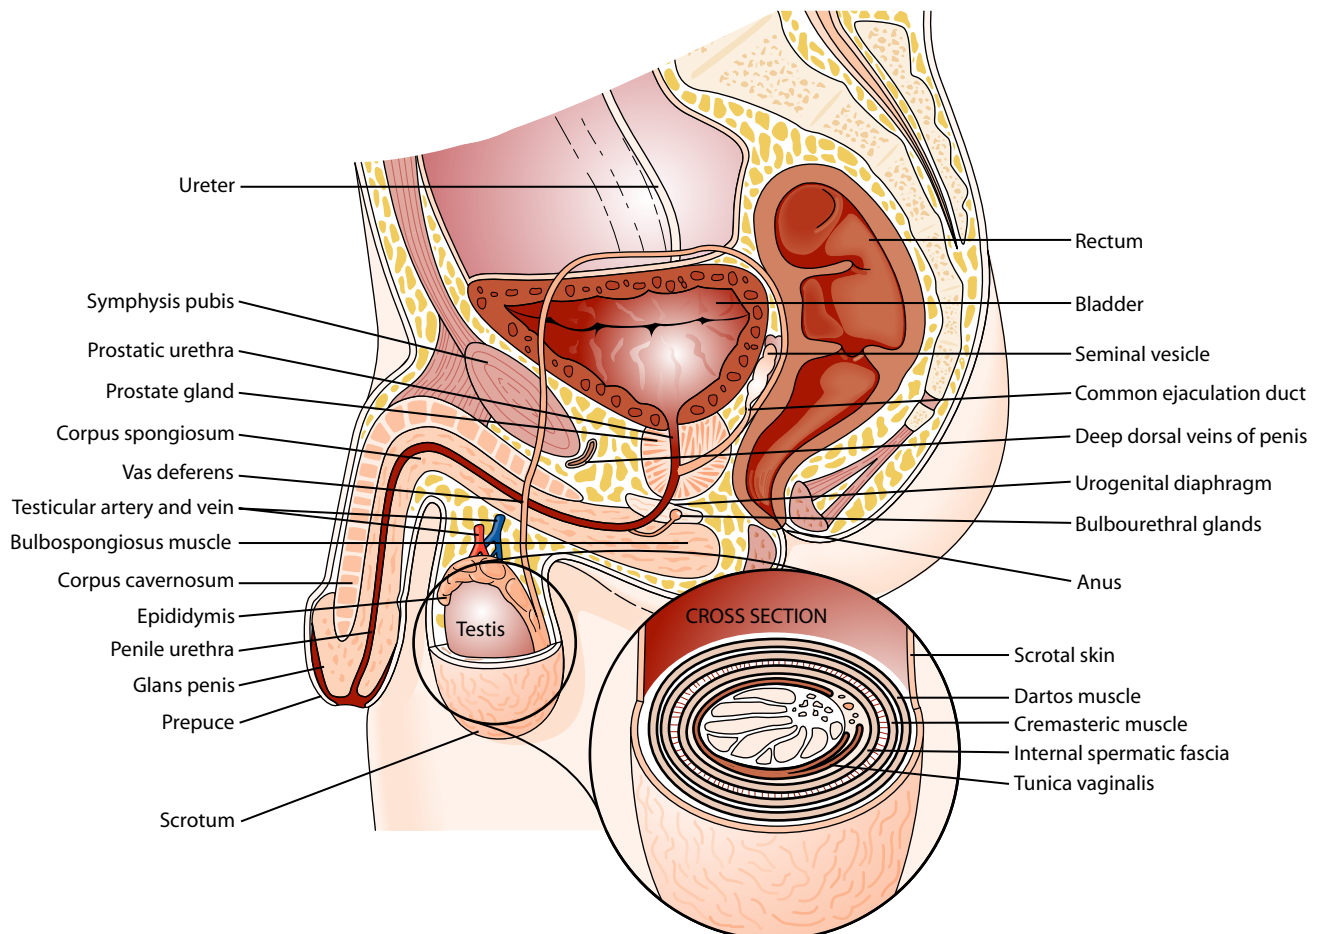

the vas deferens protected by the spermatic cord and its coverings. The scrotum not only supports the testes but also, by relaxation and contraction of its muscular layer, helps regulate temperature of the testes.

The scrotal sac consists of several tissue layers. The scrotal skin overlies the dartos muscle layer, whose smooth muscle fibers are embedded in loose connective tissue. The dartos muscle functions to contract the scrotal pouch when cold and expand it when warm. Under the dartos layer are several fascial layers (see [Figure 30-5](#)) that are continuous with the muscular layers of the abdominal wall and make up the covering of the spermatic cord. The external spermatic fascia is continuous with the external oblique aponeurosis of the abdominal wall. A few slips of skeletal muscle derived from the internal oblique muscle layer make up the cremasteric muscle, which adds to the upper part of the cord. The internal spermatic fascia is a continuation of the transverse fascia of the abdominal wall, with the transversus abdominis muscle not contributing to the cord layers. Finally, the peritoneum provides the tunica vaginalis layers, which are actually separated from the abdominal cavity by obliteration of the processus vaginalis.

The scrotum receives its blood supply from the external pudendal artery, a branch of the femoral artery. In addition, the scrotum receives blood from portions of the internal pudendal artery (a branch of the hypogastric artery) and the cremasteric and testicular arteries that transverse the spermatic cord.

### Testes

The **testes** are the male reproductive organs responsible for sperm production. They average about 4 to 5 cm in length and 2 to 3 cm in

**FIGURE 30-5** Male genitourinary anatomy, including a cross-section of the scrotum and its layers.

thickness. The testes lie within the scrotum and are suspended by the spermatic cord. The testes are covered by a thick fascial layer called the tunica albuginea. This layer invaginates posteriorly to form the mediastinum testis. This fibrous mediastinum sends fibrous septa into each testis that separate it into many different lobules. Each lobule contains one to four seminiferous tubules that if stretched to full length would measure approximately 60 cm. Spermatozoa production occurs within the epithelial lining of the seminiferous tubules (Figure 30-6).

The seminiferous tubules have a basement membrane consisting of elastic and connective tissue that supports the seminiferous cells. The seminiferous cells are either **Sertoli cells** (supporting cells) or spermatogenic cells. Found between the seminiferous tubules and embedded in connective tissue, the interstitial **Leydig cells** produce and secrete testosterone, a hormone involved in the development of male sexual characteristics (Figure 30-7). The seminiferous tubules converge on the mediastinum testis. The tubules, which are connected by the straight efferent ducts, drain into the head of the epididymis.

The testicular blood supply is derived from the internal spermatics, which arise directly from the aorta below the renal arteries. They course inferiorly through the spermatic cord and anastomose with the cremasteric arteries and the arteries of the vas; these vessels also contribute to the blood supply. The blood from the testis returns through a plexus of veins in the spermatic cord (the pampiniform plexus) that forms the spermatic veins. The left internal spermatic vein enters the left renal vein, which subsequently enters the vena cava. The right internal spermatic vein enters the vena cava directly.

### Epididymis and Ductus Deferens

The **epididymis** is a tightly coiled tube that lies along the top of and behind each testis. It is divided into the head, situated at the upper pole

of the testes; the body, lying posterior to the testes; and the tail, which is attached to the inferior pole of the testes (see Figure 30-6). The body and the tail of the epididymis form one continuous tube that serves as a conduit for maturing spermatozoa. In the epididymis, sperm develop the ability to swim.

As the convoluted tube of the tail leaves its testicular attachments, it increases in diameter to become a thick, muscular tube called the **ductus deferens**, also called the **vas deferens**. Leaving the spermatic cord, the vas deferens follows an extraperitoneal course and passes caudally and laterally along the pelvic wall. As it passes medial to the distal end of the ureter, it bends caudally to reach the midline and lies on the posterior wall of the bladder just medial to the seminal vesicles. It terminates in a dilated ampulla that courses underneath the base of the prostate. At this point the duct of the seminal vesicle joins with the duct of the ampulla, and the ejaculatory duct is formed. The ejaculatory ducts open in the prostatic urethra at the level of the verumontanum.

### Penis

The **penis** is the male organ of copulation and urinary excretion. It is composed of three erectile bodies—two paired **corpora cavernosa**, which lie dorsally, and the **corpus spongiosum**, which contains the urethra (Figure 30-8). Grossly, the penis is divided into three segments. The root of the penis consists of the proximal ends of the corpora cavernosa, which attach to the pelvic bones, and the proximal end of the corpus spongiosum, which connects to the undersurface of the urogenital diaphragm. Together these attachments provide fixation and stability to the penis. The shaft or body of the penis consists of all three erectile bodies: the two cavernous bodies lying on the dorsum, and the corpus spongiosum, which occupies a depression on their ventral

**FIGURE 30-6** Anatomy of the testis and epididymis. Note the numerous compartments of the testis that are filled with seminiferous tubules gathering into the rete testis; they join to form a markedly convoluted tubule that becomes the epididymis, which is continuous with the vas deferens. The epididymis attaches to the dorsomedial aspect of the testis, and the vas deferens joins the other structures of the spermatic cord.

surface. Finally, the glans of the penis forms the distal segment of the corpus spongiosum (see Figure 30-4).

The three erectile bodies have the capability to become engorged with blood and enlarge considerably with erection. Microscopically, these bodies have an internal spongelike network that consists of endothelium-lined spaces surrounded by smooth muscle.

Each corpus is enclosed in a fascial sheath, the tunica albuginea, and all are subsequently surrounded by a thick fibrous envelope known as the **fascia of Buck**. The overlying skin of the penis is remarkable for its thinness and looseness of connection with the fascial sheath of the penis. The skin of the penis is folded upon itself to form the **prepuce**, or **foreskin**. It is this penile skin overlying the glans that is removed with circumcision.

The arterial blood supply is primarily derived from the paired internal pudendal arteries, which are branches of the hypogastric arteries. Each internal pudendal artery branches several times in the penis. The deep or cavernous artery supplies the entire corpus cavernosum. The urethral

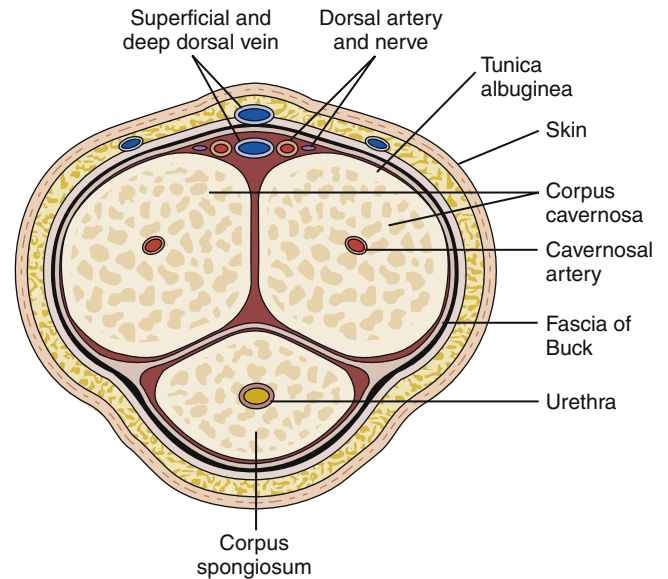

artery supplies the corpus spongiosum, and the bulbar artery supplies the bulb of the corpus spongiosum. The dorsal artery continues along the dorsum of the penis and lies below the fascia of Buck and between two dorsal veins. It provides additional supply to the glans (Figure 30-9).

Venous drainage of the penis is through several channels. The cavernous veins drain the corpora cavernosa, and the circumflex veins join the deep dorsal vein of the penis to also drain the corpora. The superficial dorsal vein drains the glans and part of the distal portion of the corpora. Finally, a bulbar branch drains the bulbous urethra and proximal portion of the corpus spongiosum (see Figure 30-9). Together these branches coalesce and pass through the urogenital diaphragm into the retropubic venous plexus of Santorini.

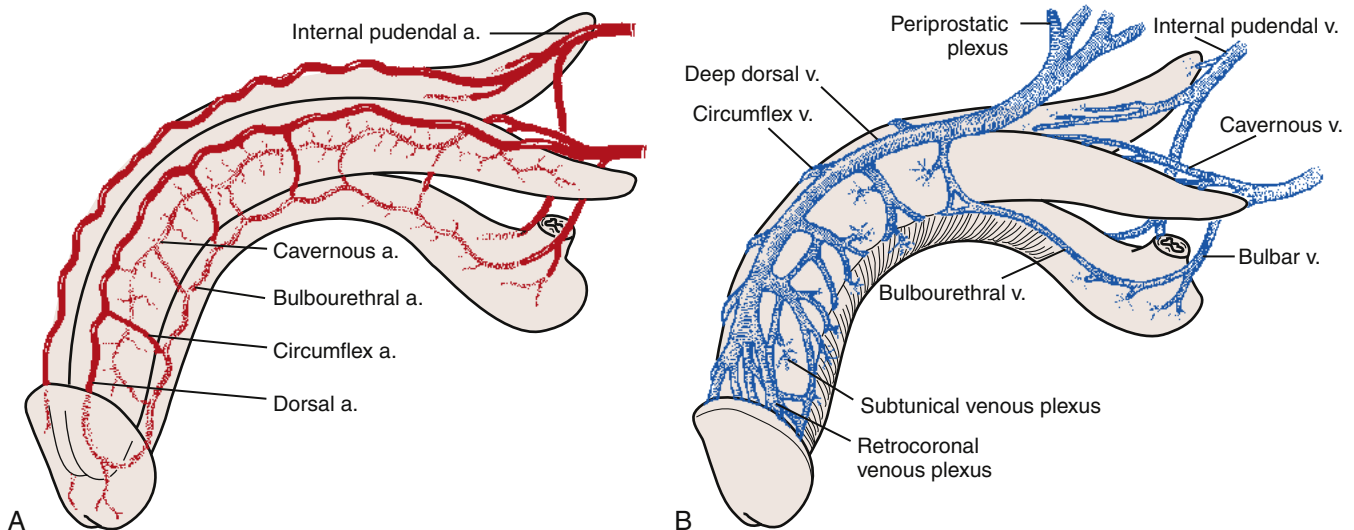

The nerve supply of the penis is formed from both parasympathetic and sympathetic components. The parasympathetic fibers arise from S2-S4, and the sympathetic component is derived from the hypogastric

**FIGURE 30-7** The interstitial Leydig cells that secrete testosterone are located in the interstices between the seminiferous tubules. (From Hall JE, editor: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

**FIGURE 30-8** Transverse section through the penis. The paired upper structures are the corpora cavernosa. The single lower body surrounding the urethra is the corpus spongiosum.

**FIGURE 30-9** Penile arterial supply (A) and venous drainage (B), longitudinal views. a., artery; v., vein. (From Walsh PC et al, editors: *Campbell's urology*, ed 7, Philadelphia, 1998, Saunders, p 1160.)

plexus. Parasympathetic stimulation from the pudendal nerve results in relaxation of vascular resistance, which increases blood flow to the penis and creates an erection. The pudendal nerve also carries sensory fibers from the penis and enters the sacral spinal cord to contribute to penile erection.

Sympathetic nerve fibers may contribute to erectile capacity, but their role has not been proved conclusively. They do innervate the proximal involuntary sphincter of the bladder neck, where contraction prevents retrograde ejaculation of semen from the prostatic urethra into the bladder. They also innervate the muscles of the seminal vesicles and prostate, which when stimulated cause ejaculation of seminal fluid into the urethra.

### KEY POINTS

- The upper genitourinary tract is composed of the kidneys and ureters. The lower genitourinary tract includes the bladder and urethra and the accessory male sexual organs.
- Ureters transport urine from the renal pelvis to the bladder. Ureters have several points of narrowing that predispose to obstruction: ureteropelvic junction, pelvic brim, and ureterovesical junction.
- The adult bladder has a normal capacity of 450 to 500 ml. With overdistention, the bladder may be palpable in the suprapubic region. The bladder is a muscular organ composed of several layers of muscle fibers. An important muscular landmark in the bladder is the trigone. Parasympathetic stimulation of the bladder results in bladder muscle contraction.
- The prostate is a key organ in the male genitourinary system with both reproductive and continence functions. It also causes many pathologic conditions as men age such as prostatitis, benign hyperplasia, and cancer.
- The urethra extends from the bladder to the meatus at the end of the penis. In addition to transporting urine, the urethra has ducts that receive fluid from the prostate, seminal vesicles, and bulbourethral glands.

- The scrotal sac supports the testes and regulates their temperature. Testes contain several cell types important in sperm production and the development of secondary sex characteristics. Spermatogenic cells produce sperm in the testes. Sertoli cells serve to support and nurture spermatogenesis. Leydig cells produce and secrete testosterone.
- Situated next to the testes, the epididymis serves as a collecting conduit for sperm. The epididymis is continuous with the ductus (vas) deferens. The vas travels along the pelvic wall and joins with the seminal vesicle duct at the prostate to form the ejaculatory duct. The ejaculatory ducts open into the urethra.
- Skin overlying the penis is very loose, which facilitates significant enlargement when the penis is engorged with blood during erection. Parasympathetic fibers forming the pudendal nerve are responsible for erection. Ejaculation is a function of the sympathetic nerve fibers.

### EMBRYOLOGY

Developmental processes in the genital and urinary systems are intimately related. To facilitate understanding of this development, the two systems will be discussed in several subdivisions. The urinary system, which is composed of the nephric system and the vesicourethral unit, will be discussed first. The genital system, which is composed of the gonads, the genital ducts, and the external genitalia, will be discussed second.

### Nephric System

The nephric system develops progressively through three distinct phases: the *pronephros*, *mesonephros*, and *metanephros*. The **pronephros** is the earliest state in humans but corresponds to the mature structure in primitive vertebrates. The pronephros consists of 6 to 10 pairs of tubules connected by a pronephric duct. It grows caudally to join the cloaca, a blind end of the hindgut. The pronephros is a temporary structure and, except for its duct, disappears by the fourth week of intrauterine life (Figure 30-10).

**FIGURE 30-10** Schematic representation of the development of the nephric system. Only a few of the tubules of the pronephros are seen early in the fourth week, whereas the mesonephric tissue differentiates into mesonephric tubules that progressively join the mesonephric duct. The first sign of the ureteral bud from the mesonephric duct is shown. At 6 weeks, the pronephros has completely degenerated and the mesonephric tubules start to do so. The ureteral bud grows dorsocranially and has met the metanephrogenic cap. By the eighth week, cranial migration of the differentiating metanephros can be seen. The cranial end of the ureteric bud expands and starts to show multiple successive outgrowths. (From Tanagho EA, McAninch JW, editors: *Smith's general urology*, ed 13, East Norwalk, CT, 1992, Appleton & Lange, p 18.)

The **mesonephros** corresponds to the mature excretory organ of some amphibians. In humans it begins developing at about the fourth to fifth week of gestation.<sup>1-4</sup> The tubules of the mesonephros are more numerous and form a cuplike outgrowth into which capillaries push to form a primitive glomerulus. The tubules communicate with the mesonephric duct, which is derived from the preceding pronephric duct. The number of mesonephros tubules reaches a maximum by about 8 weeks' gestation and then degenerates.

The final stage of development, the **metanephros**, begins in the fourth week when the ureteral bud grows out of the mesonephric duct. The bud elongates in a dorsocranial direction, where it meets a mass of mesoderm, the nephrogenic blastema, and begins to differentiate into the ureter and renal collecting system.<sup>1-4</sup> The metanephros is derived from the nephrogenic blastema and eventually differentiates into the mature mammalian kidney.

### Vesicourethral Unit

The blind end of the caudal hindgut forms the cloaca, which is separated from the outside by a thin membrane of tissue, the urogenital membrane. At about 4 weeks' gestation a septum grows downward and separates the cloaca into a posterior compartment, which will become the rectum, and an anterior compartment, which will form the urogenital sinus.

The urogenital sinus receives the mesonephric duct, which is progressively absorbed into this structure. The mesonephric duct distal to the ureteral bud is absorbed into the sinus, and its mesenchyme subsequently forms the bladder trigone. The ureter, which is derived from the ureteral bud, and the mesonephric duct, which differentiates into

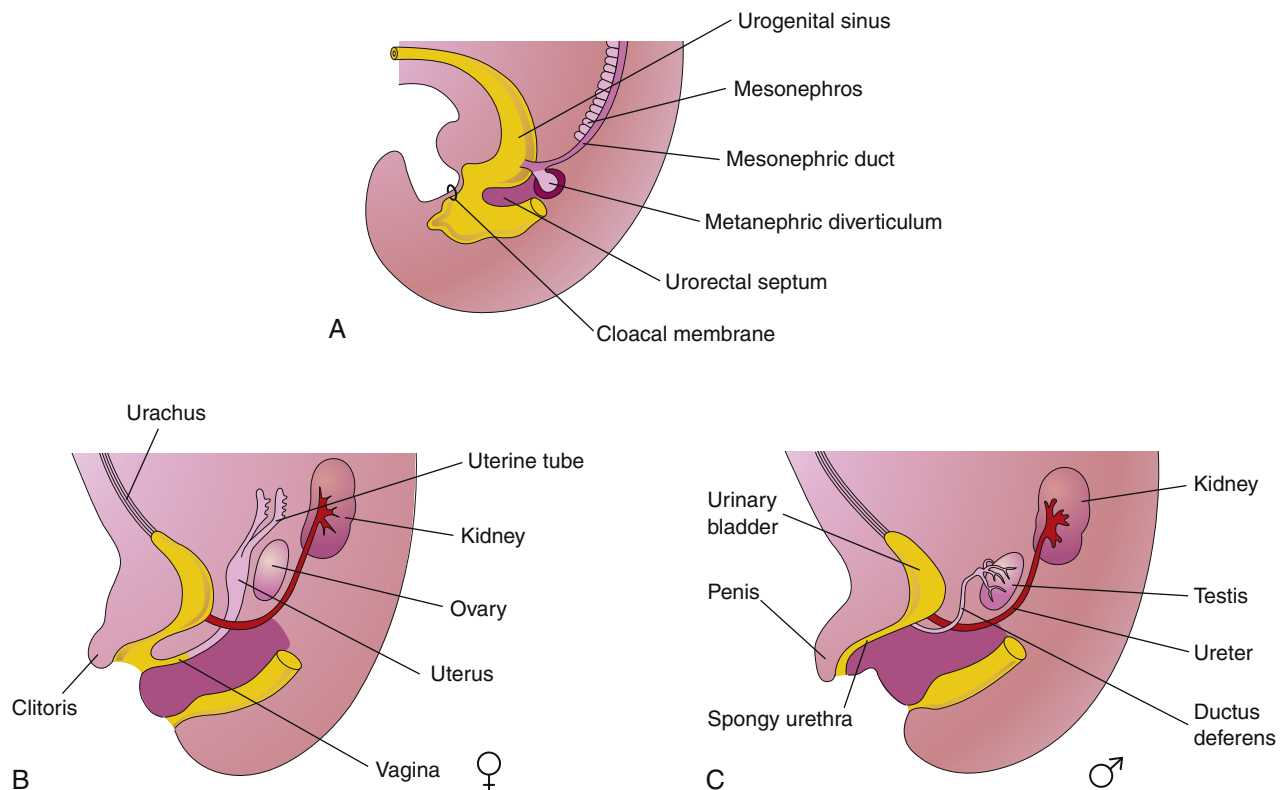

the vas deferens, merge into the sinus as well. In a complex pattern of development, the opening of the ureteral bud, which will eventually become the ureteral orifice, migrates upward and laterally. The opening of the mesonephric duct, which will become the ejaculatory duct, migrates downward and medially (Figure 30-11).

The urogenital sinus can be divided into two main segments. The ventral and pelvic portion, which receives the ureter, forms the bladder, part of the urethra in males, and the whole urethra in females. A phallic or urethral portion will receive the mesonephric ducts and in males will form a second part of the urethra. In females, this portion receives the müllerian ducts, which fuse distally to form the uterus and upper part of the vagina. The lower portion of the female urogenital sinus forms the lower part of the vagina and vaginal vestibule (Figure 30-12).

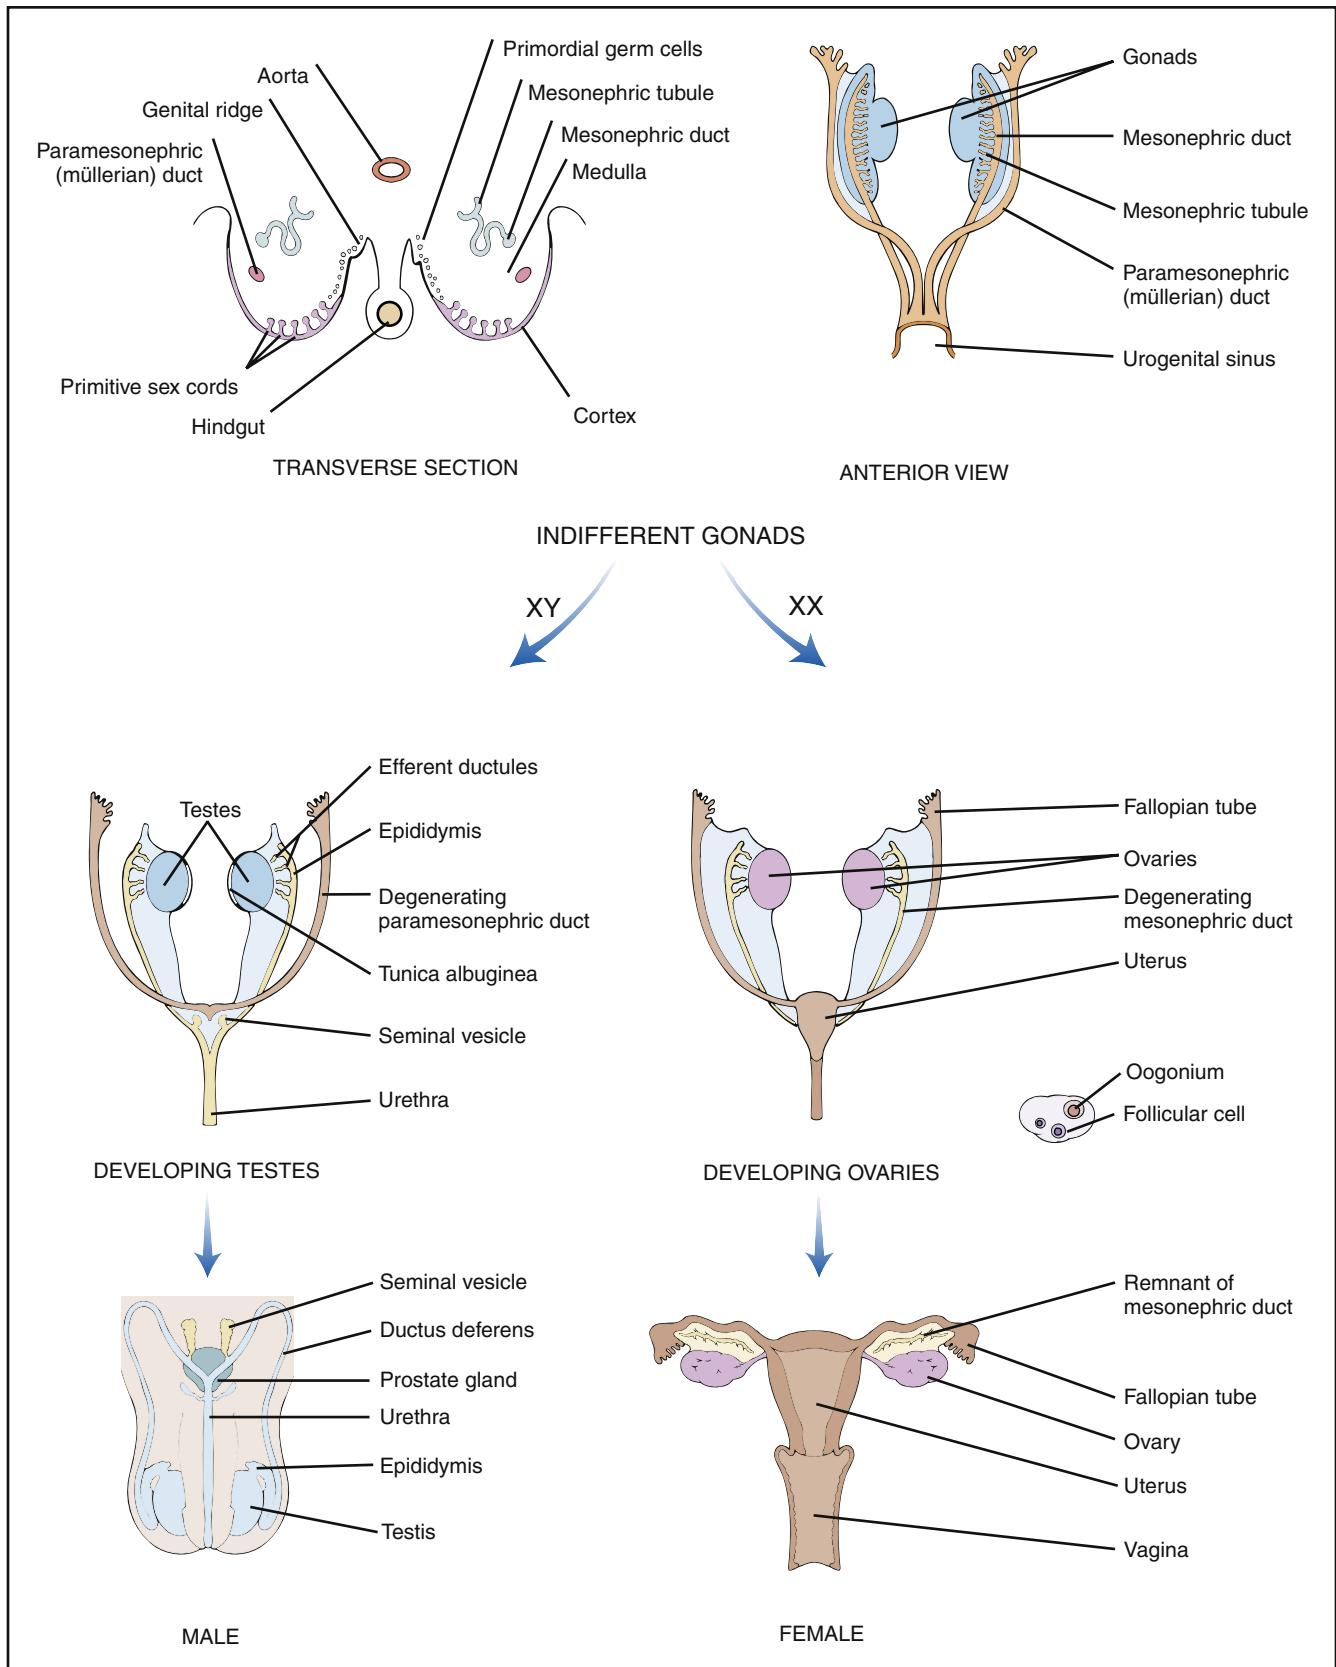

### Gonads

The undifferentiated and primitive **gonads** are derived from the urogenital ridge, a dorsal region of thickening from which the primitive kidney also forms. The gonads serve as precursors to the testes in males and the ovaries in females. During the seventh week, an individual gonad begins to assume the characteristics of either a testis or an ovary.

In the presence of testis-determining factor, which is located on the Y chromosome, a gonad develops into a testis. The gland increases in size, and the cells of the epithelium grow centrally into the organ's mesenchyme. These ingrowths become radially arranged, form cords, and begin to converge on the posterior aspect of the testis. The cords eventually differentiate into the seminiferous tubules, which produce spermatozoa. The testes descend behind the abdominal cavity in the

**FIGURE 30-11** Diagrams showing division of the cloaca into the urogenital sinus and rectum; absorption of the mesonephric ducts; development of the urinary bladder, urethra, and urachus; and changes in location of the ureters. **A**, Lateral view of the caudal half of a 5-week embryo. The stages shown in **B** and **C** are reached by the 12th week. (From Moore KL et al, editors: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders.)

**FIGURE 30-12** Transformation of the undifferentiated genital system into the definitive male and female systems. (From Nichols FH, Zwelling E: *Maternal-newborn nursing: theory and practice*, Philadelphia, 1997, Saunders, p 174.)

retroperitoneal space and into the scrotum, usually by the eighth month of gestation.

In the absence of testis-determining factor, a gonad differentiates into an ovary, and a cortex forms from the germinal epithelium and ultimately gives rise to ovarian follicles containing ova. It descends only partially through the abdominal cavity and eventually lies adjacent to the fallopian tubes.

### Genital Duct System

As the embryo develops, two different but related kinds of ducts form beside the undifferentiated gonads. The mesonephric ducts, or **wolffian ducts**, as previously explained, develop as nephric ducts but will go on to form the male genital ducts. The **müllerian ducts** develop alongside the mesonephric ducts (paramesonephric) and are genital structures from the start.

Early in development, each of the two müllerian ducts arises lateral to the mesonephric ducts, either directly from the mesonephric ducts themselves or possibly from the adjacent epithelium of the primitive abdominal cavity. Both ducts grow caudally to enter the urogenital sinus.

If a gonad differentiates into a testis, the wolffian ducts subsequently develop into the male duct system consisting of the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts. The müllerian ducts, except for a few rudimentary fragments, rapidly atrophy.

If, on the other hand, a gonad develops into an ovary, the müllerian ducts proceed to form the uterus, fallopian tubes, and upper part of the vagina. The mesonephric, or wolffian, ducts fail to develop further and remain rudimentary (see Figure 30-12).

### External Genitalia

Development of the external genitalia begins at about 12 intrauterine weeks. Before this point, three small protuberances appear on the external aspect of the cloacal membrane. The genital tubercle is located anteriorly and the genital swellings are situated on either side of the membrane. In the seventh week, rupture of the urogenital membrane gives the urogenital sinus a separate opening on the undersurface of the genital tubercle.

In males, the genital or labioscrotal swellings migrate and fuse centrally to form the scrotum. The fused genital tubercles elongate. The elongated fused tubercles form a cylindrical shape with a ventral groove communicating with the urogenital sinus. This groove subsequently becomes covered by folds of tissue and forms the penile urethra (Figure 30-13).

The female external genitalia closely resemble those of the male until about the eighth intrauterine week. At this time the genital tubercle lags behind in growth and becomes the clitoris. The urogenital sinus shortens and widens somewhat to form the vaginal vestibule, and the genital swellings form the labia majora. The urethral folds become the labia minora.

#### KEY POINTS

- The fetal gonads can become either a testis or an ovary. The presence of the testis-determining factor on the Y chromosome causes the testis to develop in the male fetus, whereas the absence of this factor allows the gonad to become an ovary in the female. Once the gonad has differentiated, it then is responsible for the cascade of events that lead to the formation of the female or male sexual organs and genitalia.
- During early embryonic development, the genital structures of males and females are similar. Two important ductal systems are the mesonephric (wolffian) ducts and the paramesonephric (müllerian) ducts. The mesonephric ducts develop to form the kidneys and the genital duct in males. In the

presence of a testis, the wolffian ducts develop into the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts. In the presence of an ovary, the müllerian ducts develop into the uterus, fallopian tubes, and upper part of the vagina, and the wolffian ducts fail to develop.

- Development of the external genitalia begins at about 12 weeks' gestation. In males the labioscrotal tissue fuses and elongates to form the scrotum and penis. In females, this tissue remains separated and forms the labia minora.

## MALE REPRODUCTIVE PHYSIOLOGY

### Hypothalamic-Pituitary-Testicular Axis

To fully understand male reproductive function, one must consider the endocrine function of the hypothalamic-pituitary-testicular axis. The components of this system function to maintain a constant level of the circulating hormones responsible for normal male sexual development and behavior, as well as the maturation of sperm necessary for fertility (Figure 30-14).

The hypothalamus is the integrating center for this hormonal axis. This organ coordinates neural messages from the central nervous system and humoral (bloodborne) messages from the testis to control the secretion of a small peptide hormone: gonadotropin-releasing hormone (GnRH). The pituitary stalk provides the route for GnRH to travel to the pituitary gland, which lies caudal to the hypothalamus. A system of veins, the pituitary portal system, traverses the pituitary stalk and maintains responsibility for transporting GnRH to the anterior portion of the pituitary gland.

In response to the secretion of GnRH, the pituitary synthesizes and releases two hormones: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Although these hormones carry names related to their function in females, they are produced by both genders through a feedback mechanism with GnRH for reproductive purposes.<sup>5</sup>

By binding to receptors on the surface of the testicular Leydig cells, LH mediates testosterone synthesis. Binding of LH produces an increase in the conversion of adenosine triphosphate to cyclic 3,5-adenosine monophosphate. This activity stimulates the production of other intracellular enzymes with subsequent increased synthesis of testosterone. Testosterone is then released into the bloodstream and adjacent seminiferous tubules.

Besides testosterone, other steroid hormones are synthesized, among them dihydrotestosterone, 17-hydroxyprogesterone, and estradiol. Dihydrotestosterone functions to differentiate and mature the male external genitalia and prostate.<sup>6</sup> In early puberty the production of androgen begins to increase, with normal adult plasma levels of testosterone and dihydrotestosterone being 300 to 1200 ng/dl and 30 to 60 ng/dl, respectively.

The function of FSH in male reproduction remains somewhat unclear. However, it appears that the production of sperm in the seminiferous tubules (spermatogenesis) requires the presence of high levels of both androgen and FSH.<sup>7</sup>

A feedback inhibition mechanism controls the secretion of both LH and FSH. Production of LH occurs in response to serum levels of testosterone and estradiol. The mechanism of the regulation of FSH is more hypothetical, but the existence of a nonsteroid factor called inhibin produced by Sertoli cells in response to FSH has been proposed.<sup>8</sup> In addition to inhibin, sex steroids also modulate FSH secretion through feedback inhibition on the pituitary.<sup>7</sup>

### Spermatogenesis

To understand spermatogenesis, one must briefly consider the histology of the testis and its seminiferous tubules. As previously stated,

**FIGURE 30-13** Development of the external genitalia from the indifferent stage (before 7 weeks) to fully differentiated stages (after 12 weeks of gestation). (From Nichols FH, Zwelling E: *Maternal-newborn nursing: theory and practice*, Philadelphia, 1997, Saunders, p 175.)

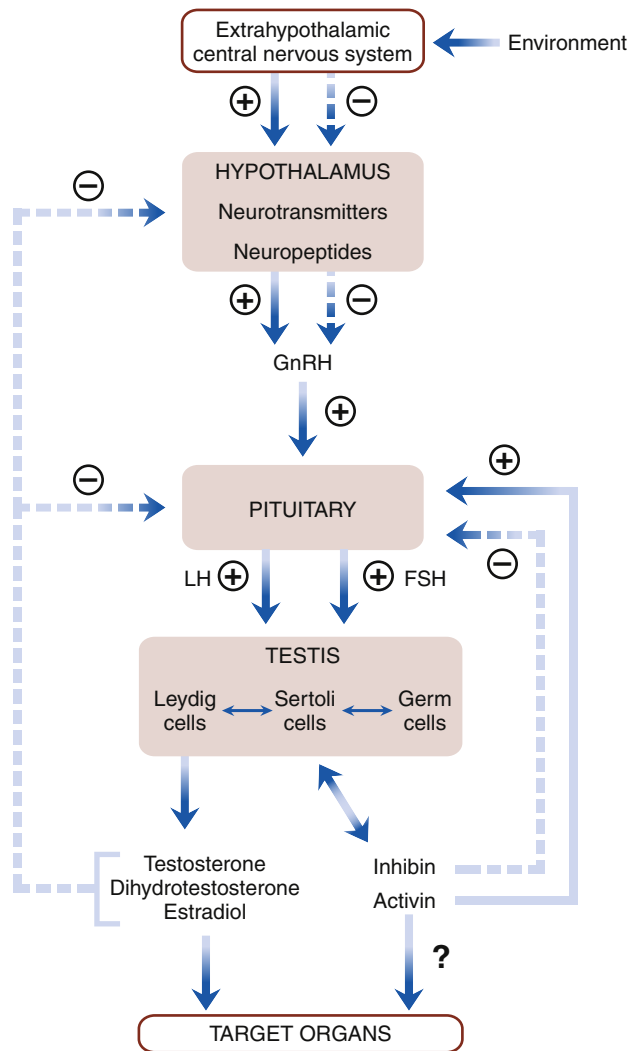

Leydig cells occur in clusters in the interstitial tissue between the seminiferous tubules. These Leydig cells are responsible for the testicular production of testosterone.

The seminiferous tubules contain both germinal elements and supporting cells, which include the sustaining cells of the basement membrane and the Sertoli cells. The Sertoli cells rest on the basement membrane of the tubule and form a unique impermeable junction with each adjacent Sertoli cell. It is through this junction that the young germinal cells, or primary spermatocytes, migrate and pass from the basal compartment to the basement membrane and then to the central or adluminal compartment of the seminiferous tubule. The junction is also responsible for maintenance of the blood-testes barrier. This barrier ensures that the more mature spermatocytes and spermatids located in the adluminal compartment are behind the barrier and

theoretically maintained in a constant intratubular environment to support the development of maturing sperm cells.<sup>8</sup>

The process of sperm production is called **spermatogenesis** and involves several phases (Figure 30-15). The proliferative phase involves division of the young germinal cells near the basement membrane (spermatogonia) either to replace their numbers or to produce daughter cells that will form spermatocytes. Next, a meiotic phase occurs in which spermatocytes undergo a reduction division. This division reduces the number of chromosomes to the monoploid number of 23 from the diploid number of 46. Finally, haploid spermatids undergo change to form mature **spermatozoa**.

While sperm cells mature and move from the basement membrane to the adluminal compartment, the Sertoli cells have an important nutritional role in the spermatogenic process. As the spermatid matures,

**FIGURE 30-14** Diagram of the hypothalamic-pituitary-testicular axis. *FSH*, Follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone. (Redrawn from Walsh PC et al, editors: *Campbell's urology*, ed 7, Philadelphia, 1998, Saunders, p 1240.)

it elongates and develops a tail, or **flagellum**, that attains a form similar to that of the mature spermatozoon. Mature spermatozoa are released into the tubular lumen and rapidly flow out to the rete testis and into the epididymis. Although each spermatogonium, one of the primitive male germ cells, requires about 70 days to develop into a mature sperm cell, or spermatozoon, within each tubule are spermatozoa in all stages of development. This characteristic allows new spermatozoa to be continuously produced across the male life span. The effects of aging on the male reproductive system are described in the Geriatric Considerations box.

### Anatomy of Spermatozoa

The human spermatozoon is approximately 60  $\mu\text{m}$  in length. The oval head contains a nucleus that is highly condensed and stabilized by cross-links between its molecules, which makes it very resistant to physical injury during its passage and storage in the epididymis. An outer membrane, the acrosome, contains the enzymes required for penetration of the female egg before fertilization.

The tail accounts for 90% of the length of the spermatozoon and is divided into a middle piece, principal piece, and end piece. The spermatozoon derives its motile ability from the motor apparatus of the

## GERIATRIC CONSIDERATIONS

### Male Fertility and Reproductive Organ Function

A decline in male fertility and reproductive organ function usually occurs with aging. However, the magnitude of functional decline of the male reproductive organs is variable. For example, some elderly men maintain their fertility into their 70s and 80s.

Male reproductive organ variability is due to organ-specific tissue changes. Active male germinal cells continue to produce spermatozoa (spermatogenesis), although the number of sperm produced declines proportionally over time. The testes become smaller as a result of the increased amount of connective tissue, fibrosis of the tubules, and decreased numbers of capillaries. The number of active seminiferous tubules declines with aging. The number of Leydig cells that produce testosterone decreases, leading to a decrease in testosterone level with aging.

The arteries and veins in the penis become increasingly sclerotic. The penis itself becomes smaller, with an increase in fibroelastic tissue. Penile sensation is decreased. Sexually, the aging male has a longer refractory period after orgasm and decreased force of ejaculation.

tail, which is called the **axoneme**. The axoneme, which runs the length of the tail, is composed of a central pair of tubules surrounded by a ring of nine pairs of tubules (the 9 + 2 pattern). This ring of tubules is surrounded by a supporting structure of nine noncontractile dense fibers. Within the middle piece, a circular sheath of mitochondria<sup>9</sup> (Figure 30-16) surrounds these outer dense fibers.

The mitochondria contain the enzymes required for the production of adenosine triphosphate, the energy source for the cell. Within the axoneme are enzymes and structural proteins. These enzymes convert chemical energy from adenosine triphosphate to the mechanical energy of sperm cell movement to aid in fertilization of the egg.

### Transport of Spermatozoa

Once mature spermatozoa are released from the Sertoli cells into the seminiferous tubules, they must pass through approximately 6 m of duct in the male reproductive tract before leaving the urethral meatus and being deposited in the vagina during sexual intercourse. From the seminiferous tubules, the spermatozoa are deposited into the rete testis, a collecting chamber for all the seminiferous tubules. From the rete testis, the sperm travel through the efferent ductules, 12 to 20 channels that pass into a single compact duct, the epididymis. The epididymis is a tightly convoluted duct that is divided into three regions: the caput (globus major), the corpus (body), and the cauda epididymis (tail, or globus minor). Unfolded and stretched, the epididymis would measure 12 to 15 feet.

After leaving the epididymis, the sperm enter the ductus or vas deferens. Embryologically, this duct is derived from the mesonephric duct. It passes through the scrotum, traverses the inguinal canal into the pelvis, and then passes behind the bladder to enter the prostatic urethra at the ejaculatory ducts of the verumontanum. The terminal portion of the vas deferens is known as the **ampulla**. It is joined by the ducts of the seminal vesicle before entering the ejaculatory ducts.

As one passes in a proximal-to-distal direction from the efferent ducts to the vas deferens, the thickness of the muscle gradually increases. In the vas deferens, three interconnected smooth muscle layers form a thick muscular wall, with the ratio of wall thickness to lumen being the greatest in any human structure.<sup>7</sup> This thick muscular wall facilitates rapid sperm transport at the time of ejaculation.

Aside from serving as a conduit and storage depot for spermatozoa, the epididymis probably sustains maturational processes. Most studies have demonstrated that sperm taken directly from the testes

FIGURE 30-15 Process of meiosis in spermatogenesis.

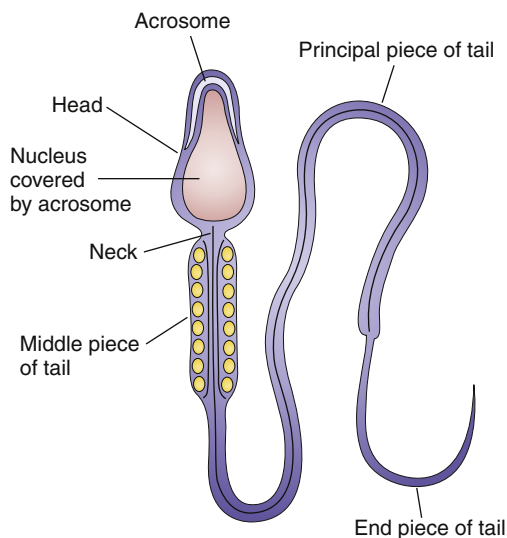

FIGURE 30-16 Anatomy of a mature sperm cell. (From Moore KL et al, editors: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders.)

are incapable of fertilizing eggs. It appears that the development of motility and increased fertility are acquired during transit through the epididymis.<sup>7</sup>

Because epididymal sperm are probably immotile, other mechanisms must be involved in their transport. Initially, spermatozoa are carried into the efferent ducts by fluid from the rete testis. Within the efferent ducts, motile cilia within the lumen function to reabsorb testicular fluid and help move spermatozoa into the epididymis. Within the epididymis, the spermatozoa are probably transported by rhythmic contraction of the smooth muscle cells.<sup>7</sup>

Ejaculation accelerates the passage of spermatozoa through the vas deferens and distal end of the epididymis. In young men, approximately 200 million sperm can be found in the reservoir of the epididymis. About 50% are found in the cauda region. With ejaculation, sperm from the distal part of the epididymis and vas deferens are deposited into the prostatic urethra, where they account for less than 10% of the normal ejaculate.<sup>10</sup>

### Erection, Emission, and Ejaculation

To penetrate the vagina and deposit sperm, the penis must be erect. The physiology of **erection** is a complicated interaction of vascular, neurologic, and hormonal factors. Although erection has classically been thought of as a parasympathetic function, it is more complex. Erection may be mediated by either local stimulation, which causes a reflexogenic erection through the sacral spinal cord, or psychological stimulation, which causes a psychogenic erection through cerebral

centers. The presence of erections in patients with spinal cord injuries attests to the presence of reflex erections. Such patients have an intact sacral spinal cord and its reflex arc of afferent and efferent nerves below the site of spinal cord injury.

The penis receives sensory innervation from the pudendal sensory nerves entering the sacral spinal cord. The pudendal nerve is a mixed nerve that provides motor innervation to the pelvic floor musculature and penile sensory fibers. The efferent nerve to the erectile tissue is provided by sacral parasympathetic fibers. Although erection is possible in patients with spinal cord injuries, in intact men it is a much more controlled process influenced to a great extent by the cerebral cortex. Impulses may traverse the spinal cord from the cerebral cortex in the lateral columns and exit the spinal cord through sacral parasympathetic and possibly the thoracolumbar sympathetic nerves as well.<sup>7</sup>

During erection, the vascular spaces that make up the spongy vacuous tissues of the corpora cavernosa and corpus spongiosum fill with blood. The relaxation of smooth muscle tone in these structures that allows filling and subsequent penile erection is modulated by an undetermined neurotransmitter, most likely nitric oxide (NO). Research indicates that erectile function cannot be fully explained by parasympathetic or sympathetic mechanisms; this observation has led to consideration that nonadrenergic and noncholinergic neuromodulators may be involved in such function.<sup>11</sup> For example, penile injection of certain prostaglandins has been shown to induce smooth muscle relaxation and has been used to induce erections in some men experiencing erectile dysfunction.<sup>12</sup>

Ejaculation may be divided into two phases: *emission* and *ejaculation*. During **emission**, secretions from the periurethral glands, seminal vesicles, and prostate are deposited with sperm from the vasa deferentia and the cauda epididymis into the prostatic urethra. Control of emission is mediated primarily through the sympathetic nerves, which stimulate contraction of smooth muscle in these genital structures.

With **ejaculation**, the bladder neck or internal sphincter closes. This closure is also mediated through the sympathetic nervous system. Next, the external sphincter relaxes and the perineal and bulbourethral muscles surrounding the bulb of the corpus spongiosum contract and expel the ejaculate from the posterior urethra and through the urethral meatus.

The physiologic function of the secretory products of the accessory sex glands is uncertain. These secretions make up most of the seminal plasma, with the sperm and testicular fluid probably composing less than 10% of the final ejaculated semen volume. Although some investigators have demonstrated that sperm removed directly from the epididymis are capable of fertilization, these secretions most likely optimize conditions for sperm motility, survival, and transport in both the female and the male reproductive tracts.

### Capacitation

Capacitation of the spermatozoa refers to the multiple changes that activate the sperm and enhance their ability to participate in the final process of fertilization. Although sperm are anatomically complete and highly motile when ejaculated, the complex process of capacitation is necessary before the sperm are actually capable of fertilizing the egg. The capacitation process occurs over a period of 1 to 10 hours and occurs in sperm only after they have been introduced into the vagina of the female. Once the sperm are inside the female, the uterine and fallopian tube fluids wash away the various inhibitory factors that had suppressed sperm activity in the male genital ducts. During the time that the spermatozoa were in the fluid of the male genital ducts, they were continually exposed to many floating vesicles from the seminiferous tubules containing large amounts of cholesterol. This cholesterol,

continually donated to the cellular membrane covering the sperm acrosome, toughens the outside membrane and prevents release of its enzymes. After ejaculation, the sperm that are deposited in the vagina swim away from the cholesterol vesicles upward into the uterine fluid, and they gradually lose much of their excess cholesterol during the next few hours. As the cholesterol is lost, the membrane at the head of the sperm becomes much weaker.

The membrane of the sperm head also becomes much more permeable to calcium ions. Large amounts of calcium enter the sperm to increase the powerful whiplike motion of the flagellum beyond its previously weak, undulating motion. In addition, the calcium ions probably also alter the intracellular membrane covering the leading edge of the acrosome, thus making it possible for the acrosome to release its enzymes very rapidly and easily as the sperm penetrates the granulosa cell mass surrounding the ovum. These enzymes are released even more rapidly and easily as the sperm attempts to penetrate the zona pellucida of the ovum itself.<sup>13</sup>

### KEY POINTS

- Normal male sexual development and spermatogenesis depend on the appropriate secretion of reproductive hormones. GnRH, secreted by the hypothalamus, induces the anterior pituitary gland to secrete LH and FSH. The bloodstream receives these hormones, which then travel to the testes where they bind to testicular cells.
- Leydig cells in the testes possess LH receptors and respond by increasing production of testosterone. Testosterone and related androgens are necessary for maturation of the male external genitalia. The function of FSH is less well understood, but appears to be necessary for spermatogenesis.
- Spermatogenesis occurs when germinal cells within the seminiferous tubules undergo meiosis to form haploid (23 chromosomes) spermatids. Spermatids then develop into mature spermatozoa with the assistance of Sertoli cells. Sperm require 70 days to mature, and they are continuously produced and released into the epididymis.
- Sperm are well formed to perform their function in that they have a highly stabilized nucleus that is resistant to physical trauma, a mobile tail (axoneme) for swimming, and specialized enzymes to enhance penetration of the egg.
- Sperm traveling from their site of origin in the testes must pass through approximately 6 m of tubules before arriving at the penile meatus. This tubular system includes the seminiferous tubules in the testes, epididymis, vas deferens, and urethra. About 200 million sperm may be stored in the epididymal reservoir. Increased motility and fertility appear to be acquired by sperm as they pass through the epididymis. Sperm account for less than 10% of the ejaculate volume.
- The physiologic process of erection is a complex interplay of vascular, neurologic, and hormonal factors. The sacral parasympathetic nerves provide important innervation to the penis. Acetylcholine from parasympathetic nerves causes relaxation of penile smooth muscle with subsequent engorgement. Injected prostaglandins may also induce penile erections.
- The sympathetic nervous system mediates the process of ejaculation. Sympathetic actions include contraction of the internal sphincter to prevent retrograde ejaculation and relaxation of the external sphincter to allow emission.
- Sperm deposited in the vagina undergo further changes in a process known as capacitation. This process improves the chances of sperm successfully producing fertilization of an egg. Enzymes are released (acrosome reaction) to facilitate penetration of the ovum, a process that further increases the chances of successful fertilization.

### Acrosome Reaction

The head of a sperm is essentially a highly compact package of genetic chromatin material covered by a specialized **acrosome** and acrosomal (head) cap. Stored in the acrosome of the sperm are large quantities of hydrolytic (water-splitting) enzymes that are released during capacitation. The specialized acrosomal enzymes first break down cervical mucus to allow sperm to pass into the uterus and uterine tubes. If an ovum is present in the female reproductive tract when semen is introduced, continued release of acrosomal enzymes results in digestion of proteins in the structural elements of the outer covering of the egg. A high sperm count is essential for male fertility because the female ovum, once it is expelled from the ovarian follicle into the abdominal cavity and fallopian tube, contains multiple layers of granulosa cells. Before a sperm can fertilize the ovum, it must first pass through the granulosa cell layer, and then it must penetrate

the thick covering of the ovum itself, the **zona pellucida**. It is believed that the acrosomal enzyme hyaluronidase plays an important role in opening pathways between the granulosa cells so that the sperm can reach the ovum.

On reaching the zona pellucida of the ovum, the anterior membrane of the sperm binds specifically with a receptor protein in the zona pellucida. Then the entire anterior membrane of the acrosome rapidly dissolves, and all the acrosomal enzymes are immediately released. Within minutes, these open a penetrating pathway for passage of the sperm head through the zona pellucida.

The head at first enters the perivitelline space lying beneath the zona pellucida but outside the membrane of the underlying oocyte. Within 30 minutes, the membranes of the sperm head and the oocyte fuse; the sperm genetic material enters the oocyte to cause fertilization, and the embryo begins to develop.

### SUMMARY

The male genitourinary tract may be divided into upper and lower tracts, with the upper tract composed of the kidneys and ureters and the lower tract composed of the bladder and urethra. Auxiliary genital glands that lie adjacent to or surround the urethra include the prostate, seminal vesicles, and bulbourethral glands. The external genitalia of the male consist of the scrotum, testes, epididymis, and penis.

Embryologic development of the male and female genital and urinary systems is closely related. The nephric system develops progressively through three distinct phases: the pronephros, mesonephros, and metanephros. The gonads are derived from the urogenital ridge,

from which the primitive kidney also forms. Finally, the genital duct systems develop from two different but related ducts adjacent to the undifferentiated gonads, the müllerian ducts and the mesonephric, or wolffian, ducts.

Male reproductive function depends on an intact hypothalamic-pituitary-testicular endocrine axis. Spermatogenesis takes place in the seminiferous tubules. Spermatozoa mature in their transit through the male reproductive tract. Through erection, emission, and ejaculation, sperm enter the vagina. Through capacitation and the acrosome reaction, spermatozoa acquire the ability to fertilize ova residing in the female reproductive tract.

*Prostatitis, 650*

*Prostate Cancer, 651*

The male genital system is susceptible to numerous congenital, acquired, and infectious conditions and, to a lesser extent, neoplasms. These disorders may interrupt the normal functions of urinary excretion and sexual function and fertility and directly affect the quality of life. This chapter will identify and explain the most common conditions that come to the attention of practitioners.

## DISORDERS OF THE PENIS AND MALE URETHRA

### CONGENITAL ANOMALIES

#### Micropenis

**Micropenis** is defined as a small, normally formed penis with a stretched length more than two standard deviations below the mean.<sup>1</sup> The normal range in newborns is 2.0 to 3.5 cm, so micropenis may be defined as a stretched length of less than 1.9 cm.<sup>2</sup>

**Etiology and pathogenesis.** Penile development and growth are both testosterone dependent. Therefore, micropenis may result from defects in testosterone production or a deficiency that results in poor growth of the organs that are targets of this hormone.

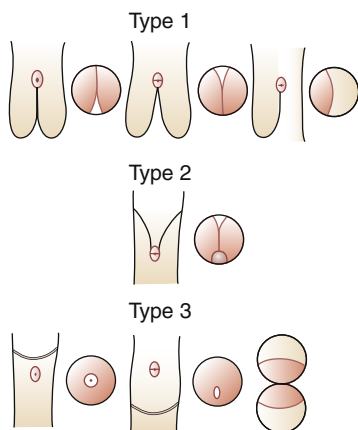

**Diagnoses and treatment.** Patients with micropenis must be evaluated for endocrine abnormalities. To check for these, one should measure serum levels of testosterone, luteinizing hormone, and follicle-stimulating hormone (FSH). Depending on the results of these measurements, the problem may be determined to involve the hypothalamic-pituitary axis (Prader-Willi and Kallmann syndromes) or to be some form of a testicular disorder (Klinefelter syndrome).<sup>3</sup>

Treatment depends on administering testosterone, either intramuscularly (IM) or topically, to stimulate penile growth. Such treatment requires caution because growth may be altered by premature closure of the epiphyseal growth plates in the long bones. In rare cases, when micropenis fails to respond to testosterone, a female sex assignment is indicated.<sup>3</sup>

#### Urethral Valves

The vast majority of **urethral valves** are posterior in location and occur in the distal prostatic urethra. They are the most common cause of urinary obstruction in male newborns and infants. These valves are mucosal folds that resemble thin membranes and cause obstruction when the child attempts to void (Figure 31-1).

**Etiology.** Many theories have been given to explain how valves develop. It has been suggested that several different processes may occur to form different posterior valves. Most commonly, posterior

**FIGURE 31-1** Posterior urethral valves. (Redrawn from Young HH, Frontz WA, Baldwin JC: Congenital obstruction of the posterior urethra, *J Urol* 3:289, 1919.)

valves may result from abnormal insertion and persistence of the distal wolffian ducts. Less frequently, a persistent urogenital membrane may result in valves and obstruction.<sup>4</sup>

**Clinical manifestations.** Children with posterior valves may have variable degrees of obstruction. In the most severe cases, intrauterine renal failure may cause oligohydramnios (decreased amniotic fluid), pulmonary hypoplasia (incomplete lung development), and either stillbirth or extreme distress at the time of delivery. More frequently, inability to void is noted shortly after birth (normal voiding occurs within 48 hours after birth), or the infant has abdominal masses representing a thickened palpable bladder or hydronephrotic kidneys. Varying degrees of azotemia and renal failure occur with this scenario. Finally, urinary ascites (extravasated urine in the peritoneum) may result from a urinary leak that is usually difficult to localize. In an infant with abdominal distention, the diagnosis of urethral valves is confirmed by a plain abdominal radiograph showing the bowel “floating” in the center of the abdomen. Prenatal ultrasounds often suggest the diagnosis before birth so immediate evaluation and treatment can take place upon delivery.

Older infants with a urethral valve are less likely to have a palpable kidney or ascites. Rather, urinary tract infection, poor stream with straining to void, or occasionally hematuria may be present. Urethral valves in these older male infants may not produce much obstruction, thus making the diagnosis more difficult.<sup>5</sup>

**Treatment.** Management of posterior valves involves initial management of the metabolic abnormalities with appropriate fluid management and electrolyte replacement. In patients with a urinary tract infection, drainage of urine with a urethral or occasionally a suprapubic catheter is necessary. Finally, ablation of the valves with an endoscopic resectoscope should be performed. In infants, this step may be delayed and a cutaneous vesicostomy made to temporarily divert and drain the urine. This approach reduces the risk of traumatizing the infant’s delicate urethra, which may create urethral stricture disease.

Rarely, urethral valves are located anteriorly in the penile urethra. Valves in this location are a very rare congenital anomaly and most likely represent urethral dilation or a diverticulum proximal to the valve.<sup>6</sup> Endoscopic resection will correct the problem.

#### Urethrorectal and Vesicourethral Fistulas

**Etiology.** Urethrorectal and vesicourethral fistulas are rare and almost always associated with an imperforate anus. Failure of the urorectal septum to develop completely leads to persistent communication between the rectum posteriorly and the urogenital tract anteriorly.

**Clinical manifestations and treatment.** Children with a urethrorectal or vesicourethral fistula may pass fecal material and gas through the urethra. If the anus has formed normally with an external opening, urine may drain through the rectum. The diagnosis is made with cystoscopy and contrast-enhanced radiography to delineate a blind rectal pouch or communication. Surgery is needed to resect the fistula and open the imperforate anus.

#### Hypospadias

In **hypospadias**, the urethral meatus is located on the ventral undersurface of the penis or on the perineum (Figure 31-2). The condition may occur with varying degrees of severity. In the least severe cases, the meatus is located distally on the penis, either at the corona or on the undersurface of the glans. With increasing severity of the condition, the meatus assumes a more proximal location and is more often associated with chordee, or curvature of the penile shaft (Figure 31-3).

**Etiology and treatment.** Hypospadias is the result of incomplete fusion of the urethral folds, so the meatus may be found anywhere

**FIGURE 31-2** Varying forms of hypospadias. **A**, Glanular hypospadias. **B**, Subcoronal hypospadias. Note the dorsal hood of foreskin. **C**, Penoscrotal hypospadias with chordee. **D**, Perineal hypospadias with chordee and partial penoscrotal transposition. **E**, Megameatal variant of hypospadias diagnosed following circumcision; note absence of hooded foreskin. (From Kliegman RM et al: *Nelson textbook of pediatrics*, ed 19, Philadelphia, 2011, Saunders.)

along the phallus from the perineum to the glans. In the majority of cases hypospadias occurs distally, with about 85% of all cases involving the glans or corona.<sup>7</sup> Because incomplete fusion of urethral folds may indicate insufficient masculinization, it is recommended that the more severe penoscrotal and perineal openings be evaluated for conditions of intersex.<sup>8</sup>

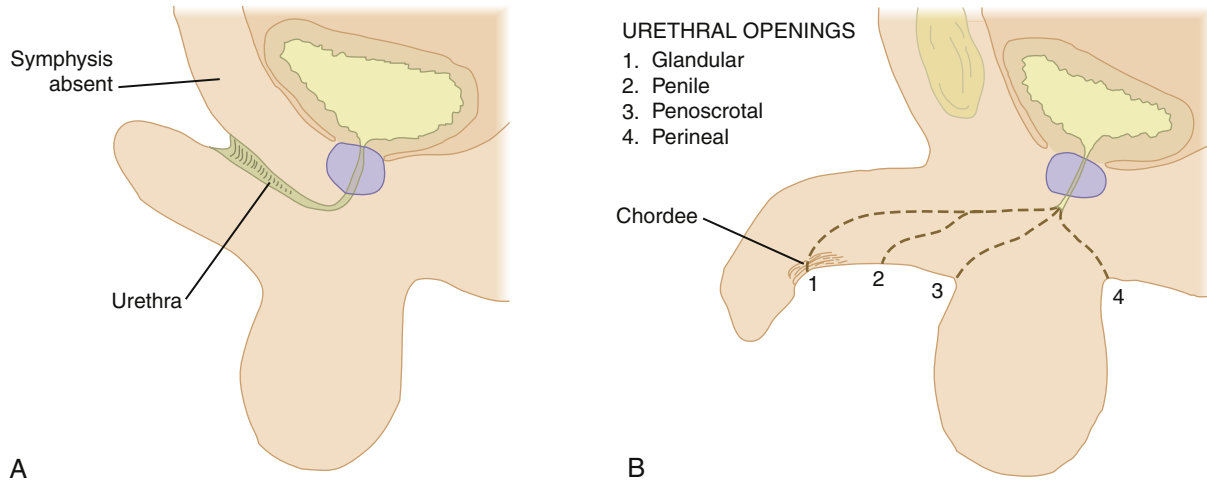

Management of hypospadias involves surgical repair. Many procedures are available, with several repairs indicated for each type of hypospadias. The goal of surgery is a good overall cosmetic appearance that will allow the patient to stand and direct his urinary stream and will also allow normal sexual function.

### Epispadias

In **epispadias**, the urethra opens on the dorsal aspect of the penis at a point proximal to the glans (see [Figure 31-2](#)). Although much less common than hypospadias, it can be considerably more disabling.

**Etiology and treatment.** The embryogenesis of epispadias is related to another congenital condition, exstrophy of the bladder. In this condition, the abdominal wall fails to form below the level of the umbilicus. At birth, the back wall of the bladder is exposed to the external environment.<sup>9</sup> The development of epispadias is simply a mild degree of exstrophy, with a deficiency of abdominal wall formation present inferiorly. Most commonly, the defect extends proximally to involve the urinary sphincter and results in urinary incontinence. Less commonly, the urethral meatus is located more distally along the dorsum of the penis and is accompanied by urinary continence because the sphincter is not affected (see [Figure 31-3](#)).

Management of exstrophy and proximal epispadias with incontinence is difficult and involves staged surgical procedures to reconstruct a continent bladder neck and a functional urethra. The less common distal epispadias is usually managed with tubular reconstruction procedures similar to those used for repair of hypospadias.

**FIGURE 31-3** Epispadias (**A**) and hypospadias (**B**) showing possible locations of the urethral meatus. (From Black JM, Matassarin-Jacobs E: *Medical-surgical nursing: clinical management for continuity of care*, ed 6, Philadelphia, 2001, Saunders, p 971.)

## ACQUIRED DISORDERS

### Priapism

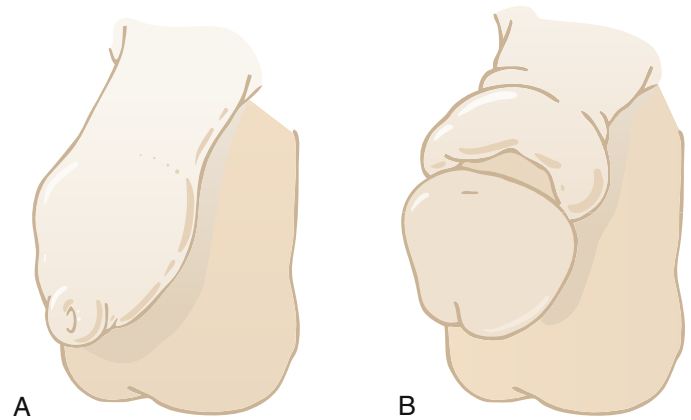

**Priapism** may be defined as a painful, persistent erection. The patient usually reports several hours of painful erection in which the corpora cavernosa are tense with congested blood. The corpus spongiosum and glans are characteristically soft and uninvolved.

**Etiology and treatment.** The causes of priapism are multiple. Most cases are idiopathic, with the next most common cause being sickle cell disease. Other etiologic factors include use of anticoagulant therapy, presence of diabetes mellitus or leukemia, and use of certain antidepressant medications.<sup>10</sup> Recently, intracavernosal injection of vasoactive substances for the management of impotence has been noted to cause priapism. On a rare occasion, oral erectile dysfunction medications can cause priapism. Although multiple causes exist, the common abnormality is probably an obstruction of venous drainage resulting in the buildup of viscous, poorly oxygenated blood in the corpora.<sup>11</sup> If the process is allowed to continue, fibrosis of the corpora cavernosa will eventually occur and may cause impotence.

Management of priapism may involve a combination of measures, depending on the cause and duration of the condition. Initial therapy for priapism secondary to sickle cell disease includes sedation and oxygen.<sup>12</sup> For the management of priapism secondary to other causes, initial measures may include aspiration of blood from the corpora, as well as injection of  $\alpha$ -adrenergic agents.<sup>13</sup> If the priapism remains refractory to these initial measures, a surgical shunting procedure may be necessary in which a shunt is created between the erect corpora cavernosa and the detumesced corpus spongiosum.

### Phimosis and Paraphimosis

**Etiology, clinical manifestations, and treatment.** **Phimosis** occurs when the uncircumcised foreskin cannot be retracted over the glans of the penis (Figure 31-4, A). Phimosis is usually the result of chronic inflammation and infection from poor hygiene. Calculi and squamous cell carcinoma may occur, although it is usually the presence of erythema, tenderness of the phimotic foreskin, or a discharge that prompts the patient to seek medical attention.<sup>14</sup> Management involves treating the infection with antifungal agents or antibiotics, followed by circumcision.

**FIGURE 31-4** A, Phimosis. B, Paraphimosis.

**Paraphimosis**, on the other hand, occurs when a foreskin that has been retracted over the glans up onto the shaft of the penis cannot be replaced in its normal position (see Figure 31-4, B). In this condition, which is usually secondary to chronic inflammation under the foreskin, a constricting ring of skin forms around the base of the retracted glans. The constriction causes venous congestion of the glans, with further swelling and edema making the condition worse. Treatment entails reducing the paraphimotic foreskin back over the glans, which can usually be accomplished by compressing the glans to reduce the edema. Occasionally, a slit or formal circumcision is needed to manage the problem.

### Peyronie Disease

**Etiology and treatment.** **Peyronie disease** refers to the formation of palpable, fibrous plaque on the surface of the corpora cavernosa. This plaque subsequently causes curvature of the penis with painful, incomplete erections. No satisfactory treatment for this disease is available, although some cases may remit with time. Conservative therapies that have had limited success include the use of vitamin E or aminobenzoate potassium (Potaba), colchicine, and pentoxifylline (Trental). In addition, several operative procedures have been developed. These procedures involve excising the plaque and repairing the corporal defect with a graft or plicating the corporal bodies.<sup>15</sup>

### Urethral Strictures

**Etiology.** Urethral strictures are fibrotic narrowings of the urethra and are usually composed of scar tissue. Most acquired strictures are due to a prior infection such as gonorrhea or trauma. Traumatic causes can be both iatrogenic, such as large urethral catheters and instrumentation, and noniatrogenic, such as straddle injuries.

**Clinical manifestations and treatment.** A decreased urinary stream is the most common complaint. Other common complaints include urethral discharge, infection, and urine retention. Urethral strictures are usually diagnosed by cystoscopy or retrograde urethrography, which would demonstrate a narrowing of the urethra. Management of urethral strictures involves procedures to dilate, incise, or reconstruct the urethra, depending on the extent and duration of the stricture.

### Erectile Dysfunction

Erectile dysfunction (ED) is the inability to achieve or maintain an erection sufficient for satisfactory sexual performance.<sup>17</sup> It is highly prevalent in aging men, affecting approximately 50% of men older than 60 years of age.<sup>16</sup> Its prevalence and incidence are highly connected with risk factors such as hypertension, elevated cholesterol level, presence of diabetes mellitus and/or metabolic syndrome, and lifestyle choices such as smoking, obesity, and lack of exercise.<sup>18</sup>

The physiologic process of penile erection is a complex interaction of the vascular, hormonal, and neurologic systems. **Impotence** may be primary or secondary. Primary impotence refers to the inability to attain an erection throughout life and is often related to deep-seated psychiatric problems of some duration. Occasionally, vascular trauma sustained during early childhood or adolescence may account for primary impotence.<sup>18</sup>

There are many causes of secondary ED ranging from psychogenic to traumatic. As our knowledge of the disease has advanced, we understand that most ED is due to physiologic changes in the vasculature of the corporal bodies of the penis. These changes may be due to surgery (e.g., radical prostatectomy or cystectomy), trauma (penile or neurologic), disease (diabetes mellitus, hypertension, pelvic irradiation, hyperlipidemia, hypogonadism), and aging.<sup>19</sup>

**Etiology.** Far more common than primary impotence is secondary impotence. An individual with secondary impotence is no longer able to achieve normal erections but did have normal erections in the past. The causes of secondary impotence are multiple and may be discovered by examining the patient's medical history. Common causes of secondary impotence are peripheral vascular disease, the use of certain medications, endocrine problems, trauma, iatrogenic causes, and psychological causes. To differentiate organic causes from psychogenic impotence, one relies on the history, physical, and basic laboratory testing such as measurement of serum glucose and testosterone levels. Penile tumescence testing can also be utilized to make this distinction.

Arterial insufficiency of the penis may occur from obstruction of the arterial supply. Several processes may account for this obstructive arteriosclerosis. Stenosis of the arteries secondary to atheromatous plaque may be the most common etiologic factor. Diabetes mellitus not only may result in occlusion of arterial vessels but also may cause a neuropathy of the pudendal nerve that might result in erectile dysfunction.<sup>20</sup> Most investigators have suggested that erectile dysfunction may result from excessive venous drainage from the penis. This occurs because the blood is not adequately trapped in the corpora.

The list of medications that may cause erectile dysfunction is long. Several antihypertensive agents, including propranolol, monoamine oxidase inhibitors, and thiazides, have been associated with varying degrees of impotence. Other medications linked to erectile dysfunction include phenothiazines, antihistamines, and some antidepressants.<sup>21</sup>

Endocrinopathy accounts for a small percentage of impotence cases.<sup>22</sup> Pituitary dysfunction resulting in decreased or no secretion of luteinizing hormone may result in decreased secretion of testosterone. Primary failure of the testes may also occur, resulting in decreased secretion of testosterone. Finally, excessive secretion of the hormone prolactin by the pituitary gland may result in low testosterone levels.

Trauma to the penis resulting in penile fractures and damage to penile erectile tissue may occasionally lead to partial or complete impotence. More common injuries include pelvic fractures with subsequent damage to the penile vascular and nervous supply. Iatrogenic trauma secondary to several commonly performed operations, including aortoiliac vascular surgery, and radical pelvic cancer operations may also result in impotence.

A newer concept in erectile dysfunction is the idea of vascular endothelial damage, which can be diffuse throughout the body. Some researchers believe impotence may be an indicator of coronary artery disease.

Finally, it must be remembered that successful sexual function depends not only on intact vascular, hormonal, and neurologic systems but also on intact psychological and social responses. Several psychological factors may be manifested as problems of low desire, erectile failure, or premature ejaculation. A discussion of the psychological contribution to impotence is beyond the scope of this book.

**Treatment.** Management of erectile dysfunction requires an initial evaluation to differentiate organic causes from psychogenic causes. Further evaluation to distinguish among the various organic causes may then be needed. Once a psychogenic cause has been ruled out, several therapeutic options exist. Surgical options include the insertion of an inflatable or semirigid prosthetic device into the corpora cavernosa. In the past few years, several investigators have discovered that intracavernous injection of various vasoactive substances can cause an erection. Several of these substances, including papaverine, phentolamine, and prostaglandin E<sub>1</sub>, are commonly used and afford a nonsurgical treatment option.

Viagra, the first oral therapy for erectile dysfunction, is the citrate salt of sildenafil, a selective inhibitor of cyclic guanosine monophosphate (cGMP)-specific phosphodiesterase type 5 (PDE5). To understand its clinical pharmacology, a review of some of the physiologic mechanisms of erection follows. Briefly, erection of the penis involves release of nitric oxide in the corpus cavernosum during sexual stimulation. Nitric oxide then activates the enzyme guanylate cyclase, and the subsequently increased levels of cGMP produce smooth muscle relaxation in the corpus cavernosum and allow inflow of blood. Sildenafil has no direct relaxant effect on isolated human corpus cavernosum, but it enhances the effect of nitric oxide by inhibiting PDE5, which is responsible for degradation of cGMP in the corpus cavernosum. When sexual stimulation causes local release of nitric oxide, inhibition of PDE5 by sildenafil causes increased levels of cGMP in the corpus cavernosum, smooth muscle relaxation, and inflow of blood to the corpus cavernosum, which results in erection (Figure 31-5). Sildenafil citrate at the recommended doses appears to have no effect in the absence of sexual stimulation and affords another nonsurgical treatment option. Two newer agents for erectile dysfunction are Levitra and Cialis. In any particular patient, one of the three available oral medications may work better than the others. None of these agents should be used in conjunction with nitrate medications.

Another nonsurgical alternative entails the use of a vacuum device to sustain an erection. Finally, in very specific cases of erectile dysfunction, surgical procedures may be done to revascularize the arterial supply of the penis or ligate the penile venous drainage.

### Premature Ejaculation

Premature ejaculation (PE) is the most common male sexual dysfunction and is present in up to 30% of all males. The World Health

**FIGURE 31-5** Mechanism of corpus cavernosum smooth muscle relaxation. Smooth muscle relaxation in the corpus cavernosum is the underlying mechanism of erection. The principal neurotransmitter is NO acting through cGMP and G-protein. Pharmacologic agents that produce erection act through this pathway by regulation of the intracellular balance of Ca<sup>2+</sup> and K<sup>+</sup> concentrations. *ATP*, Adenosine triphosphate; *cAMP*, cyclic adenosine monophosphate; *cGMP*, cyclic guanosine monophosphate; *GTP*, guanosine triphosphate; *NO*, nitric oxide; *eNOS*, nitric oxide synthase; *PDE<sub>s</sub>*, phosphodiesterase type 5. (Redrawn from Lue TF: Erectile dysfunction, *New Engl J Med* 342:1802-1813, 2000.)

**TABLE 31-1 MEDICAL THERAPY OPTIONS FOR THE TREATMENT OF PREMATURE EJACULATION\***

ORAL THERAPIES	TRADE NAMES <sup>†</sup>	RECOMMENDED DOSE <sup>‡§</sup>
<b>Nonselective Serotonin Reuptake Inhibitors</b>		
Clomipramine	Anafranil	25-50 mg/day or 25 mg 4-24 hr preintercourse
<b>Selective Serotonin Reuptake Inhibitors</b>		
Fluoxetine	Prozac, Sarafem	5-20 mg/day
Paroxetine	Paxil	10, 20, 40 mg/day or 20 mg 3-4 hr preintercourse
Sertraline	Zoloft	25-200 mg/day or 50 mg 4-8 hr preintercourse
<b>Topical Therapies</b>		
Lidocaine/prilocaine cream	EMLA cream	Lidocaine 2.5%/prilocaine 2.5% 20-30 min preintercourse

\*This list does not reflect order of choice or efficacy.

<sup>†</sup>Trade names listed may not be all-inclusive.

<sup>‡</sup>Peak plasma concentrations occur 2 to 8 hours (hr) postdose and half-lives range from 1 to 3 days.

<sup>§</sup>Titrate doses from low to high based on response.

Organization (WHO) defines PE as “persistent or recurrent ejaculation with minimal stimulation before, on, or shortly after penetration and before the person wishes it, over which the sufferer has little or no voluntary control, which causes the sufferer and/or partner bother or distress.”<sup>23</sup>

**Etiology and treatment.** The etiology of PE is not well-defined but can be both biological and psychosocial. The diagnosis is achieved with a careful medical and sexual history and physical examination.

There are no FDA-approved medications for treatment but several are currently being used off label (Table 31-1). Further research will elucidate the causes and allow for better treatment in the future.

## INFECTIOUS DISORDERS

Sexually transmitted infections (STIs) are common in the male genital system. A more in-depth discussion of STIs is provided in Chapter 34.

## NEOPLASTIC DISORDERS

### Neoplasms of the Penis

**Etiology.** Although cancer of the penis is rare in the United States and accounts for fewer than 0.2% of cancer deaths, its prevalence fluctuates widely among various locations. The causes are poorly understood, but phimosis of the foreskin accompanied by chronic inflammation has been thought to be the primary etiologic factor. The incidence of penile cancer among circumcised men is extremely low.<sup>24</sup>

The majority of penile cancer cases are squamous cell carcinoma (97%). They usually occur on the glans or the inner surface of the foreskin. Metastasis occurs by lymphatic dissemination, with initial involvement of the palpable inguinal lymph nodes. Death from penile

carcinoma is a result of uncontrolled lymphatic spread and subsequent necrosis of the overlying skin, debilitation, and sepsis.

Penile carcinoma is staged as follows<sup>25</sup>:

*Stage I:* The lesion is limited to the glans or foreskin.

*Stage II:* The tumor involves the shaft of the penis.

*Stage III:* The inguinal nodes are involved but the lesion is operable.

*Stage IV:* The disease is disseminated.

The lesion of penile cancer is usually ulcerative and fungating in appearance and may be associated with pain, bleeding, and urethral discharge. Inguinal adenopathy is present in more than 50% of patients at the time of diagnosis, although frequently the adenopathy represents an inflammatory response secondary to the lesion rather than metastasis.

**Treatment.** Therapy for penile carcinoma depends on the stage of the lesion. Topical chemotherapy and radiation therapy may be considered for certain small superficial lesions. Larger distal penile lesions usually require partial penectomy, whereas proximal lesions may require total penectomy with creation of a perineal urethrostomy. Finally, removal of the involved inguinal lymph nodes by inguinal lymphadenectomy may be performed in cases of suspected stage III disease. Systemic chemotherapy is also used to treat metastatic disease.

The prognosis of penile carcinoma depends on the stage of disease. The 5-year survival rate for men with tumors localized to the penis is 65% to 90%. With inguinal node involvement, 5-year survival rates drop to about 30% to 50%, and if distant metastases are present, the 5-year survival rate is virtually zero.<sup>25</sup>

### KEY POINTS

- Congenital disorders of the penis may result from hormonal deficiencies or abnormalities in embryonic development. Micropenis, for example, is usually a result of testosterone deficiency. Urethral valves, fistulas, and malpositioning of the urinary meatus (hypospadias, epispadias) are related to abnormal embryonic development.
- Priapism is a persistent, painful erection, most commonly of unknown cause. Priapism may occur in conditions that cause obstruction of venous drainage, including sickle cell anemia, anticoagulant therapy, diabetes mellitus, certain antidepressant medications, and PDE5 inhibitors such as Viagra.
- Phimosis and paraphimosis are disorders of the foreskin. Phimosis is associated with chronic inflammation and poor hygiene and results in a foreskin that cannot be retracted. Paraphimosis refers to a foreskin that remains retracted and cannot be returned to its normal position.
- Urethral strictures may be congenital or acquired. Most acquired strictures are secondary to gonorrheal infection or urethral trauma. Weak urinary stream, bladder infections, and retained urine are common manifestations.
- Impotence is the inability to achieve a sustained erection. Causes of impotence are categorized as primary and secondary. Primary impotence is rare and usually related to adolescent vascular trauma or psychiatric problems. Secondary impotence may be due to a variety of factors, including vascular disease, medications, endocrine disorders, trauma, and psychological distress.
- A number of infections are sexually transmitted and affect the penis and urethra, including gonococcal urethritis, nongonococcal urethritis, syphilis, herpes, and genital warts. Gonococcal and nongonococcal urethritis and syphilis are effectively managed with antibiotics. Herpes and genital warts are associated with viruses and tend to be chronic, with intermittent recurrence.
- Penile neoplasms are rare, particularly in circumcised males. Phimosis and chronic inflammation may be important etiologic factors. Like other neoplasms, penile cancer has a better prognosis if managed before dissemination.

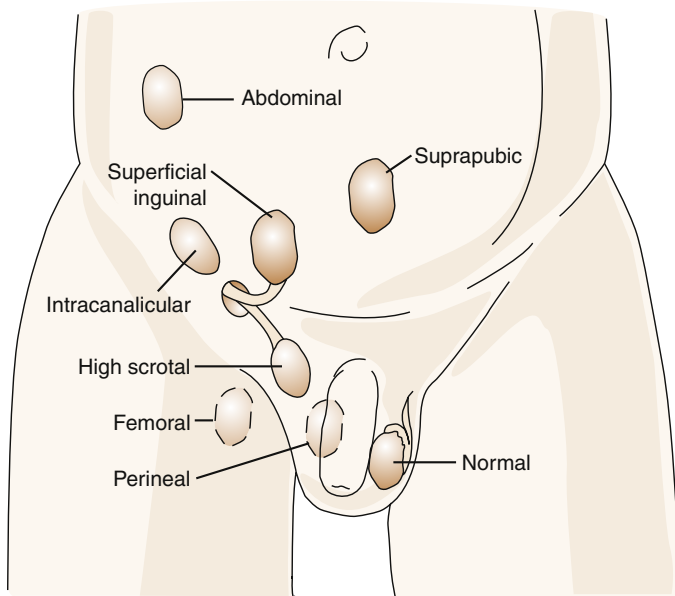

FIGURE 31-6 Sites of ectopic testes.

## DISORDERS OF THE SCROTUM AND TESTES

### CONGENITAL DISORDERS

#### Cryptorchidism

**Cryptorchidism** means “hidden testis” and refers to any testis that occupies an extrascrotal position. The cryptorchid testis may be incompletely descended and as such be located intraabdominally, within the inguinal canal, or just external to the canal but above the scrotum. Occasionally the testis may emerge from the external ring of the inguinal canal and be misdirected into an abnormal extrascrotal position. In this situation the testis may be called ectopic. An ectopic testis may be located in any of several locations but is most commonly found in a superficial inguinal pouch<sup>26</sup> (Figure 31-6).

The incidence of cryptorchidism is about 0.7% to 1.0% of male infants at 1 year of age. The cause of the condition is uncertain but may be related to an intrinsic testicular defect or a subtle hormonal deficiency.<sup>26</sup>

The incompletely descended, cryptorchid testis undergoes deleterious changes. The tubules become fibrotic, with a deficiency of spermatogenesis and subsequent infertility. More important is the increased incidence of testicular malignancy in cryptorchid testes.<sup>27</sup> Several studies have revealed an increased prevalence of testicular tumors in subjects with a history of cryptorchidism.

**Treatment.** Because of the increased risk of malignancy and infertility, treatment at an early age to bring the testis into a normal scrotal position is recommended. An operative procedure (*orchiopexy*) is usually required, although in certain situations descent may be stimulated by the administration of human chorionic gonadotropin, which is given in a series of intramuscular injections.<sup>28</sup>

### ACQUIRED DISORDERS

#### Hypogonadism

Androgen deficiency in the aging male (ADAM)—or andropause—is increasingly recognized as a problem for American men. The U.S. Food and Drug Administration estimates that between 4 and 5 million men suffer from hypogonadism.<sup>29</sup> There are multiple causes (Box 31-1) but primary testicular failure is the most common etiology.

### BOX 31-1 ETIOLOGIES OF ADULT-ONSET HYPOGONADISM

#### PRIMARY

- Cancer chemotherapy
- Excessive heat
- Iatrogenic injury
- Klinefelter syndrome
- Malnutrition
- Mumps orchitis
- Sickle cell disease
- Testicular radiation
- Testicular trauma

#### SECONDARY

- Adrenal or testis tumor
- AIDS
- Hemochromatosis
- Hepatic cirrhosis
- Hypercortisolemia
- Hyperprolactinemia
- Hypothyroidism
- Medications (glucocorticoids, spironolactone, cimetidine, phenytoin, flutamide, ketoconazole)
- Obesity
- Occupational exposures
- Pituitary ablation (surgical or external radiation therapy)
- Pituitary or hypothalamic tumor
- Severe systemic illness
- Uremia

From Carson CC et al: Evolving concepts in the management of androgen deficiency in the aging male, *Urol* 62:105-109, 2003.

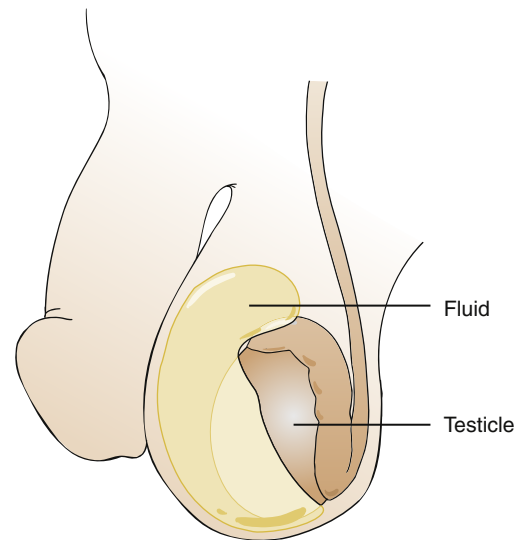

FIGURE 31-7 Hydrocele.

The effects of ADAM include erectile dysfunction (ED), loss of muscle tone, osteoporosis, and lipid metabolism changes. It is also associated with metabolic syndrome.

The diagnosis is made by determining the serum testosterone level. Other laboratory tests may include measurement of prolactin and luteinizing hormone (LH) levels.<sup>29</sup>

**Treatment.** Fortunately, it is quite easy to treat because there are multiple forms of testosterone that can be administered, including IM injections, patches, gels, and subcutaneous pellets. Patients receiving replacement therapy need to be monitored for prostate cancer and polycythemia.

#### Hydrocele

**Etiology and clinical manifestations.** A **hydrocele** consists of a fluid collection surrounding the testicle or spermatic cord and contained within the tunica or processus vaginalis (Figure 31-7). Scrotal

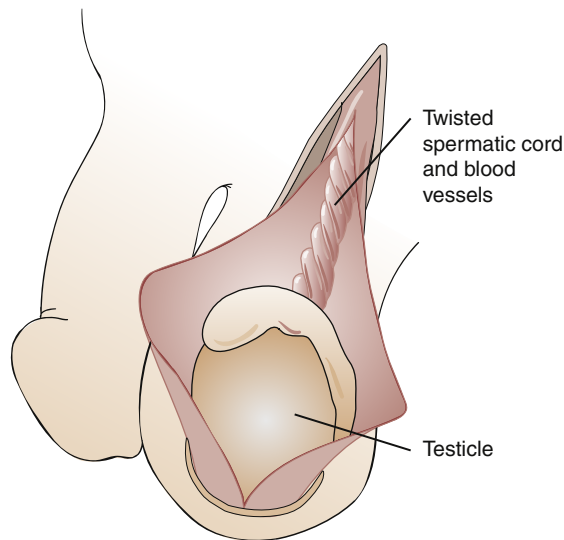

FIGURE 31-8 Testicular torsion.

swelling in infants or young boys may indicate a hydrocele. These congenital hydroceles exist because of communication between the abdominal cavity and scrotum through the processus vaginalis. The scrotum is characteristically small and soft in the morning but larger and tense at night as it fills with fluid from the abdominal cavity.

Hydroceles may also develop secondary to scrotal injury, radiation therapy, infection of the epididymis, or testicular neoplasms. More commonly, however, the cause is uncertain, with the hydrocele developing slowly over time and occurring in middle-aged or elderly men. These acquired hydroceles may vary in size and consistency from small and soft to large and tense. The fluid is usually clear and yellow.

**Treatment.** Because hydrocele is a benign condition, treatment is required only if the fluid collection becomes uncomfortable for the patient. Occasionally, a tense hydrocele might restrict circulation to the testicle. Management usually involves a surgical procedure to drain the fluid with either resection or plication of the hydrocele sac to prevent reaccumulation of the fluid. Aspiration of the hydrocele may be performed, although fluid often reaccumulates.

### Spermatocele

**Etiology and treatment.** Spermatoceles are painless, cystic masses containing sperm. Although they are usually small, they may be quite large and difficult to distinguish from a hydrocele. The cause of spermatoceles is uncertain; they may arise from the tiny tubules that connect the epididymis to the testis (vasa efferentia) or from the epididymis itself. Like hydroceles, spermatoceles need not be treated unless they become large enough to trouble the patient, in which case an operative procedure to excise the spermatocele may be performed.

### Testicular Torsion

**Torsion** of the testicle is described as a twisting of the spermatic cord with subsequent compromise of the testicular vascular supply and testicular ischemia, followed by infarction (Figure 31-8). Although torsion may occur in the neonatal period, the majority of cases occur in prepubertal boys.

**Clinical manifestations.** The diagnosis is suggested by the onset of severe pain in one testis, followed by swelling of the scrotum. Lower abdominal pain accompanied by nausea and vomiting may also occur. The condition may be differentiated from epididymitis (inflammation of the epididymis), which is also associated with scrotal swelling, by the presence of vascular echoes detected with a Doppler ultrasound.

### BOX 31-2 CORRECTABLE CAUSES OF MALE INFERTILITY

Endocrinologic causes	Obstruction
Testicular abnormalities	Vasal
Retractile testes	Epididymal
Cryptorchidism	Ejaculatory
Torsion	Disorders of ejaculation
	Sexual dysfunction
	Varicocele

From Galarneau GJ, Nagler HM: Cost-effective infertility therapies in the '90s: to treat or to cure? *Contemp Urol* 11:32-45, 1999.

A testis made ischemic by torsion will not demonstrate blood flow, whereas the inflammation of epididymitis and its hypervascularity show increased vascular flow. Testicular nuclear scanning is another way to diagnose testicular torsion.

**Treatment.** Management of torsion involves an operation to open the scrotum, untwist the testis, and “pex” (secure) it to the scrotal wall. Because the chance of torsion also involving the contralateral testis is increased, the contralateral testicle is “pexed” to the scrotal wall as well. If detorsion is accomplished within 12 hours of the event, the prognosis for testicular viability is usually good. If torsion has been present for more than 24 hours, viability of the testis is doubtful.

### Male Infertility

**Etiology and pathogenesis.** Approximately 15% of couples are unable to conceive after 1 year of unprotected intercourse.<sup>30</sup> A male factor is solely responsible in about 20% and contributory in another 30% to 40% of infertility cases.<sup>1</sup> An abnormal semen analysis is present in almost all cases of male infertility, but other factors may also be involved. Some causes of male infertility are identifiable and can be corrected, such as ductal obstruction varicocele or hypogonadotropic hypogonadism (a hormone abnormality)<sup>31</sup> (Box 31-2). Other problems can be diagnosed but not corrected such as bilateral testicular atrophy. Many cases are simply idiopathic or unexplained.

**Diagnosis and treatment.** The purpose of evaluating the male partner in infertility couples is to determine the cause of the infertility if possible so appropriate treatment and counseling can be accomplished. In some couples, treatment can result in pregnancy through intercourse. In others more advanced treatments are necessary.

In some patients there is no effective treatment and they can be appropriately counseled. Other patients will have a risk of transmitting genetic abnormalities and will need to be made aware of that potential. In some patients a life- or health-threatening condition may underlie the infertility and need treatment.<sup>30</sup>

As with all medical evaluations there should be a complete and specific history and physical examination. Lab testing includes two semen analyses (Box 31-3), and usually an endocrine evaluation (testosterone and FSH). More evaluation could include postejaculatory urinalysis, transrectal ultrasound, scrotal ultrasound, specialized semen tests, and karyotyping.

There are multiple treatments for male factor infertility. In men with varicoceles surgical repair or embolization can often improve fertility. Ductal obstruction can sometimes be surgically treated. In other cases more advanced treatment is necessary such as microsurgical epididymal sperm aspiration (MESA) or percutaneous testicular sperm extraction (TESE). This allows for retrieval of sperm that can then be used for in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). Some patients will improve their semen analysis with endocrine therapy and in some couples intrauterine insemination (IUI) will

be successful. For some couples the best option may be donor sperm or adoption.

## INFECTIOUS DISORDERS

### Epididymitis

**Etiology.** Epididymitis, or inflammation of the testis, has several causes. It may occur as a result of trauma or the reflux of sterile urine up the vas deferens. However, the majority of cases are probably secondary to a bacterial cause, with both sexually transmitted organisms (*Neisseria gonorrhoeae* and *Chlamydia trachomatis*) and non-sexually transmitted organisms (*Pseudomonas* and *Escherichia coli*) involved.

**Clinical manifestations and treatment.** With epididymitis the scrotum may be enlarged, reddened, and tender. The pain may radiate along the spermatic cord into the inguinal area. Fever may also occur, as may urethral discharge, cystitis, and cloudy urine. Laboratory testing usually reveals an elevated white blood cell (WBC) count, and urine culture may reveal the infecting organism.

Treatment for the condition involves bed rest, scrotal support, and administration of antibiotics. In advanced cases, incision and drainage with the intravenous administration of antibiotics may be needed to effectively manage a resulting scrotal abscess. On rare occasions, the testicle may need to be removed.

### Fournier Gangrene

**Etiology, clinical manifestations, and treatment.** Fournier gangrene is a severe but rare condition involving gangrenous necrosis of the scrotum. Symptoms are pain and swelling of the scrotum, fever and chills, and sepsis.<sup>32</sup> The diagnosis can often be made by history and physical examination. Additional tests such as ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) can also be helpful in diagnosis. Usually, an underlying disease such as diabetes, alcoholism, or another general debility predisposes the patient to such an aggressive infection. Extravasation of infected urine from urethral trauma, a perforated urethral diverticulum, or a non-urinary tract source such as a perirectal abscess may act as the source of infection.

\*World Health Organization, 1987.<sup>8</sup>

†World Health Organization, 1992.<sup>9</sup>

‡Kruger (Tygerberg) Strict Criteria, World Health Organization, 1999.<sup>1,5</sup>

Treatment, which must be instituted swiftly, includes incision and drainage of fluctuant areas and debridement of necrotic tissue along with administration of antibiotics. This often is a fatal disease unless it is managed quickly and aggressively.

## NEOPLASTIC DISORDERS

### Neoplasms of the Testis

Although testicular tumors are rare, with a prevalence of 3.7 cases per 100,000 population, their peak incidence is in late adolescence to early adulthood. These neoplasms therefore represent the most common solid tumors of U.S. men ages 20 to 34 years.<sup>33</sup> Testicular self-examination is an important tool for early detection because prompt treatment is associated with a higher success rate. Figure 31-9 shows an ultrasound image demonstrating cancer in a testis.

**Etiology.** Although the cause of testicular tumors is uncertain, a strong association is seen between cryptorchidism and the subsequent development of malignancy. Nevertheless, the majority of patients with testicular tumors have no history of cryptorchidism, which suggests that several unrecognized factors may be contributing to the pathogenesis.

Histologically, testicular tumors may be considered in two groups. In the first group are nongermlinal neoplasms, including tumors that originate from either the Leydig cells or other stromal tissue cells of the testis. In the second group are germinal neoplasms, which are derived from the germinal cells of the testis. This group accounts for the vast majority (95%) of testicular tumors. Germinal neoplasms may be further subdivided into two groups: seminomas and nonseminomas.

**Treatment.** Although germinal tumors may consist entirely of one histologic subtype, many contain elements of more than one subtype. Treatment and prognosis vary according to the subtype of germinal tumor. For example, seminoma in its early stages is exquisitely sensitive to and easily cured with radiation therapy. On the other hand, nonseminomatous germ cell tumors in the early stage are usually successfully managed with surgery. The prognosis is also variable. Pure choriocarcinomas are usually first seen at an advanced stage with distant metastases. Treatment is usually less effective for this aggressive lesion. However, the majority of germ cell tumors may be effectively managed even if lymph node metastases are present.

Except for choriocarcinomas, which disseminate by vascular means, testicular germ cell tumors usually metastasize through the lymphatic system. They usually disseminate in a stepwise manner, first involving the retroperitoneal lymph nodes lying adjacent to the great vessels.

FIGURE 31-9 Testis ultrasound demonstrating cancer.

If unmanaged, the disease may progress to involve other lymph nodes and other organs such as the lungs.

Multiple staging systems have been devised to classify the extent of this disease. Most are a variation of the system proposed by Boden and Gibb in 1951.<sup>33</sup> One commonly used system is as follows:

*Stage I:* The tumor is confined to the testis.

*Stage II:* The tumor has spread to retroperitoneal lymph nodes.

*Stage III:* The tumor has spread to nodes above the diaphragm.

*Stage IV:* The tumor has spread to other organs.

Because the management of testicular tumors is complicated and somewhat controversial, a complete discussion is not possible here; however, several issues can be highlighted. After diagnosis of a testicular tumor, an operation to remove the testicle is performed. This procedure involves an inguinal incision with removal of the testis from the scrotum, followed by ligation and removal of the spermatic cord and testicle together. Histologic classification, additional staging studies, and other factors then determine further treatment. This treatment may involve close observation with frequent radiologic studies, and other factors then determine further treatment. This treatment may involve close observation with frequent radiologic studies to determine new progression, surgery to remove the retroperitoneal lymph nodes (Figure 31-10), chemotherapy, or radiation therapy. Some situations may call for a combination of these measures.

**KEY POINTS**

- Cryptorchidism refers to a testis located in a position other than the scrotum. Often the testis has failed to descend completely and is located in the inguinal canal. Undescended testes are associated with infertility and an increased risk of testicular malignancy.
- A hydrocele is a collection of fluid in the testicle or spermatic cord. In the pediatric age group it is associated with a communication between the abdominal cavity and the scrotum (hernia). Hydroceles are benign and treated only if they become uncomfortable. A spermatocele is a cyst that contains sperm. Like hydroceles, they are benign and do not require treatment unless they cause discomfort.
- Testicular torsion refers to a twisting of the spermatic cord with subsequent testicular ischemia and infarction. Sudden onset of severe testicular pain is common. If the torsion is reduced within 12 hours, the testicle may be viable.

- Inflammation of the epididymis, called epididymitis, is most commonly associated with infectious agents. Manifestations include a swollen, tender, reddened scrotum with associated bladder infection and cloudy urine. Antibiotics are indicated. Aggressive infections of the scrotum may result in Fournier gangrene manifested by gangrenous necrosis of the scrotum.
- Although rare in the population, testicular cancer is the most common solid tumor in men ages 20 to 34 years. The great majority of testicular neoplasms originate in the germ cells. Most germ cell tumors can be effectively managed even after lymph node metastasis. Management includes surgical removal of the testis and spermatic cord, with irradiation and chemotherapy as indicated.

**DISORDERS OF THE PROSTATE**

**Benign Prostatic Hyperplasia**

**Benign prostatic hyperplasia**, also referred to as benign prostatic hypertrophy (BPH), is a very common disorder. An estimated 80% of men older than 60 years experience some degree of BPH. It is important to recognize that BPH and prostate cancer are not related entities, and no study has conclusively demonstrated that BPH predisposes to the development of prostate cancer.<sup>34</sup>

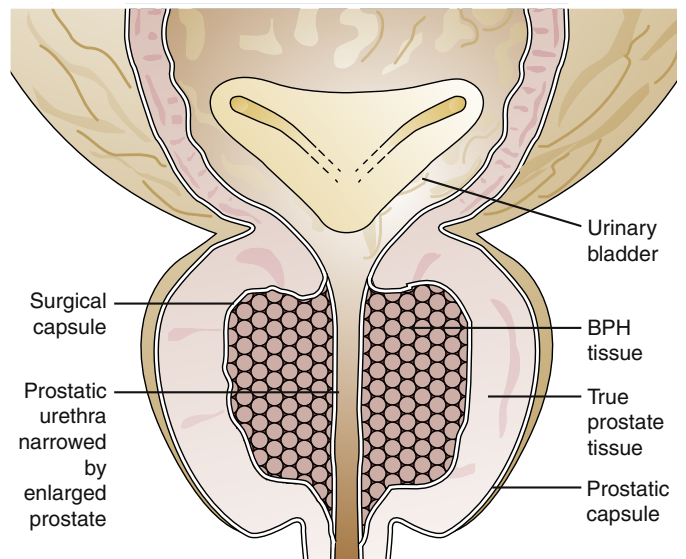

**Etiology.** Although the exact cause of BPH is unknown, the occurrence of the disease with aging suggests a relationship to changes in the aging male endocrine system. The process involves hyperplasia of the glands surrounding the prostatic urethra (Figure 31-11). As this tissue increases in size, it compresses the urethra and produces symptoms of bladder outlet obstruction.

**Clinical manifestations.** Symptoms of obstruction may be minimal at first but may eventually progress to complete obstruction and urinary retention. A decrease in the force of the urinary stream, hesitancy or difficulty in initiating a urinary stream, and interruption of the stream may occur. Because the bladder may fail to empty completely, infection associated with residual urine may occur. Figure 31-12 illustrates possible complications of benign prostatic enlargement.

The diagnosis of BPH usually involves recognition of the characteristic symptoms. Rectal examination disclosing an enlarged prostate, urethral catheterization or bladder scanning to document a large post-void urinary residual, and radiographic evidence of hypertrophy and

**FIGURE 31-10** CT scan demonstrating large retroperitoneal lymph nodes.

**FIGURE 31-11** Gross appearance of hyperplastic prostatic tissue obstructing the prostatic urethra. BPH, Benign Prostatic Hypertrophy.

**FIGURE 31-12** Sites for potential complications caused by benign prostatic enlargement (*right*) are compared with a normal kidney, ureter, bladder, and prostate (*left*).

obstruction on CT scan (Figure 31-13) or abdominal ultrasound are some of the measures that may be used to confirm the diagnosis. Urodynamics are sophisticated measures of urinary function that can help confirm the diagnosis.

**Treatment.** The treatment of BPH has changed markedly over the last several years. The first line of treatment is with medication such as  $\alpha$ -blockers or 5 $\alpha$ -reductase inhibitors. The former treatment decreases the tension in the prostate by relaxing the muscle fibers in the gland. This reduces pressure in the bladder neck and urethra, allowing easier flow. The latter treatment actually decreases the size of the gland by blocking the conversion of testosterone to dihydrotestosterone. This can shrink the gland by up to one third and thereby reverse the years of growth that have caused impingement of the urethra.

The next forms of treatment are the minimally invasive treatments that are usually performed in the physician's office. These include microwave therapy, needle ablation, and some other forms of treatment to decrease the tissue squeezing the urethra closed. They are usually well tolerated but may not cause total relief of the obstruction, and the long-term results are variable.

The last form of treatment is surgery. The classic operation for BPH is called a transurethral resection of the prostate (TURP). This procedure uses a resectoscope that is passed through the penis and into the prostate. An electric wire is then used to resect chips of tissue from the interior of the gland to form an open channel for urination.

A newer alternative to the TURP is laser therapy. In this approach, a scope is passed via the urethra into the prostate, and the tissue is vaporized with a laser fiber to create an open channel.

In some patients with extremely large glands or other bladder pathology, an incision is made and an open simple prostatectomy can be performed to remove the adenoma (inner portion of the gland). This creates a large cavity and channel for the urine to pass through.

All of the treatments have various side effects and risks. Therefore, each patient should have his treatment tailored to his specific situation.

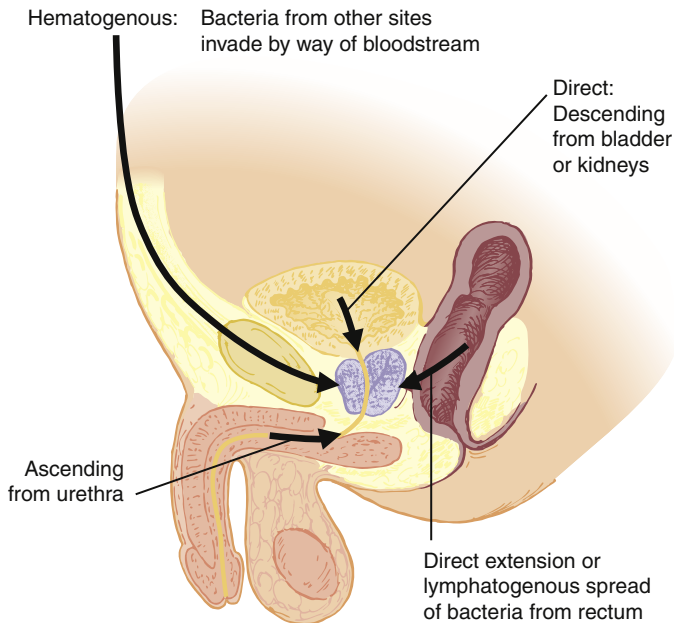

### Prostatitis

**Prostatitis**, or inflammation of the prostate, has several causes and encompasses several syndromes. A common classification of prostatitis proposed by Drach and colleagues<sup>34</sup> in 1978 considers four types: acute bacterial prostatitis, chronic bacterial prostatitis, nonbacterial prostatitis, and prostatodynia.<sup>35-38</sup>

The causative organism in bacterial prostatitis is usually *E. coli*, with species of *Proteus*, *Klebsiella*, *Enterobacter*, *Pseudomonas*, *Serratia*,

**FIGURE 31-13** CT scan demonstrating BPH.

**FIGURE 31-14** Postulated pathways of infection to the prostate gland. (From Black JM, Matassarin-Jacobs E: *Medical-surgical nursing: clinical management for continuity of care*, ed 6, Philadelphia, 2001, Saunders, p 963.)

*Staphylococcus*, and *Enterococcus* occurring less commonly.<sup>35-36</sup> Possible routes of infection include ascending infection up the urethra, reflux of infected urine into the prostatic ducts, hematogenous infection, and invasion of rectal bacteria by direct extension or lymphogenous spread (Figure 31-14). Many cases of prostatitis result from periurethral infection associated with an indwelling urethral catheter.<sup>36-37</sup>

**Clinical manifestations, diagnosis, and treatment.** Acute bacterial prostatitis is characterized by the onset of fever, chills, low back pain, and the voiding symptoms of frequency, urgency, and dysuria. Rectal examination usually reveals a tender, swollen prostate, and subsequent urinalysis may show the presence of WBCs and bacteria.

The diagnosis of bacterial prostatitis is usually suggested by the initial symptoms and signs. Microscopic inspection of the urine and expressed prostatic secretions may reveal WBCs and bacteria. A urine culture with sensitivity testing for the offending organism is recommended to direct therapy with an appropriate antibiotic. In the event of high fever and an elevated WBC count, intravenous antibiotics are recommended.

Chronic bacterial prostatitis may be associated with variable symptoms. Although some men with chronic bacterial prostatitis may report a history of acute bacterial prostatitis, many have no history of this problem. Most men complain of voiding symptoms with pain localized to various areas, including the perineum, back, suprapubic area, and, occasionally, the testis. High-grade fever and chills are uncommon with this entity, as opposed to acute bacterial prostatitis.

In chronic bacterial prostatitis, pathogenic organisms may persist in prostatic tissues unaltered by the administration of several antibiotics. Because most antibiotics accumulate poorly in prostatic secretions, discontinuation of antibiotic use often results in reinfection and recurrence of symptoms. It is this occurrence of relapsing infections, often caused by the same organism, which is typical of chronic bacterial prostatitis. Several antibiotic agents, such as trimethoprim-sulfamethoxazole (Septra, Bactrim), when used for a prolonged period (4 to 6 weeks) have a better cure rate because of their capability to penetrate prostatic tissue.

Prostatitis may also occur secondary to nonbacterial inflammation. In fact, nonbacterial prostatitis probably accounts for the majority of cases of prostatitis. The symptoms of this entity are variable but usually include irritative voiding; symptoms of urgency, frequency, and

nocturia; as well as occasional perineal and suprapubic pain. Although these symptoms are similar to those of bacterial prostatitis, patients have no history of positive urine cultures or urinary tract infections. Treatment may include a course of antibiotics, oral antiinflammatory agents (e.g., ibuprofen),  $\alpha$ -blockers, prostatic massage, and, occasionally, sitz baths. Symptoms are often intermittent, and patients should be reassured that the disease is not contagious and does not predispose to the development of cancer or other serious disease.

The final classification of prostatitis, **prostatodynia**, is typified by symptoms of prostatitis but no history of urinary tract infection and no evidence of inflammation in prostatic secretions. The cause of this entity is uncertain and may involve spasm of the pelvic floor musculature. Treatment may involve the use of  $\alpha$ -adrenergic receptor-blocking agents and occasionally diazepam (Valium).<sup>37-38</sup>

### Prostate Cancer

Other than skin cancers, prostate cancer is now recognized as the most prevalent form of cancer in men. About 200,000 cases are diagnosed annually in the United States, with approximately 30,000 deaths annually attributed to the disease. Prostate cancer ranks as the second leading cause of cancer death among men. Cancer of the prostate rarely occurs in men younger than 50 years, and its incidence increases with age. The majority (95%) of prostate cancers are adenocarcinomas with abnormal proliferation of prostatic glandular structures.<sup>38-39</sup>

**Etiology.** The precise cause of prostate cancer is undetermined, although genetic, hormonal, dietary, and viral factors have all been suggested. Varying degrees of aggressiveness of prostate cancer have been recognized, with different tumors expressing different malignant potential and ultimately carrying a different prognosis. Attempts to classify prostate cancer into separate groups of cancer have been made, with different tumors expressing different malignant potential and ultimately carrying a different prognosis. Such attempts to classify prostate cancer into different groups consider the structure and internal architecture of tumor cells and their pattern of proliferation. For example, cells of the more aggressive or poorly differentiated prostate cancers have more indistinct cell borders, larger nuclei, and loss of acinar (gland) formation.

Prostate cancer is staged as follows:

**Stage 1:** The tumor is microscopic and intracapsular.

**Stage 2:** The tumor is palpable on rectal examination but confined to the prostate.

**Stage 3:** The tumor has extended beyond the capsule of the prostate.

**Stage 4:** The tumor has metastasized to distant organs.

**Diagnosis.** The diagnosis of prostate cancer may involve several clinical scenarios. The disease may be diagnosed after microscopic inspection of prostate tissue removed for the management of presumed BPH. Prostate cancer may also be detected on rectal examination in patients with or without voiding symptoms. Occasionally, patients have urinary retention or even azotemia and renal failure secondary to obstructive nephropathy. Much interest has focused on the search for effective measures to detect prostate cancer in its early and most easily manageable stages. Two new techniques, a blood test for serum prostate-specific antigen (PSA) and transrectal ultrasonography, have generated considerable excitement within the field of urology. Several initial investigations have shown efficacy in the early detection of prostate cancer.

The diagnosis of adenocarcinoma of prostate cancer is usually made by checking the PSA level. This simple blood test has been a major factor in the early detection of adenocarcinoma of the prostate. Although it is not very accurate, it is helpful in identifying men who are at risk of having cancer. Since the adoption of its widespread use, most patients have been diagnosed before becoming symptomatic. However, many patients will have symptoms of BPH because of a benign enlargement of the gland, which is common in the age group that also is at risk for prostate cancer. If a patient has symptoms from his cancer, it is

**FIGURE 31-15** Bone scan demonstrating skeletal metastases.

often too late for cure because the symptoms usually indicate extensive disease. These symptoms include hematuria, weight loss, malaise, anorexia, and back pain.

Most patients will be diagnosed on the basis of an abnormal PSA blood test result, which usually leads to a transrectal ultrasound (TRUS) and biopsy of the prostate.

Since most patients are now diagnosed at an early stage there is little need for further staging tests. However, if there is concern for more extensive cancer, then they can be evaluated with a bone scan (Figure 31-15) or CT scan of the abdomen and pelvis.

**Treatment.** Management of prostate cancer depends on several factors, including the stage of the tumor, as well as the age and health of the patient. Debate exists over treatment for men with localized disease, with options ranging from aggressive therapy to “watchful waiting.” Watchful waiting may be an option for older men with asymptomatic stage A prostate cancer. Younger men may be candidates for the more aggressive approach, which includes surgery to remove the prostate and surrounding tissue (radical prostatectomy), radiation therapy, or cryotherapy (freezing the gland). It is important to note that approximately 70% to 90% of men who undergo radical prostatectomy will experience impotence. Urinary incontinence may also occur. Given the effects of surgical intervention, it is important that patients have access to preoperative and postoperative counseling about issues arising from their diagnosis and the effect of various treatments and potential complications.

In addition to radical prostatectomy or radiation therapy, in some cases lymph nodes in the pelvis are also removed (pelvic lymph node dissection). Advanced lesions may respond to hormonal manipulation. Orchiectomy, oral administration of estrogens, or intramuscular injection of luteinizing hormone–releasing hormone agonist and antagonist may reduce the patient’s serum testosterone level. Many prostate cancers are androgen sensitive and may be temporarily controlled with androgen ablation. In more advanced cases that are no longer hormonally responsive, palliative measures such as spot radiation treatment of painful areas of bone metastasis and analgesics may be required.

In the last several years there have been advances in chemotherapy for the treatment of hormone-resistant prostate cancer. One of the latest treatments is Sipuleucel-T. This therapy is based on autologous cellular immunotherapy to induce the patient’s immune system to attack the prostate cancer cells.<sup>39</sup> A great deal of research is being conducted to identify vaccines and other therapies to prevent and cure this highly prevalent cancer.

## GERIATRIC CONSIDERATIONS

### Prostate Cancer

Cancer of the prostate rarely occurs in men younger than 50 years, and its incidence increases with age. Symptoms vary depending on the stage of the disease. Men who are older and have stage A prostate cancer may be monitored closely without any treatment. Men with more advanced stage disease may be treated more aggressively.

### KEY POINTS

- Symptoms of BPH include diminished force of the urinary stream, hesitancy, and poor bladder emptying. Transurethral resection of the obstructing prostatic tissue is the usual treatment.
- Inflammation of the prostate, or prostatitis, is characterized by low back pain, urinary frequency, urgency, and dysuria. Fever and chills may also be present with acute bacterial prostatitis. *E. coli* is the most commonly associated organism. Prostatitis may also occur in the absence of infection.
- Prostate cancer is usually detected as a lump or enlargement of the prostate gland. As with other cancers, early, accurate diagnosis is important for effective therapy. Surgical resection, radiation therapy, and hormone therapy (to reduce androgen levels) may be used. The choice of treatment depends on the grade and stage of the disease and the individual’s age, general health, and life expectancy.

## SUMMARY

Disorders of the penis and male urethra may be grouped into congenital and acquired anomalies, infections, and neoplasms. Common congenital anomalies include urethral valves and hypospadias. Common acquired disorders involve phimosis, urethral strictures, and impotence. Sexually transmitted diseases are some of the most common infections involving the penis and urethra; they include gonococcal urethritis, nongonococcal urethritis, syphilis, genital herpes, and genital warts. Neoplasms of the penis and urethra are relatively rare.

Congenital disorders of the scrotum and testes include cryptorchidism. This condition is one of the most common problems seen

by pediatric urologists. Testicular torsion and Fournier gangrene are two of the more immediate urologic emergencies. Finally, neoplasms of the testes, although rare, may afflict younger men in the prime of life.

Disorders of the prostate account for a majority of the visits to a practicing urologist. Briefly, these disorders can be divided into problems of benign prostatic hyperplasia, prostatitis, and prostatic cancer. Prostate cancer is the most frequently diagnosed cancer in men, with more than 200,000 cases diagnosed and approximately 30,000 deaths yearly.

- Case Studies
- Key Points Review

### KEY QUESTIONS

- What are the major structures of the internal and the external female reproductive tract?
- What are the major hormonal events of the female reproductive cycle?
- Which hormones are involved in breast development during pregnancy and lactation, and what are their specific functions?
- What are the physiologic changes associated with pregnancy?
- What gestational events occur in the fetus during each of the three trimesters of pregnancy?
- What hormonal changes lead to menopause?
- What physiologic changes and complications may result from menopausal hormone deficiencies?

Menopause, 667

The female reproductive system is complex both in structure and in function. From birth to senescence, the organs of the female reproductive system function in concert with each other, with the brain, and with other endocrine organs. This integrated functioning constitutes some of the most intricate and elegant processes of the human body. This chapter presents an overview of these functions, beginning with the development of the female reproductive tract.

The major processes related to the reproductive tract throughout life, including the menstrual cycle, pregnancy, lactation, and menopause, are then described with an emphasis on recent research findings. Health care providers must also consider the developmental, cognitive, functional, social, and financial aspects of women's reproductive lives.<sup>1-3</sup> Because the functioning of the female reproductive system has an enormous impact on the life of the individual woman, increased importance has been placed on the active involvement of women in understanding their own health care needs. Health care professionals are encouraged to include women as collaborators in decisions about their reproductive health.<sup>4,5</sup>

## REPRODUCTIVE STRUCTURES

### Organization of the Female Reproductive Organs

The internal organs of the female reproductive system include the ovaries, **oviducts** (fallopian tubes), uterus, cervix, and vagina (Figure 32-1). These organs are situated in the pelvic cavity and are supported and anchored in place by a series of ligaments (Figure 32-2).

### Ovaries

The two ovaries, which are the female gonads, are located close to the lateral walls of the pelvic cavity. When the ovary is in its normal

position, its long axis is nearly vertical with respect to the horizontal axis of the body. The size of the ovary varies with age and with the stage of the menstrual cycle. It is somewhat larger before than after pregnancy and further reduces in size with the aging process.<sup>6</sup>

The ovary is covered with a single layer of epithelium. Underneath the epithelium is a layer of dense fibrous connective tissue called the tunica albuginea. The tunica albuginea constitutes the outer portion of the cortex of the ovary. The remainder of the cortex consists of connective tissue called the *stroma*, which contains ova in various stages of maturation. The innermost part of the ovary, the medulla, consists of loose connective tissue that is richly supplied with blood and lymph vessels and nerve fibers.<sup>7</sup>

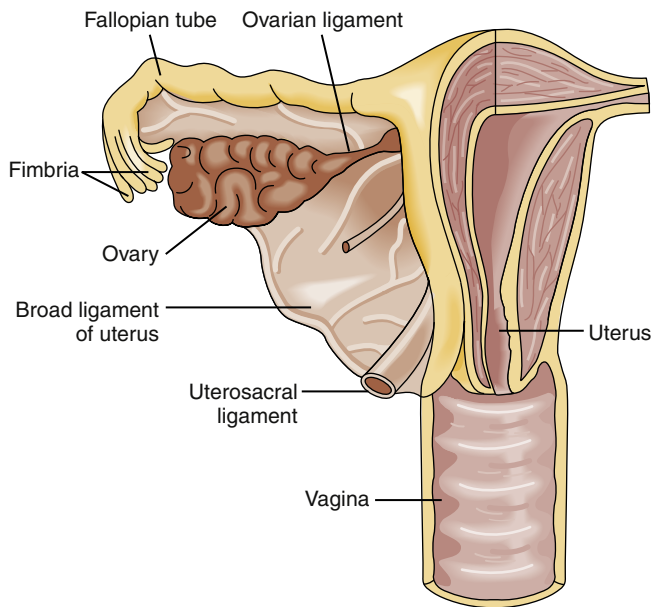

Before birth, hundreds of thousands of **oogonia** (cells that develop into ova) are present in the ovaries. Thus the entire lifetime supply of ova is established during embryonic development; no new oogonia arise after birth. Each oogonium is surrounded by a cluster of granulosa cells. The oogonium and its granulosa cells constitute a follicle. During prenatal development, the oogonia increase in size and become primary oocytes. By the time of full gestational development, the primary oocytes are in the prophase of the first meiotic division. Ovarian follicular development is shown in Figure 32-3. During childhood and into adult life, the oocytes enter a nonactive phase. After puberty, a few of the oocytes develop in follicles each month in response to follicle-stimulating hormone (FSH) secreted by the anterior pituitary gland. The vast majority of follicles and their oocytes die by atresia. Generally, each month, only one mature follicle will develop to eject an oocyte through the wall of the ovary in the process of ovulation, which is described in more detail in the Menstrual Cycle section.

**FIGURE 32-1** Cross-sectional view of the female genitourinary system. (From Jarvis C: *Physical examination and health assessment*, ed 6, St Louis, 2012, Elsevier, p 728.)

### Oviducts

The two **oviducts**, also called the fallopian or uterine tubes, are each about 10 cm long and located in the upper margin of the broad ligament. Each oviduct runs laterally from the uterus to the uterine end of the ovary. The free end of the oviduct adjacent to the ovary is called the *infundibulum*. It is shaped like a funnel with long, fingerlike projections termed *fimbriae*. The ampulla, the longest part of the oviduct, has an inner lining consisting of ciliated mucous membrane arranged in longitudinal folds. Beneath this ciliated lining is a double layer of smooth muscle with a thick outer layer of peritoneal serosa. The oviduct has an active role in propelling the ovum toward the uterus; the current created by the beating cilia and the peristaltic contractions of

**FIGURE 32-2** View of the female pelvis showing the ovarian and uterine ligaments.

the muscular wall are powerful forces that move ova along the oviduct. Once inside the oviduct, the ovum is moved through the ampulla to the isthmus (the short, narrow portion near the uterus) and finally through the intramural passageway to the uterus. Fertilization of the ovum occurs in the upper third of the oviduct, and the **zygote** (fertilized ovum) begins developing as it moves through the oviduct. If no fertilization occurs, the ovum undergoes degeneration in the oviduct.<sup>7</sup>

### Uterus

The uterus varies in size, shape, location, and structure during various phases of a woman's life and reproductive status. In the nonpregnant state, the uterus is about 8 cm long, 4 cm wide in its upper part, and 2 cm thick. The rounded part of the uterus, which lies above and in front of the openings of the oviducts, is called the *fundus*; the main portion of the uterus is the *corpus*, or body. The lower, narrow portion of the uterus is the *cervix*, which extends downward to the opening within the vagina. The cervix contains a narrow canal that joins the uterine cavity at the internal os and opens into the vagina at the external os.

The wall of the body and fundus of the uterus consists of three layers: endometrium, myometrium, and serosa (Figure 32-4). The outermost layer of the uterus, the serosa, consists of a single layer of mesothelial cells supported by a thin layer of loose connective tissue. The middle layer, the myometrium, consists of three layers of smooth muscle with the muscle fibers arranged in a different direction in each layer. The innermost lining of the uterus, the **endometrium**, consists of two layers: a thin deep layer called the *basilar layer* and a thick superficial layer referred to as the *functional layer*. During a woman's reproductive years, the endometrium displays a constant cyclic activity of alternate proliferation and sloughing of the functional layer in response to **estrogen** and **progesterone** secretion.<sup>8</sup> These changes will be discussed in more detail in the Menstrual Cycle section.

### Vagina

The vagina is the sexual organ that enfolds the penis during sexual intercourse, serves as an exit for discarded endometrium, and forms the lower end of the birth canal. It is located anterior to the rectum and

**FIGURE 32-3** Ovarian follicles. Female gametes mature within follicles in the outer region of an ovary. Follicles in early stages of development (**A**) and late stages of development (**B**) exhibit a developing oocyte (immature ovum) surrounded by hormone-secreting follicular (granulosa) cells. Notice that the more mature ovarian follicle in (**B**) has a fluid-filled cavity called the antrum. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Elsevier, p 1067.)

posterior to the urethra and urinary bladder. The vagina surrounds the cervix at one end and opens to the vestibule at its other end. The vagina is a highly elastic muscle that is capable of considerable distention. Two longitudinal ridges run along the anterior and posterior walls, with numerous transverse folds called *rugae*. The vagina is lined by a mucous membrane of stratified squamous epithelium overlying a layer of connective tissue.<sup>7</sup> The vaginal wall is subject to thinning with aging; this and other age-related changes in the female sexual organs are described in the Menopause section.

**External Genitalia**

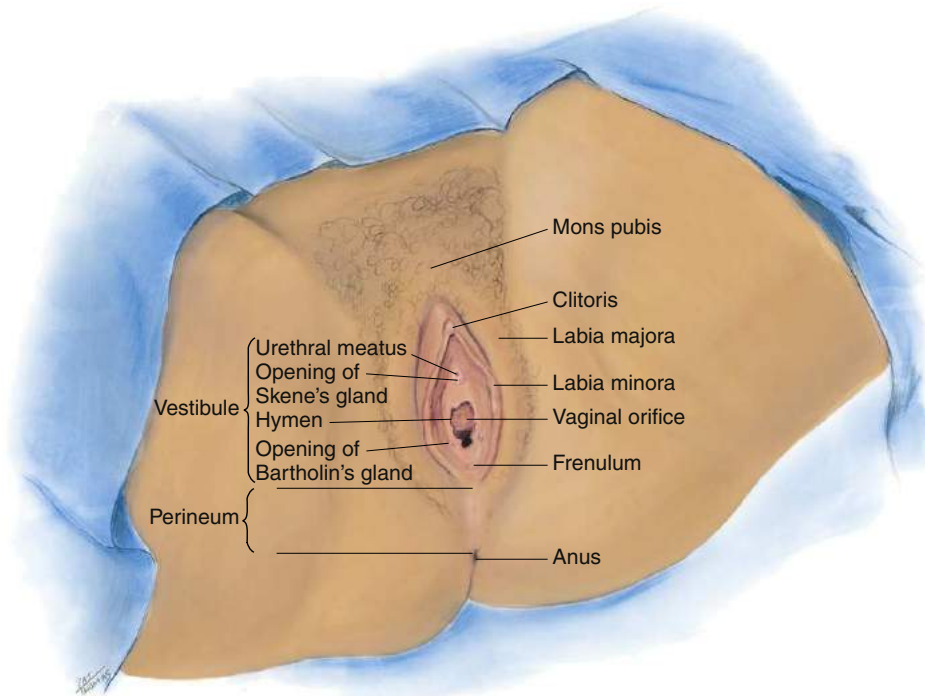

The external female genital structures include the mons pubis, labia majora, labia minora, clitoris, and vestibule of the vagina (Figure 32-5). The stages of development of the female external genitalia are depicted in Figure 32-6. The mons pubis is a rounded elevation in front of the pubis symphysis. It consists primarily of an accumulation of fat. After puberty, the skin over it is covered by coarse hair. The labia majora, which are

**homologous** (i.e., corresponding in structure) with the scrotum of the male, are folds of skin that run downward and backward from the mons pubis to the area behind the vaginal opening. After puberty, the labia majora become pigmented and covered with hair. The labia minora are two small folds of skin located between the labia majora on either side of the vaginal opening. The vestibule of the vagina is the cleft between the labia minora and contains the openings of the vagina, the urethra, and the ducts of the greater vestibular glands (also called *Bartholin glands*). These glands, along with the lesser vestibular or Skene glands, secrete mucus to provide lubrication during sexual intercourse.<sup>7</sup>

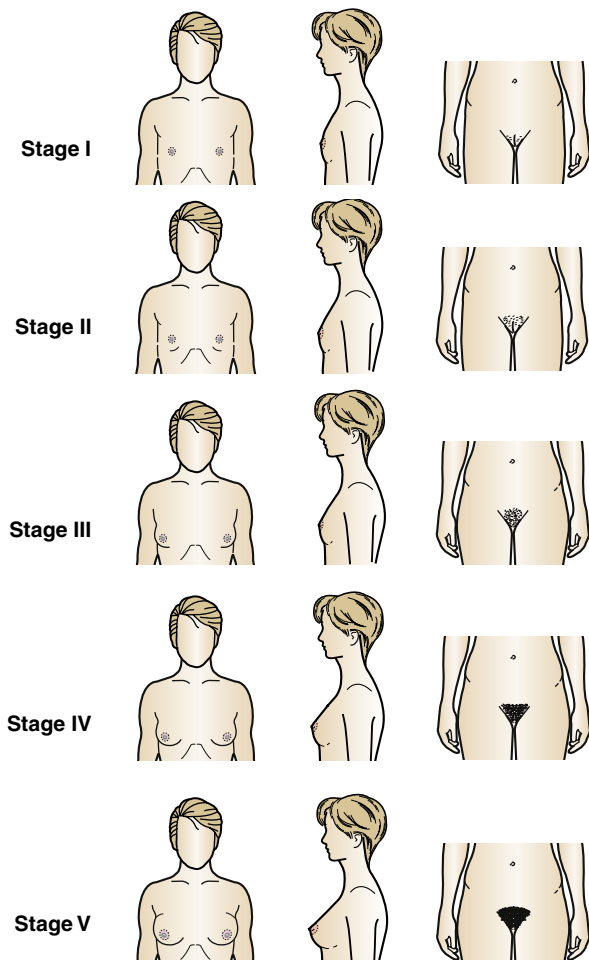

The clitoris is a body of erectile tissue that projects from the anterior end of the vulva at the anterior junction of the labia minora. It is about 2 cm long and 0.5 cm in diameter and is covered by a fold of tissue called the prepuce, which is formed by the merging of labial tissue. The glans of the clitoris is the rounded elevation on the free end of the body and is highly sensitive to stimulation. During sexual arousal, the erectile tissue of the clitoris becomes engorged with blood.<sup>7,8</sup>

**FIGURE 32-4** Internal female reproductive organs (posterior view). **A**, Diagram shows left side of uterus and upper portion of the vagina and the left uterine tube in a frontal section. The broad ligament has been removed from the posterior surface of the uterus and adjacent structures. **B**, Cadaver dissection showing uterine cavity and cervical canal, exposed by removal of parts of their posterior walls. Note that the uterine wall consists of an epithelial lining from which uterine glands extend through the full thickness of the mucosa. Beneath the endometrium, a portion of myometrium is shown. (**A**, From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Elsevier, p 1066. **B**, From Gosling J et al: *Human anatomy*, ed 4, Philadelphia, 2005, Mosby.)

**FIGURE 32-5** External female genitalia. (From Jarvis C: *Physical examination and health assessment*, ed 6, St Louis, 2012, Elsevier, p 726.)

**FIGURE 32-6** Five tanner stages of sexual maturity ratings (SMRs) in girls.

#### KEY POINTS

- Organs of the female reproductive tract include the ovaries, oviducts, uterus, cervix, and vagina. Ovaries contain a lifetime supply of ova at birth. After puberty, a few of the ovarian follicles develop about every 28 days in response to secretion of FSH.
- The oviducts (fallopian tubes) actively propel the ovum toward the uterus by ciliary action and peristaltic contractions. The uterine lining undergoes a cyclic process of proliferation and then sloughing in response to estrogen and progesterone.
- External genitalia in the female include the mons pubis, labia majora, labia minora, clitoris, and vestibule of the vagina. The urinary meatus, vaginal opening, and vestibular gland ducts are located in the vaginal vestibule.

#### MENSTRUAL CYCLE

From **menarche** onward, the normal reproductive years of the female are characterized by rhythmic changes in hormonal secretion and corresponding changes in the sexual organs, which are called the *target organs* of the female hormones. This rhythmic pattern is called the **menstrual cycle** (Figure 32-7). Two significant results of the menstrual cycle are stimulation of the production of an ovum and preparation of the uterine endometrium for the implantation of a fertilized ovum at the appropriate phase of the cycle.<sup>8</sup>

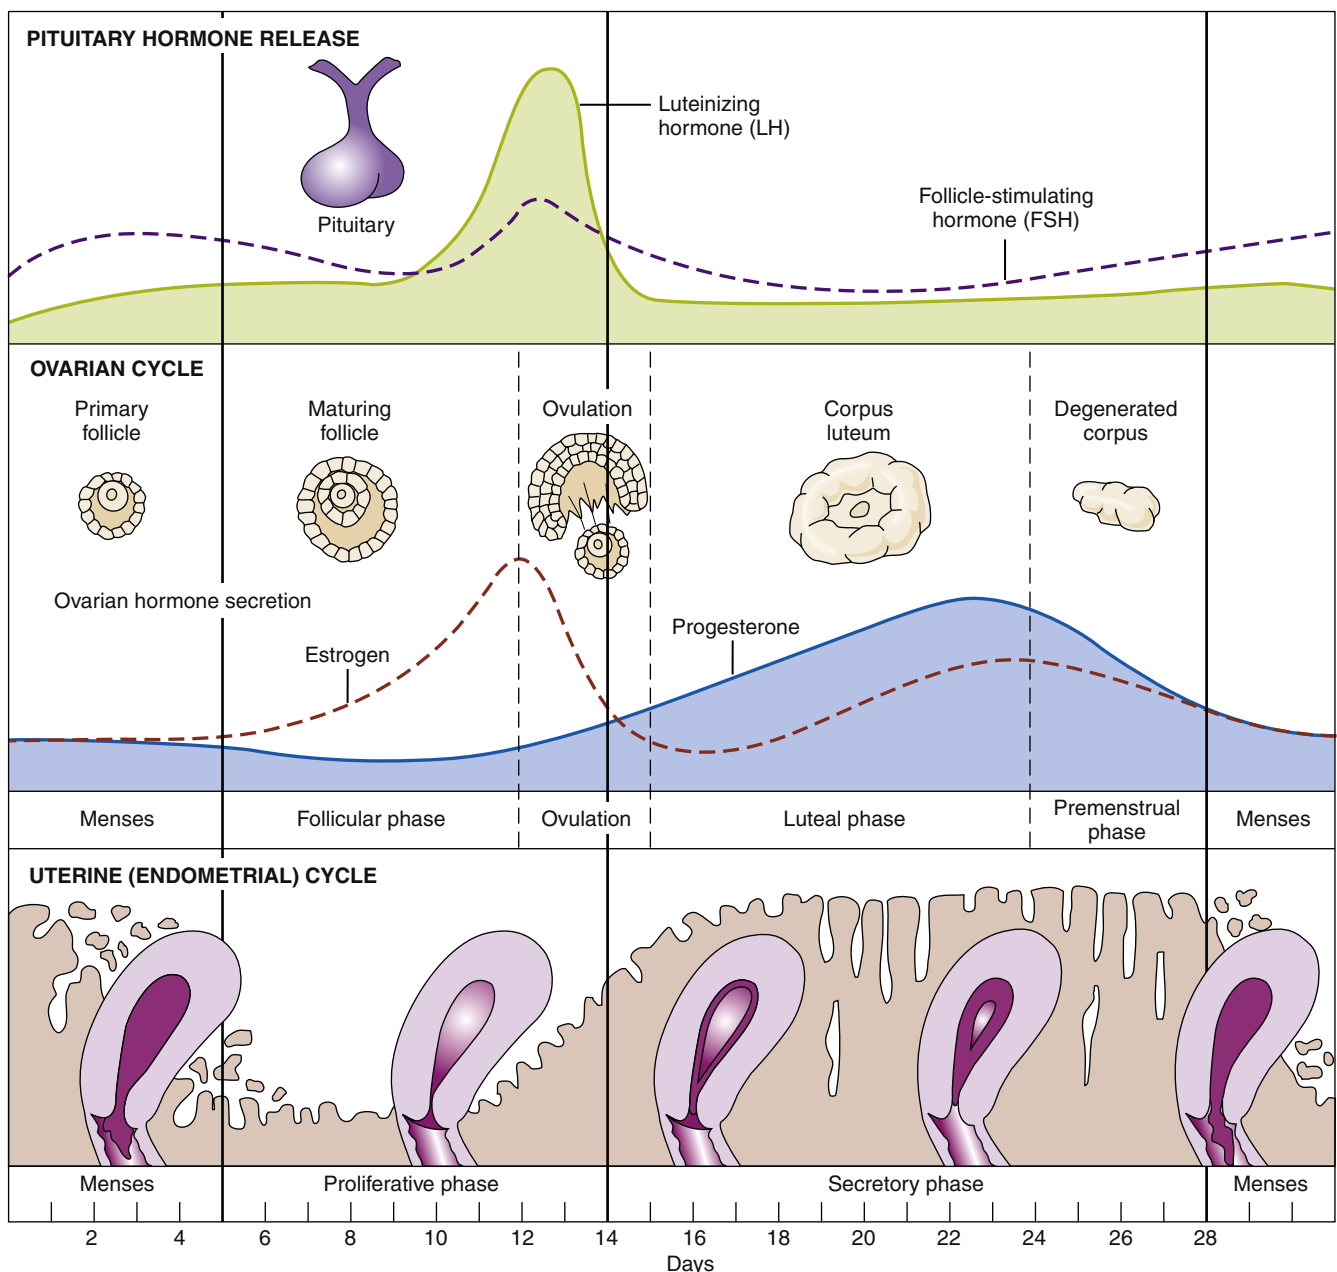

Although considerable variation can be found in human females, an average menstrual cycle is 28 days long, with cycles as short as 20 days or as long as 45 days occurring in normal women. The first day of

## CHAPTER 32 Female Genital and Reproductive Function

menstruation is considered the first day of the menstrual cycle. Ovulation occurs approximately 14 days before the next cycle begins; thus in a 28-day cycle, ovulation occurs on about day 14 of the cycle.

The release of hormones and the accompanying response of the female sexual target organs are depicted in Figure 32-7. The principal female reproductive hormones are summarized in Table 32-1. As shown in Figure 32-7, the events of the menstrual cycle require precise synchronization between the activities of the pituitary gland, ovary, and uterus. Beginning at the first day of the menstrual cycle, or the first day of menstruation, these events can be summarized as follows. The thickened functional layer of the endometrium of the uterus is gradually sloughed off, and about 35 ml of blood is lost. During this phase of the menstrual cycle, follicle-stimulating hormone (FSH) is released by the pituitary gland and stimulates a group of follicles to develop in the ovary.

In the preovulatory phase, also called the proliferative phase, theca and granulosa cells in the developing follicles in the ovary secrete estrogen, which stimulates growth of the uterine endometrium once again. At about the midpoint of the cycle, an increase in estrogen secretion from the follicles occurs. This increase in estrogen level is thought to render the anterior pituitary more responsive to luteinizing hormone-releasing hormone secreted by the hypothalamus.<sup>9</sup> The anterior pituitary gland then produces a burst of luteinizing hormone (LH). The FSH level also increases about twofold at the same time, and these two hormones act synergistically to cause the extremely rapid swelling of the follicle that culminates in ovulation.<sup>10</sup> During the process of ovulation, the secondary oocyte is ejected through the wall of the ovary into the peritoneal cavity. The free end of the oviduct is strategically located so that the ovum enters its fimbriated end almost immediately.<sup>7</sup>

**FIGURE 32-7** Menstrual cycle. The events that take place within the pituitary, ovary, and uterus are precisely synchronized. When fertilization does not occur, the cycle repeats itself about every 28 days.

TABLE 32-1 PRINCIPAL FEMALE REPRODUCTIVE HORMONES

HORMONE	TARGET ORGANS	SIGNIFICANT ACTIONS
Estrogen	Multiple sites throughout body, including reproductive structures, bone, fat, and muscle tissues	Development of reproductive organs during puberty Development of secondary sex characteristics, including breast maturation, widening of pelvis, and distribution of fat and muscle tissues in a distinctively female pattern Cyclic preparation of endometrium for implantation of an ovum
Progesterone	Primarily uterus and breasts	Cyclic preparation and maintenance of endometrium for implantation of an ovum Stimulation of development of breast lobes and alveoli
Follicle-stimulating hormone	Ovary	Stimulates ovarian follicle development; with luteinizing hormone, stimulates secretion of estrogen and ovulation
Luteinizing hormone	Ovary	Stimulates final development of ovarian follicle, process of ovulation, and development of corpus luteum

After ovulation, the postovulatory phase (also called the luteal phase) begins. During the luteal phase the site of the ruptured follicle becomes a **corpus luteum** (Latin for “yellow body”), which secretes estrogen and progesterone. These hormones stimulate continued thickening of the uterine endometrium. The cells of the corpus luteum become greatly enlarged and develop lipid, or fatty, areas that give the cells a distinctive yellow color. In a normal cycle, the corpus luteum grows to approximately 1.5 cm, with maximal development attained about 7 to 8 days after ovulation. If pregnancy does not occur, the corpus luteum begins to degenerate, and progesterone and estrogen levels in the blood fall markedly. Constriction of the spiral arteries located in the uterine wall occurs, and the portion of the endometrium supplied by these arteries becomes ischemic. As the cells in the endometrium die, tissue is sloughed off and menstruation begins again. It is presently thought that prostaglandins liberated in the endometrium may have a role in stimulating the sloughing of endometrial tissue.<sup>7,11</sup>

If fertilization of the ovum occurs, the embryo arrives in the uterus on about the fourth day of development. Small glands in the endometrium stimulated by progesterone produce a nutritive fluid for the developing embryo. On approximately the seventh day after fertilization, the embryo implants itself in the thick endometrium of the uterus, and development of the **placenta** occurs. The placenta secretes the hormone human chorionic gonadotropin (hCG), which in turn signals the corpus luteum to continue to function. Subsequent events in pregnancy are described later in this chapter.

#### KEY POINTS

- The monthly reproductive cycle averages about 28 days. Beginning on the first day of menses, the important events of the cycle are as follows:
  1. The endometrial layer is sloughed.
  2. The ovarian follicles are stimulated by pituitary FSH.
  3. Estrogen is secreted from the developing follicles.
  4. Proliferation of the endometrium occurs in response to estrogen.
  5. At the midpoint of the cycle, a burst of luteinizing hormone and a doubling of FSH secretion from the pituitary gland stimulate ovulation.
  6. The ruptured follicle changes into a corpus luteum and secretes estrogen and progesterone.
  7. In the absence of pregnancy, secretion of estrogen and progesterone drops rapidly and the endometrial lining sloughs off again to complete the cycle.
- With fertilization and implantation of the ovum, the developing placenta secretes hCG, which in turn stimulates the corpus luteum to continue to secrete estrogen and progesterone and thus prevent endometrial sloughing.

## BREAST

The breast is an important accessory organ in sexual function and human reproduction. Although its primary physiologic function is **lactation** (production of milk) to nourish the human infant, the significance of the breast as a symbol of feminine sexuality in contemporary Western culture must also be recognized.

### Structure of the Breast

The breasts are located anterior to the pectoralis major muscle and are separated from it by a layer of fat. The position of the breasts is maintained by fibrous bands called *Cooper ligaments*, which are easily stretched, especially if the breasts are large. Lymph drainage from the breasts is mainly toward the axillary lymph nodes, with some drainage toward the substernal and diaphragmatic lymph nodes.<sup>12</sup>

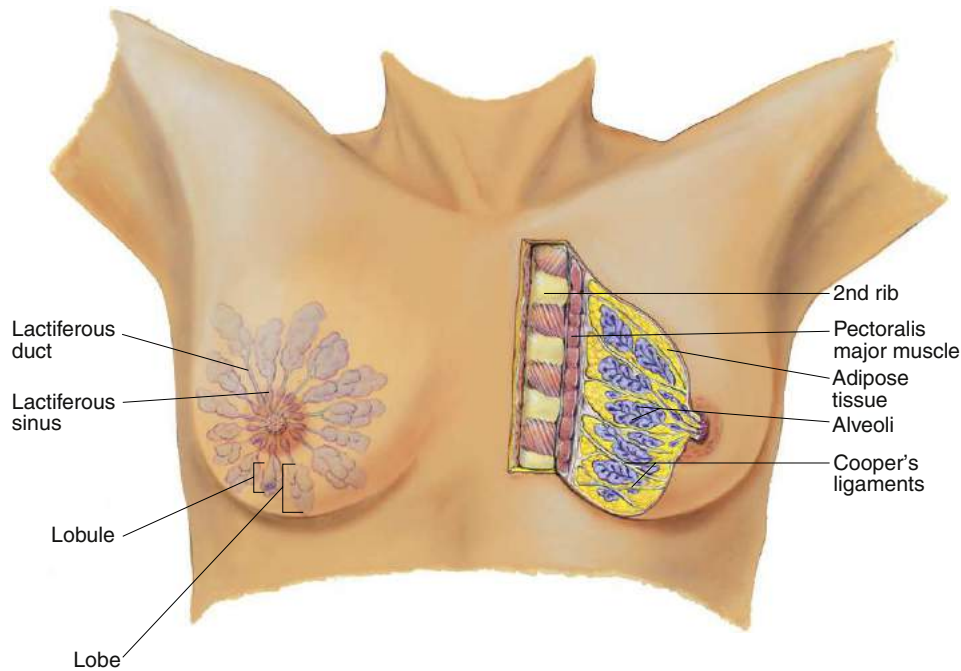

Each breast consists of 15 to 20 lobes of glandular epithelial tissue and a ductal system embedded in interstitial tissue and fat. The secretory cells that constitute the glandular epithelium are arranged in grapelike clusters called *alveoli* (Figure 32-8). Ducts or openings from each alveolus unite to form a single duct from each lobe. These main ducts then enlarge slightly into ampullae immediately before opening onto the surface of the nipple. The nipple, located at the center of the adult female breast, is composed of bundles of smooth muscle fibers with erectile properties. The areola that surrounds the nipple has a diameter of 1.5 to 2.5 cm. The openings from the lactiferous ducts are arranged radially under the areola; thus 15 to 20 small openings are located on the surface of each nipple through which milk flows in a lactating female.<sup>7</sup>

### Breast Development

The five Tanner stages of development of the female breast are depicted in Figure 32-6. As shown in this figure, the breasts contain only rudimentary glands during childhood. At puberty, estrogen and progesterone, in the presence of growth hormone and prolactin, promote the development of glandular tissue and ducts and the deposition of fat characteristic of the adult female breast. Throughout the reproductive years, some women note swelling of the breast around the latter part of each menstrual cycle before the onset of menstruation. The water retention and subsequent swelling of breast tissue during this phase of the menstrual cycle are thought to be due to high levels of circulating progesterone stimulating the secretory cells of the breast.<sup>12</sup>

### Lactation

During pregnancy, high concentrations of estrogen and progesterone produced by the corpus luteum and the placenta stimulate the

**FIGURE 32-8** Mature female breast. (From Jarvis C: *Physical examination and health assessment*, ed 5, St Louis, 2008, Elsevier, p 409.)

development of glands and ducts in the breast. During the first trimester of pregnancy, the ducts proliferate; in the second trimester, the ducts group together to form large lobules with new alveoli formation. In the third trimester, the existing alveoli dilate in preparation for lactation. Toward the end of pregnancy and until 1 to 3 days after childbirth, the mammary glands form colostrum, which contains protein and lactose but little fat. After birth of the infant, the hormone **prolactin** secreted by the mother's anterior pituitary gland stimulates milk production, and milk is produced by the third day after delivery. The initiation and maintenance of lactation are a complex neuroendocrine process involving sensory nerves in the nipples and breast tissue, the spinal cord and hypothalamus, and the pituitary gland. The suckling movements of the infant on the breast stimulate the release of prolactin from the anterior pituitary gland and **oxytocin** from the posterior pituitary gland. These hormones in turn stimulate lactation and ejection of milk from the alveoli into the ducts, where it is accessible to the infant. Oxytocin then promotes the actual release of milk, called the "milk ejection reflex."<sup>7,13</sup>

#### KEY POINTS

- At puberty, breast development occurs in response to estrogen and progesterone in cooperation with growth hormone and prolactin. During pregnancy, high estrogen and progesterone levels stimulate further development of the mammary glands and ducts.
- Milk production and release are stimulated by the pituitary hormones prolactin and oxytocin in response to suckling.

## PREGNANCY

During the 9 months of human gestation, the single-celled zygote gives rise to an infant with a complex set of physiologic systems.

The fertilized ovum contains the entire genetic complement—or encoded genetic instructions—to develop into a fully functioning term infant, given adequate nutrition and time. Three basic developmental processes—growth, **morphogenesis**, and cellular differentiation—are involved in this transformation.<sup>14</sup> Growth denotes the proliferation of new cells by mitosis, a necessary but not sufficient process for development. The arrangement of cells in a particular order is called *morphogenesis* and is essential to the elaboration of higher forms of life. In addition to growth and morphogenesis, cellular differentiation is needed for cells to specialize structurally and biochemically in a myriad of ways. This section describes the sequence of events in which growth, morphogenesis, and cellular differentiation function to transform a human zygote with encoded genetic information into a human infant. In addition, this section will describe the response of the mother's body to pregnancy. Information on genetic control of inheritance and genetic disorders is contained in Chapters 5 and 6, respectively, and the reader may wish to refer to these chapters for specific content in these areas.

## Early Human Development

Fertilization of the ovum occurs in the oviduct. Within 24 hours after fertilization, the zygote begins a series of divisions by the process of mitosis; this process is referred to as *cleavage* (Figure 32-9). From a two-cell entity the zygote soon divides multiple times, and its cytoplasm begins to be partitioned into specific cells that will serve as the building blocks of the embryo. As more cleavage takes place, the embryo is transported through the oviduct to the uterus. This process takes about 4 days. The embryo receives nutrition during this time from secretions released by the epithelial cells lining the oviduct. After the embryo enters the uterus, the zona pellucida, the membrane surrounding the embryo, dissolves. About day 4, the embryo arrives in the uterus and floats freely while receiving nutrition from secretions from the endometrial glands stimulated by progesterone.

**FIGURE 32-9** Early human development. Drawings illustrate cleavage of the zygote and formation of the blastocyst. At ovulation, an ovum is released from the ovary and begins its journey through the uterine tube. While in the tube, the ovum unites with a sperm to form the single-celled zygote. After a few days of rapid mitotic division, a ball of cells called a morula is formed. After the morula develops into a hollow ball called a blastocyst, implantation occurs. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Elsevier, p 1102.)

At this point the cells of the embryo have arranged themselves into a hollow spherical structure called the *blastocyst* (Figure 32-9). The outer cells of the blastocyst, called the *trophoblast*, will ultimately become the protective and nutritive membranes (chorion and placenta) that surround the developing embryo. The inner cell mass, a small cluster of cells that projects into the cavity of the blastocyst, will develop into the structures of the embryo itself. If at this point the inner cell mass divides into two separate groups of cells, identical twins with an identical genetic complement will result. Fraternal twins develop when two ova are fertilized by two sperm cells and do not have an identical genetic complement.<sup>14</sup>

### Implantation

On approximately day 7 after fertilization, the embryo attaches to the uterine lining and then implants itself in the endometrium (Figure 32-10). Enzymes secreted by the trophoblast erode a small portion of the uterine lining, and by day 10 of development the embryo has completely penetrated the endometrium. The opening in the uterine lining is closed, initially by a blood clot and then by regeneration of uterine epithelium; all subsequent development of the embryo occurs in the wall of the uterus.<sup>7</sup>

### Fetal Membranes and Placenta

Fetal membranes protect the developing embryo or fetus and provide needed substrates for growth and development, particularly oxygen and nutrition. In addition, they serve the purpose of elimination of waste products of metabolism. All terrestrial vertebrates have four fetal

membranes: amnion, yolk sac, chorion, and allantois.<sup>14</sup> In the developing human, the yolk sac is usually thought to be a vestigial structure, although it serves as an important temporary center for the formation of blood cells between the second and sixth weeks. The allantois is also considered vestigial, although its blood supply contributes to formation of the umbilical vessels.

The amnion begins to develop at a very early stage and eventually expands to surround the entire embryo. The space between the amnion and the embryo is called the **amniotic cavity**. It is filled with a clear amniotic fluid that keeps the embryo moist and provides a measure of protection against mechanical injury.

The **placenta** serves two basic functions. It is the organ of exchange between the developing fetus and the mother; it also provides nutrients to the fetus and removes wastes. It is also an endocrine organ and produces several hormones, most notably hCG. The placenta develops from both the chorion and the maternal uterine tissue. After implantation, the chorion develops rapidly and forms highly vascularized villi while the embryonic circulation develops. The umbilical cord develops and connects the embryo with the placenta. Two umbilical arteries arise in the umbilical cord and connect with a rapidly proliferating network of capillaries in the villi. The umbilical vein, also located in the umbilical cord, carries blood from the villi back to the fetus.

The placenta eventually consists of the portion of the chorion in which villi develop, along with the uterine tissue between the villi that contains maternal capillaries and small pools of maternal blood. The placenta brings maternal blood adjacent to fetal blood, although the two circulatory systems are completely separate from each other. Thus

**FIGURE 32-10** Implantation of the early human embryo showing trophoblastic digestion and invasion of the endometrium. (From Guyton AC, Hall JE: *Textbook of medical physiology*, ed 12, St Louis, 2010, Elsevier. Courtesy Arthur Hertig, MD.)

oxygen and nutrient substrates pass from the maternal blood through the placental tissue and diffuse into the blood of the fetus, where these substances can be used for growth and development of various body tissues. Waste products of fetal metabolism from fetal blood then pass through the placenta into the maternal blood supply and are eventually transported to the maternal kidneys for disposal.<sup>14</sup>

The placenta, like the corpus luteum, secretes both estrogen and progesterone during pregnancy. These hormones serve a variety of purposes in pregnancy. Estrogen promotes enlargement of the uterus and growth of the ductal structure of the breast, as well as alters the elasticity of various pelvic ligaments and the symphysis pubis to allow passage of the infant through the pelvic structures during delivery. In addition to its role in providing early nutrition for the embryo, progesterone has the special effect of decreasing contractility of the gravid uterus, thus preventing spontaneous abortion. In addition, progesterone may have a role in preparing the breasts for lactation, as described earlier in the Lactation section.

Of major importance in the role of the placenta as an endocrine gland is its production of hCG. From the time of implantation, the trophoblastic cells begin to secrete hCG, which sends a signal to the corpus luteum that a pregnancy has begun. The corpus luteum responds by increasing its size and its secretion of estrogen and progesterone, which then promote continued development of the endometrium and the placenta. In the absence of hCG, the corpus luteum would disintegrate, as it does in a nonfertilized menstrual cycle, and the endometrium would deteriorate and be sloughed off along with the embryo. Thus, hCG is an essential element in continuation of the pregnant state.<sup>14</sup>

### Development of the Human Embryo and Fetus

From fertilization to the end of the eighth week, the developing organism is referred to as an *embryo*; from the ninth week until birth, the developing baby is referred to as a *fetus*. Development of the fetus proceeds in an orderly sequence of complex events. With recent developments in fetal physiology, it is possible to predict which structures will begin their development or function on a particular day of development after conception. Table 32-2 depicts some important developmental events from the time of fertilization to birth. Detailed information on the development of organ systems during fetal life is

**TABLE 32-2 SUMMARY OF DEVELOPMENTAL EVENTS IN HUMAN FETAL LIFE**

TIME FROM FERTILIZATION	KEY EVENTS
36 hours	Embryo has achieved two-cell stage
4 days	Embryo reaches uterus
7 days	Implantation of embryo in uterine wall
2.5 weeks	Differentiation of heart tissue Blood cell formation in yolk sac and chorion Formation of notochord and neural plate
3.5 weeks	Formation of neural tube Heart tubes begin to beat Primordial eye and ear visible Respiratory system begins development Liver bud differentiates Blood vessels established
4 weeks	Formation of three primary brain vesicles Limb buds appear
2 months	Embryo capable of movement Cerebral cortex differentiating Gonad identifiable as testis or ovary Bones begin ossification and muscles are differentiating
3 months	Major blood vessels in final positions Fetus performs breathing and sucking movements Gender is clearly identifiable
5 months	Heartbeat is audible with a stethoscope Fetus moves freely through amniotic cavity
6-9 months	Rapid growth with final differentiation of tissues and organs
266 days	Birth

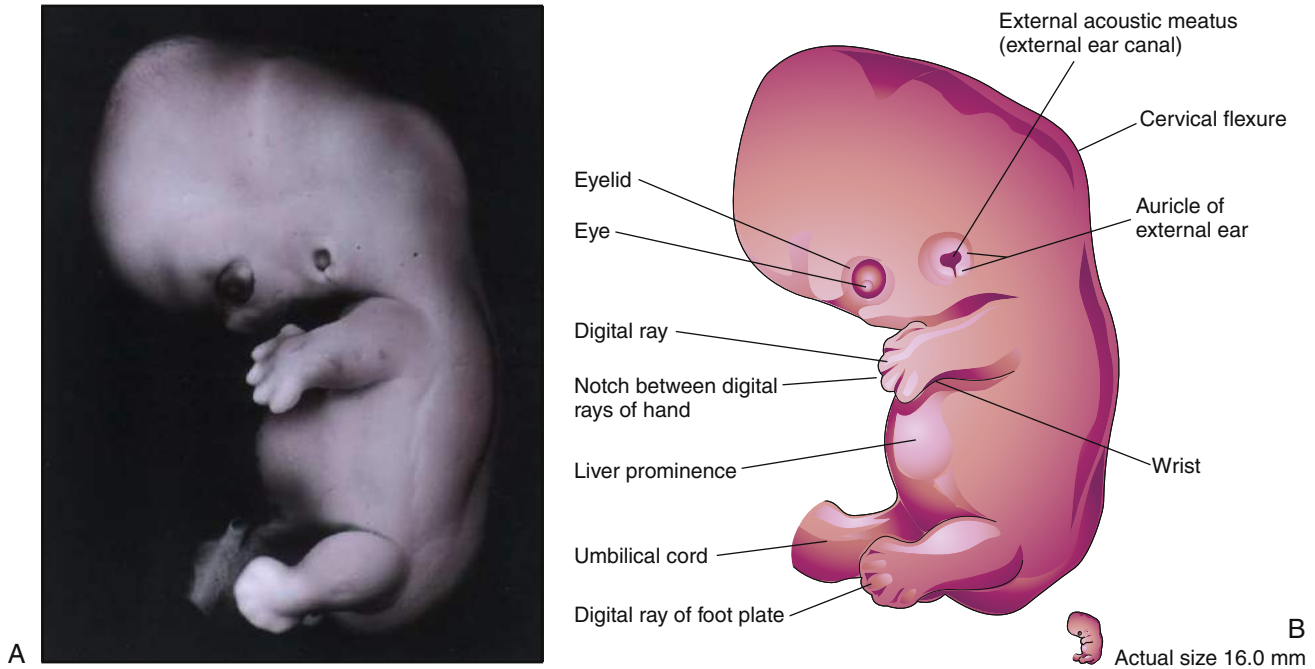

contained in the chapters in this book that focus on these organ systems; for example, Chapter 35 contains a description of the development of the gastrointestinal tract.

#### First Month

Rapid growth, morphogenesis, and cell differentiation occur early in development of the human embryo. By 2.5 weeks of development, the notochord and neural plate are formed; these structures eventually give rise to the central nervous system. In addition, the tissue that will form the heart has differentiated. By the end of the first month, an S-shaped heart beats about 60 times per minute, and the three primary vesicles of the brain have formed.

#### Second Month

Until the sixth week of gestation, the gonads in both genders are *bipotential*, which means that the gonads present in the embryo may become either testes or ovaries. Beginning about the seventh week, the so-called indifferent gonad begins to develop into either a male or a female derivative.<sup>15</sup> Recent research has demonstrated that *SRY* (sex-determining region of the Y chromosome) is the gene that influences the indifferent gonad to organize into a testis.<sup>15</sup> In a genetically female embryo, the gonad organizes into an ovary under the influence of one or more ovary-determining genes, which have not yet been well characterized. The cortex of the gonad accumulates nests of cells that differentiate into ovarian follicles, each containing a primary oocyte.

**FIGURE 32-11** Human embryo in the seventh week of development. (A, From Moore KL et al: *Color atlas of clinical embryology*, ed 2, Philadelphia, 2000, Saunders. B, From Moore KL, Persaud TVN, Torchia MG: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders, p 85.)

The wolffian ducts, the primordial structures that are precursors to the male internal reproductive organs, begin to disappear, and the müllerian ducts, the structures that will develop into the female internal reproductive organs, become dominant.<sup>16</sup>

The external genitalia of both the male and the female are identical until the eighth week of gestation. Like the gonads, the genitalia are bipotential until this time, with the capability of developing into organs of either gender. In a genetically male embryo, dihydrotestosterone, a metabolite of testosterone, binds to androgen receptors in the external genitalia and effects the differentiation of these structures into the male external genitalia. Without the influence of dihydrotestosterone, the bipotential external genitalia will spontaneously develop into female external genitalia.<sup>15</sup>

Figure 32-11 shows an embryo on day 49. All of the organs continue to develop during the second month, and the embryo becomes capable of movement. The major blood vessels assume their final positions, and the heart assumes its final shape. The brain begins to transmit impulses to regulate function of the organ systems, and a few reflexes are now present. At the end of the second month, the rudiments of all organs are present and the embryo is referred to as a *fetus*.<sup>7</sup>

### Third Month

During the third month, the ears and eyes approach their final positions, and some of the bones become distinct. The fetus performs breathing movements consisting of moving amniotic fluid in and out of the lungs and can carry on sucking movements. By the end of the third month, the fetus is almost 56 mm in length and weighs about 14 g (Figure 32-12).

### Second Trimester

A *trimester* refers to a period of 3 months during pregnancy. During the second trimester, or months 4 to 6 of development, the fetus achieves independent mobility and can move freely through the amniotic

cavity. The heartbeat of the fetus is now audible through a stethoscope and averages 150 beats per minute. By the fifth month of development, the fetus measures 250 mm (10 inches) in length, which is half its total length at birth.<sup>14</sup> Figure 32-13 shows a fetus in the second trimester at 4 months of development.

### Third Trimester

By far the greatest growth of the fetus occurs during the third trimester. The weight of the fetus almost doubles during the last 2 months.<sup>12</sup> In addition, final differentiation of tissues and organs takes place. Survival of infants born prematurely during this time has increased markedly in the past few years because of an enhanced ability to sustain vital functions such as respiration and regulation of body temperature in neonatal intensive care settings.

### Parturition

**Parturition** refers to the process by which the infant is born. Toward the end of pregnancy, the uterus becomes progressively more excitable until it begins strong rhythmic contractions that ultimately expel the infant.<sup>10</sup> At the present time, the exact cause of the increased uterine activity remains unknown. However, two sets of effects have been suggested as contributing to the increased excitability of uterine musculature at this time: progressive hormonal changes and progressive mechanical changes.<sup>12,17</sup>

### Hormonal Changes

During the latter part of pregnancy, large amounts of estrogen, which has a definite tendency to increase uterine contractility, are secreted. Concurrent with this enhanced estrogen release, the secretion of progesterone, which inhibits uterine contractility, remains constant or may decrease slightly. Thus it is hypothesized that the increased ratio of estrogen to progesterone secretion in the latter part of pregnancy may promote the increased contractility of the uterus.<sup>12</sup>

**FIGURE 32-12** Photograph of the human fetus at 11 weeks of development. (From Moore KL, Persaud TVN, Torchia MG: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders, p 97. Courtesy Professor Jean Hay [Retired], Department of Anatomy, University of Manitoba, Winnipeg, Canada.)

**Oxytocin** is a hormone secreted by the posterior pituitary gland that specifically causes uterine contraction and is thought to have a major role in promoting increased uterine contractility during parturition. The rate of oxytocin secretion is considerably increased at the time of labor (see the following discussion of Mechanical Changes), and the uterus displays increased responsiveness to a given dose of oxytocin at this time.<sup>12,17</sup>

### Mechanical Changes

Stretching smooth muscle organs increases their contractility; in addition, intermittent stretching of smooth muscle can elicit contraction. Thus it is hypothesized that the stretch or irritation of the fetal head against the cervix begins a reflex action that causes the uterus to contract. As the cycle of stretching and contraction is repeated again and again, increased contractions result. In addition, stretching of the cervix causes the release of oxytocin from the posterior pituitary. Oxytocin then stimulates additional uterine contractions, thus initiating another positive feedback cycle of stretching and contraction.<sup>17-19</sup>

### Response of the Mother's Body to Pregnancy

The presence of a developing fetus in the uterus creates an extra physiologic load for the pregnant woman, with resulting effects on her basal metabolism and specific organ systems. Normal physiologic responses

to pregnancy are described here; complications of pregnancy are discussed in Chapter 33.

### Metabolism During Pregnancy

As a result of increased secretion of many hormones, including thyroxine, adrenocortical hormones, and the sex hormones, the basal metabolic rate increases by about 15% during the latter half of pregnancy.<sup>12</sup> This increase in metabolism results in alterations in many organ systems, including the circulatory, respiratory, and urinary systems.

### Changes in the Female Reproductive Organs

The hormones secreted during pregnancy, either by the placenta or by the endocrine glands, directly promote alterations in body structures. In particular, the organs of the female reproductive tract increase markedly in size, with the uterus increasing from 30 to 1100 g and the breasts approximately doubling in size. Concurrently, the vagina enlarges with a widening of the vaginal introitus.

### Changes in the Circulatory System

In the latter stages of pregnancy, about 625 ml of blood flows through the maternal circulation of the placenta each minute. This factor, along with a general increase in metabolism, causes an increase in maternal cardiac output to 30% to 40% above normal by week 27 of pregnancy. However, for reasons not understood at the present time, cardiac output decreases to a little above normal during the last 8 weeks of pregnancy, although the high uterine blood flow continues.<sup>12</sup> As shown in Figure 32-14, an increase in maternal blood volume occurs mainly during the latter half of pregnancy. This increase is mainly due to hormonal factors. Both aldosterone and estrogens, which are greatly increased in pregnancy, promote increased fluid retention by the kidneys. In addition, bone marrow increases its activity to produce an excess of red blood cells to accompany the excess vascular volume. At the time of parturition, the mother has an additional 1 to 2 extra liters of blood in her circulatory system.<sup>12</sup>

### Changes in the Respiratory System

The increased basal metabolic rate and size of the pregnant woman result in an increase in oxygen utilization, with utilization of oxygen being 20% above normal at the time of birth. Concurrently, a commensurate amount of carbon dioxide is formed. In addition, the growing uterus is pressing upward against the abdominal organs, which in turn press against the diaphragm and cause a decrease in diaphragmatic excursion. The net result of these changes is an increase in minute ventilation of approximately 50% and a decrease in arterial  $P_{CO_2}$  to slightly below normal.<sup>12</sup>

### Changes in the Urinary System

Because of an increased load of excretory products, the rate of urine formation in pregnancy is usually slightly increased. In addition, other alterations in urinary function occur. Renal tubule reabsorption of sodium, chloride, and water is increased as a result of increased production of steroidal hormones by the placenta and adrenal cortex. Concurrently, the glomerular filtration rate often increases by as much as 50%, a change that serves to increase the rate of water and electrolyte loss in the urine. These two events tend to balance each other out, with the result that only a moderate excess of water and salt accumulation occurs under normal circumstances.<sup>10</sup> However, in the condition of toxemia of pregnancy, excess water and salt accumulation may occur with life-threatening consequences.

**FIGURE 32-13** **A**, Side view of human fetus at 17 weeks. **B**, Frontal view of 17-week fetus. (**A**, From Moore KL et al: *Color atlas of clinical embryology*, ed 2, Philadelphia, 2000, Saunders. **B**, Courtesy Dr. Robert Jordan, St. Georges University Medical School, Grenada.)

**FIGURE 32-14** Effect of pregnancy on the mother's blood volume. (From Guyton AC, Hall JE: *Textbook of medical physiology*, ed 12, St Louis, 2011, Elsevier.)

### Weight Gain and Nutrition During Pregnancy

The average weight gain during pregnancy is about 24 lb, with most of this gain occurring during the last two trimesters. Approximately 7 lb of this weight gain is the fetus; 4 lb of the increased weight is amniotic fluid, placenta, and fetal membranes; 2 lb represents an increase in uterine tissue; and another 2 lb of the weight gain is an increase in breast tissue. Thus an average 9-lb increase in weight occurs in the remainder of the woman's body. Approximately 6 lb of fluid may be excreted during the days following birth, after loss of the fluid-retaining hormones of the placenta.<sup>12</sup>

Appetite may be greatly increased during the latter part of pregnancy, in part because of fetal removal of food substrates from the mother's blood and partly because of hormonal factors. The developing fetus assumes priority in regard to many of the nutritional substrates of the mother's body fluids and will continue to grow even when maternal nutrition is inadequate. However, although fetal length may increase normally in the absence of adequate maternal nutrition, fetal weight will be considerably decreased, and abnormal

bone formation and decreased size of many bodily organs of the fetus may result.<sup>12</sup>

If the intake of nutritional elements during pregnancy is inadequate, a number of deficiencies can be present in the mother. In particular, deficiencies of calcium, phosphates, iron, and vitamins may be present. As an example, approximately 375 mg of iron is needed by the fetus to form its blood, and an additional 600 mg is needed by the mother to form her own extra blood supply. Because the normal store of nonhemoglobin iron in the mother at the beginning of pregnancy is often about 100 mg and seldom greater than 700 mg, anemia will develop in a pregnant woman without sufficient iron intake in her food.<sup>12</sup> Important also is adequate folic acid intake, which has been shown to help prevent neural tube defects.<sup>20,21</sup>

### KEY POINTS

- At about the seventh day after fertilization, the embryo attaches to the uterine lining. The placenta is the fetal lifeline that provides nutrients and oxygen and eliminates wastes. The placenta also secretes hCG, which is important in maintaining pregnancy.
- Normal gestation is about 9 months. Each 3-month period is called a trimester. By the end of the first trimester, fetal structures and organ systems are present. During the second and third trimesters, the fetus grows in size and weight.
- Near the end of the third trimester, an increase in estrogen production and mechanical stretching of the uterus and cervix are thought to induce parturition. Cervical stretching stimulates the release of oxytocin from the pituitary gland. Oxytocin stimulates uterine contractions.
- Pregnancy is associated with many physiologic changes, including an increased basal metabolic rate (15%), increased cardiac output (30% to 40%) and blood volume (1 to 2 L), increased oxygen consumption (20%) and minute ventilation (50%), increased glomerular filtration rate and tubular reabsorption of sodium and water, and increased body weight (24 lb).

**MENOPAUSE**

Although **menopause** is defined specifically as the last menstrual period in a woman’s reproductive life, the term is often used to denote the entire period of years before and after this event in which the function of the ovaries is in transition. The terms *climacteric* and *perimenopause* are used in the health care literature to describe this transitional period. At about 45 to 52 years of age the supply of ovarian follicles declines, with the majority becoming atretic or degenerated. With the depletion of ovarian follicles, secretion of estrogen and progesterone by the ovaries declines, and the menstrual cycle becomes irregular. When too little estrogen is secreted to cause endometrial growth, menstrual periods stop permanently.<sup>12</sup>

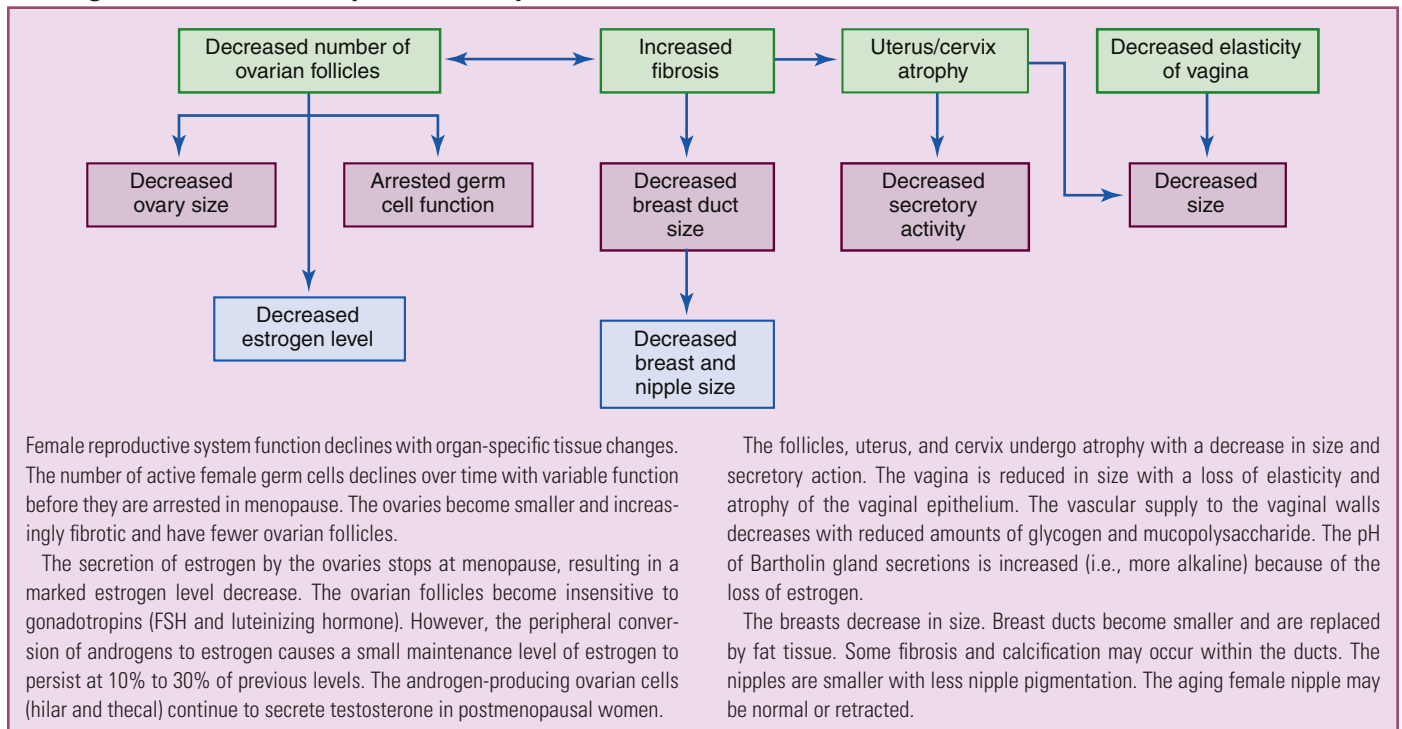

The decline in ovarian hormone production that occurs in the perimenopausal period causes important physiologic changes in a woman’s body. The decline in plasma estrogen levels may result in a number of distressing symptoms, although some women experience no symptoms during this time. Hot flashes, described by women as an unpleasant sensation of sudden warmth sweeping upward over the abdomen, chest, neck, and face, are experienced by nearly 75% of postmenopausal women. Although the precise cause of hot flashes is unknown, it is thought that decreased estrogen levels have an effect on the temperature-regulating center in the hypothalamus. Hot flashes are often accompanied by other symptoms of autonomic nervous system instability such as tachycardia, palpitations, and feelings of faintness. Other distressing symptoms, including pain and stiffness in the joints, sleep pattern disturbances, and changes in gastrointestinal

function, have been noted by women in the perimenopausal period. These symptoms are presently the focus of many nursing research projects examining the health of aging women. Although such psychological symptoms as increased nervousness have been reported in the medical literature as being related to hormonal imbalance in menopause, it has been established that psychological symptoms are not directly related to estrogen deficiency.<sup>22</sup> There is an increasing awareness of the importance of role of culture and other social factors in the understanding of how women view and experience menopause.<sup>23</sup>

With the decline in estrogen level associated with perimenopause, many structural changes occur in various organs. These changes are summarized in Geriatric Considerations: Changes in the Female Reproductive System. The epidermis of the skin becomes thinner and less elastic throughout the entire body. The breasts may decrease in size; the labia may also lose their underlying fat and become thinner.<sup>24</sup> The vaginal epithelium may become thin and atrophied, with the result that sexual intercourse may be painful. The decline in estrogen level also leads to osteoporosis and decreased bone density, particularly in white women, with resulting bone fractures. Exercise and supplemental calcium and vitamin D are recommended for postmenopausal women to prevent accelerated bone loss.<sup>25</sup> At present, most authorities recommend estrogen therapy during the perimenopausal period only to prevent and relieve symptoms such as hot flashes and vaginal atrophy.<sup>26</sup> This is due to strong evidence showing that supplemental estrogen and progestin therapy has been associated with an increased risk of breast cancer and cardiovascular disease.<sup>27,28</sup> Newer treatments that have been developed for

**GERIATRIC CONSIDERATIONS**

**Changes in the Female Reproductive System**

osteoporosis include bisphosphonates, calcitonin nasal spray, and raloxifene.<sup>29,30</sup> Work continues on the development of selective estrogen receptor modulators that may retain some of the beneficial effects of estrogen while avoiding the negative effects.<sup>31</sup> Women in perimenopause may wish to discuss the risks and potential benefits of hormone replacement therapy and other menopausal therapies with their health care providers before making an informed decision about these medications.

### KEY POINTS

- Menopause begins at 45 to 52 years of age and denotes the cessation of menstruation. A declining supply of ovarian follicles with decreased estrogen and progesterone production results in irregular menses and then complete cessation of menstruation.
- Declines in estrogen production are associated with hot flashes, tachycardia, palpitations, faintness, joint pain, and sleep disturbances. Structural changes associated with menopause include osteoporosis, thinning of the skin, and atrophy of the vaginal structures and breast tissue.

## SUMMARY

This chapter has described the major processes related to the human female reproductive tract, including the menstrual cycle, pregnancy, lactation, and menopause. In approaching this material, the reader must view the information presented within the current context of social change in which women are taking an active role in meeting their health care needs. In addition, recent research in the area of reproductive endocrinology has yielded a rapidly expanding understanding of the reproductive structures and their function.

The female reproductive structures are a complex set of organs with multiple, integrated functions. Careful review of the section on reproductive structures, including their embryologic development, will assist the reader in understanding the various alterations in these structures that occur throughout a woman's life. Although the hormonal and structural changes occurring in the female reproductive organs may at first seem overwhelmingly complex to the student, some

basic concepts will help in organizing this material. First, the menstrual cycle has two significant results: production of an ovum and preparation of the uterus for implantation of the fertilized ovum. Second, the fertilized ovum contains the entire encoded genetic instructions to produce a unique human individual. Third, pregnancy consists of three basic developmental processes—growth, morphogenesis, and cellular differentiation—to bring about this transformation, which will also result in multiple changes in the body of the mother. The breast, with its function of lactation, is also a component of the reproductive system and is subject to alterations throughout a woman's life span. Finally, menopause is not a discrete event but rather a process during which the supply of ovarian follicles declines. A review of these concepts will prepare the student for a better understanding of women's health concerns and provide a basis for approaching the next chapter, which considers alterations in reproductive functioning.

## CHAPTER 33 Alterations in Female Genital and Reproductive Function

The complex functioning of the female reproductive system described in Chapter 32 may be subject to alterations in structure and function throughout a woman's life that can have far-reaching effects on her health and well-being. This chapter is a survey of these alterations and describes the pathophysiologic basis of the most common disorders of the female reproductive system. In addition, current therapeutics for these alterations, including pharmacologic therapy, will be summarized. The information presented here is an introduction to these complex areas, and the reader may wish to consult in-depth gynecology and obstetrics texts for more detailed information.

Perhaps no other function of the human body is so closely linked to psychological, social, and spiritual concerns as reproductive function. Any alteration in reproductive status (or the perceived threat of such an alteration) may have profound effects on an individual. Clinicians caring for women experiencing alterations in functioning of the reproductive system should bear in mind the profundity of such alterations for the individual woman and must also maintain an awareness of the context in which women seek help for such problems. A clinical approach in which information is freely shared between caregiver and client and in which mutual decision making is an integral part of the therapeutic environment is a necessary component of care for women seeking help for reproductive concerns. Previous clinical approaches in which women's concerns were labeled as unimportant or merely psychogenic often resulted in anger, frustration with health

care providers, and withdrawal from the health care delivery system. Women consumers of health care are now seeking active involvement in their own care, and clinicians who care for women experiencing the alterations described in this chapter need to approach women's health concerns with sensitivity and openness.

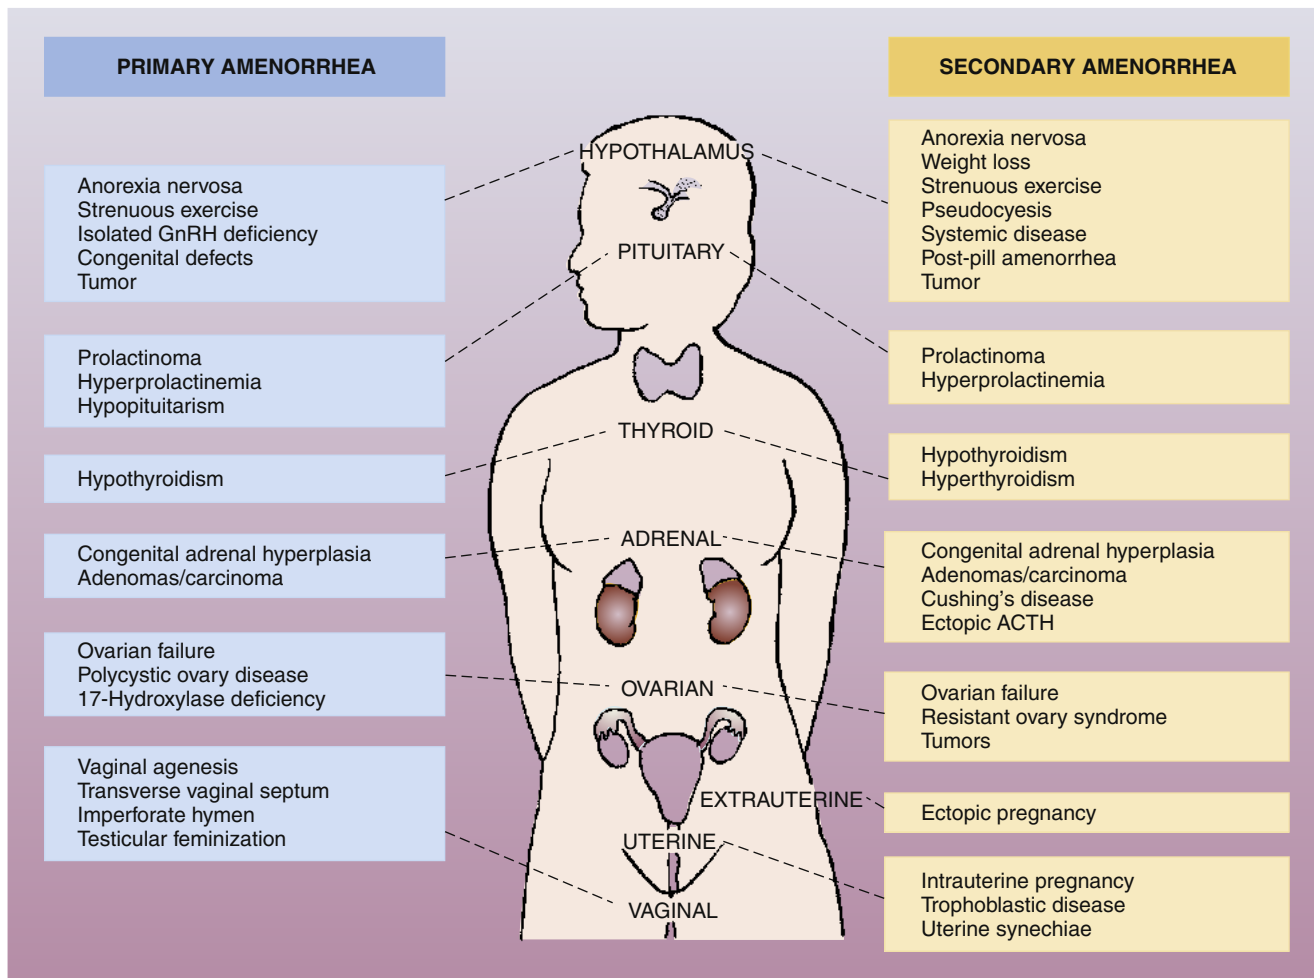

### MENSTRUAL DISORDERS

Alterations in the normal functioning of the menstrual cycle include amenorrhea (no menses), abnormal uterine bleeding patterns, and dysmenorrhea (painful menstruation). Although many pathologic conditions can cause these alterations, an obvious cause is often not found.

#### Amenorrhea

**Etiology and pathogenesis.** Amenorrhea is the absence or suppression of menstruation in a female age 16 years or older; it occurs if a woman misses three or more consecutive periods. Amenorrhea is categorized as either primary or secondary. Primary amenorrhea is the failure to begin menses by the age of 16 years. Secondary amenorrhea is the cessation of established, regular menstruation for 6 months or longer. **Figure 33-1** shows causes of primary and secondary amenorrhea.

Amenorrhea is normal before menarche (the first menstrual period at the time of puberty), after menopause, and during pregnancy and

**FIGURE 33-1** Causes of amenorrhea. ACTH, Adrenocorticotropic hormone; GnRH, gonadotropin-releasing hormone. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 915.)

lactation.<sup>1</sup> At other times, it is considered pathologic and may result from a wide range of pathophysiologic causes (see Figure 33-1). In the majority of cases, amenorrhea is due to an abnormal pattern of hormonal functioning that interrupts the normal sequence of events in which the endometrial tissue lining the uterus proliferates and then is sloughed. The endometrial tissue must be stimulated and regulated by the correct quantity and sequence of the female sex hormones estrogen and progesterone and the gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH). As described in Chapter 32, the menstrual cycle is dependent on the sequential changes in estrogen and progesterone levels. The initial rise in LH and FSH levels in the menstrual cycle occurs in response to a decline in estrogen and progesterone levels; estrogen levels then rise again in response to actions of the gonadotropic hormones, and the endometrium proliferates again in response to estrogen secretion. Thus events that prevent estrogen production, interfere with the normal fluctuations in estrogen levels, or block the action of estrogen on the endometrium will result in abnormal or absent menstrual flow.<sup>2,3</sup> Such events may include physical or emotional stress, which can interfere with normal production of the gonadotropic hormones and alter the pattern of estrogen functioning. In addition, ovarian, adrenal, or pituitary tumors may interfere with the normal production of female sex hormones or LH and FSH. Neoplasms of the ovaries or adrenal and pituitary glands may result in excess or deficient production of these hormones, with a consequent interruption in normal menstrual flow.

**Treatment.** Therapeutic strategies for amenorrhea are directed to correcting the cause of the interruption in hormonal functioning and may include the use of hormonal supplementation to reinstate a normal sequence of events in the menstrual cycle. If amenorrhea is the result of a neoplastic process, surgery may be indicated for tumor removal.

### Abnormal Uterine Bleeding Patterns

Irregular or excessive bleeding from the uterus is one of the most common alterations in the female reproductive system. Uterine bleeding that varies from a woman's normal pattern either in quantity or in frequency may occur at any age and for a variety of reasons.

**Etiology, clinical manifestations, and treatment.** The most common alterations in uterine bleeding patterns and their causes are described here. **Metrorrhagia**, or bleeding between menstrual periods, usually results from slight physiologic bleeding from the endometrium during ovulation but may also result from other causes such as uterine malignancy, cervical erosions, and endometrial polyps or as a side effect of estrogen therapy.<sup>1</sup> **Hypomenorrhea**, or a deficient amount of menstrual flow, results from endocrine or systemic disorders that may interfere with proper functioning of the hormones in the menstrual cycle, or it may be due to partial obstruction of menstrual flow by the hymen or a narrowing of the cervical os. **Oligomenorrhea**, or infrequent menstruation, usually reflects failure to ovulate because of an endocrine or systemic disorder with accompanying inappropriate hormonal function. Similarly, **polymenorrhea**, an increased frequency of menstruation, may be associated with ovulation and may be caused by endocrine or systemic factors. **Menorrhagia**, an often debilitating increase in the amount or duration of menstrual bleeding, usually results from lesions of the female reproductive organs such as uterine leiomyomas, endometrial polyps, and adenomyosis. It is often managed with surgery, oral contraceptives, and/or antiprostaglandins. More recently, a progestin-containing intrauterine device has shown promise in reducing menorrhagia, dysmenorrhea, and anemia.<sup>4,5</sup>

The term **dysfunctional uterine bleeding** is used to describe abnormal endometrial bleeding not associated with tumor, inflammation, pregnancy, trauma, or hormonal effects. Dysfunctional uterine

bleeding is most common around the time of menarche and menopause and not as common in women before menopause.<sup>6</sup> In adolescents, dysfunctional uterine bleeding is most often due to immaturity in functioning of the pituitary and ovary, which have not yet properly orchestrated their activities.<sup>7</sup> Thus an imbalance may be present in the ratio of estrogen to progesterone. Absent or diminished levels of progesterone will result in a thick and extremely vascular endometrium that lacks structural support. As a result of this fragile structure, spontaneous and superficial hemorrhage occurs randomly throughout the endometrium. In addition, the blood vessels in the endometrium fail to constrict to limit the extent and duration of bleeding.<sup>7</sup> Uterine bleeding that is abnormal in both quantity and frequency can therefore occur in a noncyclic pattern.

In perimenopausal women, dysfunctional uterine bleeding may be the result of progressive degeneration and failure of the ovary to produce estrogen. As the number of ovarian follicles diminishes, the production of estrogen by the ovary becomes unpredictable, and the secretion of LH and FSH may also assume an unpredictable pattern. As in adolescents with dysfunctional uterine bleeding, diminished or absent production of progesterone may result in unopposed stimulation of the endometrium by estrogen, with subsequent unpredictable bleeding from a fragile endometrium.<sup>6,7</sup>

### Dysmenorrhea

**Dysmenorrhea** is menstruation that is painful enough to limit normal activity or to cause a woman to seek health care. Dysmenorrhea is a widespread phenomenon that affects many women across the reproductive years, including girls of high school age through perimenopausal women. Although symptoms of dysmenorrhea tend to decrease with age, the traditional notion that childbirth permanently decreases symptoms is unfounded. In addition, the contention that women with dysmenorrhea tend to be neurotic has been refuted in well-designed psychiatric research studies.<sup>7</sup> Recent research into the physiologic process of uterine contractions has enhanced our understanding of the causes of dysmenorrhea and has thus resulted in better treatment.

**Etiology and clinical manifestations.** Dysmenorrhea is usually classified as primary (not related to any identifiable pathologic condition) or secondary (related to an underlying pathologic condition). The cramps that occur with primary dysmenorrhea are usually located in the suprapubic region and are sharp in quality. The pain may radiate to the inner aspect of the thighs and lower sacral area and may be accompanied by nausea, diarrhea, and headache.<sup>2</sup> Primary dysmenorrhea usually develops 1 or 2 years after menarche, when ovulatory cycles are established. Under the influence of progesterone, increased amounts of prostaglandins, potent hormone-like unsaturated fatty acids, are released from the endometrium. Prostaglandins have significant effects on smooth muscle and vasomotor tone; when released from the endometrium, prostaglandins promote uterine contractions and ischemia of the endometrial capillaries and thereby cause the cramping pain of dysmenorrhea.<sup>8,9</sup>

Secondary dysmenorrhea is characterized more often by dull pain that may increase with age. It is associated with pelvic disorders such as endometriosis, leiomyomas, or pelvic adhesions.<sup>8,9</sup>

**Treatment.** Recent therapeutic strategies for the management of primary dysmenorrhea have focused on the phenomenon of prostaglandin-induced enhanced uterine contractility. The use of prostaglandin synthetase inhibitors such as ibuprofen and naproxen, which inhibit the formation of prostaglandins, has been very effective in many women experiencing dysmenorrhea.<sup>10</sup> Other approaches that use steroid hormones, such as progestins or combined high-progestin/low-estrogen oral contraceptives, have also been advocated. The rationale is that production of the high menstrual levels of prostaglandins needed

to produce dysmenorrhea requires high levels of estrogen without progesterone in the proliferative phase of the menstrual cycle. Progestin administration therefore inhibits the production of prostaglandins and relieves the symptoms of dysmenorrhea.<sup>7</sup> However, the use of steroid hormones may involve significant risks, which the individual client must weigh against the benefits of such therapy.

Therapeutic strategies for secondary dysmenorrhea may involve diagnostic operative procedures such as laparoscopy, as well as medical and surgical therapy for the underlying condition.<sup>9</sup>

**KEY POINTS**

- Amenorrhea, the absence of menstruation, is most commonly due to hormonal disturbances. Stress and neoplasms (ovarian, adrenal, or pituitary tumors) may interfere with the normal patterns of hormone secretion. Treatment is aimed at the underlying cause of the hormonal imbalance.
- Irregular or excessive uterine bleeding is a common problem. Metrorrhagia is bleeding between periods, hypomenorrhea is reduced menstrual flow, oligomenorrhea is infrequent menstruation, polymenorrhea is an increased frequency of menstruation, and menorrhagia is prolonged and heavy bleeding during menstruation. These disorders may be associated with hormonal imbalances or primary lesions of the reproductive tract.
- Dysfunctional uterine bleeding is common at menarche and menopause and is due to irregular secretion of reproductive hormones. Other causes of abnormal bleeding, such as tumor, trauma, inflammation, and endocrine diseases, are ruled out before a diagnosis of dysfunctional uterine bleeding is made.
- Dysmenorrhea is painful menstruation, generally described as sharp suprapubic cramping severe enough to limit activity. Dysmenorrhea may be treated with prostaglandin inhibitors. Dysmenorrhea secondary to pelvic disorders (endometriosis, adhesions) generally has a dull quality and may increase with age.

**ALTERATIONS IN UTERINE POSITION AND PELVIC SUPPORT**

Alterations in uterine position and pelvic support may occur anytime during a woman’s reproductive years. The major support for the uterus and upper part of the vagina is provided by the thickenings of the endopelvic fascia known as the *cardinal ligaments*. Although tearing of the cardinal ligaments during labor and delivery is rare, they can be stretched abnormally during a difficult or prolonged delivery

and subsequently fail to support the pelvic organs adequately.<sup>7</sup> In addition, congenital defects in the muscles of the pelvic floor may promote alterations in position of the uterus and other pelvic structures. The two most common alterations in uterine position are **uterine prolapse** and **retrodisplacement** of the uterus. Other commonly occurring alterations resulting from a weakening of the vaginal and pelvic floor musculature are **cystocele** and **rectocele**.

**Uterine Prolapse**

**Etiology.** The axis of the uterus normally forms an acute angle with the axis of the vagina. This anatomic feature itself tends to prevent a prolapse, or sinking, of the uterus from its normal position. Descent of the uterus occurs when supporting structures, such as the uterosacral ligaments and the cardinal ligaments, relax and allow the relationship of the uterus to the vaginal axis to be altered. This relaxation permits the cervix to sag downward into the vagina. If the support of the vaginal wall is also compromised, the pressure of the abdominal organs on the uterus will gradually force it downward through the vagina into the introitus.<sup>11</sup> Uterine prolapse may occur at any age. In female infants and in women who have never given birth, congenital defects in the basic integrity of the pelvic supporting structures are usually responsible. Trauma to the ligaments during childbirth is the cause of uterine prolapse in women who have given birth, particularly if multiple deliveries have occurred. Uterine prolapse is classified as first-degree, second-degree, or third-degree according to the level to which the uterus has descended (Figure 33-2). In first-degree prolapse, the uterus is approximately halfway between the vaginal introitus and the level of the ischial spines. In second-degree prolapse, the end of the cervix has begun to protrude through the introitus. In third-degree or complete prolapse, the body of the uterus is outside the vaginal introitus. Figure 33-3 shows a third-degree, or complete, uterine prolapse.

**Clinical manifestations.** The symptoms of uterine prolapse depend on the degree of severity of prolapse. The woman may become increasingly aware of a sensation of bearing down and discomfort in the vagina. If the prolapse has advanced to the second or third degree, she may note discomfort while walking or sitting and have difficulty urinating. In addition, as the end of the cervix begins to protrude outside the body, it may be subject to trauma from friction and ulceration. Bleeding and ulceration of the cervix may be present.

**Treatment.** Uterine prolapse is one of the most common reasons for hysterectomy, usually from the vaginal approach.<sup>12</sup> In patients who are at poor risk for surgery or who choose not to have a hysterectomy, a pessary, which is a small supportive device, is inserted to hold the uterus in place.<sup>11</sup>

**FIGURE 33-2** Degrees of uterine prolapse. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 931.)

### Retrodisplacement of the Uterus

The term **retrodisplacement** refers to situations in which the body of the uterus is displaced from its usual location overlying the bladder to a position in the posterior of the pelvis.<sup>13</sup> As shown in Figure 33-4, the

**FIGURE 33-3** Complete uterine prolapse. (From Parsons L, Sommers SC: *Gynecology*, ed 2, Philadelphia, 1978, Saunders, p 1443.)

uterus may be in one of five positions: anteverted, midposition, ante-flexed, retroflexed, or retroverted.

**Etiology and clinical manifestations.** Retrodisplacement can be detected in 20% to 30% of all women.<sup>14</sup> It may be a normal variation and therefore be present throughout a woman's entire life, or it may develop after childbirth when the supporting structures are injured.

In many women, no symptoms occur from uterine retrodisplacement. In some women, symptoms of pelvic pain or pressure, dysmenorrhea, and dyspareunia (painful intercourse) may be present. In addition, infertility has been associated with retrodisplacement.<sup>7</sup>

**Treatment.** If the woman has no symptoms, no treatment is indicated. The use of a pessary to support the uterus in a normal position may relieve the symptoms, but surgical correction is sometimes indicated when symptoms are severe.<sup>7</sup> If surgery is indicated, less invasive, laparoscopic surgical procedures are often preferred.<sup>13,14</sup>

### Cystocele

**Etiology.** A *cystocele* is a protrusion of a portion of the urinary bladder into the anterior of the vagina at a weakened part of the vaginal musculature (Figure 33-5, A). The defect in the vaginal wall is usually caused by injury during childbirth or surgery but may also result from the aging process or develop as an inherent weakness. Other predisposing factors include obesity and a history of lifting heavy objects. The pressure created by this protrusion causes the anterior vaginal wall to bulge in a downward direction.

Anteflexed

Retroflexed

Retroverted

**FIGURE 33-4** Various positions of the uterus. Note that the classifications describe the position of the long axis of the uterus with respect to the long axis of the body. (From Jarvis C: *Physical examination and health assessment*, ed 6, St Louis, 2012, Elsevier, p 745.)

**Clinical manifestations and treatment.** A wide range of symptoms may be present, depending on the degree of severity of the cystocele. A mild degree of protrusion of the bladder may result in no symptoms. In moderate to severe cases, a sensation of pressure can be felt in the vagina, along with dysuria, incontinence, and back pain. Fullness at the vaginal opening may be observed, as may a soft, reducible mucosal mass bulging into the anterior of the vaginal introitus.

Surgical repair of the vagina is done to correct the cystocele and reestablish support of the anterior vaginal wall. The bladder is restored to a normal position by reinforcement of the weakened portion of the anterior vaginal wall. Prosthetic mesh may also be inserted to further support the bladder during the repair of the cystocele.

**Rectocele**

**Etiology.** A **rectocele** (also called *proctocele*) is a protrusion of the anterior rectal wall into the posterior of the vagina at a weakened part of the vaginal musculature (see Figure 33-5, B). As for a cystocele, the defect in the vaginal wall is usually caused by injury during childbirth or surgery but may also occur with aging or arise as an inherent weakness. Other predisposing factors for a rectocele include multiparity, obesity, and postmenopausal status. The rectocele forms a bulging mass beneath the posterior vaginal mucosa and pushes downward into the lower vaginal canal. Gradually, the rectum may be torn from its

fascial and muscular attachments to the pelvic wall. The levator ani muscles may also become stretched or torn.

**Clinical manifestations and treatment.** A wide range of symptoms may be present, depending on the degree of severity of the rectocele. The patient may report a history of difficulty in bowel evacuation and may have experienced chronic constipation with laxative and enema dependency. A feeling of pressure may also be reported, along with painful sexual intercourse. Physical examination reveals a mass bulging into the posterior of the vaginal introitus.<sup>5</sup>

Surgical repair of the vagina is done to correct the rectocele and reestablish support of the posterior vaginal wall. The rectum is restored to its normal location, and the levator ani muscles are realigned in proper position.

**KEY POINTS**

- Uterine prolapse occurs when supporting pelvic structures relax and the cervix sags downward into the vagina. Congenital defects, pregnancy, and childbirth are the usual contributing factors. Prolapse may be accompanied by a sensation of pelvic fullness and vaginal discomfort.
- Retrodisplacement of the uterus is common (20% to 30% of women) and may be congenital or due to pregnancy and childbirth. The body of the uterus is flexed or rotated into the posterior of the pelvis, which sometimes leads to varied symptoms of pelvic pain or pressure, dysmenorrhea, and dyspareunia.
- A cystocele may result from weakness in the vaginal musculature that allows the urinary bladder to protrude into the anterior of the vagina. Contributing factors include childbirth, surgery, aging, obesity, and heavy lifting. Vaginal pressure, dysuria, and back pain may be present.
- A rectocele may result from weakness in the posterior vaginal musculature that allows the rectum to protrude into the vagina. Contributing factors are similar to those for cystocele. Symptoms include constipation, painful bowel evacuation, and painful intercourse.

**FIGURE 33-5** **A**, Cystocele. Note the bulging of the anterior vaginal wall. The urinary bladder is displaced downward. The cystocele pushes the anterior wall downward into the vagina. **B**, Rectocele. Note the bulging of the posterior vaginal wall. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 930.)

**INFLAMMATION AND INFECTION OF THE FEMALE REPRODUCTIVE TRACT**

Inflammatory and infectious processes of the female reproductive tract may have effects that range from discomfort to life-threatening situations. Because the infectious agents responsible for inflammation and infection of the female genital tract may be sexually transmitted, some overlap in the discussion of these processes and sexually transmitted diseases is necessary. This chapter will describe the two principal inflammatory and infectious processes of the upper and lower female reproductive tract: pelvic inflammatory disease (PID) and vulvovaginitis. The reader may wish to refer to Chapter 34 for additional information on sexually transmitted infections.

**Pelvic Inflammatory Disease**

**Pelvic inflammatory disease** (PID) is any acute, subacute, recurrent, or chronic infection of the oviducts and ovaries with involvement of the adjacent reproductive organs (Figure 33-6). It includes inflammation of the cervix (cervicitis), uterus (endometritis), oviducts (salpingitis), and ovaries (oophoritis). When the connective tissue underlying these structures between the broad ligaments is also involved, the condition is called *parametritis*.<sup>1</sup>

Hospitalizations for PID have declined between 2001 and 2009.<sup>15,16</sup> The CDC reports approximately 113,000 initial physician visits for PID in 2010.<sup>15,16</sup> Significant reproductive health problems may occur as a result of PID. A substantial number of women with a history of PID eventually experience one or more long-term health problems.

**FIGURE 33-6** Spread of pelvic inflammatory disease. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing*, ed 6, St Louis, 2010, Elsevier, p 1748.)

Infertility is present in 10% to 15% of women who have experienced PID, and the incidence of ectopic pregnancy is increased six to ten times.<sup>17</sup> Chronic pelvic pain, dyspareunia, pelvic adhesions, and chronic inflammation and abscesses of the oviducts and ovaries may all occur in women after PID.<sup>7</sup>

**Etiology.** Normally, cervical secretions provide protective and defensive functions for the reproductive organs. By providing a bacteriostatic barrier, cervical mucus prevents bacterial agents present in the cervix or vagina from ascending into the uterus. Therefore, conditions or surgical procedures that alter or destroy cervical mucus may impair this bacteriostatic mechanism. PID may follow the insertion of an intrauterine device, pelvic surgery, abortion procedures, and infection during or after pregnancy. Bacteria may also enter the uterine cavity through the bloodstream or from drainage from other foci of infection such as a pelvic abscess, ruptured appendix, or diverticulitis of the sigmoid colon.<sup>1</sup>

PID can result from infection with aerobic and anaerobic organisms. *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most common causative agents because they readily penetrate the bacteriostatic barrier of cervical mucus. However, a variety of bacterial organisms may contribute to the development of PID, including staphylococci, streptococci, diphtheroids, and coliforms such as *Pseudomonas* and *Escherichia coli*. These bacteria are commonly found in cervical mucus, and PID can result from infection by one or several of these bacteria. In addition, PID may occur after multiplication of bacteria in the endometrium that are normally nonpathogenic. During parturition, the traumatized endometrium favors the multiplication of bacteria.<sup>1</sup>

**Clinical manifestations.** The associated signs and symptoms of PID vary with the affected part of the reproductive tract but generally include abdominal tenderness and tenderness or pain of the cervix or adnexa on palpation. In addition, the temperature may be elevated higher than 38° C and the white blood cell count elevated greater than 10,000/mm<sup>3</sup>. A pelvic abscess or inflammatory mass may be present on physical examination or ultrasound, and purulent vaginal discharge may be noted.<sup>1,7</sup>

**Treatment.** Early and aggressive use of antibiotic agents best suited for the causative organisms is essential in preventing the progression of PID. Various antibiotic regimens involving the use of multiple antimicrobial agents have been suggested by the Centers for Disease Control and Prevention for use in PID.<sup>18</sup> Inpatient hospitalization may be indicated for patients with rapidly progressing PID and for those requiring surgical drainage of pelvic abscesses. Rupture of a pelvic abscess is a potentially life-threatening condition, and a total abdominal hysterectomy (removal of the uterus) with bilateral salpingo-oophorectomy (removal of both oviducts and ovaries) may be indicated in this situation.

### Vulvovaginitis

Vulvovaginitis is an inflammation of the vulva (vulvitis) and vagina (vaginitis). Because the vulva and vagina are anatomically close to each other, inflammation of one location usually precipitates inflammation of the other. Vulvovaginitis may occur at any time during a girl's or woman's life and affects most females at some point in life.<sup>1</sup>

**Etiology.** Infection by *Candida albicans* (formerly called *Monilia*) accounts for approximately half of all reported cases of vulvovaginitis. (Infection by *Candida* is referred to as *candidiasis*.<sup>18</sup>) *C. albicans* is a fungus that requires glucose for growth; thus its growth may be promoted during the secretory phase of the menstrual cycle when glycogen levels increase in the vaginal environment. In addition, other conditions in which the glycogen content of the vagina is enhanced may favor candidiasis, such as diabetes, pregnancy, and the use of oral contraceptives. Other factors predisposing to the development of vulvovaginitis from *Candida* infection include the use of estrogen supplementation and antibiotics. Women using estrogen supplementation in the perimenopausal period may be at greater risk for candidal infection of the vagina inasmuch as the glycogen content of the vagina may increase with these therapies. The mechanism by which antibiotic use promotes candidiasis is presently unclear, but it is thought that destruction of the bacteria that normally exert the protective effect of consuming *Candida* results in overgrowth of the *Candida* population with subsequent infection.<sup>1,7</sup>

Other infectious agents that may result in vulvovaginitis include *Trichomonas vaginalis*, *Haemophilus vaginalis*, and *N. gonorrhoeae*. Viral agents that may cause vulvovaginitis include human *papillomavirus* (venereal warts, condylomata acuminata) or herpesvirus type 2. These organisms can be transmitted during sexual intercourse and are discussed in detail in Chapter 34.

In addition to infectious processes, vulvovaginitis may be promoted by conditions or agents that irritate the vulva and vagina. Chemical irritation or allergic reactions to detergents, feminine hygiene products, and toilet paper may be a causative factor. Trauma to the vulva or vagina or the atrophy of the vaginal wall that occurs postmenopausally may predispose to vulvovaginitis as well.<sup>1</sup>

**Clinical manifestations.** Vulvovaginitis from candidiasis results in a thick, white discharge and red, edematous mucous membranes with white flecks adhering to the vaginal wall. Intense itching (pruritus) usually accompanies this discharge. The vaginal pH is usually normal (less than 4.5), and fungal organisms are often seen on microscopic studies. Vulvovaginitis from other infectious agents may involve a malodorous, purulent discharge. Irritation and subsequent inflammation of the vulva and vagina may be manifested by red, swollen labia, pain on urination and intercourse, and itching.

**Treatment.** Appropriate medical therapy for the causative organisms is usually instituted, including local antifungal preparations for vaginal candidiasis and local and systemic antibiotic therapy for vulvovaginitis caused by bacterial agents. Cool compresses and sitz baths provide relief of itching and burning of inflamed tissues. Avoidance

of factors that promote irritation of the vulva, such as drying soaps, nonabsorbent underwear, and tight clothing, is also of therapeutic benefit.<sup>1</sup>

### Bartholinitis

Bartholinitis is an inflammation of the Bartholin glands, which are located on either side of the vaginal orifice and lubricate the vaginal introitus with a clear, viscous secretion. The location of Bartholin glands renders them susceptible to access by bacteria such as *N. gonorrhoeae*, *C. trachomatis*, and other organisms.

**Clinical manifestations and treatment.** Once bacteria are established, an abscess (also referred to as a *Bartholin cyst*) may form and cause tenderness and swelling at the site. Pus may be observed exuding from the duct orifice leading to the affected gland, and symptoms of fever and malaise are present in some individuals. Laboratory culture with proper diagnosis of the causative organism is performed, and appropriate antibiotic therapy is usually instituted. Surgical incision and drainage of the abscess may be necessary for effective management.

#### KEY POINTS

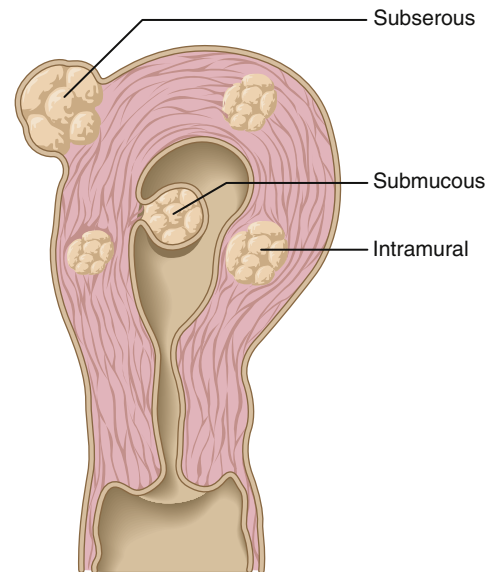

- PID refers to any infection of the oviducts, ovaries, and adjacent reproductive organs. It includes cervicitis, endometritis, salpingitis, and oophoritis. Manifestations and complications of PID include infertility, ectopic pregnancy, pelvic pain, dyspareunia, and abscesses.
- Intrauterine devices, abortion, and pelvic surgery predispose to PID. *N. gonorrhoeae* and *C. trachomatis* are the most common causative organisms, and treatment centers on aggressive antibiotic therapy.
- Inflammation of the vulva and vagina, or vulvovaginitis, is a common problem in women. Most cases are associated with fungal infection by *C. albicans* and are manifested as a white vaginal discharge and an irritated, itchy mucosa. Predisposing factors include chemical irritation from feminine hygiene products, trauma, allergic reactions, and antibiotic therapy that inhibits the growth of normal flora.
- Inflammation of the Bartholin glands, or bartholinitis, is typically a result of the entry and subsequent infection of the glands by *N. gonorrhoeae* or *C. trachomatis*. Tenderness, swelling, and pus may be present and signify the formation of an abscess within one of the Bartholin glands. Antibiotic therapy and surgical drainage are used to manage the abscess.

## BENIGN GROWTHS AND ABERRANT TISSUE OF THE FEMALE REPRODUCTIVE TRACT

Benign growths and aberrant tissue in the female reproductive tract are not uncommon; for example, uterine leiomyomas develop in approximately 50% of all premenopausal women.<sup>19</sup> The presence of benign growths or aberrant tissue in the reproductive tract may cause no symptoms and remain entirely unnoticed, or symptoms ranging from debilitating to life threatening may be present. The diagnosis of these growths or tissue abnormalities may cause anxiety in women experiencing them; in spite of their benign classification, their presence can have devastating effects on the underlying reproductive structures.<sup>19</sup> This section focuses on three of the most common forms of benign growths and aberrant tissue in the female reproductive organs: uterine leiomyomas, ovarian cysts, and endometriosis.

### Uterine Leiomyomas

Uterine **leiomyomas**, which are also called *myomas* or *fibroids*, are the most common form of uterine growths that appear in women. Their

**FIGURE 33-7** Uterine leiomyomas. (From Huether SE, McCance KL: *Understanding pathophysiology*, ed 5, St Louis, 2012, Mosby, p 812.)

actual incidence is difficult to establish because many myomas are either too small or inaccessibly placed to be palpated. Uterine leiomyomas occur in approximately 50% of all premenopausal women and affect black women three times more often than white women.<sup>20,21</sup> Age appears to be a factor in their development inasmuch as myomas are not found before the onset of puberty and rarely exhibit growth activity after menopause.

**Etiology.** Uterine leiomyomas make their appearance and exhibit growth activity during the reproductive years. Therefore, although the actual cause of myomas is presently unknown, it is thought that estrogen and human growth hormone may influence tumor formation by stimulating susceptible fibromuscular elements in the uterine wall. This theory is supported by the finding that tumor growth is enhanced with the administration of large doses of estrogen and during the later stages of pregnancy, when human growth hormone and estrogen levels are high. In addition, uterine leiomyomas usually shrink or disappear after menopause, when estrogen levels decrease.<sup>1</sup>

**Clinical manifestations.** Uterine leiomyomas can grow to a large size (Figure 33-7). Obviously, the presence of such a large mass within the uterus will cause symptoms of abdominal pain and pressure, but smaller myomas can result in such symptoms as well. Other symptoms associated with leiomyomas may include abnormal vaginal bleeding and discharge, depending on the location of the mass. If the myoma is sufficiently large to cause pressure on surrounding abdominal organs, backache, constipation, and urinary frequency or urgency may also be present. Finally, uterine leiomyomas can prevent pregnancy, and make carrying a pregnancy to term difficult.

**Treatment.** Treatment for uterine leiomyomas depends on such factors as the severity of symptoms, the size and location of the leiomyoma, and the patient's age. Small myomas that cause no health problems are generally monitored carefully for growth patterns. Large or multiple masses that promote severe uterine bleeding or interfere with functioning of the gastrointestinal or urinary tract are surgically removed, and hysterectomy may be indicated.<sup>1</sup>

### Ovarian Cysts

**Ovarian cysts** are sacs on an ovary that contain fluid or semisolid material. Ovarian cysts can develop at any time between puberty and menopause, including during pregnancy.

**Etiology.** The cause of the formation of ovarian cysts is presently unknown. They can arise in several locations in the ovaries:

1. Follicular cysts result when a maturing ovarian follicle fails to release an ovum; instead, the follicle continues to enlarge and produce estrogen.
2. Corpus luteum cysts occur when the corpus luteum fails to degenerate normally; the cyst continues to grow and produce progesterone.
3. Theca-lutein cysts are commonly bilateral and filled with clear, straw-colored fluid. Often their development is associated with hydatidiform mole, choriocarcinoma, or hormone therapy.<sup>6</sup>

**Clinical manifestations and treatment.** Normally, ovarian cysts produce no symptoms. They may be noted on periodic examination and may increase and decrease in size with the menstrual cycle. Asymptomatic simple ovarian cysts less than 10 cm in diameter have a probability of malignancy and can be followed without intervention. However, when a larger ovarian cyst ruptures, an ovarian vessel may tear, with variable amounts of intraperitoneal hemorrhage and abdominal pain. In persons with recurrent ovarian cysts, oral contraceptives may be recommended to prevent ovulation. Oral contraceptives do not promote resolution of cysts that are already formed. Occasionally, immediate surgical intervention is indicated to control the hemorrhage and repair the site of rupture.<sup>22,23</sup>

### Endometriosis

**Endometriosis** is the presence of endometrial tissue outside the lining of the uterine cavity. Because the only normal location for endometrial tissue is the endometrial lining of the uterus, the presence of this abnormal growth is associated with a variety of side effects ranging from mild symptoms to life-threatening consequences. These foci of abnormal endometrial tissue are called **endometriomas**, or endometrial implants, and usually occur within the pelvis. The most common sites of occurrence of endometriosis within the pelvis are the ovary, peritoneum of the cul-de-sac or pouch of Douglas, uterosacral ligaments, round ligament, oviduct, and the peritoneal surface of the uterus.<sup>7</sup> Less frequently, endometrial implants occur in other body sites such as the bladder or large intestine. Although endometriosis is a benign disease, it possesses certain characteristics of malignant disease, such as the ability to grow, infiltrate, and spread. Symptoms of endometriosis may have an abrupt onset or may develop over many years.

The actual incidence of endometriosis is unknown because it can exist without any significant symptoms. Conservative population estimates show that approximately 11% of women have undiagnosed endometriosis.<sup>24</sup> Active endometriosis usually occurs between 30 and 40 years of age, particularly in women who have never given birth. Endometriosis is rare in women younger than 20 years or after menopause. Although some authorities report a higher incidence of endometriosis in white women of higher socioeconomic levels,<sup>4</sup> these impressions may not be accurate given the tendency of this group to delay childbearing and to have enhanced access to health care. The infertility rate for women in whom endometriosis is diagnosed is about 30%.<sup>25</sup>

**Etiology.** At the present time, three major theories on the etiology of endometriosis have been proposed:

- **Transportation.** Endometrial tissue flows backward through the oviducts during a normal menstrual period. After this retrograde flow, endometrial fragments implant on the ovary, peritoneal surfaces, and other areas.
- **Metaplasia.** Inflammation or a hormonal change triggers metaplasia (conversion of one kind of tissue to a form that is not normal for that tissue). Thus, coelomic epithelium at certain sites converts to endometrial epithelium.
- **Induction.** In this theory, a combination of transportation and metaplasia takes place, and regurgitated endometrium

chemically induces mesenchyma to form endometrial epithelium. (At present, this theory is thought to be the most likely explanation for endometriosis.<sup>1</sup>)

Once the endometrial implants arise in their abnormal locations, they continue to be under hormonal influence, just as the endometrial lining of the uterus responds to hormonal influence. Thus they periodically proliferate and bleed in response to hormonal stimulation. In some instances they may rupture, usually immediately before or after a menstrual period. Endometriomas are filled with brown blood debris; when they rupture, their contents spill onto the sensitive pelvic peritoneum. This irritative discharge establishes a local chemical peritonitis, followed by the formation of fibrous tissue in the injured location. Dense tissue adhesions in the pelvis may result as the pelvic peritoneum undergoes repeated irritation by the cyclic activities of the endometrial implants.

**Clinical manifestations.** The most prominent symptom of endometriosis is acquired dysmenorrhea, which produces pain in the lower part of the abdomen and in the vagina, posterior of the pelvis, and back. The pain usually begins 5 to 7 days before the peak of menses and lasts for 2 to 3 days. It differs from the pain of primary dysmenorrhea, which is more cramplike and concentrated in the abdominal midline. Pain may be extremely severe, although the degree of pain does not necessarily indicate the extent of disease. Dyspareunia and pain with defecation may also be present.<sup>1,25</sup> Significant changes in the pattern of menstrual flow may occur, with excessive bleeding that may progress to anemia and fatigue.

**Treatment.** Treatment varies according to the extent of disease, and the primary goals of therapy are to relieve pain symptoms and restore or maintain fertility.<sup>26</sup> Many women with endometrial implants never experience symptoms and require no treatment; others experience a rapidly progressive set of severe symptoms requiring immediate intervention. Both medical and surgical treatment modalities may be used. Therapies to reduce endometriosis-associated pain symptoms include use of nonsteroidal antiinflammatory drugs (NSAIDs) and hormonal agents, including progestins, androgenic agents, and gonadotropin-releasing hormone (GnRH).<sup>26,27</sup> Because endometriosis responds to cyclic hormonal functioning, it is thought that the use of hormones to interrupt this cyclic pattern may result in atrophy of the endometrial implants. Surgical intervention includes removal or destruction of the endometriosis. If damage to the pelvic organs is widespread and the disease is progressing rapidly, total abdominal hysterectomy with removal of the oviducts and ovaries is performed.<sup>26,27</sup>

### KEY POINTS

- Benign fibroid tumors, or leiomyomas, are the most common uterine tumor, affecting about 20% of women older than 35 years. Depending on their size, uterine leiomyomas may be characterized by abnormal vaginal bleeding, pelvic pain, constipation, and urinary frequency.
- Ovarian cysts are usually asymptomatic and may change in size with the menstrual cycle. Rupture of an ovarian cyst may result in severe abdominal pain and hemorrhage, which occasionally necessitates immediate surgical intervention.
- Endometriosis occurs when endometrial tissue grows in areas other than the uterine lining. Endometriosis may involve the ovary, peritoneum, oviduct, outer layer of the uterus, bladder, and intestine. Although considered benign, endometriosis tends to infiltrate and spread to adjacent tissues. Endometriosis may be initiated by reflux of the uterine lining through the oviducts into the abdominal cavity during menses.
- Ectopic endometrial tissues periodically proliferate and bleed in response to fluctuations in the levels of reproductive hormones. Dysmenorrhea, with pelvic, back, and lower abdominal pain, usually begins 5 to 7 days before the peak of menses and lasts 2 to 3 days. The pain is more diffuse than that of primary dysmenorrhea. Treatment may include induction of a menopause-like state with hormone administration or the surgical excision of affected structures.

## CANCER OF THE FEMALE GENITAL STRUCTURES

Malignant neoplasms occur in every part of the female reproductive system. This section describes the incidence and pathophysiologic aspects of the most common types of malignancies in female genital structures. For further information about the process of neoplasm development, the reader may wish to refer to Chapter 7 of this text.

### Cancer of the Cervix

**Etiology.** Cancer of the uterine cervix is a neoplasm that can be detected in the early, curable stage by the Papanicolaou (Pap) test.<sup>23</sup> The main cause of cervical cancer is certain human papillomavirus (HPV) types. Other factors include having intercourse at a young age or with multiple sexual partners, becoming pregnant multiple times, or being infected by herpesvirus type 2 and other sexually transmitted infections.<sup>1</sup> The incidence of cervical cancer is decreasing in the United States; there are approximately 10,800 new cases of HPV-related cervical cancer diagnosed each year.<sup>28</sup> In 2007, 4021 women in the United States died from cervical cancer.<sup>28</sup> Widespread screening with a yearly Pap test in women at risk has continued to decrease the mortality of cervical cancer. The American Cancer Society now recommends that all women should begin cervical cancer screening about 3 years after they begin having vaginal intercourse, but no later than 21 years of age. After three consecutive negative Pap tests, women older than 30 years who are not at high risk can be tested every 2 to 3 years. Sexually active women younger than 21 years should also be tested within 3 years of first coitus. For women who have had a hysterectomy unrelated to cervical neoplasia, the Centers for Disease Control and Prevention no longer recommends Pap screening, unless surgery was done as treatment for cervical cancer or precancer.<sup>29</sup> Low-risk women who have been screened regularly may also stop screening at age 70.

**Clinical manifestations.** Preinvasive cervical cancer produces no symptoms, although the Pap test can detect changes in cells of the cervical epithelium, which may be present for 10 years before invasive cancer develops.<sup>1</sup> Early invasive cancer causes abnormal vaginal bleeding, persistent vaginal discharge, and pain and bleeding after intercourse.<sup>1</sup> When symptoms appear, the cancer has usually progressed beyond its early stages. Squamous cell carcinoma accounts for 95% of all invasive cervical cancers diagnosed, and adenocarcinomas account for most of the rest. Invasive carcinoma of the cervix spreads by direct extension to the vaginal wall, laterally into the parametrium toward the pelvic wall, and anteroposteriorly into the bladder and rectum. Metastasis to the pelvic lymph nodes is more common than spread to distant lymph nodes.<sup>7</sup>

**Treatment.** The treatment strategy depends on the clinical stage of the tumor at the time of diagnosis. Surgery—including cryotherapy, excision, and laser surgery for precancerous conditions and hysterectomy for invasive carcinoma—may be indicated. Chemotherapy and radiation therapy may be used in invasive disease. Radical surgery, including *pelvic exenteration*, or removal of all the pelvic organs, can now be performed with limited morbidity. Treatment works best at early stages of cancer. The 5-year survival rate for stage I cervical cancer is 93%. The 5-year survival rate for stage IV cancer is only 15%.

**Prevention.** In 2006 the Food and Drug Administration (FDA) licensed the first vaccine developed to prevent cervical cancer and other diseases in females caused by certain types of human papillomavirus (HPV). The quadrivalent vaccine Gardasil protects against four HPV types (6, 11, 16, 18) that are responsible for 70% of cervical cancers and 90% of genital warts. A bivalent vaccine, Cervarix, is also available, and protects against HPV types 16 and 18. The HPV vaccine is recommended for 11- to 12-year-old girls, but can be administered to girls as young as 9 years of age. The vaccine also is recommended

for 13- to 26-year-old females who have not yet received or completed the vaccine series. Ideally, the vaccine should be administered before onset of sexual activity. However, females who are sexually active also may benefit from vaccination.<sup>29,30</sup> Experts have recently also suggested similar vaccination recommendations for males.<sup>31</sup>

### Endometrial Cancer

Cancer of the endometrial lining of the uterus is less common than cervical cancer in young women, but both types of cancer occur with equal frequency in postmenopausal women.<sup>7</sup> Related factors include infertility, late menopause (older than 55 years), obesity, diabetes, and hypertension. Unopposed estrogen therapy also increases the frequency.

**Clinical manifestations and treatment.** The most common initial symptom is bleeding between menstrual periods or postmenopausal bleeding. The diagnosis of endometrial cancer is based on histologic tissue examination. Treatment strategies for endometrial cancer include radiation therapy and total hysterectomy with possible removal of the ovaries and oviducts. The 5-year survival rate for patients in whom early endometrial cancer is diagnosed early at a local stage is approximately 96%.<sup>32</sup> The 5-year survival rate drops to 17% if the cancer has metastasized before diagnosis.

### Ovarian Cancer

Ovarian cancer has replaced cervical cancer as the leading cause of death from genital cancer. The peak incidence is between 60 and 80 years of age.<sup>7</sup> Because no symptoms are noted until late in the disease, the mortality rate is high, with only a 45% 5-year survival rate.<sup>32</sup>

**Clinical manifestations and treatment.** When symptoms occur, they are related to intraabdominal metastasis and include increasing abdominal girth, weight loss, abdominal pain, dysuria or urinary frequency, and constipation. Management of ovarian cancer includes removal of the uterus, ovaries, and oviducts. Radiation therapy and chemotherapy may be used in conjunction with surgery. Increasingly, prophylactic oophorectomy or salpingo-oophorectomy is being recommended in high-risk women.<sup>33</sup>

### Vaginal Cancer

Cancer of the vagina generally occurs in women in their early- to mid-fifties, although it has an increased incidence in young women whose mothers took diethylstilbestrol during pregnancy.<sup>1</sup> Because the vagina is a thin-walled structure with rich lymphatic drainage, vaginal cancer may metastasize to the bladder, rectum, vulva, pubic bone, and other surrounding structures.

**Clinical manifestations and treatment.** The primary signs and symptoms of vaginal cancer are vaginal spotting and discharge, pain, groin masses, and changes in urinary pattern.<sup>7</sup> Early-stage therapy is designed to treat the malignant area while preserving normal parts of the vagina. Radiation therapy or surgery varies based on the size, depth, and location of the tumor.<sup>1</sup> Preservation of a functional vagina is generally possible only in the early stages, although grafting from other body sites may be performed to avoid vaginal stenosis, particularly in younger women.<sup>7</sup>

### Cancer of the Vulva

**Clinical manifestations and treatment.** Cancer of the vulva accounts for approximately 5% of all gynecologic malignancies. It can occur at any age, including infancy, but has a peak incidence in the mid-sixties. Factors that seem to predispose to the disease include sexually transmitted infections, chronic pruritus of the vulva with swelling and dryness, obesity, hypertension, diabetes, and never having been pregnant.<sup>1</sup>

Leukoplakic changes (the presence of whitish plaque-like or ulcerated lesions) in the vulva may precede the development of carcinoma. Once the carcinoma develops, vulvar masses may be present, with groin masses and abnormal urination and defecation manifesting later in the disease.<sup>1</sup> Management of vulvar cancer includes partial excision of the vulva to remove precancerous leukoplakic lesions and total vulvar excision for advanced disease.<sup>7</sup> Local relapse is common whether conservative or radical procedures are undertaken.<sup>34</sup>

#### KEY POINTS

- Cervical cancer may be detected by evaluation of cervical cells (Pap test). Early-stage cervical cancer may be asymptomatic. When they appear, symptoms include abnormal vaginal bleeding and discharge. Cervical cancer may spread to the vaginal wall, pelvis, bladder, rectum, and pelvic lymph nodes. The quadrivalent vaccine Gardasil protects against four HPV types (6, 11, 16, 18), which are responsible for 70% of cervical cancers and 90% of genital warts.
- Other cancers of the female reproductive tract include endometrial, ovarian, vaginal, and vulvar cancers. No routine screening tests are available for these cancers. Ovarian cancer has a high mortality rate because it is usually diagnosed after it has metastasized.

## DISORDERS OF PREGNANCY

Pregnancy results in a number of physiologic alterations in the mother that are usually well tolerated, particularly if adequate prenatal care is available. However, pregnancy can result in a number of conditions that may be life threatening to the mother and the developing fetus. The most common pregnancy-related disorders are described here; in addition, for information concerning diabetes in pregnancy, the reader may wish to consult Chapter 41, which covers the topic of diabetes in depth.

### Pregnancy-Induced Hypertension

**Pregnancy-induced hypertension (PIH)** is known by other names such as *toxemia* and *preeclampsia-eclampsia*. Hypertension complicates 0.5% to 10% of pregnancies in the United States and is one of the leading causes of pregnancy-related deaths.<sup>35</sup> PIH is characterized by a rapid rise in arterial blood pressure associated with the loss of large amounts of protein in the urine. Women at risk for the development of PIH include teenagers and women in their late thirties and early forties. In addition, the presence of multiple fetuses and the preexistence of hypertension, renal and cardiovascular disease, and diabetes may predispose to the development of PIH.<sup>35</sup>

**Etiology, clinical manifestations, and treatment.** The exact causes of PIH are presently unknown, although poor nutrition and genetic and immunologic factors have been suggested. PIH is characterized by salt and water retention by the kidneys, weight gain, and edema. In addition, arterial spasm occurs in many parts of the body, most significantly in the kidneys, brain, and liver. Both renal flow and the glomerular filtration rate are decreased, a condition exactly opposite the normal changes in pregnancy. The renal effects are caused by thickening of the glomerular tufts, which contain a fibrinoid deposit in the basement membranes.<sup>1</sup>

The severity of symptoms of PIH is closely related to the retention of salt and water and the degree of the increase in arterial pressure. The increasing arterial pressure seems to promote a vicious cycle in which arterial spasm and other pathologic effects give rise to further increases in arterial pressure. Milder forms of the disease are managed with bed rest. Fetal well-being is periodically assessed, and the infant is delivered if conditions deteriorate or maturity is achieved.

In its severe form, PIH is characterized by extreme vascular spasticity throughout the body, clonic convulsions followed by coma, renal failure, liver malfunction, and extreme hypertension. Usually, this severe form occurs shortly before parturition. The mortality rate in women with severe PIH who are left untreated is high. However, the immediate use of rapidly acting vasodilating drugs, seizure prophylaxis, and rapid delivery have reduced the mortality rate from PIH to less than 1%.<sup>36</sup>

### Hyperemesis Gravidarum

**Hyperemesis gravidarum** is a Latin term for excessive vomiting in pregnant women. Although transient nausea and vomiting occur in about half of women in the first trimester of pregnancy, in a few women these symptoms continue throughout the entire course of pregnancy. Intractable vomiting, or hyperemesis gravidarum, occurs in about 1 in 1000 pregnancies, sometimes with life-threatening consequences.<sup>1</sup> Severe dehydration and electrolyte imbalance, hepatic and renal damage, encephalopathy, and ultimately death may ensue if the vomiting cannot be controlled.

**Clinical manifestations and treatment.** The causes of hyperemesis gravidarum are unknown, but it is thought that an abnormal response to the production of large amounts of human chorionic gonadotropin hormone by the placenta may be implicated. Intravenous therapy to correct metabolic and nutritional abnormalities, antiemetic agents, and supportive care in a hospital environment may be needed to resolve the symptoms.

### Placenta Previa and Abruptio Placentae

**Etiology and clinical manifestations.** **Placenta previa** is a condition in which the placenta is implanted abnormally over the internal cervical os. **Abruptio placentae** is premature separation of the placenta before delivery of the fetus. Placenta previa occurs in approximately 1 in 200 deliveries and is more common in women with multiple pregnancies and previous cesarean section; its cause is unknown. Placenta previa may occur in varying degrees of severity ranging from partial to entire coverage of the internal cervical os. Abruptio placentae, or premature separation of the placenta, occurs after 20 weeks of gestation in about 1% of deliveries. The detachment may be partial or complete and may cause overt or concealed hemorrhage.<sup>7</sup> Abruptio placentae can be caused by trauma, a short umbilical cord, occlusion of the inferior vena cava, PIH, or abnormal uterine anatomy.

**Treatment.** Therapeutic strategies for placenta previa and abruptio placentae include cesarean section for fetal distress or hemorrhage control. Medications designed to control preterm labor may also be administered.

### Spontaneous Abortion

**Spontaneous abortion** is expulsion of the products of conception from the uterus before the period of fetal viability. It is usually called a *miscarriage* by laypersons, and it is differentiated from elective abortion. Although the precise incidence is unknown, it is estimated that 50% of all pregnancies end in spontaneous abortion. Among those women who know they are pregnant, the rate of spontaneous abortion is 15% to 20%.

**Etiology.** Abnormal development accounts for a large percentage of aborted pregnancies. Nearly 61% of abortuses expelled in the first trimester demonstrate chromosomal abnormalities.<sup>6</sup> In addition, abnormal development may result from faulty implantation of the fertilized ovum or from an abnormality in the uterine environment. Maternal factors responsible for spontaneous abortion include both systemic and localized conditions. Infectious processes that may contribute to spontaneous abortion include cytomegalovirus, herpesvirus, and

rubella infections. Abnormalities of the reproductive organs, immune disorders, endocrine malfunction, and physical and psychic trauma may all contribute to spontaneous abortion.<sup>7</sup>

**Clinical manifestations and treatment.** Associated signs and symptoms of spontaneous abortion include vaginal bleeding and abdominal cramps. The cramps may intensify as the cervix dilates for expulsion of the uterine contents. If the entire contents are expelled, the bleeding and cramps subside. However, if any contents remain, an incomplete abortion has occurred and intervention may be needed to control bleeding and to surgically remove the remaining uterine contents.

**KEY POINTS**

- PIH is characterized by a rapid rise in blood pressure and proteinuria. Renal blood flow and the glomerular filtration rate are reduced, and the kidneys retain salt and water. When severe, PIH may be associated with convulsions and coma. Antihypertensive therapy may be indicated.
- Excessive vomiting during pregnancy is termed *hyperemesis gravidarum*. Dehydration, electrolyte imbalance, hepatic and renal damage, and death may ensue.
- Placenta previa occurs when the placenta is implanted over the cervical os. Abruptio placentae is premature separation of the placenta. Both conditions may interrupt fetal oxygen supply and cause maternal hemorrhage. Cesarean section is indicated.
- It is estimated that 10% to 15% of known pregnancies end in spontaneous abortion. Fetal abnormalities, faulty implantation, infections, and trauma increase the risk of spontaneous abortion.

**DISORDERS OF THE BREAST**

The breast is considered an accessory organ of the female reproductive tract and is affected by many of the same factors that promote alterations in the other reproductive organs. Women's breast health has become a critical concern in the United States because the breast is the most common site of cancer in women between 25 and 75 years of age.<sup>32</sup> In addition, women are playing an increasingly important role in recognizing the symptoms of breast disease and are seeking earlier intervention with improved outcomes. It is essential that health care professionals continue to encourage this enhanced role and provide accurate information about breast health to their clients. This section includes information on specific breast disorders involving reactive-inflammatory breast disorders, benign breast disorders, and carcinoma of the breast. Before reading this information, the reader may wish to review the section on the structure and function of the breast in Chapter 32 of this text and the specific information on neoplasm development in Chapter 7.

**REACTIVE-INFLAMMATORY BREAST DISORDERS**

Breast disorders in which an inflammatory response occurs in reaction to irritation, injury, or infection include mammary duct ectasia, breast abscess, fat necrosis, and reactions to injections or implantation of foreign materials in the breast.

**Mammary Duct Ectasia**

Mammary duct ectasia is a chronic inflammatory process occurring in and around the terminal subareolar ducts of the breast (it is also referred to as *periductal mastitis*). It is more prevalent in older women, primarily postmenopausal women.<sup>37</sup> The Latin word **ectasia** means dilation, and in mammary duct ectasia the collecting ducts

beneath the nipple and areola become dilated, thinned, and filled with secretions.

**Pathogenesis.** Over time, the ducts become distended with cellular debris, and the debris begins to have an irritating effect on the duct walls. The inflammatory response is initiated, and a zone of granulation tissue is created around a small cavity filled with thick yellowish or brownish material. This area will be palpable as a mass in the central area of the breast, beneath or near the areola. By the time the duct ectasia has grown into a palpable mass, a reactive fibrosis will also have formed in the tissue around the mass. This fibrous thickening of the surrounding breast tissue causes dimpling and distortion of the breast and nipple inversion (Figure 33-8). However, a congenital inverted nipple is already present in some women with mammary duct ectasia, and it is thought that the presence of this nipple anomaly may in some way contribute to ductal wall irritation.<sup>37</sup>

**Clinical manifestations and treatment.** In addition to a palpable mass and dimpling or distortion of the breast or areola, women with mammary duct ectasia may have a persistent nipple discharge. These signs must be evaluated carefully because they may also be indicative of a malignant breast mass. A biopsy is usually performed to rule out the presence of a malignancy. After confirmation of the diagnosis of mammary ductal ectasia, surgical excision of the dilated subareolar ducts is performed.<sup>37</sup>

**Breast Abscess**

The majority of abscesses occurring in the breast are not associated with breast feeding and are referred to as *nonlactational* breast abscesses (for a complete description of abscesses or mastitis related to lactation, the reader may wish to refer to an obstetric or maternity nursing text). Nonlactational breast abscesses are most often a recurring problem and usually affect persons with conditions that predispose to infections, such as having diabetes mellitus, undergoing steroid therapy, or being afflicted with other skin lesions.

**Etiology.** Multiple factors may contribute to the formation of nonlactational breast abscesses. In some women, the presence of a congenital inverted nipple may predispose to abscess formation. Abscesses may also be part of the syndrome of mammary duct ectasia; in addition, women with the aforementioned preexisting conditions that predispose to infections may be at increased risk for the development of an infectious process in the breast tissue. Unlike breast abscesses

**FIGURE 33-8** Nipple retraction in the right breast as a result of mammary duct ectasia. (From Haagensen CD: *Diseases of the breast*, ed 3, Philadelphia, 1986, Saunders, p 359.)

occurring during breast feeding, in which *Staphylococcus aureus* is the most common causative organism, nonlactational breast abscesses usually yield multiple organisms when cultured.

**Clinical manifestations and treatment.** Signs and symptoms of these abscesses include an area of tenderness, redness, and induration under the periareolar skin.<sup>37</sup> Unfortunately, nonlactational breast abscesses do not respond well to antibiotic therapy and often recur, and it is sometimes necessary to excise the major duct system beneath the areola to prevent further recurrence.<sup>37</sup>

### Fat Necrosis

Necrosis refers to the death of a portion of tissue, and fat necrosis in the breast is the death of fat tissue after trauma or injury to the breast. The position of the breasts makes them vulnerable to trauma, particularly in larger women with pendulous breasts. This phenomenon is important for health care professionals to assess because fat necrosis may mimic or obscure carcinoma of the breast.

**Clinical manifestations and diagnoses.** Fat necrosis of the breast may have many of the same clinical signs as breast malignancy, including a painless mass in the breast that is firm, ill-defined, and poorly mobile. Skin thickening and retraction may also be present. In addition, a mammogram may not provide a clear diagnosis. Unfortunately, many women with pendulous breasts frequently sustain injuries to the breast and may be unable to recall any specific trauma; thus a diagnosis of fat necrosis may be difficult to make. If fat necrosis cannot be reliably distinguished from carcinoma based on clinical observation or mammography, excisional biopsy must be performed.<sup>37</sup>

### Reactions to Foreign Material

Surgery to enlarge the female breast has become one of the most popular of all cosmetic surgical procedures in recent years.<sup>37</sup> Since the early twentieth century, a variety of materials have been used for breast augmentation. Silicone implants, which consist of silicone gel encased in polyurethane or other materials, have been the most widely used devices for breast enlargement and have been implanted in more than 1 million women.<sup>37</sup> At present, controversy surrounds the use of silicone breast implants because some side effects, including irritation at the implantation area and other symptoms suggestive of an immune system response, have been reported. Currently, the recommendations surrounding silicone breast implants are conflicting. The use of silicone implants for routine cosmetic breast augmentation is specifically controlled in the United States, favoring implants filled with a saline solution. Health care professionals should be aware of the reported side effects of silicone breast implants inasmuch as a substantial segment of the female population in the United States and Western Europe has undergone breast augmentation with these devices. In addition, persons with silicone implants who sustain blunt trauma to the chest are at risk for rupture of the implant, with subsequent leakage of the silicone gel into surrounding tissue. After chest trauma, the communication of information regarding the presence of silicone breast implants to other health care professionals is an important consideration in planning care and preventing further tissue exposure to silicone.

## BENIGN BREAST DISORDERS

The term **benign breast disorders** encompasses a group of lesions affecting the breast. These disorders are usually divided into two categories: (1) fibrocystic breast disease and (2) specific benign neoplasms of the breast such as fibroadenomas, adenomas, and papillomas. It is important for health care professionals to understand the clinical significance of these benign disorders. Although these entities are “benign” in the sense of being differentiated from malignant breast

neoplasms, clients experiencing them may be at risk for experiencing a psychological crisis and may need to be educated regarding their potential risk for breast malignancy.

### Fibrocystic Breast Disease

Although the term **fibrocystic breast disease** is frequently used by health care professionals, it is important to understand that it is not a distinct disease entity.<sup>37</sup> Instead, it is a diagnosis classification that is applied to a condition in which the presence of palpable breast masses fluctuates with the menstrual cycle and may be associated with pain or tenderness. Laboratory examination of this breast tissue shows macroscopic and microscopic cysts, along with a variety of alterations in tissue structure such as fibrosis or overgrowth of stromal fibrous tissue. However, these alterations in breast tissue are present to some degree in all female breasts, which has led some authorities to question use of the term “disease” for such a widespread condition. Until a more precise system for classifying this type of benign breast disorder is widely adopted, fibrocystic breast disease will probably continue to be used to describe this phenomenon of tender breast masses that occur on a cyclic basis. A comparison of normal and fibrocystic breast tissue is shown in Figure 33-9.

**Etiology and clinical manifestations.** Hormonal imbalance in the reproductive years is thought to contribute to fibrocystic breast disease. Fibrocystic breast disease is more common in women ages 30 to 50 years. It is usually characterized by tenderness or pain in one or both breasts immediately before onset of the menstrual period. On palpation, the cysts tend to be firm, regular in shape, and mobile. They are located most often in the upper outer quadrant of the breasts, and their size may fluctuate throughout the menstrual cycle.<sup>37</sup>

Although it was previously thought that all women with fibrocystic breast disease were at increased risk for breast cancer, recent research has disproved this theory.<sup>37</sup> It is now known that only certain types of tissue changes may predispose a woman with fibrocystic breast disease to the development of breast malignancy. The vast majority of women with fibrocystic disease do not have these alterations in breast tissue and therefore are not at a substantially increased risk for breast cancer.<sup>37</sup>

**Diagnoses and treatment.** Diagnostic studies can include ultrasound and needle aspiration of a cyst for histologic analysis. Danazol, a weak androgen, has shown efficacy in the treatment of fibrocystic

**FIGURE 33-9** **A**, Normal breast. **B**, Fibrocystic breast tissue. Note image of cysts showing typical smooth margins, dark center, edge shadows, and a bright posterior wall. (From Lewis SL et al, editors: *Medical-surgical nursing: assessment and management of clinical problems*, ed 8, St Louis, 2011, Elsevier.)

breast disease. Oral contraceptives have also been recommended to control symptoms of fibrocystic breast disease. Other supportive measures include the application of local heat and use of a support bra. Nutritional therapies have shown success in some women, particularly avoidance of foods with methylxanthines, such as tea, coffee, cola, and chocolate. It is thought that methylxanthines tend to stimulate cyclic adenosine monophosphate and thus increase metabolic activity in the breast.<sup>37</sup> A low-fat, high-carbohydrate diet has been shown to decrease breast swelling and tenderness.

### Specific Benign Neoplasms

Specific benign neoplasms of the breast, such as fibroadenomas, adenomas, and papillomas, may occur at any time during a woman's life from childhood through old age. These neoplasms behave in a clinically "benign" fashion; that is, they do not invade the surrounding tissue or metastasize to other sites. They generally appear as freely movable, encapsulated masses that are sharply delineated from the surrounding breast tissue.<sup>37</sup> However, it is important to have any breast mass evaluated because biopsy and histologic examination may be needed to differentiate these benign neoplasms from breast carcinoma.

## MALIGNANT DISORDER OF THE BREAST

### Cancer of the Breast

Carcinoma of the breast remains the most common form of cancer in women between the ages of 25 and 75 years.<sup>26</sup> In the United States it is the leading cause of death from all causes in women between the ages of 40 and 44 years. The incidence of breast carcinoma appears to be increasing in the United States, with an estimated 178,000 newly diagnosed cases per year.<sup>32</sup> Although the disease is more common in white women, its incidence in blacks and Asians is rising.<sup>32</sup> Breast cancer does occur in males but is 100 times less common.<sup>32</sup> Even though recent advances in early detection and treatment have afforded longer survival after diagnosis, invasive breast carcinoma remains an incurable disease that continues to take the lives of a large segment of the population.

**Etiology.** A substantial number of studies conducted in the past 30 years have begun to establish the risk factors and possible causes of breast cancer. Some factors that may place a woman at risk for breast cancer include hormonal influences, reproductive factors, dietary factors, family history, age, radiation exposure, and a history of cancer.<sup>37</sup> It should be noted that helping a client understand and interpret her personal breast cancer risk is a difficult task for a health care professional. The public media have given much attention to some of the risk factors for breast cancer but have not provided much context in which to interpret evaluations for individual risk factors.

**Risk factors** are characteristics related to the probability of a certain outcome—in this case, breast cancer. These risk factors may be either causally or correlatively associated with an outcome. For example, a factor may directly *cause* an outcome (as the smallpox virus causes smallpox) or may be *correlated* with an outcome (as not wearing a seat belt is correlated with an increased degree of injury in a motor vehicle accident). The distinction between causality and correlation is an important concept to impart to clients when discussing risk factors. A client may express concern, for example, that a certain risk factor will directly cause the development of breast cancer. The ability of a health care professional to describe and discuss risk factors in a knowledgeable way will greatly enhance the client's ability to make decisions regarding such issues as hormonal replacement therapy after menopause.

**Hormonal factors.** Several hormonal factors have been shown to be linked to the development of breast cancer.<sup>37</sup> Length of exposure to

the hormones secreted by the ovary (estrogen and progesterone) has been shown to affect the risk for breast cancer in the following way. If a woman has had an early (younger than 12 years) onset of menses and a late (older than 55 years) menopause, her risk is increased. Stated another way, women with 40 or more years of menstrual activity have twice the breast cancer risk as women with fewer than 30 years of menstrual activity.<sup>37</sup> Postmenopausal hormone replacement therapy may increase the risk of breast cancer, and recent data show that the risk may be greater for women taking estrogen/progesterone combination therapies than for women taking estrogen-only therapies.<sup>38,39</sup> For some women, the known benefits of these medications may outweigh effects on cancer risk. Future research is needed to clarify the way in which hormonal exposure may foster breast cancer development and the many interactive factors associated with taking hormonal medications.

**Reproductive factors.** It has been observed in many research studies that giving birth at a young age (less than 18 years) is associated with a decreased risk of breast cancer and that giving birth for the first time at 35 years or older increases the risk.<sup>37</sup> In addition, parity (the number of viable children a woman has borne) has been associated with risk, with low parity increasing risk and high parity having a protective effect.<sup>37</sup> Breast feeding is also associated with a decrease in breast cancer.<sup>40</sup>

**Dietary factors.** It has been suggested that the amount of fat in the diet is a risk factor for breast cancer.<sup>37</sup> Researchers who favor this theory point to the relatively low rates of dietary fat ingestion in countries with low rates of breast cancer. Although the media have given a great deal of attention to this issue, scientific data have been inconclusive thus far.<sup>37</sup> Countries in which low-fat diets are widespread are typically nonindustrialized countries in which other factors, such as age at first delivery or parity, differ from those in industrialized countries. No single dietary pattern or food has been shown to "cause" cancer, just as no specific food has been shown to prevent or cure cancer.

**Family history.** The role of heredity in contributing to breast cancer has long been recognized. Specific gene mutations such as *BRCA1* and *BRCA2* have been identified in high-risk families. Research studies have indicated that women with a mother or sister with breast cancer have an increased risk of developing breast cancer, even if specific gene mutations are not identified. Women with family risk factors and gene mutations need careful care and accurate information in order to make informed choices. Women with *BRCA1* and *BRCA2* gene mutations are at risk for both breast cancer and ovarian cancer and may benefit from prophylactic salpingo-oophorectomy to reduce their risk.<sup>41</sup> Another controversial option for some high-risk women is bilateral mastectomy. Finally, chemoprevention with selective estrogen receptor modulators (SERMs) may be an option for some high-risk women.<sup>42</sup> SERMs may not be recommended in low-risk to average-risk women because they have their own adverse effects such as thromboembolic events and endometrial cancer.

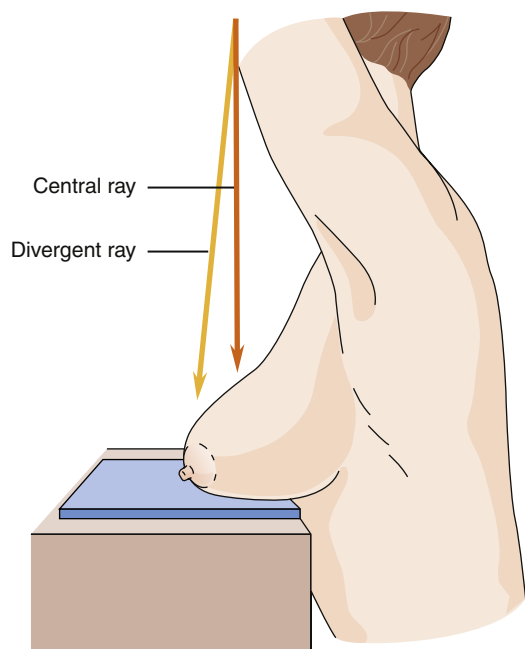

**Age.** Breast cancer is extremely rare in young women. The incidence of breast cancer begins to increase by 25 to 30 years of age and continues to increase with advancing age.<sup>37</sup>

**Other factors.** Other factors, such as radiation exposure and a history of cancer, have been shown to be risk factors for the development of breast cancer.<sup>37</sup> Several potential factors have been suggested, such as exposure to low-frequency electric or magnetic fields and a virus transmitted through lactation. More research is required to establish the role of these potential factors.<sup>42</sup>

**Clinical manifestations.** Many breast cancers are discovered by the woman herself through self breast examination (SBE). She usually finds a single lump that is painless, hard, and poorly movable. Yearly clinical breast exams by trained clinicians are also recommended

**FIGURE 33-10** Skin dimpling caused by an underlying malignant tumor. (From Donegan WL, Spratt JS: *Cancer of the breast*, ed 5, Philadelphia, 2002, Saunders, p 321.)

**FIGURE 33-11** Placement of the breast for mammography, along with the direction of the x-rays.

after the age of 40. Mammography is an important clinical tool, and according to current screening guidelines, most women should have yearly mammograms beginning at age 40. Other technologies, such as magnetic resonance imaging (MRI), are showing promise as screening tools. Improvements in technology, such as digital mammography and MRI, have greatly increased the ability to identify breast cancers.

Half of malignant tumors occur in the upper outer quadrant of the breast.<sup>37</sup> Other signs of advanced tumor development include dimpling of the skin (Figure 33-10), retraction of the nipple, changes in breast contour, and bloody discharge from the nipple. Breast cancer is diagnosed by a number of techniques that use films (mammography, xerography) (Figures 33-11 and 33-12), by computerized technologies (digital mammography), and by thermography, a technique in which “hot spots” indicate increased metabolic activity. A person of any age with a suspected breast mass should undergo mammography and biopsy.

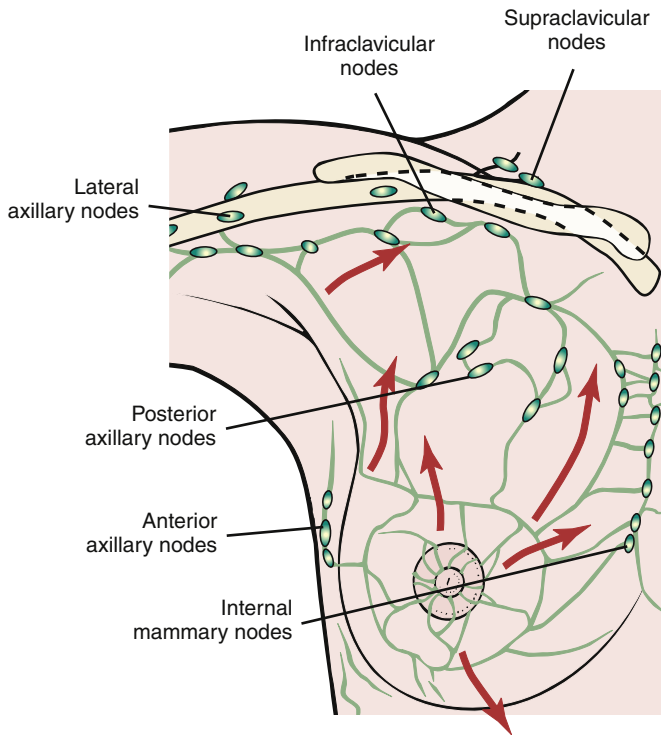

**FIGURE 33-12** Mammogram showing bilateral invasive ductal carcinoma. **A**, Left breast. The larger mass was palpable. The smaller right mass was not palpable (arrow). **B**, Right breast. Multiple masses are shown. (From Powell DE, Stilling CB: *Diagnosis and detection of breast diseases*, St Louis, 1993, Mosby.)

**FIGURE 33-13** Ultrasound scan of a carcinoma. Note the ragged appearance of this invasive, malignant lesion. (From Donegan WL, Spratt JS: *Cancer of the breast*, ed 5, Philadelphia, 2002, Saunders, p 332.)

Most breast carcinomas arise in the epithelium of the glandular ducts of the breast. The lesion(s) have infiltrating edges that begin to invade normal breast tissue (Figure 33-13). After this invasion, malignant cells begin to scatter or disseminate into the lymph system of the axilla (Figure 33-14). The breast is in close proximity to the large system of axillary lymph nodes, which makes easy dissemination of malignant cells possible. The major way by which breast carcinoma causes morbidity and death is through the dissemination of malignant cells to other body sites, most commonly lung, liver, and bone.<sup>37</sup> **Metastasis** (or spread of carcinoma) to these other body sites signifies a poorer prognosis. The prognosis is vastly better for persons with no evidence of spread of malignant cells to the regional lymph nodes. The 5-year survival rate is 98% when no lymph node involvement is found at surgery but averages 84% when lymph node involvement is present.<sup>26</sup> For women with distant spread (metastases), the rate drops to 23%.<sup>32</sup> The greater the number of positive lymph nodes (nodes with malignant cells) found at surgery, the less favorable the prognosis.

**FIGURE 33-14** Lymphatic drainage of the breast. In general, lateral lesions in the breast metastasize to axillary and supraclavicular nodes, whereas medial tumors tend to metastasize to the internal mammary and mediastinal lymph nodes, as well as the supraclavicular nodes. (From Lewis SL et al, editors: *Medical-surgical nursing: assessment and management of clinical problems*, ed 7, St Louis, 2007, Elsevier, p 1327.)

**Treatment.** Treatment for breast cancer includes surgery, chemotherapy, radiation therapy, and supportive measures. Surgical therapy is a controversial area, and various options are available. Breast conserving therapy, which includes removal of only the lesion, is called a **lumpectomy**. Lumpectomy or lumpectomy in conjunction with either chemotherapy and/or radiation is becoming increasingly preferred. Removal of only the breast is a simple **mastectomy**. Other surgical interventions include a **modified radical mastectomy**, in which the breast is removed and a portion of the axillary lymphatic system is dissected, and a **radical mastectomy (rare)**, in which the breast, lymphatic drainage, and underlying pectoral muscles are removed.<sup>37</sup>

Chemotherapy entailing a variety of hormonal and antineoplastic agents is also used. Malignant cells appear to have cytoplasmic hormone receptors that bind to hormone molecules and promote cellular division and growth. Selective estrogen receptor modulators (SERMs), estrogen antagonists, are the most common agents used. Popular

examples of SERMs include tamoxifen and raloxifene. Antineoplastic agents are given to control the spread of malignant cells.<sup>37</sup>

Radiation therapy may be used as an adjunct to the aforementioned therapy and to control pain by shrinking large tumor masses. Other supportive measures in advanced disease include operations to reduce the bulk of tumors.<sup>37</sup>

**Continuum of care.** Breast cancer is characterized by a wide variation in clinical course. Many patients who undergo therapy for breast carcinoma are able to achieve a satisfying quality of life. Educational and support programs for breast cancer patients and their families, both preoperatively and postoperatively, have been an important means of providing emotional support. Programs for continuing care after mastectomy have helped patients and families face the adaptive challenges of living with breast cancer. Follow-up care includes early detection of recurrent disease, with an emphasis on breast self-examination, yearly mammography, and regular examination by health care professionals.

**KEY POINTS**

- Chronic inflammation of the subareolar ducts may result in mammary duct ectasia. Fibrous thickening results in a palpable central mass, breast distortion and dimpling, and nipple inversion. Persistent nipple discharge may occur. These signs are similar to those of malignancy and are carefully evaluated by biopsy. Surgical excision may be performed.
- Breast abscesses in nonlactating women are commonly associated with chronic infection, diabetes, and steroid therapy. These abscesses respond poorly to antibiotics and tend to recur.
- Fibrocystic breast disease is a condition in which palpable breast masses are present and fluctuate with the menstrual cycle. Breast cysts are firm, mobile, and tender, and are usually located in the upper outer quadrant. There is no evidence that women with fibrocystic breasts are at higher risk for breast cancer. A low-fat, high-carbohydrate diet; danazol; heat therapy; and avoidance of methylxanthines may be recommended.
- Breast cancer is the most common cancer in women between 25 and 75 years of age. Malignant tumors tend to be painless, hard, and fixed in place, in contrast to benign breast tumors, which are mobile and encapsulated. Risk factors for breast cancer include a high-fat diet, a first-degree relative with breast cancer, increasing age, radiation exposure, and a previous malignancy. In addition, reproductive factors such as the age at first pregnancy and the number of pregnancies may be associated with altered cancer risk.
- Breast cancer may spread to the regional lymphatics and disseminate to other sites. Localized breast cancer, without lymph node involvement, has a 98% 5-year survival rate. The survival rate falls to 84% when lymph nodes are cancerous and to 23% when there are distant metastases. Depending on the extent of tumor spread, surgery may be performed to remove the tumor only (lumpectomy), the affected breast only (simple mastectomy), the affected breast and involved lymph nodes (modified radical mastectomy), or the breast, lymphatics, and underlying muscle (radical mastectomy). In addition, radiation therapy and chemotherapy may be initiated.

## SUMMARY

This chapter has described the most prevalent women's reproductive health problems at the present time. Any alteration in reproductive status may have profound implications for the individual; thus the reader should review this material carefully to acquire the ability to distinguish the differences and similarities in these alterations.

Commonly occurring alterations in reproductive health for women may have serious consequences and require immediate intervention. Menstrual disorders may have multiple manifestations, and such disorders as amenorrhea and abnormal uterine bleeding may occur at any time throughout a woman's life. Alterations in uterine position and pelvic support, including uterine prolapse, retrodisplacement of the uterus, cystocele, and rectocele, may result in severe symptoms and require surgical correction. Inflammation and infection of the female reproductive tract, including PID and vulvovaginitis, may have far-reaching effects for the individual experiencing them.

The reader should pay particular attention to the section on benign growths and aberrant tissue of the female reproductive tract

given the widespread nature and potentially serious consequences of these lesions. A thorough understanding of uterine leiomyomas, ovarian cysts, and endometriosis includes the ability to define these syndromes as described in this book, as well as an ability to explain them to clients. In addition, the reader is urged to review the material regarding the efficacy of the Pap smear in detecting cervical cancer at an early stage.

The section on disorders of pregnancy highlighted the most important aspects of this topic; the reader will probably wish to use this information as a basis for a more in-depth study of this area in a specialized course in maternal-child nursing. Finally, because of the widespread threat to women's health posed by disorders of the breast, the reader should pay particular attention to the final section. Specifically, the reader must be able to compare and contrast the differences between benign breast disorders and carcinoma of the breast and discuss the meaning and importance of various risk factors for breast carcinoma in a knowledgeable way.

- Case Studies
- Key Points Review

### KEY QUESTIONS

- What are the characteristic clinical manifestations and lesions of gonorrhea and chlamydial infection?
- How do the pathologic changes and clinical manifestations of syphilis differ during the incubation, primary, secondary, and tertiary phases?
- How do the lesions of herpes simplex, syphilis, and lymphogranuloma venereum differ?
- Which sexually transmitted diseases remain localized, and which have systemic consequences?
- What are the causative organisms and characteristic lesions of the following localized sexually transmitted diseases: chancroid, granuloma inguinale, molluscum contagiosum, and condylomata acuminata (genital warts)?

### CHAPTER OUTLINE

#### Urethritis, Cervicitis, Salpingitis, and Pelvic Inflammatory Disease, 689

*Human Papillomavirus Infections, 693*

#### Enteric Infections, 694

An epidemic of sexually transmitted infections (STIs) currently exists in the United States.<sup>1,2</sup> The Centers for Disease Control and Prevention (CDC) estimate that there are 19 million new infections every year.<sup>3</sup> More than 300,000 cases of gonococcal infections and 1.3 million chlamydial infections were reported in 2010.<sup>3</sup> However, the true incidence of these infections is likely to be significantly higher inasmuch as many sexually transmitted infections are unreported. The cost of STIs is extremely high. It is estimated that STIs cost the health care system \$17 billion every year.<sup>3</sup> In addition, the personal costs to the individual experiencing an STI may include pain, disfigurement, psychosocial difficulties, and reproductive problems. Because of the epidemic status of these diseases and the enormous costs associated with them, it is

imperative that health care providers become sufficiently knowledgeable to assess their patients' STI status and educate them about STIs in an accurate and compassionate manner.

The term **sexually transmitted infections** refers to a large group of disease syndromes that can be transmitted sexually, regardless of whether the disease has manifestations in genital structures.<sup>1</sup> In older texts, STIs are referred to as *sexually transmitted diseases* (STDs) and *venereal diseases*. Although STIs are more prevalent in the 15- to 25-year-old age group, they can occur at any age. These diseases are sometimes contracted by nonsexual transmission, as when a newborn infant contracts an STI from an infected mother during passage through the birth canal.<sup>1</sup>

---	--

A list of sexually transmitted organisms grouped according to type of pathogen is found in Box 34-1. A useful approach to learning the complex pathophysiologic processes of STIs is to group STIs according to the disease manifestations that the patient is most likely to exhibit when first seen by the health care provider. These categories of STIs and the disease manifestations associated with them are listed in Table 34-1. This chapter describes each of these categories and the pathophysiologic processes associated with each relevant STI.

Some diseases listed in Table 34-1 are discussed elsewhere in this text but have been included here for completeness. In particular, the reader may wish to refer to Chapter 33 for more detailed information on pelvic inflammatory disease and vulvovaginitis. Also, certain systemic infections are potentially transmitted by sexual contact. Cytomegalovirus infection, hepatitis A and hepatitis B, and human immunodeficiency virus (HIV) have the potential for sexual transmission. These diseases are covered in detail in Units III and IX, along with more in-depth information concerning infectious processes and immune responses. Before studying this chapter, the reader may wish to refer to Chapters 8 and 9 for a review of basic terminology such as *incubation period* and *period of communicability*. Health care providers caring for persons at risk for STIs should be aware of the potential for acquisition of systemic diseases by sexual contact and include assessment of these diseases as part of their overall clinical evaluation.

**URETHRITIS, CERVICITIS, SALPINGITIS, AND PELVIC INFLAMMATORY DISEASE**

Three types of STI are manifested by *urethritis* (inflammation of the urethra), *cervicitis* (inflammation of the uterine cervix), and/or *salpingitis* (inflammation of the oviduct or fallopian tube). **Gonorrhea** is an inflammation of epithelial tissue by the organism *Neisseria gonorrhoeae*. In men, nongonococcal urethritis refers to urethritis resulting from a pathogen other than the gonococcus, which is usually *Chlamydia trachomatis*. In women, mucopurulent cervicitis refers to an inflammation of the cervix, which is usually caused by either *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. *Pelvic inflammatory disease*, which was described in Chapter 33, is usually the result of acute salpingitis caused by gonococcal or chlamydial infection that has extended into nearby pelvic tissue.<sup>1,3,4</sup>

**TABLE 34-1 SEXUALLY TRANSMITTED INFECTIONS CATEGORIZED ACCORDING TO DISEASE MANIFESTATIONS**

DISEASE MANIFESTATIONS	DISEASE
Urethritis, cervicitis, and salpingitis	Gonorrhea Nongonococcal urethritis Pelvic inflammatory disease
Ulcerative lesions with systemic involvement	Syphilis Lymphogranuloma venereum Herpes simplex virus
Ulcerative lesions only	Chancroid Granuloma inguinale (donovanosis)
Nonulcerative lesions	Molluscum contagiosum Genital warts (condylomata acuminata)
Vulvovaginitis	Trichomoniasis Candidiasis <i>Gardnerella vaginalis</i> vaginitis
Systemic infections	Cytomegalovirus Hepatitis AIDS
Enteric infections	Giardiasis <i>Campylobacter</i> enteritis Shigellosis Amebic dysentery

**Gonococcal Infection**

Gonorrhea is associated with the gram-negative diplococcus *Neisseria gonorrhoeae*.

**Etiology and clinical manifestations.** In gonorrhea, disease transmission occurs through contact with exudates from the mucous membranes of infected persons, usually by direct contact. The gonococcus then attaches to and penetrates columnar epithelium and produces a patchy inflammatory response in the submucosa. Although usually asymptomatic in women, gonorrhea may produce purulent vaginal discharge, dysuria, and abnormal vaginal bleeding. The most commonly affected areas in women are the cervix, the urethra, the Skene and Bartholin glands, and the anus. Among females, adolescents (ages 15 to 19 years) and young adults (ages 20 to 24 years) now have the highest rates of gonorrhea.<sup>3</sup> In men, symptoms of urethritis, including dysuria and a purulent urethral discharge accompanied by redness and swelling at the site of infection, usually occur after a 3- to 6-day incubation period. Among males, young adults (ages 20 to 24 years) have the highest rates of gonorrhea.<sup>3</sup> In both genders, infection and inflammation of the pharynx, conjunctivae, and anus may be present. Direct extension of the infection with gonococci occurs by way of the lymphatic system. In the female, extension may spread unilaterally or bilaterally to the oviducts, with subsequent salpingitis. In the male, direct extension of the infection most frequently occurs to the epididymis.<sup>1,3</sup>

Once gonococcal infection has spread to other areas, localized infection occurs and may cause the formation of cysts and abscesses. Purulent exudate containing the organism causes damage to tissue, and fibrous tissue replaces inflamed tissue. This hardened, fibrous tissue may result in scarring and narrowing of the urethra, epididymis, or oviducts. In women, partial or complete closure of the oviducts results in sterility. Infection of the oviducts may also result in pelvic inflammatory disease if exudate is released into the peritoneal cavity.<sup>1,5,6</sup> As

described in Chapter 33, pelvic inflammatory disease may be an acute or chronic condition causing widespread damage to the pelvic organs in the female.

### Nongonococcal Infection

**Etiology.** Nongonococcal urethritis and cervicitis are often caused by strains of *C. trachomatis* that act on columnar epithelium in a manner similar to that noted for the gonococcus. The symptoms of infection with *Chlamydia* are generally less severe than those of gonorrhea. As with gonorrhea, the infection may spread by extension to the oviducts, and pelvic inflammatory disease may eventually result. Upper reproductive tract infection, whether symptomatic or subclinical, is an important cause of infertility and ectopic pregnancy.<sup>7</sup> Transmission of *Chlamydia* during birth may result in **ophthalmia neonatorum**, or infection of the eyes in the newborn.<sup>1</sup>

**Treatment.** The resistance of *N. gonorrhoeae* to antimicrobial agents continues to spread and intensify. Newer antimicrobial agents such as ceftriaxone, cefixime, spectinomycin, and cephalosporin are now being used to manage uncomplicated gonococcal infections. In 2007 the Centers for Disease Control and Prevention no longer recommended fluoroquinolones for treatment of gonococcal infections because of fluoroquinolone resistance to *N. gonorrhoeae*.<sup>8,9</sup> Increased resistance to cephalosporin is also currently being monitored.<sup>10,11</sup> Unless chlamydial infection is ruled out, dual therapy for gonococcal and chlamydial infection consisting of azithromycin or doxycycline added to one of the aforementioned agents is recommended.<sup>8</sup> Pelvic inflammatory disease is also generally managed with two agents to cover potential chlamydial and gonorrheal infection. A number of organizations now recommend *Chlamydia* (as well as gonorrhea) screening for sexually active adolescents and women through age 25 who have no symptoms in order to reduce the sequelae of infection.<sup>12</sup>

#### KEY POINTS

- Urethritis, cervicitis, salpingitis, and pelvic inflammatory disease are commonly due to gonorrheal or chlamydial infection. Transmission is usually by direct contact with infected mucous membranes. The symptoms of chlamydial infection are similar but usually less severe than those of gonorrhea.
- Gonorrhea may produce purulent discharge, dysuria, and abnormal vaginal bleeding. Cysts and abscesses may form in localized areas of infection, followed by scarring and fibrosis. Inflammation of the pharynx, conjunctivae, and anus may be present. Antibiotic therapy is indicated.

## DISEASES WITH SYSTEMIC INVOLVEMENT

Several STIs cause a distinctive ulcerative lesion and disseminate throughout the body to affect multiple organ systems. Most prominent of this type of STI are syphilis, herpesvirus infections, and lymphogranuloma venereum.

### Syphilis

**Syphilis** is a systemic infection of the vascular system consisting of five distinct stages: incubation, primary and secondary stages, latency, and late syphilis.<sup>3</sup> Syphilis is communicable by persons with primary, secondary, or early latent syphilis.<sup>1,3</sup> The incidence of syphilis has varied in the United States since reporting began in 1941. The rate of primary and secondary syphilis decreased during the 1990s to its lowest levels since 1941. However, overall rates increased again between 2001 and 2009, before decreasing again in 2010.<sup>4</sup> Increased incidence rates were attributed primarily to men who have sex with men (MSM) and to men and women who engage in high-risk sexual behavior.<sup>4</sup> An

**FIGURE 34-1** Typical syphilitic chancre, a painless, ulcerative lesion that arises at the original spirochete portal of entry. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

estimated 1.1 cases of primary and secondary syphilis per 100,000 population occurred in 2010.<sup>4</sup>

**Etiology.** Syphilis is caused by *Treponema pallidum*, an anaerobic spirochete. Syphilis is acquired when *T. pallidum* penetrates intact mucous membranes or abraded skin during sexual contact. (The process of transmission of congenital syphilis is described later.) Some of the *T. pallidum* pathogens remain at the original invasion site, whereas others migrate to regional lymph nodes within hours. During this incubation phase, *T. pallidum* is disseminated throughout the body and can invade and multiply in any organ system.<sup>1,3</sup>

**Pathogenesis.** During all stages of syphilis, invasion of tissue by *T. pallidum* results in pathologic changes in the vascular system. The inflammatory response in endothelial tissue causes the infiltration of lymphocytes and plasma cells, with subsequent endothelial swelling. The terminal arterioles and small arteries may become obliterated and no longer functional. Finally, long-term inflammation of vascular tissue results in the formation of hardened, fibrous thickening in the blood vessels and eventually tissue necrosis.<sup>1,3</sup>

After the initial incubation period of 10 to 90 days, the primary phase begins with the formation of a **chancre**, a painless, ulcerative lesion that arises at the original spirochete portal of entry (Figure 34-1). The chancre may remain unnoticed in a female if it occurs on the cervix or in the vagina; in fact, most cases of syphilis in women are undiagnosed until recognized by positive testing of the blood in the latent phase. In males, the chancre may form on the genitalia; in both genders, chancres may erupt on the anus, fingers, lips, tongue, nipples, tonsils, or eyelids.<sup>1,3</sup>

Untreated chancres will resolve spontaneously within 3 to 6 weeks and are followed by the secondary stage of syphilis, which is characterized by a low-grade fever, malaise, sore throat, headache, lymphadenopathy, and mucosal or cutaneous rash (Figure 34-2). This secondary stage occurs as *T. pallidum* is spread throughout the bloodstream and lymphatic system. The secondary stage is also self-limiting and is followed by a latent phase in which no symptoms are present. During the latent stage, the affected person will test positive for syphilis on serologic assays and may still experience infectious mucocutaneous lesions during the early latent stage. Thus, the early latent stage is considered contagious. The latent stage is of variable length and may last more than 40 years.<sup>2</sup> In approximately two thirds of patients, the infection

**FIGURE 34-2** Typical generalized skin rash of secondary syphilis. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

**FIGURE 34-3** Lymphogranuloma venereum is characterized by a small, transient genital ulcer with swollen, extremely painful inguinal lymph nodes. (From Lewis SM et al: *Medical surgical nursing*, ed 6, St Louis, 2004, Mosby, p 1392.)

remains asymptomatic and never causes a recurrence of symptoms. If syphilis remains untreated, then late syphilis—the final, destructive phase of the disease—will eventually develop in approximately one third of affected people.<sup>1,3</sup> The manifestations of late syphilis depend on the area of arterial lesions and the extent of circulatory insufficiency.<sup>3</sup> Body systems particularly at risk are the cardiovascular and central nervous systems. Damage to the cardiovascular system may include aortic necrosis and subsequent aortic insufficiency; damage to the central nervous system may be progressively widespread, with degeneration of the cortical neurons and, eventually, paresis, blindness, and mental deterioration.<sup>1,3</sup>

Transmission of *T. pallidum* from the mother to the fetus may occur transplacentally at any point during pregnancy, but an inflammatory response to the pathogen does not develop in the fetus until around the fifteenth week of gestation. Therefore, treatment of infected women before the fifteenth week may prevent damage to the fetus. Infection with syphilis before birth may result in physical deformities and developmental disabilities in the infant. Infants born to untreated or inadequately treated mothers will have active infection and must be treated.<sup>1</sup> A presumptive diagnosis of syphilis is generally based on a positive result of a serologic screening test, such as the Venereal Disease Research Laboratories (VDRL) or rapid plasma reagin (RPR) test, followed by a positive result of a treponemal serologic test.<sup>9</sup> Dark-field examination of tissue and exudates or direct fluorescent antibody tests are also useful.

**Treatment.** Penicillin G is the first choice for the management of syphilis. If the affected person is allergic to penicillin, tetracycline or doxycycline is given. Treatment is administered to all individuals with positive evidence of syphilis on laboratory testing and to people who have had sexual contact with infected individuals.<sup>1,4</sup> Response to antibiotic treatment is monitored by repeating laboratory testing for evidence of syphilis at regular intervals up to 24 months after therapy.<sup>8</sup> Management during pregnancy is complex, but it focuses on maternal cure and prevention of congenital syphilis.<sup>13</sup>

### Lymphogranuloma Venereum

**Lymphogranuloma venereum (LGV)** is a highly contagious systemic infection caused by a number of closely related strains of *Chlamydia*. The disease occurs more commonly in the tropics but has been

reported rarely in the United States.<sup>14</sup> LGV develops more often in males than in females and has a higher incidence among sexually active young adults.

**Etiology and pathogenesis.** Like syphilis, LGV has stages of development in which an initial lesion forms and systemic disease occurs after dissemination via the lymphatic system. After invasion of the mucosa by *Chlamydia* during sexual contact, a painless lesion appears on the genitalia after a 1- to 3-week incubation period. The lesion may range from a slight erosion to a small papule and often remains undetected (Figure 34-3). This lesion heals spontaneously in a few days. During this period, the pathogens are disseminated to regional lymph nodes, primarily the inguinal lymph nodes.

About 2 weeks after appearance of the primary lesion, the inguinal lymph nodes begin to swell, and the systemic symptoms of fever and malaise develop. The nodal swelling is a manifestation of inflammation of the lymphatic system in which lesions filled with polymorphonuclear leukocytes are forming in the lymph nodes. Spread of the inflammation throughout adjacent lymph nodes causes multiple nodes to become matted together and form a large abscess. These abscesses are said to be regional because they develop in one or more areas along the lymphatic system. If a person with LGV remains untreated, the abscesses rupture through the skin and other body cavities to create chronic fistulas. Thus, as the regional lymphadenitis progresses, complications such as perianal and rectovaginal fistulas develop, along with strictures of the rectum. Other complications include extreme swelling of the genitalia; this occurs because the normal lymph drainage of this area is impeded.<sup>9</sup> The diagnosis is usually made by serologic testing (antibody titers).

**Treatment.** Doxycycline is the recommended antibiotic with erythromycin being the alternative. Surgical treatment may include aspiration of lymph nodes as needed; rectal strictures and fistulas may require surgical correction.<sup>9</sup>

### Herpesvirus Infections

**Herpesviruses** are an important group of viral agents that produce infection in humans. Two types of herpes simplex virus (HSV)—type 1 and type 2—may be sexually transmitted and are discussed in this section. HSV type 1 is most often associated with herpetic infections above the waist, typically in the oral cavity and on the lips, but also in the eyes or on the epidermis. HSV type 1 can be transmitted sexually

and can cause genital herpetic infections. It is present in saliva, stool, and urine. The vesicles resulting from type 1 infection in the oral cavity are commonly referred to as *cold sores* or *chancres* and often affect children younger than 5 years.<sup>1,3</sup> HSV type 2 is implicated in most genital, anal, and perianal herpes and is sometimes referred to as *genital herpes* for this reason. Type 2 HSV can also result in oral lesions after sexual contact. Serologic studies indicate that one in five individuals in the United States have been infected with type 2 HSV.<sup>4</sup> Although type 2 is primarily transmitted through sexual contact, pregnant mothers can transmit the infection to newborns during vaginal delivery.<sup>1,3</sup>

**Etiology.** HSV types 1 and 2 have certain characteristics in common. Both produce an initial infection that is self-limiting. The lesions produced by this infection heal, but HSV continues to be present in the body. Recurrence of the lesions, usually in the area of the initial infection, may take place as the virus is reactivated. Recurrence of either type may be triggered by an infectious disease, emotional stress, or immunosuppression.<sup>1,3</sup> The exact mechanism for reactivation of the virus is presently unknown, but it is thought that ganglion neurons may contain latent forms of the virus and then receive a trigger to stimulate replication of the virus under certain conditions.<sup>1,3</sup>

**Clinical manifestations.** Genital infection with HSV type 2 is manifested by the appearance of fluid-filled vesicles after a 3- to 7-day incubation period. In the female, the cervix is usually the primary infection site, although the labia, perianal skin, vulva, or vagina may also be involved (Figure 34-4). In the male, the vesicles are located on the glans penis, foreskin, or penile shaft (Figure 34-5). Extragenital lesions may appear on the mouth or anus. In both males and females, the vesicles, which are usually painless at first, may rupture and develop into extensive shallow, painful ulcers. The virus may enter the lymphatic system and create localized lesions there; thus, the inguinal lymph nodes may be edematous and tender. Rarely, the virus spreads to visceral organs and can produce areas of necrosis in the liver, adrenal glands, lungs, and central nervous system.<sup>3</sup> In newborns and people with weak immune defenses (particularly people with acquired immunodeficiency syndrome [AIDS]), HSV type 2 may result in severe damage to these organ systems, with high related mortality.<sup>1</sup> Most human immunodeficiency virus (HIV)-infected individuals are HSV-2 seropositive, and perirectal involvement is common.<sup>15,16</sup>

**FIGURE 34-4** Primary genital herpes in the female showing herpetic vesicles and tender ulcerations. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

HSV type 1 infections may appear as single or multiple fluid-filled, tender vesicles in the oral cavity or on the lips. Usually, the appearance of the lesions is preceded by 1 or 2 days of paresthesia before the chancre or “cold sore” erupts. These lesions will generally crust and heal within 3 to 10 days. HSV infections are usually diagnosed by cell culture.<sup>2</sup> Exudate from early lesions gives the most positive results.

**Treatment.** Normally, HSV type 1 lesions are self-limiting and respond to measures that promote good oral hygiene. HSV type 2 genital lesions are usually self-limiting but may be extremely painful. The use of antiviral agents such as acyclovir, famciclovir, and valacyclovir has been shown to accelerate healing time and reduce the duration and severity of symptoms in initial episodes of HSV type 2 infection.<sup>8,16-18</sup> Long-term or episodic suppression may also be used to reduce the number or severity of recurrent episodes.<sup>8,18</sup> Consistent use of condoms reduces transmission from men to women.<sup>15,19</sup> Prevention teaching should include the possibility of asymptomatic shedding of the virus.<sup>16-19</sup> If HSV type 2 lesions are active in a pregnant mother at term, a cesarean section may be recommended to reduce the risk of transmission to the newborn.<sup>8</sup>

#### KEY POINTS

- Syphilis is caused by an anaerobic spirochete that is transmitted sexually but disseminates throughout the body during incubation. Manifestations of early syphilis include chancre formation at the portal of entry, which spontaneously resolves in 3 to 6 weeks if untreated. General malaise, fever, sore throat, and rash may then occur, followed by an asymptomatic latent phase. The latent phase may last more than 40 years. Late syphilis is characterized by central nervous system degeneration, blindness, and paresis.
- LGV is a highly contagious systemic infection caused by strains of *Chlamydia*. An initial painless genital lesion appears after 1 to 3 weeks of incubation. The infection spreads to regional lymph nodes and is accompanied by fever and malaise. Infected lymph nodes become abscessed and may rupture through the skin and body cavities, causing fistula formation.
- HSV types 1 and 2 are implicated in cases of genital herpes. Herpes lesions are fluid-filled vesicles that appear 3 to 7 days after infection. The virus may enter the lymphatics and cause inguinal lymph node tenderness. Although the lesions may disappear, the virus remains in the body, thus predisposing to recurrence. Herpes may be transmitted from mother to newborn during the birth process.

**FIGURE 34-5** Recurrent genital herpes in the male showing erythema, groups of vesicles, erosions, and edema on the shaft of the penis. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

## DISEASES WITH LOCALIZED LESIONS

### Ulcerative Lesions

Two types of STIs result in the formation of ulcerative lesions but do not progress to systemic involvement. **Chancroid** (also called soft chancre) and **granuloma inguinale** are both manifested by ulcerative lesions, although their pathophysiologic courses differ.

#### Chancroid

**Etiology.** Chancroid is an ulcerative, infectious disease of the genital tract caused by the sexually transmitted anaerobic bacillus *Haemophilus ducreyi*. Chancroid is relatively rare in the United States.<sup>4</sup> Chancroid is a cofactor for human immunodeficiency virus infection.

**Pathogenesis and clinical manifestations.** *Haemophilus ducreyi* initially invades the genital skin or mucous membranes at sites traumatized by sexual contact. The patient generally has one or more painful genital ulcers, unlike the chancre in syphilis, which is generally solitary and painless. Fresh lesions may occur from autoinoculation (self-infection). The ulcerated lesions may enlarge, continue to erode (Figure 34-6), and produce destruction of surrounding tissue. In addition, inguinal lymph nodes may become tender and painful as the infection is disseminated to this region. If the infection goes untreated, the enlarged lymph gland (called a *bubo*) may rupture, draining pus and leaving a large inguinal ulcer. The infection is communicable until the lesions heal, which may be a period of weeks.<sup>1</sup> Scarring may occur in advanced cases. Diagnosis is usually made by culture for *H. ducreyi*.

**Treatment.** Antiinfective agents recommended for management of chancroid include azithromycin, erythromycin, ceftriaxone, and ciprofloxacin.<sup>8</sup> Large ulcers may not heal for more than 2 weeks. As with all STIs, sexual partners should be treated simultaneously and reexposure avoided until therapy is completed.

#### Granuloma Inguinale

**Etiology.** *Calymatobacterium granulomatis* is the causative agent of granuloma inguinale. This intracellular bacterium is also referred to as a *Donovan body* and the disease as *donovanosis*. Granuloma inguinale is rare in the United States.<sup>4</sup>

**FIGURE 34-6** Eroded, purulent ulcer of chancroid. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

**Pathogenesis and clinical manifestations.** Transmission of granuloma inguinale is not clearly understood. It is generally thought to be an STI, but the disease is also seen in adults who are not sexually active and in young children, possibly as a result of autoinoculation. The causative bacterium is found in the rectum of nondiseased persons, which suggests that the organism may be part of the normal gastrointestinal flora in some persons.<sup>1</sup>

The incubation period is variable and ranges from a few days to months. The initial sign of the disease may be a painless papule or nodule that subsequently ulcerates into an enlarging, granulomatous, red velvety ulcer. The raised mass of granulation tissue may look more like a tumor than an ulcer. The lesions are highly vascular and bleed easily with minor contact. Single or multiple lesions may coalesce, or lesions may spread to nearby tissue.<sup>1,3</sup> Secondary infection of the ulcers and expanding tissue necrosis in lesions may lead to erosion of the genitals.<sup>3</sup> Diagnosis is by identification of the dark-staining Donovan bodies on biopsy or tissue crush preparations.

**Treatment.** Doxycycline is given for at least 3 weeks or until all lesions are healed.<sup>8</sup> Alternative agents include trimethoprim-sulfamethoxazole, ciprofloxacin, erythromycin, and azithromycin.<sup>8</sup>

### Nonulcerative Lesions

Molluscum contagiosum and infections caused by human papillomavirus (HPV) (also called genital warts) are two prevalent types of STIs that produce nonulcerative lesions. Both are caused by viral agents that invade superficial layers of the epidermis during sexual contact.

#### Molluscum Contagiosum

**Etiology.** *Molluscum contagiosum* is a viral skin disease caused by a member of the poxvirus family.<sup>3</sup> (The term *poxvirus* refers to a viral agent that causes an eruption, or “pox,” on the skin.) The manifestations are much milder than those of smallpox or chickenpox. Two forms of the disease exist. One affects children and is transmitted by skin-to-skin contact and indirect contact; the other affects young adults and is transmitted during sexual contact.

**Pathogenesis and clinical manifestations.** After invasion of the epidermis by the virus, pink to white lesions with an exudative core appear on the genitalia. The lesions are multiple, are slow to develop, and remain stable for long periods. The disease is usually asymptomatic.

**Treatment.** The goal of treatment is primarily to prevent spread of the infection for cosmetic reasons. The lesions can be removed by minor surgery or frozen with liquid nitrogen. Sexual contacts of affected persons should be examined to prevent further spread.<sup>3</sup>

#### Human Papillomavirus Infections

**Etiology.** **Human papillomavirus (HPV) infections** cause epithelial lesions of the anogenital region.<sup>1</sup> Also called *genital warts* or *Condylomata acuminata*, HPV is predominantly transmitted sexually in young adults, with the highest prevalence in the 16- to 25-year-old age group.<sup>4</sup> The risk of contracting the disease by sexual contact with an infected person is high; lesions will develop in up to two thirds of the sexual contacts of affected persons. Nonsexual transmission has also been documented, and lesions have been found in infants.<sup>1</sup> The period of communicability is unknown but is thought to last as long as the lesions persist, and perhaps even after they are clinically removed.<sup>1,3</sup>

**Pathogenesis and clinical manifestations.** After invasion of the epidermis by HPV, an incubation period of 1 to 20 months (usually about 4 months) precedes the appearance of lesions. It is thought that the virus infects single epithelial cells and stimulates the cells to divide and proliferate into the wartlike lesions. The lesions can be single or multiple, and may have a soft pink to brown coloring. They can be small or large, and raised or flat (Figure 34-7). The lesions are generally

**FIGURE 34-7** Human papillomavirus of the vulva. (From Morse SA et al: *Atlas of sexually transmitted diseases and AIDS*, ed 4, St Louis, 2010, Elsevier.)

asymptomatic but may be pruritic (itchy), painful, or friable (bleed easily). In females, HPV may be found in the vagina and cervix, as well as in the anogenital area.<sup>1</sup> In males, HPV lesions may occur in the anterior urethra and anogenital area.

**Treatment.** External genital warts may be treated with patient-applied podofilox or imiquimod topical preparations.<sup>8</sup> Providers can perform cryotherapy; administer podophyllin, trichloroacetic acid, or bichloroacetic acid; or carry out surgical excision of the warts.<sup>8</sup> Patient-applied preparations are also available, and include podofilox (0.5%) and imiquimod (5%) cream. Alternative regimens include intralesional interferon and laser surgery. Malignant transformation to invasive carcinoma has been observed with some types of genital warts. Persistent infections of HPV types 6, 11, 16, and 18 are thought to be responsible for 70% of cervical cancers and 90% of genital warts. Therefore, it is generally agreed that affected persons should be treated or monitored carefully.<sup>8</sup> Because HPV has been associated with cervical cancer, there has been an increasing use of human *papillomavirus* testing in evaluating abnormal Papanicolaou smears.<sup>3</sup>

In 2006 the Food and Drug Administration (FDA) licensed the first vaccine developed to prevent cervical cancer and other diseases in females caused by certain types of human papillomavirus (HPV) (see Chapter 33). The HPV quadrivalent vaccine is recommended for 11- to

12-year-old girls, but can be administered to girls as young as 9 years of age. The vaccine also is recommended for 13- to 26-year-old females who have not yet received or completed the vaccine series. Ideally, the vaccine should be administered before onset of sexual activity. However, females who are sexually active also may benefit from vaccination.<sup>20,21</sup> Recent 4-year follow-up research suggests that the vaccine is safe and tolerated well.<sup>22</sup> Researchers are also reporting promising results of studies examining the efficacy of the HPV quadrivalent vaccine in males.<sup>23</sup>

#### KEY POINTS

- Chancroid is caused by infection with an anaerobic bacillus. Initially the lesion is a small erythematous papule, and after 2 to 3 days the painful lesion ulcerates. Lesions resemble those of syphilis; however, the lesions of syphilis are painless.
- Granuloma inguinale is caused by an intracellular bacterium. The initial papule is painless and subsequently ulcerates into a growing granulomatous ulcer resembling a tumor.
- Molluscum contagiosum is associated with infection by a poxvirus. Genital lesions are pink to white with an exudative core. The disease is usually asymptomatic and self-limiting.
- Condylomata acuminata, or genital warts, are associated with infection by human papillomavirus. Warts are pink to brown and painless and may occur in clusters. Persistent human papillomavirus infection is an important risk factor for cervical cancer.

## ENTERIC INFECTIONS

Until recently, information regarding the transmission of enteric infections of the gastrointestinal tract through sexual contact was limited. Enteric pathogens may be transmitted sexually among any individuals who engage in direct or indirect fecal-oral contact. Enteric organisms that may be transmitted through sexual contact include *Giardia*, *Campylobacter*, *Shigella*, and the agents causing amebic dysentery.<sup>8</sup>

The pathophysiologic process of enteric infections of the gastrointestinal tract is described in Chapter 36, and the reader may wish to refer to this material. In general, persons who have acquired enteric infections by sexual contact will have variable manifestations. Some individuals may experience no symptoms, whereas others will have marked symptoms of enteritis or proctitis. All individuals who engage in oral-anal sexual practices should be monitored for the presence of enteric infections with laboratory studies and diagnostic examinations. Education for persons at risk for sexually transmitted enteric infections includes an emphasis on protective hygienic practices. Infected persons should avoid all sexual contact until all partners are examined and treated if necessary. After completion of appropriate therapy for enteric infections, affected individuals should be retested for assessment of therapeutic effectiveness.

## SUMMARY

Because of the epidemic nature of STIs, it is essential for readers preparing for careers in the health sciences to have a complete grasp of the material in this chapter. The STIs considered in the chapter are grouped according to the disease manifestations that the patient is most likely to exhibit. Gonorrhea, most chlamydial infections, and pelvic inflammatory disease are manifested by urethritis, cervicitis, or salpingitis. A second group of STIs cause ulcerative lesions with systemic involvement. Syphilis, herpes, and LGV all cause a distinctive ulcerative lesion and may disseminate throughout the body to affect multiple organ systems.

In reviewing the material on STIs related to ulcerative and nonulcerative lesions, the reader should compare and contrast the appearance of these lesions and consider the differing pathophysiologic characteristics of each type. Finally, the reader should consider how he or she would incorporate this material into an overall assessment process. Nurses and other health care providers caring for persons at risk for STIs should be aware of the potential for acquisition of these diseases as well. The overall goal in learning the material in this chapter is to be able to assess and educate clients with STIs in a comfortable and accurate manner.

### KEY QUESTIONS

- What are the major structures of the gastrointestinal tract and their corresponding functions?
- How does the autonomic nervous system influence gastrointestinal motility?
- How do segmental and propulsive movements influence the digestive and absorptive functions of the small intestine?
- What are the major secretions of each of the following secretory cells and glands: salivary, gastric, intestinal epithelium, pancreas, and gallbladder?
- How and where are complex carbohydrates, proteins, and lipids digested and absorbed?
- How and where are water and electrolytes absorbed?
- What alterations in gastrointestinal function occur in association with very young or very old age?

Gastrointestinal Function Across the Life Span, 716

Maturation, 716

Age-Related Changes, 717

The gastrointestinal (GI) system represents a remarkable interface between the human organism and the external environment for the purpose of providing nutrients for the body. The components of the GI tract can be thought of as a continuous tube about 7 m in length extending from the mouth to the anus. Beginning with the mouth and pharynx, the GI tract includes the esophagus, stomach, and small and large intestines (Figure 35-1). Other parts of the GI system located

outside the GI tract include the salivary glands, the pancreas, and the biliary system (liver, gallbladder, and bile ducts).

The process of ingesting nutrients, propelling them through the GI tract, and transforming them into a form capable of absorption into the body's internal milieu is remarkably complex. The general functions of the GI tract can be divided into (1) movement of nutrients, including propulsive and mixing movements; (2) secretion of digestive

**FIGURE 35-1** The gastrointestinal system. (From Monahan FD, Neighbors M: *Medical surgical nursing: foundations for clinical practice*, ed 2, Philadelphia, 1998, Saunders, p 950.)

**FIGURE 35-2** Oral cavity. Structures of the mouth and location of the salivary glands. (From O'Toole M, editor: *Miller-Keane encyclopedia and dictionary of medicine, nursing, and allied health*, ed 7, Philadelphia, 2003, Saunders.)

juices; (3) digestion of nutrients; and (4) absorption of nutrients.<sup>1,2</sup> This chapter describes each of these functions in detail and provides an overview of the structure and organization of the GI tract and its growth and alteration across the life span.

## STRUCTURE AND ORGANIZATION OF THE GASTROINTESTINAL TRACT

### Embryology

As early as **the third week of gestation**, the embryonic structure begins to fold inward to create the primitive gut. By the fourth week structures of the foregut, midgut, and hindgut are in place.<sup>3</sup>

The foregut develops into the pharynx, the esophagus, the stomach, the duodenum proximal to the opening of the common bile duct, the hepatobiliary system, and the pancreas. The midgut forms the small intestine (below the opening of the common bile duct), the cecum, the appendix, the ascending colon, and the proximal portion of the transverse colon. The hindgut develops into the distal part of the transverse colon, the descending and sigmoid colon, the rectum, and the superior portion of the anal canal.

Developmental abnormalities are relatively common as a result of incomplete partitioning during gut differentiation. The trachea and esophagus share a common developmental origin, and incomplete development of these structures may lead to **tracheoesophageal fistula**, an anomaly characterized by an abnormal connection between the trachea and esophagus (often accompanied by **esophageal atresia**, where the esophagus is closed off in a blind pouch). These disorders occur in about 1 in 4000 live births, with about one third of affected infants born prematurely. One of the most serious surgical emergencies in newborns, tracheoesophageal fistula requires immediate diagnosis and surgical correction.<sup>4</sup> The current prognosis for such infants is very good, with about 90% survival beyond the neonatal period.

Failure of normal partitioning between the foregut and midgut can lead to intestinal atresia, a condition in which the lumen of the small intestine is obliterated. This is an important cause of intestinal obstruction in the newborn and necessitates prompt surgical correction.<sup>4</sup> Failure of the midgut to develop or rotate properly with respect to the umbilical cord can result in omphalocele, a congenital herniation of viscera into the base of the umbilical cord.

Congenital malformations resulting from inappropriate development of the anorectal portion of the GI tract include **colonic** or **anal agenesis**, a condition in which the rectal pouch ends blindly. This condition has been rarely reported with congenital varicella syndrome.<sup>4</sup> Other developmental anomalies of this portion of the GI tract include anal stenosis, in which the anal aperture is small, and anal atresia (or imperforate anus), in which the anal membrane persists and covers the aperture to create an obstruction.

After its initial embryologic development, the GI tract continues to grow in length and diameter until somatic growth ends with puberty. General factors such as adequate nutrition and appropriate levels of insulin, growth hormone, thyroid hormone, cortisol, androgens, and estrogens play a role in GI development, as well as local factors such as the direct effect of ingested nutrients, GI hormones, and secretions.<sup>5</sup>

### Functional Anatomy

Each part of the GI tract is uniquely adapted for a specific function in providing nutrients for the body. The role of each major component of the GI tract will be described in some detail.

#### Oral Cavity and Pharynx

The mouth, or oral cavity, is the usual point of entry for nutrients and is the site of the initial breakdown of nutrient substances into a form usable by the body. Food is pushed toward the side of the mouth by the tongue to facilitate chewing and grinding on the surfaces of the molar and premolar teeth. As the food is manipulated and broken down, it is moistened by saliva secreted by three major pairs of salivary glands: the parotid, submandibular, and sublingual glands (**Figure 35-2**). Saliva serves three major functions: (1) by its moistening action, saliva allows the tongue to convert a mouthful of food into a bolus, or semisolid mass, that can be swallowed easily; (2) it allows for taste perception by the papillae on the surface of the tongue, which are sensitive to chemical differences among dissolved food molecules; and (3) the digestive enzyme contained in saliva, **salivary amylase** (also called ptyalin), initiates carbohydrate digestion by breaking down polysaccharides (also called starch) into the simpler molecular structures of dextrin and maltose.<sup>6,7</sup> Important changes in oral structure and function that occur with aging are detailed in Geriatric Considerations: Changes in the Mouth.

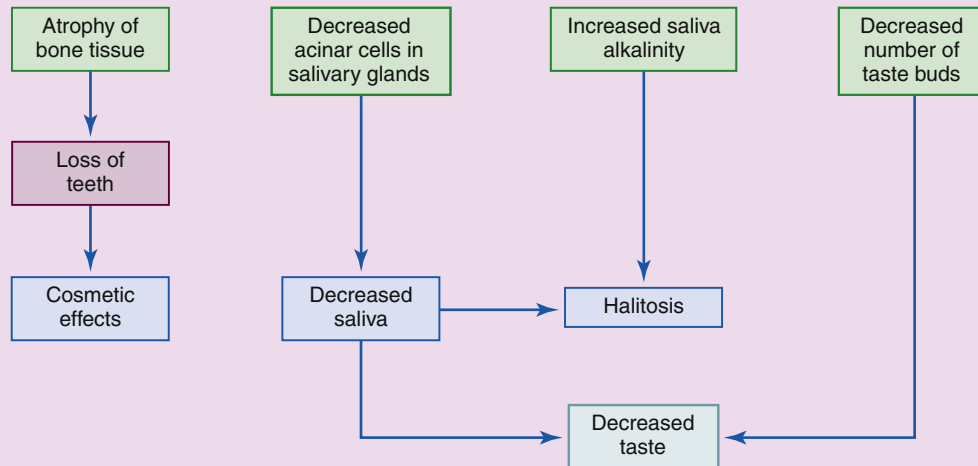

## GERIATRIC CONSIDERATIONS

*Changes in the Mouth*

Elderly people experience a decline in taste. This decline is due to both an increase in the sensation threshold for all four tastes and a decrease in the number of papillae. For example, children have more than 200 taste buds, whereas the elderly have fewer than 100. Of the four basic tastes, elderly people experience a particular decrease in salt and sugar tastes.

Older individuals also experience a decrease in the number of acinar cells in the salivary glands, leading to a reduction in salivary secretion. These changes can contribute to halitosis (bad breath).

Loss of teeth in the elderly is due to atrophy of gum and bone tissue as well as actual tooth deterioration. As tooth enamel is destroyed, dentin is exposed, allowing development of caries (cavities). Gingival epithelial loss may occur as a result of pathologic processes as well as normal aging.

The pharynx, or throat, is about 12 cm long and serves as the entryway for both the respiratory and the GI systems. The oropharynx, the portion of the pharynx posterior to the mouth, is separated from the nasopharynx, the portion of the pharynx posterior to the nose, by the soft palate. The laryngopharynx is the portion of the pharynx that opens into the larynx and the esophagus. During swallowing, the soft palate is pulled upward to close off the nasopharynx. The bolus of food being swallowed is propelled by reflex movements of muscles in the pharynx through the laryngopharynx and into the esophagus. Simultaneously, the opening to the larynx is closed by the epiglottis. This coordinated set of actions prevents food substances and liquids from inadvertently entering the respiratory system, a potentially life-threatening occurrence referred to as aspiration.

**Esophagus**

The esophagus is a muscular tube approximately 25 cm in length that initiates the progress of food through the gut after ingestion. Passage of food through the esophagus is greatly facilitated by mucus secreted by cells in the epithelial lining. Extremely rough or fibrous foods may potentially penetrate the mucous lining of the esophagus and cause damage. The stratified squamous epithelium lining the esophagus is constantly renewed by cells moving to the surface from below, thus providing a means of epithelial renewal. The esophagus propels nutrients to the stomach by means of strong muscular contractions. (**Presbyesophagus**, or abnormal esophageal motility occurring with advanced age, is described in detail in the Age-Related Changes section.) When the body is in an upright position, gravity assists in the downward movement of food to the stomach. However, the muscular contractions of the esophagus are extremely strong and are sufficient to transport nutrients to the stomach even in the absence of gravity, as

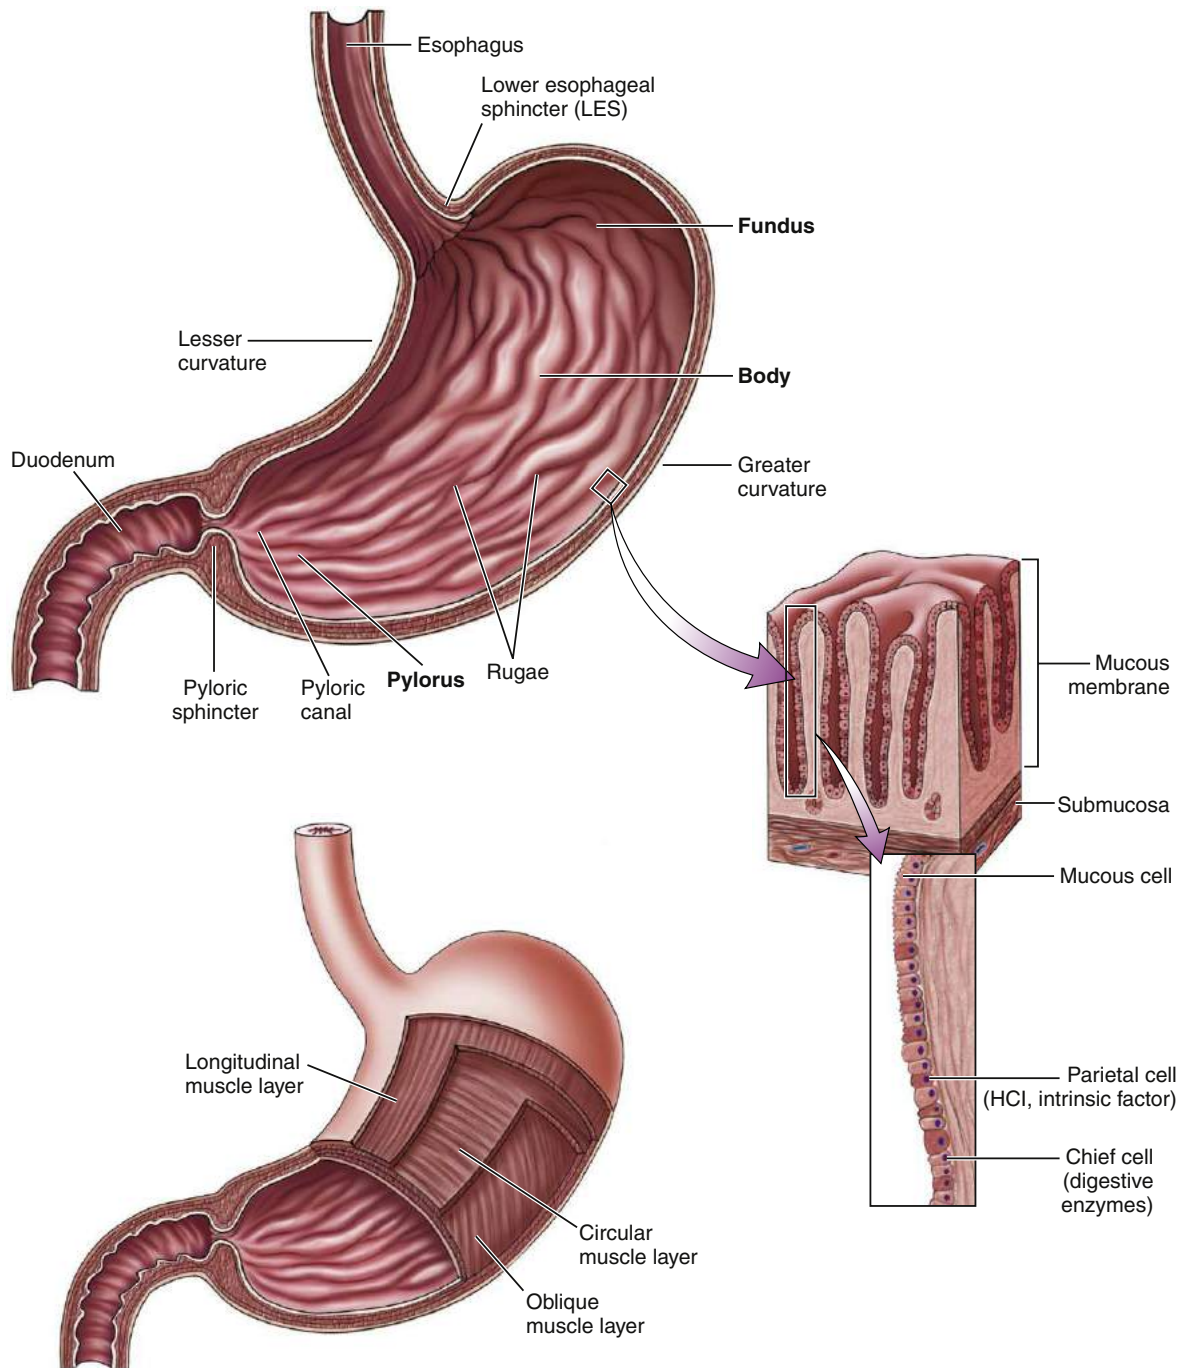

persons living (and eating) in the weightless conditions of space have demonstrated.<sup>1,3</sup>

At the lower end of the esophagus, about 2 to 5 cm above its junction with the stomach, the circular muscle of the esophagus functions as a sphincter; this region is referred to as the **lower esophageal sphincter (LES)**. Although anatomically this sphincter is no different from the remainder of the esophagus, it remains tonically constricted, in contrast to the middle and upper portions of the esophagus, which are completely relaxed under normal conditions.<sup>2</sup> Thus the LES serves to prevent the highly acidic gastric contents from moving in a retrograde motion back into the esophagus. Under certain conditions the LES does not function properly, and reflux of gastric contents into the esophagus gastroesophageal reflux disease (GERD) may occur. The resulting subjective sensation of irritation and spasms of the distal portion of the esophagus is often referred to as heartburn or dyspepsia.

**Stomach**

The stomach (Figure 35-3) is essentially an elastic food reservoir. Under normal circumstances, its capacity is 1000 to 1500 ml, although a capacity of as much as 6000 ml is possible.<sup>2</sup> The portion of the stomach immediately below the LES is called the cardia. The fundus is the part of the stomach that continues lateral to and above the cardia; the body of the stomach extends from the cardia to the antrum, which stretches from the angulus to the pylorus. The antrum differs markedly from the rest of the stomach in function and is distinguished by the absence of rugae, the folds present in the mucous membrane of the other areas of the stomach. The **pylorus** is a muscular sphincter between the stomach and duodenum that serves to control gastric emptying and limits the reflux of bile from the small intestine.

The stomach is lined with simple columnar epithelium containing millions of gastric glands that extend down to the mucosa.

**FIGURE 35-3** Physiologic anatomy of the stomach. *HCl*, Hydrochloric acid. (From Herlihy B: *The human body in health and illness*, ed 4, Philadelphia, 2011, Saunders.)

A typical gastric gland is shown in Figure 35-4. As shown in this illustration, gastric glands are lined by several types of specialized cells. Chief cells produce pepsinogen, the inactive form of the enzyme pepsin; parietal cells produce hydrochloric acid and also a substance called intrinsic factor that is needed for adequate intestinal absorption of vitamin B<sub>12</sub>.<sup>8</sup> Mucous cells produce an alkaline mucus that serves to shield the stomach wall and neutralize the acidity in the immediate area of the lining. A layer of mucus more than 1 mm thick continuously bathes the free surfaces of the gastric epithelial lining. In addition to these cells, gastrin cells are located in the antral epithelium and have surface microvilli that monitor

intra-gastric pH. The role of these cells and the substances they secrete in the digestion of nutrients are described in detail in the Secretory Function section.

### Small Intestine

The small intestine of an adult is approximately 5 to 6 m long (the longest portion of the GI tract). The first 22 cm of the small intestine is called the duodenum; the jejunum constitutes the next 2 m, and the ileum forms the remainder. The entire inner wall of the small intestine is marked by circular folds of a mucous membrane called the plicae circulares, permanent ridges that do not lose their elasticity when the intestine is distended.

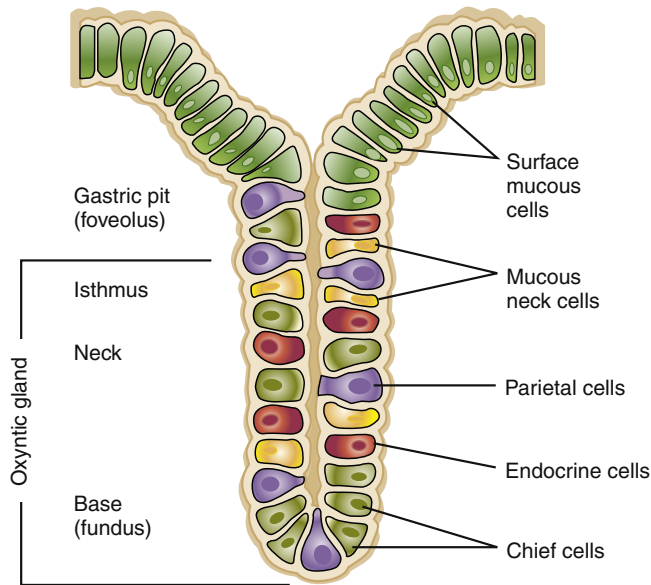

FIGURE 35-4 Gastric mucosa and gastric glands.

On microscopic examination, the lining of the small intestine contains millions of fingerlike projections called **intestinal villi** (Figure 35-5). Like the circular folds just described, these villi serve to increase the surface area of the intestine for digestion and absorption of nutrients. Each villus has its own microscopic projections called microvilli, which in turn are covered by a fuzzy coat (called the **brush border** because of its brushlike appearance when viewed with an electron microscope) containing many digestive enzymes. The combined effect of the circular folds, villi, and microvilli is to increase the surface area of the small intestine by about 600 times, thereby creating a remarkably efficient interface for nutrient digestion and absorption. Figure 35-6 shows a microscopic section of the small intestine.

Between the villi are situated the intestinal glands, or crypts of Lieberkühn. The intestinal glands secrete about 2 L of fluid daily into the lumen of the intestine, but most of the fluid is quickly reabsorbed by the villi. Goblet cells throughout the intestinal mucosa secrete large amounts of mucus. In addition, specialized mucous glands located in the first few centimeters of the duodenum, called Brunner glands, release a thick coating of mucus to protect the mucosa from the potentially damaging effects of acidic gastric juice that may enter through the pylorus.

Although the details of the process of digestion and absorption of nutrients in the intestinal mucosa will be covered in greater detail in subsequent sections, a unique and salient feature of the villus epithelial cells is described here. Villus epithelial cells have both digestive and absorptive functions, apparently dependent on their current stage of maturation. The rapidly dividing cells at the base of the intestinal glands are responsible for secretion, but as they migrate to the villus, they mature into absorptive cells and are eventually pushed out of the villus tip. Turnover of cells in the small intestine occurs in 48 to 72 hours, one of the fastest cell turnover rates in the body. Therefore, conditions such as malnutrition or substances that interfere with cell replication or protein synthesis, such as chemotherapeutic agents, may adversely affect intestinal function.

The **ileocecal valve**, a sphincter between the small and large intestines, is normally closed so that the contents of the large intestine cannot reflux back into the small intestine. As peristaltic contractions move intestinal contents toward the large intestine, the ileocecal valve opens.

## Large Intestine

The large intestine (Figure 35-7) is a muscular tube 1.5 m long and 6.5 cm in diameter that forms a frame around the small intestine. The portion of the large intestine from the cecum to the rectum is known as the colon. The ascending colon extends from the cecum straight up to the lower border of the liver; the transverse colon then extends across the abdomen, anterior to the small intestine. The descending colon turns downward on the left side of the abdomen, finally becoming the S-shaped sigmoid colon, which empties into the rectum. The rectum has its outlet at the anus, the opening for elimination of feces (see Figure 35-7).

The vermiform appendix, attached to the cecum, is a worm-shaped blind tube containing specialized lymphatic structures. It contains T and B lymphocytes, secretes immunoglobulin A (IgA), and contributes to gut-associated lymphoid function.<sup>9</sup> Inflammation of the appendix, or appendicitis, is a life-threatening occurrence that can lead to peritonitis if not diagnosed and managed promptly.

The mucosa of the large intestine has no villi and does not produce digestive enzymes (Figure 35-8). The epithelial surface of the colon consists of absorptive cells that predominantly absorb water and electrolytes.<sup>10</sup> Mucus-producing goblet cells line the glandular crypts present in the surface epithelium. Endocrine cells are also present, perhaps helping coordinate colon neurologic activity, but at present the function of hormones in the large intestine is poorly understood. The turnover time of cells in the colonic mucosa is 3 to 8 days, comparatively longer than that of cells in the small intestine.

### KEY POINTS

- Tracheoesophageal fistula, esophageal and duodenal atresia, and anal agenesis are congenital disorders that occur with abnormal development of the GI tract. These disorders are usually manifested as obstructions.
- The major structures and corresponding functions of the GI tract can be summarized as follows:
  - **Mouth and salivary glands:** Mastication, moistening, and the beginning of starch digestion (by the enzyme salivary amylase) of foodstuff.
  - **Pharynx:** Transport of food to the esophagus and protection of the airway from aspiration of food particles.
  - **Esophagus:** Movement of food to the stomach by peristaltic waves. The LES prevents reflux of stomach contents.
  - **Stomach:** Reservoir for food, mixing, and initial digestion of proteins (by the enzyme pepsin); secretion of hydrochloric acid, intrinsic factor, and gastrin. The pyloric sphincter prevents reflux of intestinal contents.
  - **Small intestine:** Digestion and absorption of nearly all nutrients in the duodenum and jejunum; absorption of bile salts in the terminal ileum. The brush border contains numerous digestive enzymes. The enzymes secretin and cholecystokinin are secreted by intestinal mucosa.
  - **Pancreas and gallbladder:** The pancreas delivers digestive enzymes and bicarbonate to the duodenum. The gallbladder delivers bile salts to the duodenum.
  - **Large intestine:** Reabsorption of water and storage of feces. Feces are delivered to the rectum for defecation.

## GASTROINTESTINAL MOTILITY

The way in which nutrients and their eventual waste products are propelled through the GI tract is a complex and fascinating process, involving an exquisitely timed set of autoregulatory actions and responses. A summary of the characteristics of the intestinal wall, innervation of the gut, and hormonal control of GI motility will provide a basis for a description of how nutrients move through the GI tract.

**FIGURE 35-5** The intestinal wall showing the layers of muscle, mucosal villi, and the brush border microvilli. Villi contain blood capillaries and a lacteal (lymph capillary). Villi and microvilli significantly increase the surface area available for absorption. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 8, St Louis, 2013, Mosby, p 876.)

**FIGURE 35-6** Microscopic section of the small intestine. (From Kumar V et al: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders, p 803.)

**FIGURE 35-7** Divisions of the large intestine. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 878.)

**FIGURE 35-8** Normal colon histology showing a flat mucosal surface and abundant vertically oriented crypts. (From Kumar V et al: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders, p 803.)

**FIGURE 35-9** Cross-section of a typical segment of the intestinal wall showing the four principal layers and associated structures: mucosa, submucosa, muscularis, and serosa. Although different areas of the GI tract specialize in function, the anatomy of the wall is similar in structure. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 863.)

### Characteristics of the Intestinal Wall

A typical cross-section of the intestinal wall is depicted in Figure 35-9. From the outer surface inward are five main layers: the serosa, a longitudinal muscle layer, a circular muscle layer, the submucosa, and the mucosa. A small layer, the muscularis mucosa, is located between the mucosa and submucosa. The muscular movements of the GI tract are performed mostly by the different layers of the smooth muscle, which extends from the distal end of the esophagus through most of the large intestine. However, skeletal muscle has a key role in motility at both ends of the GI tract; motility from the mouth through the proximal portion of the esophagus at the upper end and through the external sphincter of the anus at the lower end is mediated by the action of skeletal muscle.<sup>2</sup>

The general characteristics of smooth muscle are covered in Chapter 5. One of the specific characteristics of smooth muscle in the gut that enables its unique function is the close proximity of these fibers to each other. In most areas of the GI tract, smooth muscle fibers are extremely close; about 12% of their membrane surfaces are actually fused with the membranes of other adjacent muscle fibers to form a nexus, or junction. This allows intracellular current to travel very easily from one muscle fiber to another. Action potentials originating in one smooth muscle fiber in the GI tract are generally propagated from fiber to fiber; therefore, the GI tract acts as a **functional syncytium**, where separate cells have the ability to function in a unified manner.<sup>1</sup>

### Neural Control

Movement of nutrients through the GI tract is controlled by the central nervous system through its autonomic division and is modulated by numerous hormonal interactions.<sup>2,3,8</sup> In addition, the GI system has an intrinsic nervous system of its own affecting most GI functions.<sup>9-12</sup> The intrinsic nervous system is composed of two layers: (1) the myenteric, or Auerbach, plexus, which lies between the longitudinal and circular

muscular layers; and (2) the submucosal, or Meissner, plexus, which lies in the submucosa. The myenteric plexus is largely responsible for control of GI movements; the submucosal plexus serves to control secretion and is also involved in many sensory functions, with information being received from the gut epithelium and stretch receptors in the intestinal wall. The entire intrinsic nervous system, including both the myenteric plexus and the submucosal plexus, is responsible for many reflexes that occur locally in the GI tract, such as the localized secretion of digestive juices by the submucosal glands or an increase in gut smooth muscle activity.

In general, when the myenteric plexus is stimulated, activity in the GI tract increases. This stimulation has four principal effects: (1) tonic contraction of the intestinal wall increases; (2) rhythmic contractions increase in intensity; (3) rhythmic contractions increase in rate; and (4) the velocity of conduction of excitatory waves along the intestinal wall increases. As part of the parasympathetic nervous system, these excitatory fibers of the myenteric plexus are primarily cholinergic (i.e., secrete acetylcholine), in addition to one or more other excitatory transmitter substances. However, some myenteric plexus fibers have an inhibitory effect and may secrete purine-based transmitter substances such as adenosine triphosphate (ATP).

Input from the sympathetic and parasympathetic nervous systems can strongly affect the activity of the intrinsic nervous system. In general, sympathetic stimulation decreases the activity of the intrinsic nervous system whereas parasympathetic stimulation increases its activity.

### Parasympathetic Innervation

The parasympathetic supply to the GI tract is divided into cranial and sacral divisions. Cranial parasympathetic stimulation is transmitted almost entirely by the vagus nerves, which provide extensive innervation to the esophagus, stomach, pancreas, and the first half of the

large intestine (with little innervation of the small intestine). The sacral parasympathetic division originates in the second, third, and fourth sacral segments of the spinal cord and innervates the distal half of the large intestine. The sigmoid, rectal, and anal regions of the large intestine are especially well supplied with parasympathetic fibers; these fibers have a key role in the defecation reflex.

### Sympathetic Innervation

The sympathetic fibers that innervate the GI tract have their origin in the spinal cord between T8 and L3. After exiting the cord, the pre-ganglionic fibers enter the sympathetic chains and then pass through these chains to various ganglia adjacent to the GI tract, such as the celiac ganglion and the mesenteric ganglia. From these locations, postganglionic fibers radiate out to all parts of the gut. These sympathetic fibers supply essentially all parts of the GI tract (in contrast to the concentration of parasympathetic innervation at locations close to the entry and exit points of the gut).<sup>2</sup> The sympathetic nerve endings in the GI tract secrete norepinephrine, which promotes the inhibitory effect of the sympathetic nervous system on the GI tract in the following ways: Norepinephrine acts directly on smooth muscle in the GI tract to inhibit activity; in addition, norepinephrine has an inhibitory effect on the neurons of the intrinsic nervous system of the GI tract. Strong stimulation of the sympathetic nervous system can effectively stop motility in the gut and therefore block the movement of nutrients through the GI tract. Gastrointestinal sympathetic activity can also initiate vomiting through a complex sequence of events mediated by various neurotransmitters.<sup>13-15</sup>

### Afferent Nerve Fibers

The GI tract is richly supplied with afferent nerve fibers arising from the gut that transmit important information about the status of the GI tract. Afferent fibers that have their cell bodies in the submucosal plexus and terminate in the myenteric plexus transmit signals in response to irritation of the gut mucosa, excessive distention, or the presence of specific chemical substances. These signals can result in excitation or, in some circumstances, inhibition of intestinal motility or secretion. Other afferent fibers with cell bodies in the dorsal root ganglia of the spinal cord or cranial nerve ganglia can transmit signals to higher levels of the central nervous system by traveling along sympathetic or parasympathetic pathways. For example, the vagus nerves contain many afferent fibers that transmit signals to the medulla; this information is then used to initiate and modulate vagal signals that control many important functions of the GI tract.

### Electrical Activity of Gastrointestinal Smooth Muscle

Electrical activity is almost constantly present in the smooth muscle layers of the GI tract. Two basic types of electrical wave activity have been identified in the gut: slow waves and spikes (the latter named for the spiking appearance of these sudden increases in membrane potential).<sup>1,2</sup> These two types of electrical wave patterns are shown in Figure 35-10. **Slow-wave electrical activity** represents an ongoing basic oscillation in membrane potential that occurs in the smooth muscle of the GI tract, especially in the muscle in the longitudinal layer. Normally, between 3 and 12 slow waves occur per minute, ranging from 40 to 50 millivolts (mV) in amplitude. Slow waves can be any degree of intensity and are not the “all-or-nothing” type of action potential seen in other smooth muscle fibers in the body. In contrast to these nearly continuous slow waves, spikes occur under certain circumstances. When the muscle layer in the GI tract is stimulated by being stretched or by the effects of acetylcholine or parasympathetic excitation,

**FIGURE 35-10** Membrane potentials in intestinal smooth muscle. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

the intracellular resting membrane potential of the muscle fibers becomes relatively more positive. The entire potential level of the slow waves is raised—an effect called depolarization.<sup>1</sup> As shown in Figure 35-10, when depolarization rises above a certain level (around  $-40$  mV), sudden increases in the membrane potential, or spikes, start to appear on the peaks of the slow waves. If the resting potential rises further, spikes appear more frequently. With very strong stimulation, the spikes generally disappear because the membrane now remains entirely depolarized. Figure 35-10 also illustrates the response of smooth muscle fibers to stimulation by norepinephrine or sympathetic excitation. In this situation, the resting membrane potential is decreased, or hyperpolarized, and electrical activity is almost abolished.

### Hormonal Control

The following section on secretory function of the GI tract describes in detail the role of hormones in controlling GI secretion. It is important to note that many of these same hormones are involved in controlling motility in different portions of the GI tract. Gastrin, which is secreted by specialized endocrine cells (G cells) of the stomach mucosa in response to food entry, increases stomach motility and is the primary mediator of gastric acid secretion. In addition, it promotes increased constriction of the LES, which serves to prevent reflux of stomach contents into the esophagus. Gastrin may also have a small effect in increasing motility of the small intestine and gallbladder.<sup>2,3</sup>

Cholecystokinin, which is secreted mainly by I cells of the jejunum in response to the entry of fatty substances, has an extremely strong effect on gallbladder contractility. This stimulation of gallbladder activity results in an outpouring of bile, which plays an important role in fat digestion and absorption. Cholecystokinin also stimulates pancreatic secretion, helps regulate gastric emptying and bowel motility, and induces satiety.<sup>3</sup>

Secretin, which is produced by the mucosa of the duodenum in response to the entry of acidic gastric juice from the stomach, stimulates pancreatic fluid and bicarbonate secretion, with the effect of neutralizing the acidity of intestinal contents. It also has a mild inhibitory effect on motility in most of the GI tract.<sup>2,3</sup>

Other important gastrointestinal polypeptide hormones include vasoactive intestinal polypeptide (VIP), glucagon, glucose-dependent insulinotropic polypeptide (GIP, also called gastric inhibitory

polypeptide), somatostatin, motilin, leptin, and ghrelin.<sup>3</sup> Somatostatin analogues (e.g., octreotide) have been used therapeutically for the treatment of some forms of diarrhea, endocrine tumors, parietal hemorrhage and to reduce fluid output from pancreatic fistulas.<sup>14</sup>

Ghrelin is a recently discovered peptide secreted by the stomach that increases appetite, stimulates growth hormone secretion, and produces weight gain. It helps regulate mealtime hunger and meal initiation, and as such has been the focus of intense research as a mediator for obesity, with the potential for a therapeutic antiobesity drug that would block ghrelin's effects on the body.<sup>16-21</sup>

## Movement in the Gastrointestinal Tract

### Contraction of Gastrointestinal Smooth Muscle

In general, most contraction in the GI tract occurs in response to spike potentials; slow waves without superimposed spikes ordinarily do not lead to contraction. **Spike potentials** occurring in GI smooth muscle are analogous to action potentials in cardiac muscle and are responsible for the membrane changes that initiate contraction. As calcium enters the cell membrane and passes to the interior of the smooth muscle, it initiates a reaction between actin and myosin,<sup>1</sup> a process described in detail in Chapter 17.

The electrical activity occurring in the smooth muscle of the gut develops into tonic contractions and rhythmic contractions, both of which occur in most types of smooth muscle. Tonic contraction is continuous, instigated by pacemaker cells that reside at the interface between the longitudinal and circular muscle layers. The intensity of tonic contraction varies with the frequency of spike potentials and determines the amount of pressure in that segment. Thus, the degree of contraction exerted by the pyloric, ileocecal, and anal sphincters serves to regulate the movement of nutrients through the GI tract.

The degree of rhythmic contraction varies in different parts of the GI tract. These differing rhythmic frequencies are dependent on the rate of slow wave activity in a particular segment and may occur at rates of 3 to 12 times per minute. These slow wave–dependent contractions are responsible for the mixing and peristaltic propulsive movements present in the GI tract.

Two types of muscular activity are involved in the digestive and absorptive functions of the GI tract: mixing movements and propulsive movements. In different portions of the GI tract these movements may serve different functions to achieve proper digestion and absorption of nutrients. For example, mixing movements in the stomach and small intestine promote digestion by mixing the digestive juices with the food that enters from the esophagus. In the small intestine and proximal segment of the large intestine, mixing movements facilitate absorption by exposing newly arrived intestinal contents into contact with absorbing surfaces. In the case of propulsion, the rate at which nutrients are propelled through the GI tract depends on the function of the different organs of the tract. For example, the passageway for nutrients from the mouth through the pharynx and esophagus is simply a conduit; essentially no digestive or absorptive function occurs there and the transit of nutrients is quite rapid. In contrast, transit from the stomach and through the small and large intestines is quite slow. This slow rate of passage allows for completion of the digestive and absorptive processes that occur in these portions of the GI tract.

Although the characteristics of mixing and propulsive movements differ in various parts of the GI tract and will be described separately in the next section, a description of the general characteristics of these movements is presented here.

### Propulsive Movements

The basic propulsive movement of the GI tract is called peristalsis (Figure 35-11). Nutrients are propelled by the slow advancement of

**FIGURE 35-11** Peristalsis is a progressive type of movement, propelling material from point to point along the GI tract. **A**, A ring of contraction occurs where the GI wall is stretched, pushing the bolus forward. **B**, The moving bolus triggers a ring of contraction in the next region, which pushes the bolus even farther along. **C**, The ring of contraction moves like a wave along the GI tract, pushing the bolus forward. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 906.)

a circular constriction that squeezes the materials in front of the constricted area forward. Peristalsis is an inherent property of any smooth muscle tube that, like the intestine, is a functional syncytium. However, effective intestinal peristalsis requires the presence of an intact myenteric nerve plexus. The usual stimulus for peristalsis is distention of the intestinal walls. The entry and subsequent stretching of the intestinal wall by a bolus of food will have the effect of stimulating the gut wall 2 to 3 cm above this point, and a circular constriction will then occur and propel the food with a peristaltic movement. Although peristalsis can move in both directions in the gut, it normally moves toward the anus. It is thought that the myenteric plexus is organized in such a way that preferential transmission of signals downward occurs simultaneously with relaxation of the distal portion of the intestine below the distended stimulus point.

### Mixing Movements

Segmental contractions serve to keep the intestinal contents thoroughly mixed on a constant basis. These movements may vary according to the specific function of each portion of the GI tract (see the Secretory Function section).

### Movement of Nutrients

The path taken by foods ingested into the GI tract, as these nutrients travel down the tract and are digested and absorbed, will be traced beginning with the mouth. Although this process is described here as a linear sequence, it is important to note that several steps may occur simultaneously. The individual steps involved in nutrient ingestion constitute a synergistic process, and an inability to perform one phase of the process will ultimately have a profound effect on the entire GI tract. In addition, individuals manifest a great deal of variability in such aspects of digestive function as tolerance of certain nutrients and defecation patterns. Such variations may represent age-related differences or conditioned responses to environmental cues.

## Chewing

The entry of solid food into the mouth results in the action of chewing, an important first step in the process of nutrient digestion. The process of moving the food around in the mouth and mixing it with saliva results in stimulation of the taste buds and olfactory epithelia; this sensory input greatly increases the subjective enjoyment of eating. As the food is mixed with saliva, it becomes softened and formed into a mass of appropriate size (bolus) that can be swallowed. The action of the molars and premolars in crushing more rigid forms of foods serves to prepare rough substances for transport down the esophagus. Although the act of chewing is under voluntary control, it is also partly reflexive in nature. The entry of food into the mouth has been shown to stimulate chewing in animals in the absence of full cerebral function. The movements of the skeletal muscles responsible for chewing are coordinated by impulses traveling through cranial nerves V, VII, IX, X, XI, and XII. Interruption of the proper transmission of impulses through these nerve tracts places an individual at risk for decreased voluntary control of the chewing function, with a resultant risk of aspiration (improper entry of oral or esophageal contents into the airways).

## Swallowing

Swallowing is the transport of material from the mouth to the stomach. The process of swallowing has been divided into three stages that describe the regions through which the bolus of nutrients passes on its way to the stomach: (1) the oral stage, (2) the pharyngeal stage, and (3) the esophageal stage.<sup>2,3,9</sup>

During the oral stage, the bolus is passed from the mouth to the pharynx through the space called the fauces. The bolus, either solid or liquid, is rolled toward the back of the tongue, and the front of the tongue is then pushed up against the hard palate. Respiration is inhibited briefly in this phase, while the pharyngeal muscles constrict to force the bolus of food into the pharynx. In the pharyngeal stage the bolus is passed through the pharynx into the esophagus, a process taking about 0.2 seconds. Continued contraction of the pharyngeal muscles and the position of the tongue prevent reentry of the bolus into the oral cavity. The soft palate is pulled upward to block the nasopharynx; simultaneously, food is prevented from entering the larynx by elevation of the larynx and approximation of the vocal cords, both actions serving to close the glottis. As these openings are blocked, the pharyngeal constrictors contract and force the bolus of food into the esophagus. Respiration is now resumed, and pressure in the pharynx rises as a result of the muscular activities that have occurred.

The muscular characteristics of the esophagus are of particular importance in effecting the third, or esophageal, stage of swallowing. The upper one third of the esophagus consists of skeletal muscle, whereas the lower two thirds consists of predominantly smooth muscle. In the normal resting stage, the upper part of the esophagus is closed by the tonic contraction of a band of skeletal muscle that serves as the pharyngoesophageal sphincter. The pressure exerted by the pharyngoesophageal sphincter in this region is normally about 20 to 40 cm H<sub>2</sub>O above atmospheric pressure; this zone of high pressure keeps air from entering the esophagus during inspiration. Almost immediately after initiation of a swallow, the sphincter relaxes and pressure in the region drops to atmospheric pressure, thus allowing the bolus to be forced into the esophagus by the pressure generated in the pharynx. Pressure in the pharyngoesophageal junction region then rises as a result of contraction of skeletal muscle in this area, thus preventing reflux of food from the esophagus back to the pharynx. Pressure in this region then gradually subsides to a resting level while muscular relaxation occurs.

If the bolus being swallowed is a liquid, it is propelled through the esophagus by the initial force of swallowing and travels by gravity to the stomach in about 1 second. If the bolus is a semisolid mass, it is propelled

**FIGURE 35-12** Neural pathways of the swallowing mechanism. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

down the esophagus by means of a peristaltic wave. This esophageal peristalsis is caused by a contraction of circular muscle that forces the bolus ahead of it toward the stomach, with a transit time of about 4 to 6 seconds.

Although no well-differentiated muscular structure is located in the area where the esophagus joins the stomach, the region approximately 2 to 5 cm above the juncture with the stomach is referred to as the LES and is described in the Esophagus section. Almost immediately after initiation of a swallow, pressure at the LES drops and remains low during the time that a peristaltic wave is passing down through the lower end of the esophagus. Once the bolus has passed through the lower esophageal region and pressure in the lower portion of the esophagus has fallen to a resting level, the pressure in the LES rises and remains elevated for about 10 seconds before declining to a resting level once again.<sup>2</sup>

**Neural control of swallowing.** Figure 35-12 illustrates the neural pathways involved in the swallowing mechanism. Swallowing receptors in the posterior of the mouth and throat transmit impulses in response to a stimulus to the mucous membranes in the mouth, such as the presence of a moderate amount of fluid. These impulses travel mainly through the trigeminal nerve (cranial nerve V) into the reticular substance of the medulla oblongata, where the swallowing center is located. Once this center has been activated, the sequence of muscular reactions described earlier occurs automatically and usually cannot be voluntarily stopped. The swallowing center then sends impulses over a number of efferent nerves to the numerous skeletal and smooth muscles involved in the swallowing process to allow the complete act of swallowing to occur in the appropriate sequence. The glossopharyngeal (cranial nerve IX) and hypoglossal nerves (cranial nerve XII) are primarily concerned with the oral and pharyngeal stages, whereas the vagus nerve (cranial nerve X) is important in activating the esophageal stage.

The gag reflex is an important protective mechanism that aborts the normal swallowing response and helps eliminate potentially harmful ingestions. The afferent limb of the reflex is controlled by the glossopharyngeal nerve, and the efferent limb is regulated by the vagus nerve. Disorders of the gag reflex such as stroke or neuropathy can lead to life-threatening obstruction or aspiration.

### Motor Functions of the Stomach

The motor functions of the stomach include the storage of ingested nutrients for variable lengths of time and the discharge of gastric contents into the small intestine at an appropriate rate for optimal digestion and absorption. The stomach also aids in the digestive process by its mixing movements, which convert large pieces of food to a finer, liquid consistency.

**Gastric filling and storage.** On entering the stomach from the esophagus, newly arrived food forms concentric circles in the body and fundus of the stomach, with the most recently ingested food lying closest to the esophagus and older food lying closer to the stomach wall. The smooth muscle in the fundus and body of the stomach can adapt to the volume of contents so that relatively large contents can be introduced with little increase in intragastric pressure. The fundus and body of the stomach maintain a consistent pressure at all times. This tonic contraction continually presses on the food mass and aids in its delivery to the pyloric antrum.

Peristaltic contractions occur in the stomach once every 20 seconds. These rippling peristaltic waves begin in the corpus and move at a velocity of about 1 to 2 cm/sec. When they reach the more thickly walled pyloric antrum, they become much more vigorous and also increase in speed. These strong peristaltic contractions in the pyloric antrum are largely responsible for mixing ingested nutrients with gastric secretions. As ingested food is churned and mixed to a greater degree of fluidity, the mixture takes on a milky white sludge appearance and is then called **chyme**.

**Emptying.** As pressure in the antrum rises momentarily because of peristaltic contraction, a pressure differential exists between pressure in the antral pylorus and pressure in the duodenal bulb. The higher pressure in the antrum is sufficient to overcome the resistance of the pyloric sphincter, and the contents of the stomach are then propelled into the duodenum. Concurrently, the degree of constriction of the pyloric sphincter may increase or decrease, depending on several factors discussed in the next section. Because this process is dependent on the muscular activity of the antrum as well as the muscular tone of the pylorus, gastric emptying is largely regulated by mechanisms that affect each of these regions.

**Regulation of gastric emptying.** Factors that may affect the rate at which the stomach empties include the degree of distention of the gastric wall and the release of the hormone **gastrin** in response to certain types of food in the stomach. Both of these factors increase the rate of gastric emptying by increasing the force of antral contractions, while simultaneously inhibiting pyloric constriction. Distention of the gastric wall results in stimulation of mechanoreceptors in the stomach with subsequent activation of reflexes over the vagus and the intrinsic nerve plexuses. These neural influences, along with contractile activity as a direct response to the stretch of gastric muscle, constitute a major stimulus for gastric emptying. Gastric emptying time can vary depending upon the food ingested (e.g., whether solid or liquid) and generally ranges from 1 to several hours.<sup>3</sup>

Gastrin is released from the antral mucosa in response to stretching of the gastric wall, as well as the presence of certain foods, particularly meat. The role of gastrin in promoting the secretion of highly acidic gastric juices will be discussed later. With respect to stomach emptying, gastrin has a key role in enhancing peristalsis while at the same time relaxing the pylorus.

In addition to these influences, many of the mechanisms that affect gastric emptying are initiated in the duodenum. Reflex nervous signals are transmitted from the duodenum back to the stomach in response to intraluminal stimuli; these signals likely help control both peristaltic activity and the degree of pyloric constriction. Stimulation of the duodenum in a variety of ways has the effect of slowing gastric emptying; both the chemical and the physical properties of chyme entering the duodenum may affect the rate of gastric emptying. A variety of both

duodenal cells and duodenal receptors, including osmoreceptors, mechanoreceptors, and chemoreceptors, respond to intraluminal stimuli to produce hormonal and reflex inhibition of gastric motor activity and enhancement of pyloric tone. The presence in the duodenum of chyme containing the breakdown products of proteins, and to a lesser extent fats, may impede gastric emptying. Also, the presence of highly acidic or highly hypertonic or hypotonic chyme in the duodenum may inhibit the rate of gastric emptying. The degree of distention of the duodenum, as well as the presence of any degree of irritation of the duodenum, may also slow emptying of the stomach. These inhibitory mechanisms have a protective function and are effective in preventing the intestinal mucosa from overloading its digestive and absorptive abilities and potentially being damaged by chemical or mechanical sources.

Although regulation of gastric emptying is largely dependent on factors in the stomach and duodenum, gastric motility may be stimulated or inhibited reflexively from a variety of regions of the body. For example, stomach emptying is inhibited when the ileum is full and when the anus is mechanically distended. Stimulation of visceral and somatic pain receptors may result in inhibition of gastric motility. Various strong emotions such as anger, fear, and anxiety may produce changes in motility of the stomach, but whether these states tend to predispose an individual to inhibition or excitation of gastric motility is not always predictable.<sup>3</sup>

**Vomiting.** Vomiting is rapid emptying of the contents of the stomach through the esophagus and into the mouth. The major force for vomiting is supplied by the skeletal muscle of the diaphragm and abdomen, rather than by contraction of the muscles of the stomach wall. Vomiting is the result of an extremely complex set of neural events coordinated by the nucleus tractus solitarius (NTS), a center located in the medulla. Afferent impulses from receptors in various regions of the body, including the sensory nerve endings of the pharynx, abdominal viscera, and the labyrinths, arrive at this center to initiate the vomiting reflex. This reflex causes closure of the glottis and trachea, relaxation of the gastroesophageal sphincter, and contraction of the diaphragm and the abdominal muscles, which forcibly expels the contents of the stomach.

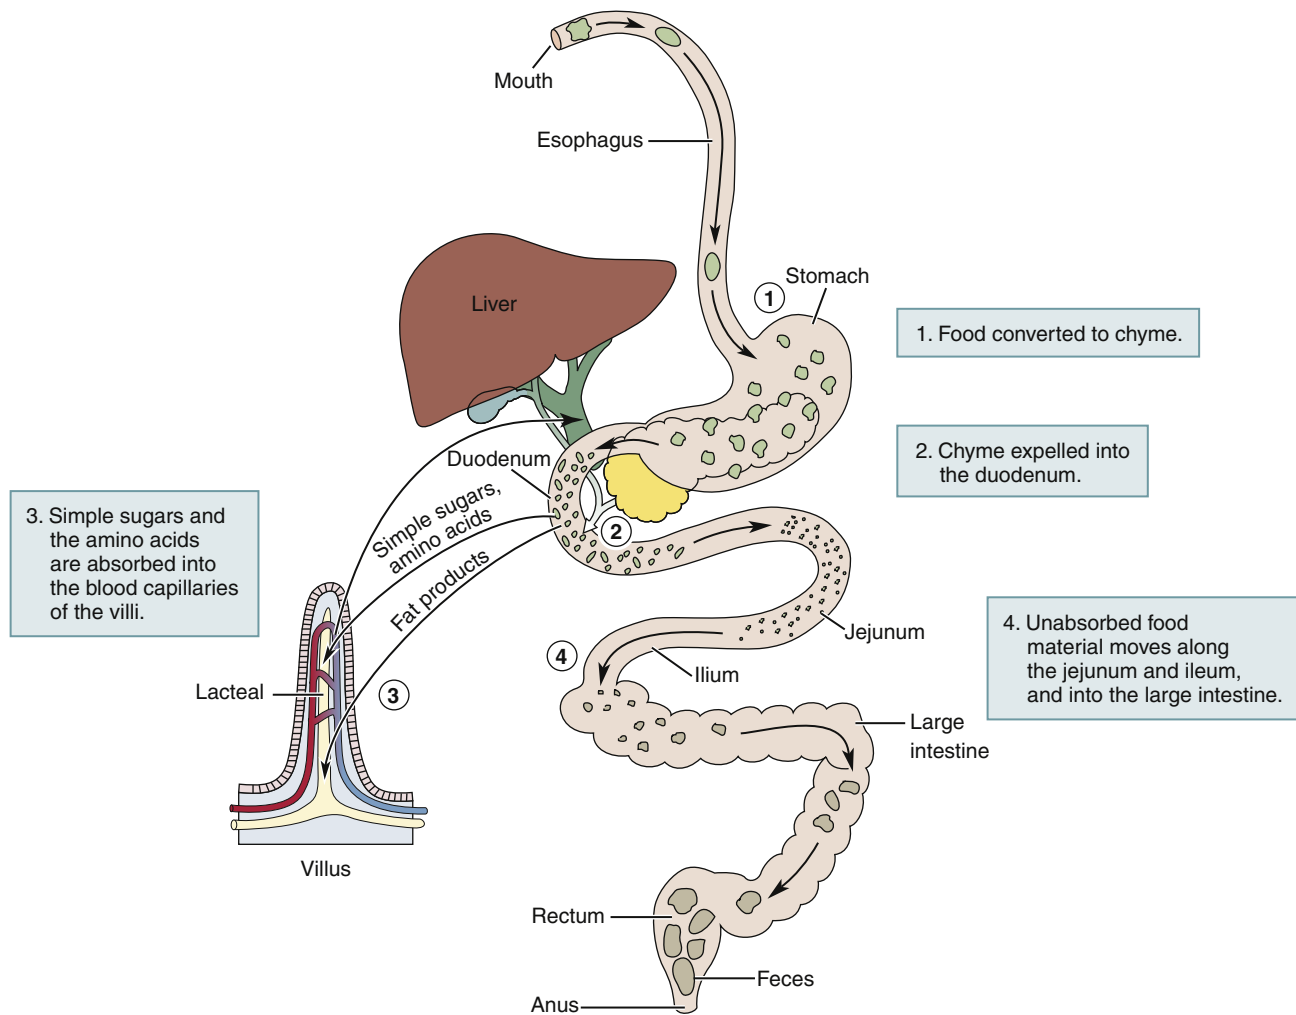

### Motility of the Small Intestine

After intact food entering the mouth has been liquefied and partially digested in the stomach, it enters the small intestine, where the major part of digestion and absorption occurs. As in other parts of the GI tract, movements of the small intestine can be described as propulsive and mixing movements, which in the small intestine generally occur simultaneously.

**Propulsion.** Chyme is propelled through the small intestine by peristaltic waves that move at a rate of 0.5 to 2 cm/sec, with a faster rate at the proximal part of the intestine and a slower rate in the terminal portion. Approximately 3 to 5 hours is normally needed for the passage of chyme from the pyloric sphincter to the ileocecal valve, but this period may vary in some disease states. Peristaltic activity in the small intestine is greatly increased after the ingestion of a meal. The increase in contractile activity in the stomach caused by distention of the stomach wall is conducted principally through the myenteric plexus down along the wall of the small intestine. This so-called gastroenteric reflex serves to increase the activity of the small intestine, with an enhancement of both intestinal motility and intestinal secretion.

The usual stimulus for peristalsis in the small intestine is distention of the intestinal walls; stretch receptors in the gut wall are sensitive to circumferential stretch and initiate a local myenteric reflex in response to this stimulation. The resulting contraction of longitudinal muscle, followed by the contraction of circular muscle, spreads downward in a peristaltic motion.

The peristaltic waves in the small intestine not only propel chyme downward toward the ileocecal valve but also spread the chyme along

**FIGURE 35-13** Chyme and the process of absorption of nutrients. (Modified from Herlihy B: *The human body in health and illness*, ed 4, Philadelphia, 2011, Saunders.)

the intestinal mucosa, thus facilitating the process of absorption of nutrients (Figure 35-13). As additional chyme enters the small intestine, this spreading process intensifies while peristalsis increases. When chyme reaches the ileocecal valve, it is sometimes stationary for several hours until the individual eats another meal and a new gastroenteric reflex intensifies the peristaltic process and propels the remaining chyme through the ileocecal valve.

Certain disease states, particularly those that involve intense irritation of the intestinal mucosa, may result in a peristaltic rush, a powerful peristaltic wave that travels long distances in the small intestine in a short period. The peristaltic rush clears the contents of the small intestine into the colon, thus relieving the small intestine of either irritating substances or excessive distention.<sup>2,9</sup>

**Mixing.** In addition to propulsive peristaltic movements, a set of movements characterized as **segmentation contractions** also occur in the small intestine. The primary effect of these contractions is progressive mixing of solid chyme particles with secretions of the small intestine. As their name implies, segmentation contractions involve contraction of the small intestine in regularly spaced segments that have the appearance of sausages (Figure 35-14). As one set of segmentation contractions is completed, a new set begins, with contractile points located at different locations along the small intestine. Segmentation contractions occur at a rate of 7 to 12 times per minute and effectively chop and mix the chyme, as

well as assist in propelling the chyme toward the ileocecal valve (see Figure 35-14).

**Control of motility.** The electrical and mechanical activities of the small intestine are closely associated. Slow waves, as described previously in this chapter, occur at the membranes of the longitudinal smooth muscle, with frequencies of 11 to 12 per minute in the duodenum decreasing to 7 to 9 per minute in the terminal ileum. Slow waves do not directly produce muscular contractions in the small intestine but provide the conditions under which contractions can occur. Although slow waves determine the velocity and direction of peristalsis, other factors determine whether action potentials and thus contraction will occur. Local mechanical and chemical stimulation by chyme is probably largely responsible for the initiation and continuance of contraction in the small intestine. Thus when the intestinal tract becomes overly distended or when the mucosa becomes irritated, myenteric reflexes enhance the electrical activity of the gut and spike potentials are superimposed on the slow waves. These spike potentials then spread through both longitudinal and circular muscle, and contraction results.

Intestinal motility may also be influenced by stimulation from sources extrinsic to the colon. Stimulation of the vagus nerve generally causes increased intestinal motility, with sympathetic stimulation resulting in inhibition. Intestinal motility can be altered reflexively by stimulation of many sensory areas. For example, trauma to organs outside the GI tract, such as irritation of the peritoneum or urinary tract, may cause

**FIGURE 35-14** Segmentation. Segmentation is a back-and-forth action that separates chunks of food and mixes in digestive juices. **A**, Ringlike regions of contraction occur at intervals along the GI tract. **B**, Previously contracted regions relax and adjacent regions now contract, effectively “chopping” the contents of each segment into smaller chunks. **C**, Locations of the contracted regions continue to alternate back and forth, chopping and mixing the contents of the GI lumen. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 906.)

intestinal inhibition. A condition called paralytic ileus, in which intestinal motility is inhibited as the result of reflex inhibition, may occur as a response to intraabdominal infection or surgery in this area.<sup>3</sup>

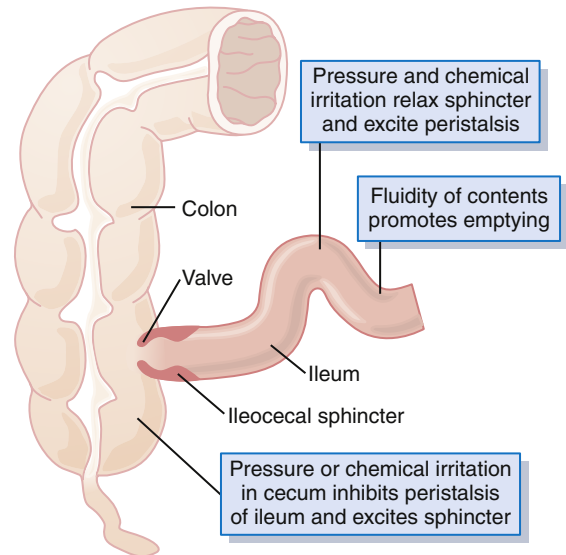

Much current research is focused on the involvement of gastrointestinal hormones in the regulation of GI tract motility.<sup>2,3</sup> Cholecystokinin, a hormone released from the mucosa of the jejunum in response to fatty substances in chyme, has been shown to block the increased gastric motility caused by gastrin. Another hormone, secretin, which is released mainly from the duodenal mucosa in response to gastric acid entering the duodenum, has the general effect of decreasing GI motility. The hormone gastric inhibitory polypeptide (GIP), which is released from the upper portion of the small intestine in response to fat in chyme, as well as to carbohydrates, is known to inhibit gastric motility under some conditions. These hormones will be described in more detail in the Secretory Function section.

### Ileocecal Sphincter

Chyme from the small intestine is eventually propelled downward to the terminal ileum immediately proximal to the cecum, where the last 2 to 3 cm of the muscular coat is thicker than that in the rest of the ileum. This region, called the ileocecal sphincter, has a high resting pressure (about 20 cm H<sub>2</sub>O above atmospheric pressure) and is normally closed. Distention of the distal ileum lowers the pressure in the ileocecal sphincter. Thus, when intestinal contents are present in the terminal ileum at sufficient quantity and are ready to be propelled into the cecum, the sphincter reflexively relaxes and the intestinal contents are pushed into the cecum by the propulsive movements of the distal small intestine. Conversely, distention of the cecum after it is filled with contents passing through the ileocecal valve results in increased pressure in the sphincter, which prevents reflux back into the ileum (Figure 35-15).

### Motility of the Colon

The movements of the colon are effective in promoting the two major functions of the colon: (1) absorption of water and electrolytes from

**FIGURE 35-15** Emptying of the ileocecal valve. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

chyme and (2) storage of the fecal mass until it can be expelled from the body by defecation.

**Colonic movements.** For most of the time, the large intestine in humans is inactive. However, the presence of material in the proximal end of the colon results in a type of mixing movement in the haustra (the outpouchings in the colon wall), termed **haustral churning**, that is similar to the segmenting movements in the small intestine. This movement is the major type of motility in the large intestine. Haustral churning exposes the contents of the large intestine to the mucosa, thus promoting the absorption of water. Normally, about 500 ml of chyme enters the proximal part of the colon each day. Out of this total volume, 400 ml—mostly water and electrolytes—is reabsorbed before defecation takes place, with an average volume of 100 ml of feces remaining for eventual disposal from the body.<sup>1</sup>

At infrequent intervals of about three to four times a day, a strong peristaltic movement termed a mass movement occurs and propels the fecal material long distances. These strong contractions may reach a peak of 100 cm H<sub>2</sub>O pressure in the segment undergoing the contraction. Fecal material may be transported all the way from the ascending colon to the descending colon by a mass movement. Feces are then stored in the distal end of the colon until defecation occurs.

**Defecation.** Under normal conditions, it takes about 18 hours for intestinal contents to reach the distal end of the colon after leaving the small intestine. Fecal material is stored in the distal part of the colon for varying lengths of time; defecation may take place 24 hours or longer after the ingestion of food. Ordinarily the rectum is empty, but fecal material is occasionally shifted into it after one of the mass movements, and the resulting distention of the rectum initiates the urge to defecate. The act of defecation is a combination of voluntary and involuntary movements. Contraction of the distal end of the colon and relaxation of the internal anal sphincter, which are regions composed of smooth muscle, are involuntary movements. Relaxation of the external anal sphincter, which consists of striated muscle, is a voluntary movement. Other voluntary movements that may assist in the act of defecation are contraction of the abdominal muscles and forcible expiration with closure of the glottis (the Valsalva maneuver, often referred to as “bearing down”).

**Regulation of colonic motility.** Movements in the proximal portion of the colon are largely initiated by distention in the colonic

walls, which stimulates contractile activity by triggering short reflexes through the intrinsic nerve plexuses. Although the proximal part of the colon receives extrinsic innervation via the vagus nerve, it functions in a relatively autonomous manner in the absence of extrinsic motor innervation and is thus a somewhat self-regulating structure. Extrinsic nerves may occasionally modify proximal colonic activity, however; for example, entry of food into the stomach or duodenum may result in a mass contraction in the proximal end of the colon. Sometimes termed the gastrocolic or duodenocolic reflexes, these strong mass movements are most evident after the first intake of nutrients in the morning and are often followed by a strong need to defecate.

In contrast, the distal part of the colon is somewhat more dependent on its extrinsic nerve supply, so movements in this region, including the act of defecation, may be entirely abolished after injury to these nerves. However, weak movements return eventually, and defecation can still occur without voluntary control after the initial response to injury has passed.<sup>3</sup>

### KEY POINTS

- Movements of the GI tract are due to contraction of two layers of smooth muscle (i.e., the longitudinal and circular layers). Smooth muscle exhibits two types of electrical potentials: basic oscillations (slow waves), which do not result in contraction, and action potentials (spikes), which trigger calcium entry and result in contraction. Contraction of smooth muscle results in two types of intestinal motility: propulsive (peristalsis) and mixing (segmental).
- GI motility is regulated by the enteric nervous system, the autonomic nervous system, and hormonal mediators. The enteric nervous system has two branches—myenteric and submucosal—that coordinate reflexive contraction and relaxation along the entire GI tract.
- Luminal distention is an important stimulus for reflexive motility. Sympathetic nervous system activity is generally inhibitory to GI motility (and secretion). Parasympathetic nervous system activity generally enhances motility. Regulatory hormones include gastrin (increases gastric motility), GIP (decreases gastric motility), cholecystokinin (stimulates gallbladder contraction), and secretin (decreases GI motility).
- Swallowing is a complex function coordinated by a swallowing center in the medulla.
- Swallowing is partially voluntary and partially involuntary. Cranial nerves IX, X, and XI mediate the various stages of swallowing.
- Regulation of gastric emptying involves gastric and duodenal factors. Gastric distention and the release of gastrin from gastric mucosa promote gastric emptying. Duodenal distention, acidity, hypertonicity, and high protein and fat concentrations inhibit gastric emptying.
- Chyme remains in the small intestine for 3 to 5 hours, where it is continually mixed by segmental contractions and slowly propelled toward the ileocecal valve by peristalsis. Distention of the terminal ileum results in relaxation of the ileocecal sphincter, which allows contents to enter the large intestine.
- Segmental contractions (haustra) in the large intestine promote water absorption. About 18 hours is required for the contents to traverse the large intestine and reach the distal end of the colon. Three to four times a day a peristaltic mass movement sweeps fecal material along the colon. Mass movements may be initiated by entry of food into the stomach and duodenum (gastrocolic reflex).
- An urge to defecate occurs when feces enters the rectum. Contraction of the distal end of the colon and relaxation of the internal anal sphincter occur involuntarily as feces enter the rectum. The external anal sphincter is under voluntary control and inhibits defecation until voluntarily relaxed.

## SECRETORY FUNCTION

### Secretion of Gastrointestinal Juices

The many glands associated with the GI tract generally produce enzymes that participate in the digestive process to break down the major nutrient components of carbohydrates, fats, and proteins. The somewhat archaic term juices is still used to describe the fluids secreted in the GI tract, which contain a complex mixture of salts and protein enzymes. Secretion of these digestive juices is stimulated by various factors, including mechanical and chemical stimulation by chyme, parasympathetic stimulation (in certain regions of the GI tract), and various hormones.

### Gastrointestinal Hormones

Table 35-1 lists the major hormones of the GI tract and their sources, target organs, major actions, and factors that stimulate release. These hormones are released from the GI mucosa in response to distention or the presence of certain nutrient substances. They are then absorbed into the blood and carried to glands in target tissues (i.e., tissues on which they exert their effects), where they stimulate secretion. Chemically, GI hormones are polypeptides or polypeptide derivatives. Receptors for the peptide hormones are widely distributed throughout the body, including in the brain and central nervous system, and much current research is focused on the varied effects of these complex chemicals.<sup>17,18</sup>

In addition to their effects on motility, as mentioned previously, gastrin, secretin, cholecystokinin, and GIP have critical roles in mediating secretion of gastrointestinal juices. Gastrin is secreted by the stomach mucosa and stimulates the exocrine (secretory) cells of the gastric glands to produce their specific products, including hydrochloric acid (HCl). Research over the last two decades has shown that gastrin exerts its primary effect on enterochromaffin-like cells (ECL cells), provoking them to release histamine.<sup>19-21</sup> Histamine, an amine with multiple roles in human physiologic processes, including an ability to constrict bronchial smooth muscle, diffuses readily into nearby parietal cells to induce acid release (Figure 35-16). The development of specific medications that block the action of histamine (H<sub>2</sub> antagonists) led to the first effective treatment for peptic ulcers by reducing gastric acid secretion.

Secretin was one of the first of the body's many hormones to be discovered. The most potent stimulus for secretin release is hydrochloric acid, and the presence of acidic chyme in the duodenum promotes its release into the blood from the duodenal mucosa. It is carried to the pancreas, where it stimulates the secretion of a large volume of alkaline juice rich in sodium bicarbonate. In the duodenum, sodium bicarbonate then neutralizes the HCl of the chyme, thus protecting the duodenal mucosa from potential damage and creating a slightly alkaline medium that is optimal for chemical digestion by pancreatic intestinal enzymes. Although the liver produces bile continuously, secretin is effective in increasing the rate of bile secretion. Hormonal regulation is the most important mechanism governing the activity of the pancreas, and cholecystokinin has a key role in stimulating the release of large amounts of digestive enzymes from the pancreas. Cholecystokinin also stimulates the gallbladder to release the bile it stores. GIP acts to slow stomach emptying by decreasing gastric motor activity.<sup>1</sup>

Stimulation of the parasympathetic nerves to certain regions of the GI tract will also increase the rates of glandular secretion. Those glands in the upper portion of the GI tract that are innervated by the vagus and other cranial parasympathetic nerves (particularly the salivary, esophageal, and gastric glands; the pancreas; and some duodenal glands) are especially subject to parasympathetic stimulation. Glands in the distal portion of the large intestine are also affected by parasympathetic stimulation because this region is innervated by the pelvic

TABLE 35-1 MAJOR HORMONES OF THE GASTROINTESTINAL TRACT

HORMONE	SOURCE	TARGET ORGAN	MAJOR ACTIONS	STIMULATED BY
Gastrin	Stomach (mucosa)	Stomach (gastric glands)	Stimulates gastric glands to secrete specific substances	Distention of stomach by food; other specific substances (e.g., partially digested proteins, caffeine)
Secretin	Duodenum (mucosa)	Pancreas	Stimulates release of alkaline component of pancreatic juice	Acidic chyme acting on duodenal mucosa
Cholecystokinin	Duodenum (mucosa)	Liver	Increases bile secretion rate	Presence of fatty acids and partially digested proteins in duodenum
		Pancreas	Stimulates release of digestive enzymes	
Glucose-dependent insulinotropic polypeptide (gastric inhibitory peptide)	Duodenum (mucosa)	Stomach	Stimulates gallbladder contraction and emptying	Presence of fat or carbohydrate in duodenum
			Reduces motor activity of stomach; slows rate of gastric emptying	

parasympathetic nerves. In the small intestine, the major stimulus for intestinal secretion is local and mechanical stimulation of the intestinal wall, which initiates the excitation of local myenteric reflexes and subsequent release of secretions.

#### KEY POINTS

- Major secreting glands and secretions in the GI tract can be summarized as follows:
  - **Salivary glands:** Secrete salivary amylase.
  - **Gastric glands:** Chief cells secrete pepsinogen; parietal cells secrete HCl and intrinsic factor. HCl activates the conversion of pepsinogen to pepsin, and intrinsic factor enhances vitamin B<sub>12</sub> absorption. Parietal cell secretion is stimulated by acetylcholine, histamine, and gastrin. G cells secrete gastrin into the bloodstream. Gastrin increases gastric motility and stimulates chief and parietal cell secretion.
  - **Intestinal epithelium:** Secretes brush border enzymes (peptidases, lipases, sucrase, lactase), secretin (stimulates pancreatic secretion), and cholecystokinin (stimulates gallbladder contraction).
  - **Pancreas:** Secretes bicarbonate-rich fluid containing amylase, trypsin, chymotrypsin, and lipase into the duodenum when stimulated by secretin.
  - **Gallbladder:** Secretes concentrated bile salts into the duodenum when stimulated by cholecystokinin.

## DIGESTION AND ABSORPTION

Substances contained in foods that are important to maintenance of the body include carbohydrates, fats (also called lipids), proteins, vitamins, inorganic salts, and water. Many of the nutrient constituents that compose intact food substances are structurally complex and cannot be easily absorbed from the GI tract in their original forms. During the process of digestion, digestive juices and the enzymes contained in these secretions convert these complex organic molecules to smaller molecules (Figure 35-17). These simpler compounds are then capable of absorption—transfer across the wall of the small intestine into the blood and lymph, and subsequent transfer to the cells. This complex task of digestion and absorption of nutrients is the primary task of the GI tract, and an inability to perform this function would be life threatening. This section describes the mechanisms of digestion of the three major groups of nutrients—carbohydrates, lipids, and proteins—and then considers the absorption of these substances.

### Digestion of Carbohydrates

In terms of calories, carbohydrates account for approximately half of the American diet. The major digestible carbohydrate in food is the polysaccharide plant starch, a large molecule composed of straight and branched chains of glucose. A summary of carbohydrate digestion is presented in Table 35-2.

Digestion of starch begins in the mouth as salivary amylase breaks down polysaccharides to the much smaller disaccharide molecules maltose and dextrin. In the stomach, this action of salivary amylase continues until the enzyme is eventually inactivated by acidic gastric juice. In the duodenum, the pancreatic enzyme amylase completes the task of splitting any remaining undigested polysaccharides and dextrans to small maltose units. Then maltase, an enzyme located in the brush border of the epithelial cells lining the duodenum, hydrolyzes each maltose molecule to two molecules of glucose. Other carbohydrates that are present in the diet in smaller quantities are the disaccharides sucrose, which is table sugar (glucose-fructose), and lactose, which is milk sugar (glucose-galactose). These two carbohydrates remain chemically unaltered until they reach the duodenum, where the enzyme sucrase in the brush border converts sucrose to the monosaccharides glucose and fructose. The enzyme lactase hydrolyzes lactose into the monosaccharides glucose and galactose.<sup>5</sup>

Glucose, the major product of carbohydrate digestion, accounts for about 80% of the monosaccharides obtained from food, whereas fructose and galactose account for the other 20%. Humans do not secrete an enzyme capable of digesting cellulose—a plant polysaccharide found in the cell walls of plants and present in large amounts in fibrous vegetables. Although cellulose consists of glucose molecules, it contains molecular linkages different from those of starch. Consequently, much of this complex carbohydrate passes through the digestive tract without being digested and is excreted in the feces.

### Digestion of Lipids

Lipids in the diet are mostly in the form of triglycerides but also include phospholipids, cholesterol, and the fat-soluble vitamins A, D, E, and K. Digestion of lipids occurs in the small intestine, where fats are emulsified by the action of bile; neither salivary nor gastric enzymes appear to have any effect on triglycerides. As the lipid particles enter the duodenum from the stomach, bile exerts a detergent action on them in which the surface tension of the particles is decreased. This decrease in surface tension promotes fragmentation of the particles into smaller particles as they are blended by the mixing movements of the small intestine. The emulsification process is an

**FIGURE 35-16** Schematic diagram of the complex regulation of acid ( $\text{H}^+$ ) secretion from parietal cells in the gastric pits. Gastrin stimulates enterochromaffin-like cells (ECL cells), which in turn release histamine onto  $\text{H}_2$  receptors on the parietal cell. Gastrin also stimulates acid secretion directly as does acetylcholine. *ACh*, Acetylcholine; *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *Pi*, inorganic phosphate; *PSNS*, parasympathetic nervous system.

**FIGURE 35-17** Chemical digestion. **A**, Amylases and disaccharidases break carbohydrates down into monosaccharides. **B**, Lipases break fats down to fatty acids and glycerol. The large fat globule must first be emulsified by bile. **C**, Proteases and peptidases break proteins down into amino acids. (From Herlihy B: *The human body in health and illness*, ed 4, Philadelphia, 2011, Saunders.)

TABLE 35-2 SUMMARY OF CARBOHYDRATE, PROTEIN, AND LIPID DIGESTION

LOCATION OF DIGESTIVE PROCESS	SOURCE OF DIGESTIVE ENZYME OR SUBSTANCE	BASIC DIGESTIVE PROCESS
<b>Carbohydrates</b>		
Mouth, stomach	Salivary glands (salivary amylase)	Polysaccharides → salivary amylase → maltose + dextrin
Small intestine lumen	Pancreas (pancreatic amylase)	Undigested polysaccharides/dextrins → pancreatic amylase → maltose
Brush borders	Intestine (maltase, sucrase, lactase)	Maltose → maltase → glucose + glucose Sucrose → sucrase → glucose + fructose Lactose → lactase → glucose + galactose
<b>Lipids</b>		
Small intestine	Liver Pancreas	Lipid particle → bile salts → emulsified fat (triglycerides) Triglyceride → lipase → fatty acids + glycerol
<b>Proteins</b>		
Stomach	Stomach (gastric glands)	Protein → pepsin polypeptides
Small intestine lumen	Pancreas	Polypeptides → trypsin, chymotrypsin → tripeptides + dipeptides → carboxypeptidase → free amino acids
Brush borders (and within cytoplasm of epithelial cells)	Small intestine	Tripeptides and dipeptides → peptidase → free amino acids

entirely mechanical action, because bile contains no enzymes and thus performs no chemical digestion.

Eventually, the detergent action of bile salts reduces the particles of fat to tiny droplets so that their surface area is greatly increased. This enhancement of surface area allows for maximal exposure to pancreatic lipase, an enzyme that (along with intestinal lipase, to a lesser extent) hydrolyzes the triglycerides to free fatty acids and glycerol. Some monoglycerides (glycerol with one fatty acid still attached) may remain; in fact, some fat may escape digestion entirely or be reduced only to diglycerides (glycerol with two fatty acids attached). A summary of triglyceride digestion is presented in Table 35-2.

Cholesterol, a steroid type of lipid, is ingested in the form of cholesterol esters, which cannot be directly absorbed. An esterase in pancreatic juice degrades cholesterol esters to cholesterol and fatty acid, which then undergo absorption.

### Digestion of Proteins

Proteins are composed of molecular subunits called amino acids that are linked together by peptide bonds. Proteins that undergo digestion in the small intestine include both protein from food and protein from desquamated cells and the many enzymes of the GI tract. This protein of endogenous origin constitutes a sizable portion of the total protein subjected to digestion and absorption.

Protein digestion involves breakage of the peptide bonds by hydrolysis and release of free amino acids. It begins in the stomach with the action of the enzyme pepsin, which is secreted by the gastric glands. By its action on peptide bonds, pepsin reduces most proteins to intermediate-sized polypeptides. Pepsin is also capable of breaking down collagen, a protein component of intercellular connective tissue, thus rendering cellular proteins more accessible to enzymatic action in the GI tract. In the duodenum, the trypsin and chymotrypsin contained in pancreatic juice reduce the polypeptides to small peptides (tripeptides and dipeptides). Carboxypeptidase, which has its source in the pancreas, and peptidases in the brush borders of the intestinal epithelial cells split some of these peptides into free amino acids. Free amino acids, in addition to dipeptides and tripeptides, are absorbed into the intestinal

epithelial cells. Within the cytoplasm of epithelial cells the small peptides are then hydrolyzed by various peptidases into free amino acids before their passage into the circulation. Numerous proteolytic enzymes are involved in protein digestion, and each enzyme acts on a slightly different type of peptide linkage. Protein digestion is summarized in Table 35-2.

### Absorption

Intestinal absorption is the movement of water and dissolved materials, such as the products of nutrient digestion, vitamins, and inorganic salts, from the inside of the small intestine through the semipermeable intestinal membrane and into the blood and lymph. A major feature of the intestinal absorptive surface is the villus, the small fingerlike projection lined with epithelial cells that was described earlier in this chapter. Within each villus is a network of capillaries that branch from a miniscule artery and empty into a miniscule vein. A central lymph vessel called a lacteal is also located in the villus. In the process of absorption, nutrient molecules pass through the single layer of epithelial cells lining the villus and through the single layer of cells forming the wall of the capillary or lacteal. A number of transport systems specific to certain nutrient components function in the intestinal epithelium to promote this process of absorption.<sup>4</sup>

Operation of the intestinal transport systems is dependent on adenosine triphosphate (ATP) production by the epithelial cells. These systems are capable of moving the products of nutrient digestion and inorganic salts from the intestinal lumen into the blood against electrochemical gradients (active transport). In addition to active transport, some molecules may move across the intestinal epithelium by passive means when a difference in concentration on the two sides of the epithelium exists. The rate of molecular transfer based on diffusion gradients is dependent not only on the magnitude of the difference in concentration but also on the size of the molecules and the lipid solubility of the substances involved.

Almost all substances capable of intestinal absorption disappear from the lumen of the small intestine by the time that the intestinal contents reach the mid-jejunum. The ileum is not involved in absorption to any significant degree, because the proximal regions of

the small intestine have usually completed the process of absorption before the intestinal contents reach the ileal region. Nevertheless, the distal end of the small intestine has the capability of absorption and may do so in situations in which absorption has not taken place in the proximal part of the small intestine. Thus about 50% of the small intestine can be surgically removed without compromising absorptive ability. However, it is important to note that vitamin B<sub>12</sub> and bile salts are absorbed specifically in the terminal ileum, and surgical removal of this portion of the small intestine will result in impaired absorption of these substances.<sup>6</sup> Intrinsic factor produced by the parietal cells of the gastric antrum is also required for B<sub>12</sub> absorption; intrinsic factor deficiency leads to a condition known as pernicious anemia.<sup>3</sup>

The intestinal contents arriving at the terminal ileum contain no digestible carbohydrate, very little fat, and only 15% to 17% nitrogen-containing substances. Most of the contents of the terminal ileum consist of bacteria, desquamated epithelial cells, digestive secretions, and the residue of foods that are undigested and therefore unabsorbed, such as the cellulose walls of fibrous plants and connective tissue from animal sources.

### Carbohydrates

Carbohydrates are absorbed in the form of monosaccharides. Polysaccharides and disaccharides lack the capacity for absorption; apparently the intestinal epithelium is impermeable to carbohydrates of such high molecular weight, and no transport systems exist for these types of carbohydrate molecules. The monosaccharides glucose and galactose are absorbed by an active, energy-requiring process in which a carrier molecule located on the luminal border of epithelial cells transports them across the border. It is theorized that the same carrier molecule that ferries glucose and galactose also carries sodium and that the carrier affinity for monosaccharides is greatest when sodium is bound to the carrier. In contrast to the other monosaccharides, the monosaccharide fructose is absorbed passively by means of a diffusion gradient.<sup>5</sup>

### Lipids

Absorption of lipids occurs by a highly complex, unique process. As fatty acids and monoglycerides are freed during digestion, they become dissolved in bile salt micelles, which are colloidal particles composed of many molecules. Within the micelles, the products of lipid digestion are now soluble and can be absorbed far more efficiently. The bile salt micelles transport the lipid products to the epithelial brush borders, where the monoglycerides or fatty acids, which are highly soluble in the lipid cell membrane, diffuse into the epithelial cells and leave the micelle behind. The micelle is now emptied of its cargo and can pick up more fatty acids and monoglycerides and transport them to the cell membrane.

Bile salts, which are required for micelle formation, are absorbed mostly in the terminal ileum and then recycled in the liver. In the absence of bile, the amount of lipid absorbed in this manner is reduced by more than 25%. In this situation, the absorption of fat-soluble vitamins (vitamins A, D, E, and K) is compromised. Several cholestatic conditions, such as primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC), may be associated with deficiencies of fat-soluble vitamins.<sup>20</sup>

Monoglycerides may be further degraded into glycerol and fatty acids by the enzyme lipase within the epithelial cell. Short-chain fatty acids (those with fewer than 12 carbon atoms) can be absorbed directly into the blood at this point. Long-chain fatty acids and glycerol, however, are reassembled into triglycerides by the endoplasmic reticulum. These newly synthesized triglycerides are aggregated into droplets that become progressively larger during passage through the cell. These

lipid droplets are stabilized by enclosure with absorbed cholesterol and phospholipids and encased by a protein coat. The final product, called a chylomicron, passes out of the cell and into the lacteal of the villus. From the lacteal, chylomicrons pass through a series of lymph vessels that eventually drain into the general circulation.

### Proteins

Amino acids are transported across the epithelial membrane by means of an active transport carrier system in much the same way as monosaccharides. It is currently thought that different carrier systems exist to carry the different chemical classes of amino acids (i.e., neutral, basic, dicarboxylic, and imino acids). As is the case for the transport of monosaccharides, brush border membrane carriers are involved in the transfer of amino acids across the intestinal epithelial cell; these carriers require energy and are coupled to the transport of sodium. After being transported to the epithelial cells of the villi, amino acids diffuse through the base of the cell and into the blood. Both amino acids and monosaccharides are transported directly to the liver by the hepatic portal vein.

### Water and Electrolytes

Water and inorganic ions, which are in the GI tract as a result of ingestion and secretion, are absorbed mainly from the small intestine and, to a lesser extent, from the colon. The process of absorption of water and ions is the same in both the small and large intestines: sodium is actively transported to the blood, and water follows passively in response to the osmotic gradient created by the removal of sodium from the intraluminal fluid. About 8000 ml of water is absorbed every day by the small intestine and about 300 to 400 ml by the colon. Frequently, diarrhea is the result of failure of the small intestine to absorb water appropriately. If large quantities of water are allowed to enter the colon from the small intestine because of some malfunction of the small intestine's absorptive ability, the colonic absorptive mechanism may be overwhelmed, and diarrhea is the result (Figure 35-18).

#### KEY POINTS

- Digestion, the process of converting large molecules to simpler forms, is accomplished by mechanical and enzymatic processes. Digestion is a necessary prelude to absorption because only simple molecules can cross the intestinal epithelia.
- Digestion of complex carbohydrates is initiated in the mouth, where salivary amylase begins to cleave polysaccharides into disaccharides. Pancreatic amylase continues this process in the small intestine. Disaccharides (e.g., maltose, sucrose, lactose) are cleaved into monosaccharides (e.g., glucose, fructose, galactose) by brush border enzymes (e.g., maltase, sucrase, lactase) on the intestinal epithelia. Glucose and galactose are absorbed across the intestinal epithelia by a sodium-dependent cotransporter. Fructose is absorbed passively by facilitated diffusion. Monosaccharides then travel via the bloodstream to the liver.
- Lipid digestion begins in the small intestine, where bile salts from the gallbladder mix and emulsify the fatty substances. Emulsification mechanically separates the lipids into small drops that are more accessible to enzymatic digestion. Pancreatic lipase and brush border lipases digest the lipids into free fatty acids and glycerol, which remain associated with the bile salts and form micelles. Cholesterol is digested by pancreatic esterase. Fatty acids are transported to the intestinal epithelia by micelles. Free fatty acids diffuse out of the micelle and into the epithelial cell passively. Epithelial cells synthesize large protein-lipid complexes (chylomicrons) that enter the lymphatic system.

- Protein digestion begins in the stomach, where HCl from parietal cells activates the conversion of pepsinogen to pepsin. Pepsin cleaves proteins into smaller polypeptides. Pepsin is neutralized in the duodenum, and pancreatic trypsin, chymotrypsin, and carboxypeptidase take over protein digestion. Brush border peptidases split tripeptides and dipeptides into single amino acids. Amino acid transport into intestinal epithelial cells is mediated by a sodium-dependent cotransport system similar to monosaccharide transport. Small peptides may also undergo endocytosis and be cleaved into amino acids within the epithelial cells.
- Amino acids pass into the bloodstream and travel to the liver.
- Absorption of water occurs passively by osmosis. An osmotic gradient for water absorption is created as electrolytes are absorbed.

## GASTROINTESTINAL FUNCTION ACROSS THE LIFE SPAN

### Maturation

During the first months of life, the newborn's GI tract undergoes many maturational changes. In the first 3 to 4 months of life, sucking reflexes are present, and extrusion reflexes protect against the ingestion of solids

**FIGURE 35-18** Absorptive function of the large intestine. (From Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

## PEDIATRIC CONSIDERATIONS

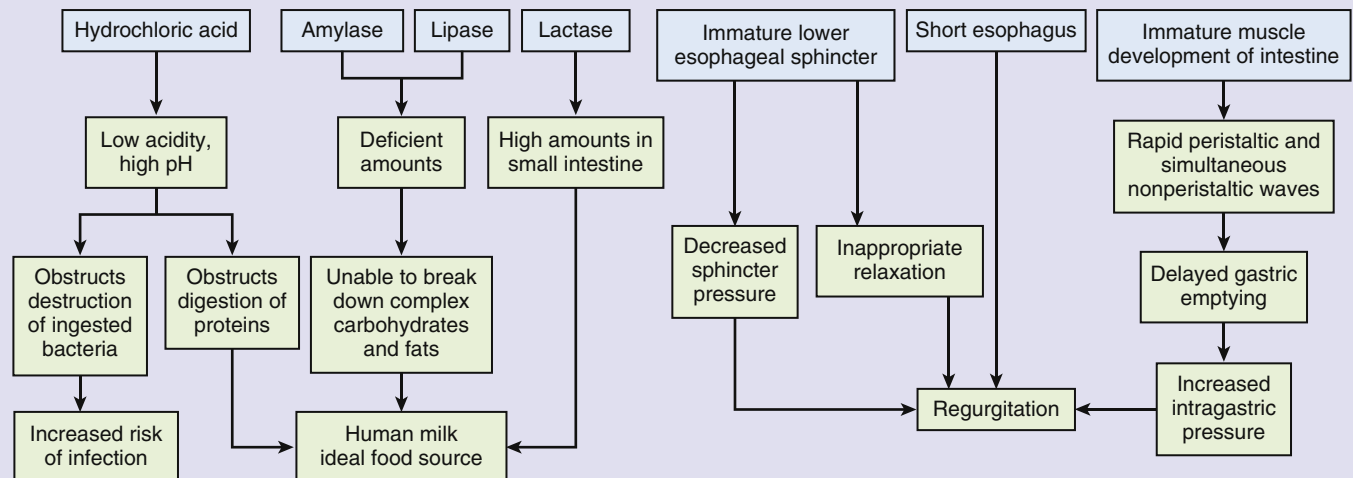

### Changes in the Gastrointestinal System in the Infant

The acid and enzymes present in the infant's gastrointestinal system are different than those in the adult's GI tract and affect the infant's ability to digest nutrients. The stomach depends on hydrochloric acid to begin digestion of human milk. Although hydrochloric acid is present, the acidity is low. This low acidity limits the gastrointestinal system's ability to destroy ingested bacteria, which causes the infant to be more susceptible to gastrointestinal infections. The acidity is also too low to digest protein in the stomach via the enzyme pepsin. As the child matures, the acidity of the gastric contents continues to increase until it reaches adult levels in the late school-age years.

Lipase and amylase in the stomach are limited for the first 4 months of the infant's life (Hockenberry & Wilson, 2011). The infant is unable to digest fats and complex carbohydrates until the levels of these enzymes are sufficient. Levels of the enzyme lactase, found in the small intestine, are extremely high in the newborn. This is essential for digestion of the human milk diet of the infant. The lactase levels decline during infancy and for most individuals lactase levels are absent by adulthood (MacGregor, 2008). Because of the enzyme composition in

the infant gastrointestinal system, human milk is the ideal food source for an infant.

Several factors of the gastrointestinal system predispose the infant to regurgitation. The lower esophageal sphincter is immature in the infant. This immaturity leads to inappropriate relaxation of the sphincter and the pressure of the sphincter is decreased. The infant also has a shorter esophagus, which results in less distance for gastric contents to travel and increases the likelihood of regurgitation. Muscle development is immature in the intestine. This immaturity leads to rapid peristaltic waves and simultaneous nonperistaltic waves. This inconsistency of the intestine to move food efficiently leads to delayed gastric emptying. As the gastric contents increase, the pressure of the stomach increases and exceeds the pressure of the lower esophageal sphincter. Once the pressure of the sphincter is exceeded, regurgitation occurs. The combination of all of these factors predisposes the infant to regurgitation. As the infant grows, the gastrointestinal system develops and is fairly complete by the beginning of toddlerhood (Hockenberry & Wilson, 2011).

From MacGregor J: *Introduction to the anatomy and physiology of children: a guide for students of nursing, child care and health*, ed 2, New York, 2008, Routledge; Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 9, St Louis, 2011, Mosby.

that the immature GI tract is still unable to digest. The pressure in the LES remains low during this time, and “spitting up” of gastric contents is common because intragastric pressure often exceeds LES pressure. Gastric motility is not well coordinated for the first 3 to 4 months, so antral mixing is inadequate for the digestion of solid foods. At about 12 weeks of age, intestinal peristalsis similar to that in adults begins to develop, but it is one third slower. This slower transit in infants may serve to improve nutrient digestion and absorption by increasing the exposure of nutrients to the intestinal mucosa. The motor function of the large intestine appears to be fully developed at birth. During the first 2 years of life, the secretory and absorptive functions of the intestine mature and begin a pattern of functioning that continues into senescence.<sup>5,10</sup>

### Age-Related Changes

Changes in GI function in older adults occur simultaneously with other age-related changes such as a decrease in lean body mass and impaired homeostasis of multiple body systems. Within the GI tract, a variety of changes occur that may place an aging individual at risk for health problems related to GI functioning and nutrition. Important elements of this process are summarized in Geriatric Considerations: Changes in the Gastrointestinal System.

Loss of dentition and reduced taste and smell acuity may promote a decreased interest in food intake as chewing becomes difficult and the sensory enjoyment associated with food becomes impaired. A condition called **presbyesophagus**, in which esophageal motility is

slowed or disorganized, may develop in older adults. Presbyesophagus may be manifested as difficulty in swallowing and may cause discomfort as food passes through the esophagus. The incidence of hiatal hernia, where part of the stomach moves into the chest cavity through an enlarged diaphragmatic opening, is also increased in the aging population, affecting two-thirds of persons older than 70 years. The transit time for intestinal contents to pass through the GI tract is increased in older persons; this factor, coupled with a decreased perception of the sensory stimuli that produce the urge to defecate, may promote constipation in the aging population. Conversely, a confused or neurologically impaired older individual may experience fecal incontinence because the sensation and tone of the rectum diminish with aging.<sup>5,21</sup>

#### KEY POINTS

- Infants may experience GI dysfunction because of immaturity of the GI tract. Motility is not well coordinated until 3 to 4 months of age, making digestion of solids difficult in infancy. Pressure in the LES is low, which leads to “spitting up” and gastric distention. Maturation of the GI tract is complete by about 2 years of age.
- Elderly individuals may experience GI dysfunction for a number of reasons. Poor dentition, loss of taste and smell acuity, and reduced esophageal motility may lead to poor intake of nutrients. Hiatal hernia and constipation are common in the elderly.

## GERIATRIC CONSIDERATIONS

### Changes in the Gastrointestinal System

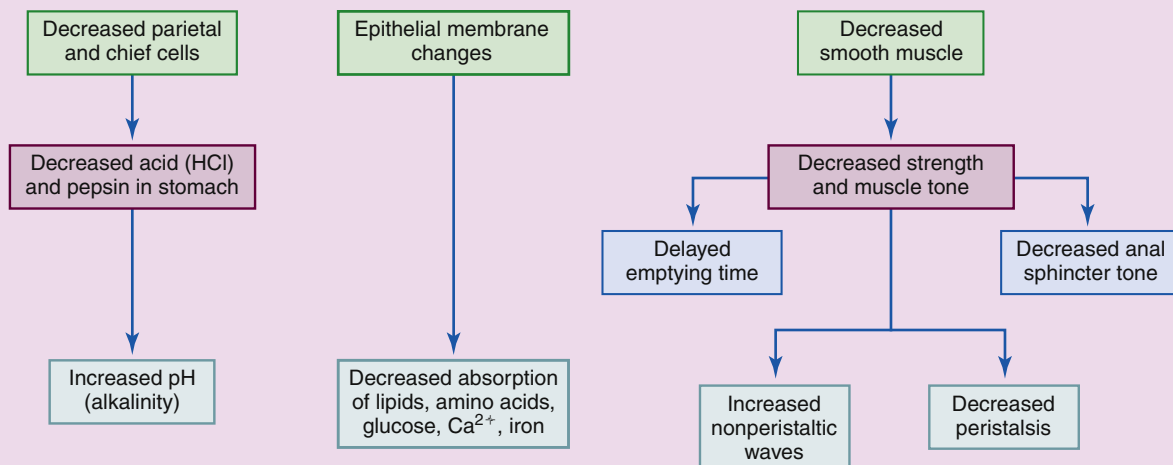

As a person ages, gastrointestinal muscle strength and movement decrease, leading to reduced peristalsis and decreased gastrointestinal motility throughout the system.

In the esophagus, the elderly person experiences greater numbers of muscle movements that do not propel the contents onward. These nonperistaltic waves are common in the lower esophagus. The phenomenon of presbyesophagus—in which the esophageal sphincter fails to relax and the lower esophagus becomes dilated—may not necessarily be normal to the elderly.

In the stomach, decreased numbers of parietal and chief cells result in diminished acid (HCl) and pepsin secretion. This leads to increased pH and a more alkaline secretion. The amount of protective alkaline viscous mucus in the

stomach is also decreased. The loss of smooth muscle in the stomach can delay emptying time, which increases and prolongs the exposure of gastric epithelial cells to the gastric contents.

The amount of small intestinal smooth muscle, Peyer patches, and lymphatic follicles is decreased. Normal intestinal absorption in the elderly is not well understood and may be influenced by a number of factors, including bowel motility, epithelial membranes, vascular perfusion, and gastrointestinal membrane transport. However, absorption of lipids, amino acids, glucose, calcium, and iron is known to be decreased. Normal changes in the large intestine have been difficult to determine. As a result of smooth muscle changes, anal sphincter tone decreases.

## SUMMARY

This chapter describes the structure of the human GI system and the process by which it provides nutrients for the body. A thorough understanding of the structure and motility of the GI tract, secretion of digestive juices, and digestion and absorption of nutrients is needed as a basis for understanding other principles of health and disease.

GI motility is a complex process involving a set of carefully timed autoregulatory action responses (Figure 35-19). You may wish to trace the path and destiny of the apple you ate for lunch as an example of this process. As you track the movement of nutrients through the GI tract, consider the ways in which secretion of digestive juices occurs in

response to the ingestion of your apple, which contains a great deal of carbohydrate (fructose), small amounts of protein, and minimal lipid. Consider also how digestion and absorption of these nutrients are occurring. What part of the apple will you use, for example, for energy to study this text? What part of the apple will your body “throw away,” and how will this be accomplished? Finally, will your GI tract respond the same way to eating an apple when you are 85 years old? A careful review of the elegant and nearly automatic function of the human GI tract will prepare you to care for individuals experiencing interruptions in proper nutrient digestion and absorption.

**FIGURE 35-19** Summary of digestive function. (From Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby, p 985.)

Alterations in function of the gastrointestinal (GI) tract may have far-reaching consequences in an individual's life. The ability to take in nutrients, convert them to usable forms for body functions, and dispose of their waste products goes beyond physiologic function and is intimately associated with social and psychological functioning. A person with an alteration in GI function may experience great emotional distress and be unable to participate fully in social activities, which in American society are often centered on food consumption. Certain symptoms that may accompany GI disorders, such as chronic diarrhea and abdominal pain, may severely limit an individual's ability to maintain employment. It has been estimated that 200,000 people miss work daily because of GI-related problems.<sup>1</sup> In addition, GI diseases account for more hospital admissions in the United States than any other category of disease. Because many chronic GI conditions begin in midlife and continue into old age, their prevalence will likely increase as the U.S. population continues to age.

This chapter describes the pathophysiologic processes of the most common disorders of the GI tract and summarizes current treatment for these conditions. Because knowledge about many GI disorders is expanding rapidly, some current research on selected GI conditions is described. Finally, because of the intimate relationship between GI function and the integrity and well-being of the person, a discussion of the psychological and emotional aspects of GI disorders across the life span is included.

## MANIFESTATIONS OF GASTROINTESTINAL TRACT DISORDERS

As a basis for discussing individual types of GI disorders, a description of some common manifestations of these disorders and their pathophysiologic mechanisms is presented. Common manifestations include dysphagia, esophageal and abdominal pain, vomiting, intestinal gas, and alterations in bowel patterns.

### Dysphagia

**Dysphagia** is a subjective difficulty in swallowing (Figure 36-1). It may include the inability to initiate swallowing or the sensation that the swallowed solids or liquids “stick” in the esophagus. In certain disorders, **odynophagia**, or pain with swallowing, may accompany dysphagia. The physiologic mechanism of normal swallowing is described in Chapter 35.

### Categories

The pathophysiologic basis for dysphagia usually falls into three major categories: (1) problems in delivery of the bolus of food or fluid into the esophagus as a result of neuromuscular incoordination; (2) problems in transport of the bolus down the body of the esophagus as a result of altered esophageal peristaltic activity; and (3) problems in bolus entry into the stomach as a result of lower esophageal sphincter (LES) dysfunction or obstructing lesions.<sup>2</sup>

In the first category of dysphagia, individuals have a decreased ability to accomplish the initial steps of swallowing in an orderly sequence. The normal sequence of contraction of the pharynx, closure of the epiglottis, relaxation of the upper esophageal sphincter, and initiation of peristalsis by contraction of the striated muscle in the upper portion of the esophagus is altered, or certain steps in the sequence may be absent. Persons experiencing this type of dysphagia may cough and expel the ingested food or fluids through their mouth and nose or aspirate when they attempt to swallow. These symptoms are usually worse with liquids than with solids in this type of swallowing dysfunction.

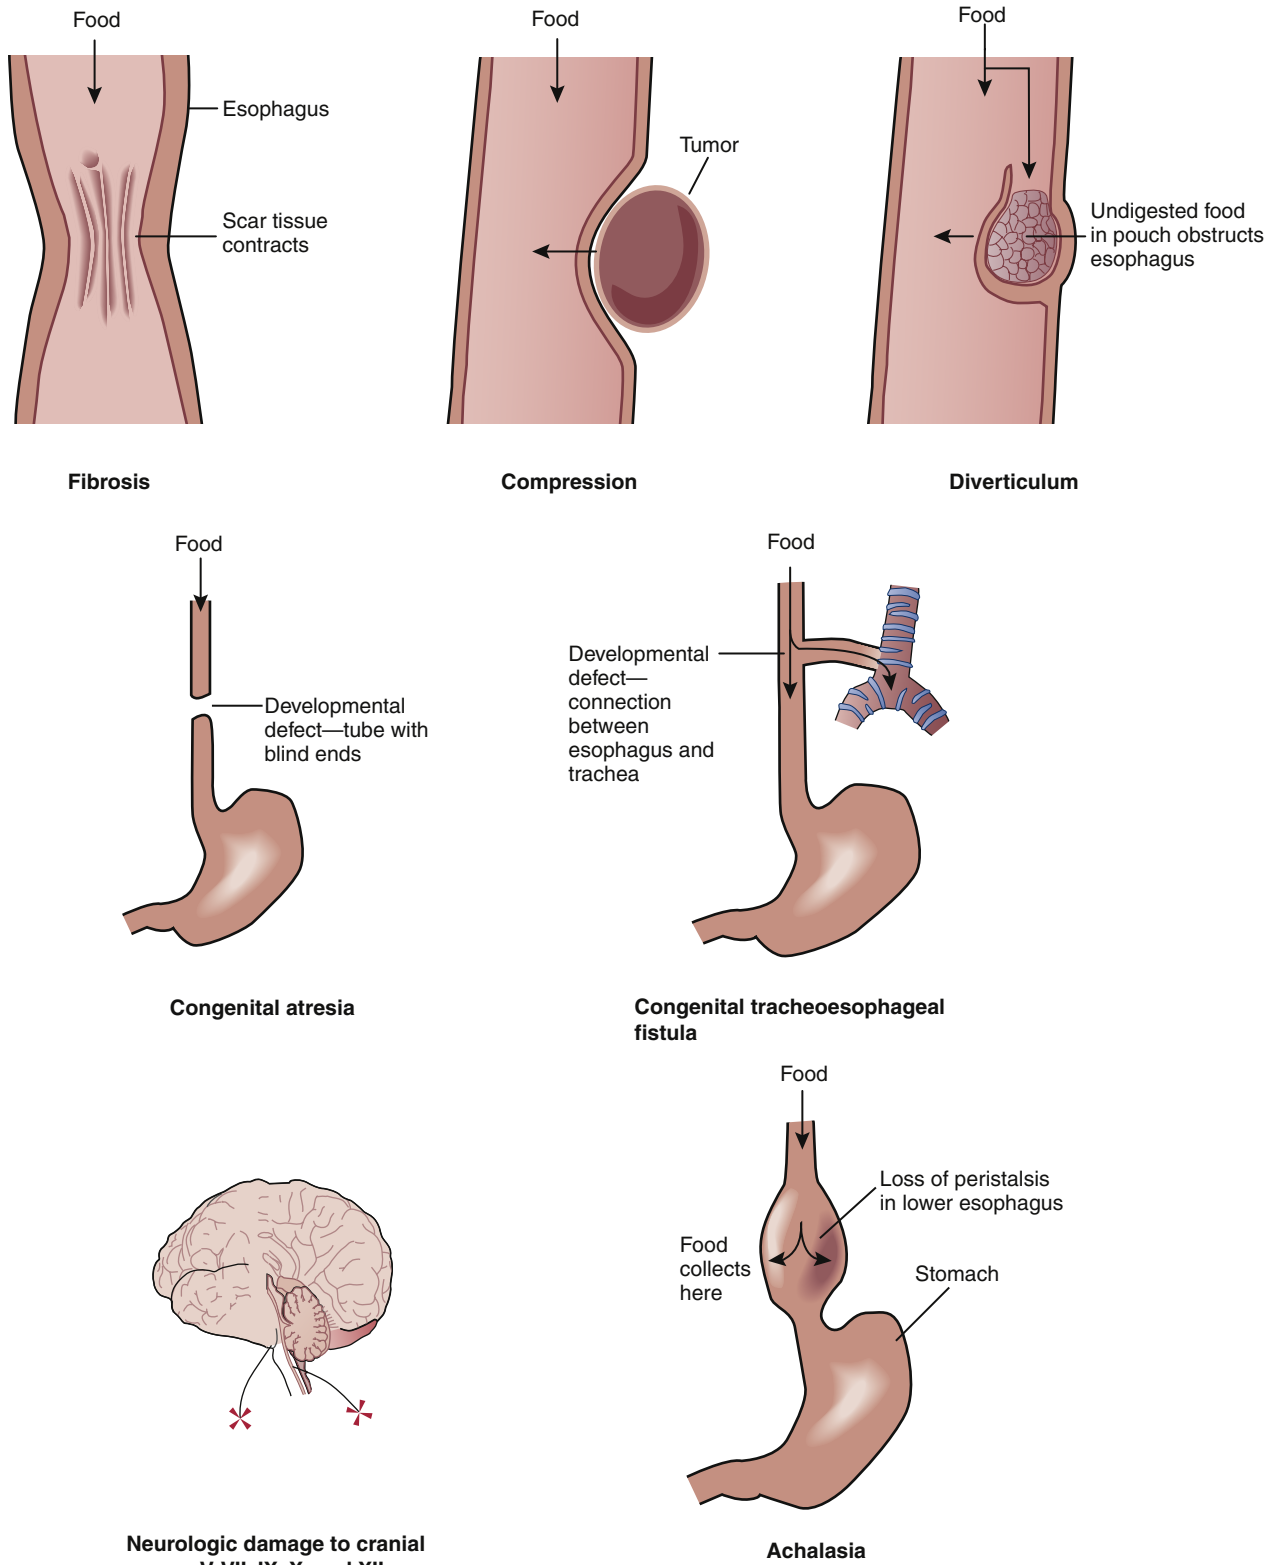

The second type of dysphagia may be the result of any disorder, structural or neuromuscular, in which the peristaltic activity of the body of the esophagus is altered. The presence of (1) esophageal **diverticula**, or outpouchings of one or more layers of the esophageal wall; (2) **achalasia**, a disorder of esophageal smooth muscle function; or (3) structural disorders such as neoplasms or strictures may interfere with proper peristaltic activity in the esophagus.<sup>2,3</sup> This alteration in peristalsis may be simply weak peristaltic activity, aperistalsis (the absence of all peristaltic activity), or disorganized and therefore ineffective peristalsis. With this type of dysphagia the individual may have the sensation that food is “stuck” behind the sternum. Initially, dysphagia may be noted with solid foods; if the underlying pathologic process fosters a worsening of peristaltic ability, the passage of liquids may also become impaired.

The third category of dysphagia, which results from problems of bolus entry into the stomach, is secondary to any condition in which the LES functions improperly or is obstructed by a lesion. Tumors of the mediastinum, lower part of the esophagus, or gastroesophageal junction may invade the myenteric plexus or produce an obstruction at the LES, thus interrupting normal LES function by neural invasion or direct obstruction. In addition, motor disorders resulting from neuromuscular diseases or chronic lower esophageal inflammation from the reflux of acidic gastric contents may limit the ability of the LES to function properly. This type of dysphagia may be manifested as tightness or pain in the substernal area during the swallowing process.

### Esophageal Pain

Two types of pain occur in the esophagus: (1) heartburn (also called **pyrosis**) and (2) pain located in the middle of the chest, which may mimic the pain of angina pectoris. Heartburn is caused by the reflux of gastric contents into the esophagus and is a substernal burning sensation that may radiate to the neck or throat. Two common mechanisms contribute to the development of heartburn. First, the highly acidic gastric contents may be a noxious stimulant to sensory afferent nerve endings in the esophageal mucosa. Second, spasm of the esophageal muscle instigated by acid stimulation may produce esophageal pain.

Chest pain other than heartburn may be the result of esophageal distention or powerful esophageal contractions. These stimuli may

**FIGURE 36-1** Causes of dysphagia. (From Gould BE: *Pathophysiology for the health professions*, ed 4, Philadelphia, 2011, Saunders.)

arise from esophageal obstruction or a condition called diffuse esophageal spasm (DES), in which high-amplitude, simultaneous contractions in the smooth muscle portion of the esophagus alternate with normal peristalsis.<sup>1</sup> This type of esophageal pain is similar to that of

angina pectoris, particularly in its pattern of radiation into the neck, shoulder, arm, and jaw. Odynophagia may accompany diffuse esophageal spasm and can be indistinguishable from esophageal chest pain, except that it is triggered specifically by swallowing.

Infections of the esophagus attributable to herpes simplex virus, cytomegalovirus, or *Candida* species occur in immunocompromised patients. Patients with infectious esophagitis may experience a dull, aching chest pain. Swallowing generally worsens the sensation of heartburn or chest pain.

### Abdominal Pain

Pain in the abdominal region may be the first sign of a disorder of the GI tract and is often an important impetus for seeking medical care. Although abdominal pain may result from GI tract disorders, it may also be the result of reproductive, genitourinary, musculoskeletal, or vascular disorders, as well as toxins or drug use. Abdominal pain is usually categorized into three types, which may manifest separately or in combination: (1) Visceral pain develops from stretching or distending an abdominal organ or from inflammation. The pain is diffuse and poorly localized and has a gnawing, burning, or cramping quality. (2) Somatic pain arises from injury to the abdominal wall, the parietal peritoneum, the root of the mesentery, or the diaphragm. In contrast to visceral pain, it is sharper, more intense, and generally well localized to the area of irritation. (3) Referred pain is felt at a location distant from the source of the pain but in the same dermatome or neurosegment. Referred pain is usually sharp and well localized and may be felt in the skin or deeper tissues.

Abdominal pain may be acute with instantaneous onset, such as pain caused by a perforated ulcer or a ruptured internal organ. A more gradual development of abdominal pain may accompany such chronic states as diverticulitis or ulcerative colitis (UC). Abdominal pain seldom occurs as a solitary manifestation of GI disorders; it is usually accompanied by other manifestations such as vomiting or alteration in bowel patterns to a variable degree.

### Vomiting

Vomiting is the forceful expulsion of gastric contents through the mouth. Usually accompanied by a feeling of nausea, vomiting results from a coordinated sequence of abdominal muscle contractions and reverse esophageal peristalsis. Although vomiting is a common sign of GI disorders, it may also occur with metabolic, endocrine, vestibular (inner ear), and cardiac disorders, as well as with infection and fluid and electrolyte imbalances. It is also associated with such nonpathologic causes as pharmacologic agents, surgery, and the first trimester of pregnancy.

Vomiting associated with GI disorders may be the result of alterations in the integrity of the GI tract wall, such as gastroenteritis, or alterations in the motility of the GI tract, such as intestinal obstruction. The characteristics of the vomitus and the presence of blood or fecal matter may suggest the nature of the GI disorder and the level of the GI tract at which the disorder is located.

### Intestinal Gas

Gas normally occurs in the GI tract and is the result of the swallowing of air, bacterial and digestive action on intestinal contents, diffusion from the blood, and the neutralization of acids by bicarbonate within the upper GI tract. The manifestations of excess intestinal gas may include excessive belching, distention of the abdomen, and excessive flatus. These manifestations may occur singly or in combination and may stem from a variety of causes. Belching is a normal phenomenon caused by the eructation of swallowed air but may also be the result of a motility disorder or gastric outlet obstruction. Abdominal distention may be due to failure to adequately digest a particular nutrient, such as the carbohydrate lactose. In the absence of adequate lactase (the digestive enzyme that breaks down lactose into glucose and galactose in the intestine), lactose undergoes bacterial fermentation, which

results in gas production in the intestinal lumen. In some individuals, abdominal distention from excess gas may result from a defect in intestinal motility in which the intestinal contents are not propelled in a regular fashion, rather than from the production of too much gas. Excessive flatus may have causes similar to those of abdominal distention. Usually it is the result of increased amounts of gas produced by the action of bacteria on nutritional substrates that are particularly gas-producing, such as certain vegetables and legumes. Some individuals are particularly sensitive to the flatulent effects of beans, for instance.

### Alterations in Bowel Patterns

Both constipation and diarrhea are difficult to define with precision, as a wide variation in bowel patterns can be found in different individuals. In addition, cultural and family socialization may play a role in the way in which an individual perceives bowel patterns. Alterations in bowel patterns may be the result of a change in GI tract motility or may be a component of a functional GI disorder such as irritable bowel syndrome (IBS).

### Constipation

**Constipation** may be defined as small, infrequent, or difficult bowel movements.<sup>2</sup> Authorities have agreed on a norm of fewer than three stools per week as a guideline for defining constipation.<sup>1</sup> Dietary factors, particularly a diet low in fiber, have been shown to contribute to constipation. The presence of cellulose, the carbohydrate component of dietary fiber that is indigestible in the human intestine, may be effective in promoting regular peristaltic movement in the GI tract by forming bulk within the intestinal lumen to stimulate propulsion. In addition, because exercise stimulates intestinal peristalsis, a lack of exercise has been implicated in the development of constipation. In elderly persons the slowed rate of peristalsis that occurs with the aging process coupled with a decreased level of physical activity may promote chronic constipation. These factors may eventually contribute to the development of fecal impaction, a condition in which a firm, immovable mass of stool becomes stationary in the lower GI tract. Constipation may also be the result of pathologic conditions, including processes that alter the motility of the GI tract (such as intestinal obstruction) or processes that alter the integrity of the GI tract wall (such as diverticulitis).

### Diarrhea

**Diarrhea** is defined as an increase in the frequency and fluidity of bowel movements and is often a primary sign of GI tract disorders. Although stool weight in excess of 200 g in 24 hours is an easily obtainable, objective definition of diarrhea,<sup>3</sup> most persons consider increased liquidity as the primary determinant. Diarrhea may be present as an acute or chronic manifestation. Acute diarrhea may be the result of an acute infection, emotional stress, or leakage of liquid stool around impacted feces. Chronic diarrhea is usually defined as symptoms lasting longer than 4 weeks and may be the result of a chronic GI tract infection (often associated with immune system compromise), alterations in the motility or integrity of the GI tract, malabsorption disorders, or certain endocrine disorders. Diarrhea that occurs on an episodic basis may be related to a food allergy or may be due to the ingestion of irritants to the GI tract, such as caffeine. Diarrhea in children frequently results from infection, although malabsorption disorders, anatomic defects, and allergy issues may also be causative factors.<sup>4</sup>

**Pathophysiologic mechanisms.** Four major pathophysiologic mechanisms have been identified in the development of diarrhea: (1) In osmotic diarrhea, increased amounts of poorly absorbable, osmotically active solutes such as a carbohydrate or magnesium sulfate cause sodium and water influx into the bowel lumen, resulting

in diarrhea. (2) In secretory diarrhea, a pathophysiologic event such as the presence of a bacterial toxin causes enhanced secretion of chloride ion and water in the small intestine by simultaneously stimulating active secretion and inhibiting resorption. Diarrhea of 1 L or more per day may result from this inappropriate secretion of fluid across the intestinal mucosa.<sup>2</sup> Causes of secretory diarrhea include enterotoxins produced by such organisms as *Vibrio cholerae* and *Staphylococcus aureus*. (3) Exudative diarrhea is the result of exudation of mucus, blood, and protein from sites of active inflammation into the bowel lumen. This creates an increased osmotic load and a subsequent shift of water across the epithelium. In addition, if a large surface area of the bowel has an alteration in its integrity, intestinal absorption will be severely impaired, further compounding the diarrhea produced. Diarrhea associated with Crohn disease and UC may be the result of this exudative process.<sup>2</sup> (4) Diarrhea related to motility disturbances is a result of the decreased contact time of chyme with the absorptive surfaces of the intestinal lumen. If inadequate absorption takes place in the small intestine, large amounts of fluid will be delivered to the colon and may overwhelm the absorptive capability of the colon and cause diarrhea. In addition, if the fatty acids and bile salts present in chyme have not been adequately absorbed in the small intestine, they may induce a secretory diarrhea once they reach the colon, further compounding the process of diarrhea formation. Diarrhea associated with postgastrectomy dumping syndrome and IBS are examples of this type of diarrhea.

#### KEY POINTS

- Dysphagia is the perception of difficulty in swallowing. Dysphagia caused by neuromuscular disorders may be accompanied by coughing and aspiration, particularly with liquid ingestion. Altered esophageal peristalsis is associated with the sensation that food has become “stuck” behind the sternum. LES dysfunction may be manifested as substernal pain.
- Pain is a common symptom of GI disorders. A heartburn type of pain is associated with esophageal reflux. Chest pain similar to anginal pain may result from esophageal distention and obstruction. Abdominal pain may be visceral (diffuse, poorly localized), somatic (sharp, well localized), or referred (at a distance from the source but in the same dermatome).
- Nausea and vomiting are manifestations of many GI and other disorders. Alterations in bowel motility or integrity are causative factors. Excess gas may result from altered motility or lack of digestive enzymes. Gas is generated by swallowed air and bacterial action on nutritional substrates.
- Constipation is defined as small, infrequent (less than three per week), or difficult bowel movements. Lack of exercise, lack of dietary fiber, slowed peristalsis, and pathologic conditions that alter motility (e.g., obstruction) may produce constipation.
- Diarrhea is defined as an increased frequency and fluidity of bowel movements. Acute infection, stress, fecal impaction, malabsorption disorders, and ingestion of bowel irritants may produce diarrhea. Osmotic diarrhea is due to increased amounts of poorly absorbed solutes in the intestine. Secretory diarrhea is usually due to toxins that stimulate intestinal fluid secretion and impair absorption. Exudative diarrhea (mucus, blood, protein) results from inflammatory processes. A decreased transit time in the small intestine results in diarrhea because the absorptive capacity of the large intestine is exceeded.

## DISORDERS OF THE MOUTH AND ESOPHAGUS

The mouth and the esophagus are the portals of entry for nutrients into the GI tract. An impairment in the proper functioning of these structures may have a profound effect on the ability of the individual

to ingest adequate nutrients and begin the initial steps of the digestive process. Although disorders of the mouth and esophagus may not be acute, life-threatening emergencies, they may have severe long-term consequences for the well-being of the individual experiencing them.

## ORAL INFECTIONS

### Stomatitis

**Etiology.** Stomatitis is defined as an ulcerative inflammation of the oral mucosa that may extend to the buccal mucosa, lips, and palate. Among its many causes are pathogenic organisms, including bacteria and viruses; mechanical trauma; exposure to such irritants as alcohol, tobacco, and other chemical substances; certain medications, particularly chemotherapeutic agents; radiation therapy; and nutritional deficiencies, especially vitamin deficiencies. Stomatitis is a central manifestation of several autoimmune disorders, including Reiter syndrome and Behçet syndrome.<sup>5</sup> Stomatitis may also be idiopathic; that is, it has no identifiable cause.

One of the most commonly encountered types of stomatitis is acute herpetic stomatitis, also called herpetic gingivostomatitis, or more colloquially cold sores. It is caused by infection with herpes simplex virus (HSV), which has an affinity for the skin and nervous system. This type of stomatitis is commonly acquired by children between the ages of 1 and 3 years, although it may occur at any age. In primary infection, a brief period of prodromal tingling and itching may be present along with fever and pharyngitis. Vesicles may erupt on any part of the oral mucosa, particularly the tongue, gums, and cheeks. Vesicles form on an erythematous base, eventually rupture, and leave a painful ulcer. Once herpes simplex virus is acquired, it remains latent in the dorsal ganglia of the spinal cord and may be reactivated by physical or emotional stressors.

**Treatment.** The pharmacologic therapy used for stomatitis depends on its cause. The antiviral drugs acyclovir, famciclovir, and valacyclovir have been approved for treating acute herpetic stomatitis. Unfortunately, in a significant number of cases stomatitis is idiopathic or not amenable to specific therapy (e.g., stomatitis attributable to chemotherapy). In all types of stomatitis, measures designed to provide adequate oral hygiene and increase comfort in the oral cavity will be helpful in preventing decreased nutritional intake during the period of inflammation and assist in promoting the healing process. Topical mucosal barriers and corticosteroids may be of some benefit (e.g., triamcinolone [Kenalog] in Orabase)<sup>5</sup> whereas pentoxifylline, colchicine, dapsone, and thalidomide have been used for recalcitrant cases of idiopathic stomatitis.<sup>6</sup>

## ESOPHAGEAL DISORDERS

### Gastroesophageal Reflux Disease

Gastroesophageal reflux disease (GERD) is the backflow of gastric contents into the esophagus through the LES. GERD may or may not produce symptoms.

**Pathogenesis.** The production of GERD is a multifactorial process. Any condition or agent that **alters the closure strength and efficacy of the LES or increases intraabdominal pressure may predispose an individual to GERD.** For example, the closure strength of the LES may be adversely affected by the intake of fatty foods, caffeine, and alcohol; cigarette smoking; sleep position; or obesity. In addition, pharmacologic agents such as progesterone-containing medications (e.g., birth control pills), narcotics, benzodiazepines, calcium channel blockers, and theophylline may decrease the pressure of the LES. Pregnancy increases the risk of reflux both by increasing intraabdominal pressure and by affecting hormonal mechanisms. Certain anatomic

features, especially hiatal hernia, have been associated with GERD. The extent and severity of damage to the esophagus from GERD reflect the frequency and duration of exposure to refluxed material, as well as the volume and acidity of the gastric juices being refluxed.<sup>2,3</sup> The role of *Helicobacter pylori*, a cause of gastric and duodenal ulceration, in GERD is poorly understood and controversial.<sup>7</sup>

**Clinical manifestations.** The most common manifestations of GERD are heartburn, regurgitation, chest pain, and dysphagia. These symptoms are related to **reflux esophagitis**, which is esophageal inflammation caused by the highly acidic refluxed material. Complications of persistent GERD include esophageal strictures, Barrett esophagus (see Complications section), and pulmonary symptoms related to reflux esophagitis, such as cough, asthma, and laryngitis.

**Treatment.** Appropriate therapy is directed to increasing LES pressure, enhancing esophageal clearance, improving gastric emptying, and suppressing gastric acidity. Dietary and behavioral changes, such as avoiding tobacco and aggravating food and drink, are indicated for all patients, whereas over-the-counter antacids and histamine (H<sub>2</sub>)-blocking medications may be effective for occasional GERD. Proton pump inhibitors (PPIs) are the mainstays of treatment for chronic GERD and have proven very successful in halting and even reversing the changes of chronic GERD.<sup>8</sup> If reflux esophagitis has progressed in severity, tissue damage, including ulceration, fibrotic scarring, and strictures, may be present in the distal third of the esophagus. Upper GI endoscopy is indicated for patients with ongoing symptoms, and some patients with stricture may require endoscopic dilatation. Surgical intervention, such as thoracoscopic Nissen fundoplication, may be helpful for intractable GERD.<sup>9</sup>

**Complications.** **Barrett esophagus** is a complication of chronic GERD and involves columnar tissue replacing the normal squamous epithelium of the distal esophagus. It carries a significant risk for esophageal cancer, and patients with Barrett esophagus should undergo regular endoscopic screening for cancer, along with pharmacologic control of their reflux.<sup>10</sup> For patients with documented dysplastic changes, endoscopic eradication therapy is a relatively low-morbidity option for treatment.<sup>11</sup>

### Hiatal Hernia

A **hiatal hernia** is a defect in the diaphragm that allows a portion of the stomach to pass through the diaphragmatic opening into the thorax. Two types of hiatal hernia are commonly recognized: (1) a sliding hernia, in which both a portion of the stomach and the gastroesophageal junction slip up into the thorax so that the gastroesophageal junction is above the diaphragmatic opening; and (2) a paraesophageal hernia, in which a part of the greater curvature of the stomach rolls through

the diaphragmatic defect (Figure 36-2). “Mixed” hiatal hernias with features of both of these types may also occur. Sliding hernias are 3 to 10 times more common than paraesophageal and mixed hernias combined. The incidence of hiatal hernia increases with age and occurs more often in women than in men.

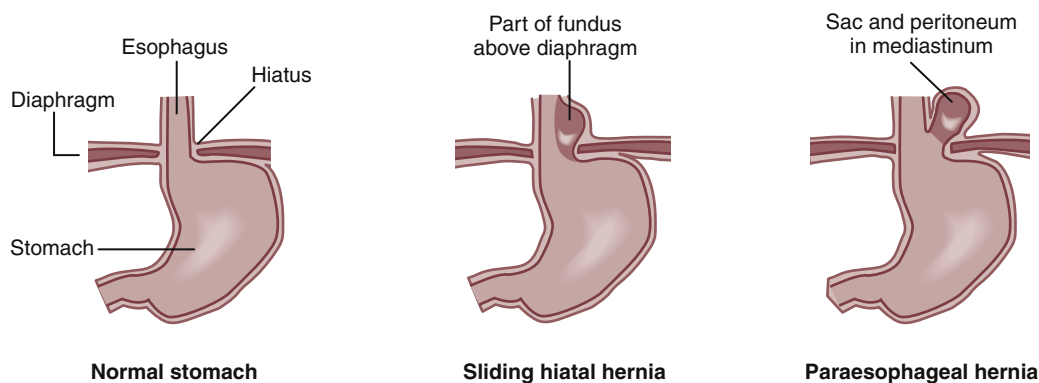

**Etiology.** Although the cause of the anatomic deformity leading to hiatal hernia is not well understood, certain conditions seem to predispose to loosening of the muscular band around the esophageal and diaphragmatic junction. Conditions in which intraabdominal pressure increases, such as ascites, pregnancy, obesity, and chronic straining or coughing, have been associated with the development of hiatal hernia.

**Clinical manifestations and treatment.** Individuals with hiatal hernia are predisposed to GERD and may experience symptoms such as heartburn, chest pain, and dysphagia. Ulcerations can develop along the mucosal surface of the stomach as it slides through the diaphragmatic opening, so-called Cameron ulcers. This is a fairly uncommon cause of chronic upper GI blood loss.<sup>12</sup> A potentially life-threatening situation can develop if a large portion of the stomach becomes caught above the diaphragm and is incarcerated, although this is extremely rare. Medical therapy for hiatal hernia is the same as that for GERD, detailed previously. Indications for surgery include acute incarceration or intractable reflux.

### Mallory-Weiss Syndrome

**Etiology.** **Mallory-Weiss syndrome** is bleeding caused by a tear in the mucosa or submucosa of the cardia or lower portion of the esophagus. The tear is usually longitudinal and is primarily caused by forceful or prolonged vomiting in which the upper esophageal sphincter fails to relax during the vomiting process. Approximately 75% of individuals with Mallory-Weiss syndrome are men with a history of excessive ingestion of alcohol or salicylates.<sup>2</sup> Other factors and conditions that may contribute to the development of esophageal tearing in Mallory-Weiss syndrome are coughing, straining during bowel movements, trauma, hiatal hernia, esophagitis, and gastritis. Use of polyethylene glycol as a preparation for colonoscopy has also been associated with Mallory-Weiss tears.<sup>13</sup>

**Clinical manifestations and treatment.** Manifestations of Mallory-Weiss syndrome include vomiting of blood and passing of large amounts of blood rectally after an episode of forceful vomiting. Epigastric or back pain may also be present. Bleeding may range in severity from mild to massive. It is often profuse when the tear is near the cardia of the stomach and may proceed to fatal shock in this circumstance. Identification is made by endoscopic examination during an episode of acute upper GI bleeding. The majority of patients require at least one blood transfusion, but in most cases bleeding stops spontaneously.<sup>14-19</sup>

**FIGURE 36-2** Types of hiatal hernia. (From Gould BE: *Pathophysiology for the health professions*, ed 4, Philadelphia, 2011, Saunders.)

Control of active bleeding may be achieved through endoscopic multipolar electric coagulation or similar techniques, epinephrine injection, or through interventional radiologic procedures (e.g., vasopressin infusion, Gelfoam embolization).<sup>20</sup> In selected cases, surgical intervention may be necessary.

### Esophageal Varices

Esophageal varices represent a complication of portal hypertension, which in Western society is generally the result of cirrhosis attributable to alcoholism or viral hepatitis. In developing tropical countries, chronic infection with the *Schistosoma* species of liver flukes is a major cause of portal hypertension, along with cirrhosis attributable to chronic hepatitis B infection. Varices will affect more than half of cirrhotic patients, and approximately 30% of these patients experience an episode of variceal hemorrhage within 2 years of the diagnosis of varices.<sup>21</sup> The diagnosis and management of varices are discussed in detail in Chapter 38.

#### KEY POINTS

- Stomatitis is inflammation of the oral mucosa. It may result from pathogenic organisms, trauma, chemical irritants, chemotherapy, radiation therapy, or nutritional deficiencies.
- Common esophageal disorders are GERD with esophagitis, hiatal hernia, and bleeding. Reflux esophagitis is manifested as heartburn, chest pain, and dysphagia and may be precipitated by gastric overdistention or poor LES tone. Fatty foods, cigarettes, morphine, theophylline, and progesterone may inhibit LES tone.
- Hiatal hernias may be sliding or rolling (paraesophageal). Conditions that increase intraabdominal pressure predispose to the development of hiatal hernia. Esophageal reflux often accompanies hiatal hernia, and the manifestations are similar: heartburn, chest pain, dysphagia.
- Bleeding from the esophagus may pose a life-threatening situation. Mallory-Weiss syndrome is bleeding caused by tears in the lower end of the esophagus or upper part of the stomach. Alcohol and salicylate ingestion appear to be factors. Esophageal bleeding may also be precipitated by coughing, straining, or esophagitis. Rupture of esophageal varices is a dreaded complication of cirrhosis with portal hypertension and carries a high mortality.

## ALTERATIONS IN THE INTEGRITY OF THE GASTROINTESTINAL TRACT WALL

Alterations in the integrity of the GI tract may occur at any location along the approximately 30 feet of its length, resulting from infection, an inflammatory process, or weakness of the intestinal wall. Such alterations may present as an acute, life-threatening situation or as a chronic, disabling condition. When the integrity of the GI tract wall is compromised, the ability to perform digestive and absorptive functions may also be compromised because the surface area or motility (or both) is altered.

## INFLAMMATION OF THE STOMACH AND INTESTINES

### Gastritis

**Etiology.** Gastritis is defined as an inflammation of the stomach lining. Acute inflammation of the stomach lining may occur after the ingestion of alcohol, aspirin, or irritating substances, as well as

be caused by viral, bacterial, or autoimmune illnesses. (Some experts prefer use of the term gastropathy for toxic gastric inflammation, with gastritis defined as gastric inflammation attributable to infection or autoimmune disorders.<sup>17</sup>) In Western countries, overuse of nonsteroidal antiinflammatory drugs (NSAIDs) and overindulgence in alcohol and tobacco are preeminent causes of acute gastritis.

**Pathogenesis.** Chronic gastritis is currently the focus of extensive research. The factors promoting chronic gastritis have always been poorly understood. However, in 1983 identification of the bacterium *Helicobacter pylori* proved to be a landmark event.<sup>18</sup> Since that time, *H. pylori* has generated worldwide attention for its role in the promotion of chronic gastritis, peptic ulcer disease (PUD), and gastric carcinoma and lymphoma. Circumstantial evidence suggests that the mode of transmission of *H. pylori* is primarily person to person.<sup>19</sup> Some studies suggest a fecal-oral route, with the possibility of a reservoir in water sources.

It is now known that *H. pylori* causes chronic, superficial gastritis in virtually all infected persons.<sup>2</sup> Once established in the gastric mucosa, *H. pylori* establishes a destructive pattern of persistent inflammation. This persistent inflammation may resolve spontaneously, with clearance of the organism over time, leading to a decreased prevalence of *H. pylori* infection among older individuals. Consequences of *H. pylori* gastritis include PUD (discussed in a later section), atrophic gastritis, gastric adenocarcinoma, and mucosa-associated lymphoid tissue (MALT) lymphoma. The diagnosis and management of *H. pylori* infection will be discussed below.

**Clinical manifestations.** Although gastritis may be asymptomatic, manifestations of acute gastritis include anorexia, nausea, vomiting, and postprandial discomfort. Occasionally, **hematemesis** may occur in response to damage to the gastric epithelial mucosa. These manifestations usually disappear when the causative agent is removed, and the gastric epithelium undergoes a process of renewal after sloughing off the layer of damaged cells.

### Gastroenteritis

**Etiology.** Gastroenteritis refers to inflammation of the stomach and small intestine, and may occur on an acute or chronic basis. Chronic gastroenteritis is usually the result of another GI disorder, such as Crohn disease, and is discussed in a later section. Acute gastroenteritis is the result of direct infection of the GI tract lining by a pathogenic organism such as the Norwalk virus, or it can occur from ingestion of preformed bacterial toxins (e.g., *Staphylococcus aureus*, *Bacillus cereus*) or bacteria that produce toxins (e.g., *Clostridium perfringens*). Acute gastroenteritis may also be caused by an imbalance in the normal bacterial flora of the GI tract precipitated by the introduction of an unusual bacterial strain, as may occur during travel.

**Clinical manifestations and treatment.** Acute gastroenteritis in adults is usually a self-limiting, nonfatal disease with manifestations of diarrhea, abdominal discomfort and pain, nausea, and vomiting. An elevated temperature and malaise may also be present. The manifestations vary according to the type of causative pathologic organism and the region of the GI tract affected. Many pathogenic organisms induce a severe secretory type of diarrhea (see the earlier discussion on the pathophysiologic mechanism of secretory diarrhea). In children and the elderly, fluid losses from diarrhea and vomiting can have serious consequences and may be life-threatening, particularly in underdeveloped countries. Supportive treatment designed to provide fluid and electrolyte replacement may thus be required for many patients experiencing severe acute gastroenteritis.

### Peptic Ulcer Disease

The term **peptic ulcer disease (PUD)** refers to disorders of the upper GI tract caused by the action of hydrochloric acid and pepsin. These

disorders may include injury to the mucosa of the esophagus, stomach, or duodenum and may range from a slight mucosal injury to severe ulceration (Figures 36-3 and 36-4). Peptic ulcer disease seems to be the result of an increase in factors that tend to injure the mucosa relative to factors that tend to protect it. The presence of an intact gastric mucosal barrier and the ability of the mucosa to renew its epithelium serve to protect it against injury. On the other hand, the presence of hydrochloric acid, which potentiates the actions of pepsin and other injurious substances such as aspirin and NSAIDs, will promote injury to the mucosa.

Previously, PUD was attributed to a stressful lifestyle and an irritating diet, and treatment revolved around removing spices from the diet and promoting a more relaxing lifestyle. In recent years, however, research has suggested that the organism *H. pylori* is a major precipitant of PUD, along with NSAIDs. A brief review of the current understanding of the pathogenesis of PUD is presented as a basis for further discussion of the manifestations and management of PUD.

**Etiology and pathogenesis.** Most peptic ulcers arise in the stomach and duodenum. Although the precise mechanisms of ulcer formation remain incompletely understood, the process involves the interplay of mucosal defense mechanisms, pepsin, and acid.<sup>3</sup> It is

**FIGURE 36-3** Radiograph of an ulcer in the lesser curvature of the stomach (arrow). (From Laufer I: *Double contrast gastrointestinal radiology with endoscopic correlation*, Philadelphia, 1979, Saunders.)

thought that a breakdown in the normally protective epithelial lining of the stomach occurs (Figure 36-5). In the formation of a gastric peptic ulcer, the barrier of the epithelial layer and the slightly alkaline layer of mucus may be interrupted by the chronic presence of such injurious substances as aspirin, NSAIDs, alcohol, and bile acids, which may be regurgitated from the duodenum. These substances apparently strip away the surface mucus and cause degeneration of the epithelial cell membranes, with diffusion of hydrochloric acid into the gastric epithelial wall.

Inappropriate excess secretion of acid is a major factor in the development of PUD in the duodenum (Figure 36-6). Studies have documented that the basal activity of the vagus nerve is increased in persons with PUD of the duodenum, particularly during a fasting state and at night. This stimulates the pyloric antrum cells to release gastrin, which travels via the bloodstream and acts on the gastric parietal cells to release hydrochloric acid (HCl). The result is an inappropriately high level of HCl in the duodenum. Interestingly, PUD patients also have lower bicarbonate levels in the duodenum as a consequence of the effect of *H. pylori* on the duodenal mucosa.<sup>20</sup>

*H. pylori* has a key role in promoting both gastric and duodenal ulcer formation (Figure 36-7). It has been reported that up to 75% of persons with duodenal ulcers and 60% of persons with gastric ulcers have *H. pylori* infection.<sup>2</sup> *H. pylori* thrives in acidic conditions; thus, infection with *H. pylori* renders a person with PUD subject to a slow rate of ulcer healing and a high rate of recurrence, and clearance of *H. pylori* promotes ulcer healing.<sup>21</sup> Although the precise mechanisms for the development of PUD remain complex and poorly understood, *H. pylori* virulence is associated with several factors, including the

**FIGURE 36-4** Photograph of an ulcer. (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

**FIGURE 36-5** Lesions caused by peptic ulcer disease. (From Monahan FD, Sands JK, Neighbors M, Marek JF, Green-Nigro CJ: *Phipps medical-surgical nursing: health and illness perspectives*, ed 8, St Louis, 2007, Mosby.)

presence of unique, lengthy DNA sequences known as pathogenicity islands, particularly cytotoxin-associated gene A (*CagA*).<sup>22</sup>

Other cofactors in the development of PUD have been investigated. Stress has long been considered a key factor in PUD. Glucocorticoids released in response to stress may have a role in the promotion of excess acid production or the destruction of gastric mucosal defenses. Smoking is an important risk factor, as identified by epidemiologic studies showing that PUD is twice as likely to develop in smokers as in nonsmokers.<sup>23</sup> In addition, smoking is related to poor ulcer healing and high rates of ulcer recurrence. Heredity is thought to have a role in the development of PUD. Certain patterns of gastrin release and pepsin secretion have been identified as genetic traits in families with an increased incidence of PUD.<sup>9</sup> Somewhat surprisingly, there is little evidence of a pathogenic role for alcohol, spicy foods, and caffeine.<sup>2</sup>

**Clinical manifestations and diagnoses.** Manifestations of PUD include epigastric burning pain that is usually relieved by the intake of food (especially dairy products) or antacids. The pain of gastric ulcers

typically occurs on an empty stomach but may present soon after a meal. Duodenal ulcer pain classically occurs 2 to 3 hours after a meal and is relieved by further food ingestion. Other manifestations that may occur in individuals with PUD include nausea, abdominal upset, and chest discomfort. A significant proportion of ulcers are asymptomatic, and life-threatening complications, such as GI bleeding, may occur in patients with no warning. The symptoms of PUD are not specific enough to allow for a diagnosis, and malignant conditions can mimic benign PUD.

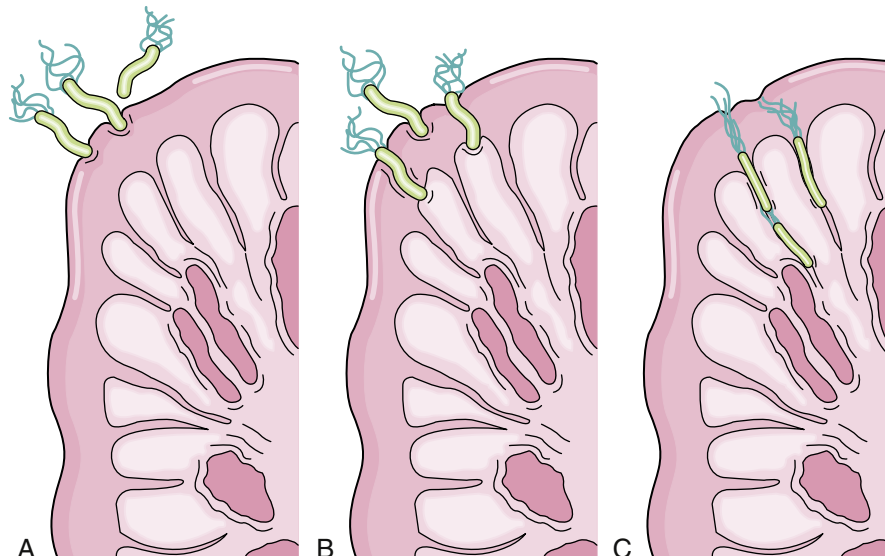

Diagnosis can be accomplished by upper GI barium contrast radiography or by endoscopy. The finding of a duodenal ulcer indicates a high probability of *H. pylori* and a low probability of malignancy, and the condition can be managed on this basis. All gastric ulcers should be visualized with endoscopy and biopsied to rule out malignancy and confirm the presence of *H. pylori*.<sup>2</sup> The necessity of testing for *Helicobacter* in patients with uncomplicated duodenal ulcers, given the very high pretest probability, is somewhat controversial. Most authorities do recommend testing for this organism in the case of gastric ulcers. Testing modalities include noninvasive tests such as the urease breath test, serologic analysis, and fecal antigen testing; invasive endoscopic tests include the tissue urease test, histologic analysis, and bacterial culture.<sup>24</sup>

**Treatment.** The major treatment objectives for PUD are to encourage healing of the injured mucosa by reducing gastric acidity and to prevent recurrence. Proton pump inhibitors are generally given to block acid secretion. Agents such as sucralfate form a protective coating over the injured mucosa and may be useful under some circumstances. Eradication of *H. pylori* infection with antibiotics has led to a marked reduction in the recurrence rate of PUD to less than 10%.<sup>22,25,26</sup>

In addition to these pharmacologic strategies, such measures as cessation of smoking, avoidance of aspirin and NSAIDs, and reduction of stress are all part of a comprehensive program to manage PUD. At the present time, no conclusive research has demonstrated that any specific diet has a therapeutic effect. Susceptible people are generally advised to avoid foods that seem to exacerbate symptoms, including caffeinated beverages and alcohol.

**FIGURE 36-6** Duodenal bulbar ulcer. (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

**FIGURE 36-7** Penetration of the mucosal layer by *Helicobacter pylori*. **A**, After penetration, *H. pylori* forms clusters near membranes of surface epithelial cells. **B**, Some attach to the cell membrane. **C**, Others lodge between the epithelial cells.

## INFLAMMATORY BOWEL DISEASE

The term **inflammatory bowel disease (IBD)** refers to the two separate disease entities of UC and Crohn disease. IBD is generally a life-altering chronic illness with serious consequences for people and their families who must cope with it. Both UC and Crohn disease have their onset most commonly in childhood and young adulthood, with obviously profound implications. This section describes the pathophysiologic aspects of UC and Crohn disease; a later section in this chapter discusses the psychosocial aspects of IBD.

### Ulcerative Colitis

**Ulcerative colitis** (Figure 36-8) is an inflammatory disease of the mucosa of the rectum and colon. Approximately one fifth of patients have total colitis, one third have subtotal disease extending beyond the sigmoid, and one half have disease limited to the rectum and rectosigmoid.<sup>2</sup> The changes are usually most severe in the rectum and extend for a variable extent around the colon, although there are several exceptions to this general rule. IBD is typically characterized by exacerbations and remissions. Its causes are poorly understood, but recent research has focused on genetic, environmental, and immunologic factors.<sup>27</sup> The immunologic basis for the disease is supported by the fact that UC frequently accompanies other autoimmune conditions such as thyroid disease and pernicious anemia. The annual incidence in North America has been estimated between 2 and 14 per 100,000 persons.<sup>28</sup>

**Etiology and clinical manifestations.** Ulcerative colitis begins as an inflammation at the base of the crypts of Lieberkühn. Damage to the crypt epithelium results, with eventual invasion of leukocytes and the formation of abscesses in the crypts. When multiple abscesses form in close proximity and begin to coalesce, large areas of ulcerations develop in the epithelium. Concurrent with this destructive process are attempts at repair of damaged tissue, along with the development of fragile and highly vascularized granulation tissue. The manifestations of UC are the result of these processes and include abdominal pain, diarrhea, and rectal bleeding. Bleeding occurs as a result of mucosal destruction and ulceration, as well as damage to newly developed granulation tissue. Diarrhea is a result of the mucosal destruction in the colon, which leads to a decreased ability of the bowel to absorb water and sodium and thus to an increased volume of fluid in the intestinal contents.

The progression of UC may be highly variable. In some individuals it may have very mild manifestations; in others it may rapidly progress

**FIGURE 36-8** Ulcerative colitis. (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

to a life-threatening disorder. Approximately 5% to 10% of persons with UC have only one attack, with no further recurrence. However, 65% to 75% of those with UC experience an intermittent series of exacerbations and remissions. Rarely, patients with UC will manifest toxic megacolon, a life-threatening condition in which the colon becomes massively enlarged. This condition generally requires urgent colectomy. A number of conditions in other organ systems complicate UC, the most devastating of which is the relentlessly progressive liver condition primary sclerosing cholangitis, which occurs in 3% of UC patients.<sup>2</sup>

An additional concern is increased risk for the development of colon cancer in persons who have had UC for more than 7 to 10 years. Authorities recommend monitoring these individuals carefully with regular endoscopy and biopsy. The presence of high-grade dysplasia should prompt consideration of prophylactic complete colectomy. Recent surgical advances, such as the ileoanal pouch, have allowed colectomy patients to avoid colostomy and have close to normal bowel function.

**Treatment.** Management of UC is complex and ever evolving. Corticosteroids have long been the mainstay of treatment of acute exacerbations, but side effects limit their long-term use. Patients with signs of systemic toxicity, especially those with impending or full-blown toxic megacolon, should receive broad-spectrum antibiotics. Important categories of disease-modifying agents include the salicylate analogues, and immunomodulating agents such as azathioprine and mercaptopurine. Intravenous followed by oral cyclosporine is a relatively new treatment for steroid-refractive UC that may help patients avoid colectomy.<sup>29</sup> Infliximab (Remicade) is another option for refractory UC whose exact role has yet to be determined.<sup>30</sup> It may help some patients with steroid-refractory UC who cannot take cyclosporine avoid colectomy.

### Crohn Disease

**Crohn disease**, also called regional enteritis or granulomatous colitis, is an inflammation of the GI tract that extends through all layers of the intestinal wall (Figure 36-9). It most commonly affects the proximal portion of the colon and, less often, the terminal ileum. It may affect multiple portions of the colon, with intervening normal areas left between the affected regions. The manifestations of Crohn disease differ in some respects from those of UC, although some overlap may occur and distinction may be difficult. In Crohn disease, abdominal pain is often constant and in the right lower quadrant of the abdomen. A palpable abdominal mass may be present in the right lower quadrant, reflecting significant ileocecal involvement. The stool may be bloody, although not usually to the extent of that seen with UC. The cause of Crohn disease is unknown at the present time. There are fascinating parallels with UC as well as unexpected distinctions. For instance, smoking has been shown to protect against UC but to increase the risk of Crohn disease.<sup>31</sup> The annual incidence of Crohn disease in North America has been estimated from 3 to 15 per 100,000, and up to 5% of people with Crohn disease have 1 or more affected relatives.

**Etiology and pathogenesis.** Certain features of the pathogenesis of Crohn disease differ from those of UC. Crohn disease appears to be the result of a process in which the lymphoid and lymphatic structures of the GI tract become blocked. Subsequent engorgement and inflammation of surrounding tissue lead to the development of deep linear ulcers in the bowel wall. Eventually, all layers of the GI tract wall may become involved, and the portion of intestine that is affected may become thickened by fibrous scar tissue. Deep fissures may develop into fistulas, which may extend into adjacent tissue of other organs such as the bladder wall or even the skin. One of the cardinal features

**FIGURE 36-9** Crohn disease. (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

of Crohn disease on histopathologic analysis is granulomas, which is generally diagnostic of this disorder.

**Clinical manifestations.** The manifestations of Crohn disease are the result of the pathologic changes just described, as the bowel becomes incapable of adequately absorbing the intestinal contents. Complications such as perianal fissures, fistulas, and abscesses are common in Crohn disease and may be the symptoms that lead individuals to seek health care. The onset and course of Crohn disease may vary a great deal; unlike UC, the symptoms present during a period of Crohn exacerbation may be subtle but persistent. At the present time, it is unclear whether a significantly increased incidence of intestinal cancer occurs in persons with Crohn disease. However, when Crohn disease involves the large bowel, the risk of colorectal cancer appears to be similar to that for UC of similar extent.<sup>32</sup> Toxic megacolon and primary sclerosing cholangitis also occur with Crohn disease but are much less frequent than in patients with UC. Many extraintestinal manifestations occur, including spondyloarthritis and uveitis.

The diagnosis of Crohn disease is typically made on the basis of the clinical history, radiographic changes, and typical biopsy findings of granulomatous intestinal inflammation. Several immunologic tests are also available, but these are expensive and generally reserved for cases where the diagnosis is uncertain.<sup>2,3</sup>

**Treatment.** Because the etiology of Crohn disease is unknown, therapeutic strategies are focused on alleviating and reducing inflammation. Therapeutic drug categories are similar to those for UC. Prednisone or sulfasalazine is generally used as initial therapy to achieve remission. The antibiotic metronidazole is particularly useful for colonic Crohn disease. Options for the treatment of refractory patients include azathioprine, 6-mercaptopurine, methotrexate, and biological therapies.

New types of treatments include the anti-tumor necrosis factor agents infliximab, adalimumab, and certolizumab, all of which have shown success in trials and are indicated for refractory Crohn disease.<sup>33</sup> Despite these advances, there is no cure for this challenging condition.

## ENTEROCOLITIS

### Antibiotic-Associated Colitis (Pseudomembranous Colitis)

**Etiology.** Antibiotic-associated colitis (AAC), also known as pseudomembranous colitis, is an acute inflammation and necrosis of the large intestine caused by *Clostridium difficile*, usually affecting the mucosa but sometimes extending to other layers.<sup>34</sup> Exposure

to antibiotics is the major factor predisposing to the development of this disorder, and patients with cancer or who have undergone abdominal surgery are at particular risk. The disease is mediated by bacterial toxins, leading to mucosal necrosis and the characteristic pseudomembrane composed of leukocytes, mucus, fibrin, and inflammatory cells.

**Clinical manifestations and treatment.** Resulting manifestations include diarrhea (often bloody), abdominal pain, fever, leukocytosis, and, rarely, colonic perforation. AAC is a major cause of fever and leukocytosis (elevated white blood cell count) among hospitalized patients receiving antibiotics. Treatment involves stopping the offending antibiotic, if possible, treating ischemia and other contributing conditions, and using antibiotics such as oral metronidazole or vancomycin. Recurrences are relatively common and may necessitate retreatment. In rare cases a fecal transplant (transfer of fecal material from another healthy person to the source patient via enema or gastric tube) or colectomy may be necessary to clear the infection.

### Necrotizing Enterocolitis

**Etiology.** Necrotizing enterocolitis (NEC) is a disorder occurring most often in premature infants (less than 34 weeks' gestation) and infants with low birth weight (less than 5 lb or 2.25 kg). This disorder is characterized by diffuse or patchy intestinal necrosis accompanied by sepsis.

**Clinical manifestations and treatment.** Early manifestations include a distended abdomen and stomach. The major complication of NEC is intestinal perforation, which may necessitate surgery. Various theories regarding the etiologic progression of NEC include perinatal oxygen deficit with insufficient blood flow to the viscera, and the use of hypertonic feeding formulas in newborn infants. Greater than 90% of infants with NEC have a history of milk feeding as well. A special form of necrotizing enterocolitis, called typhlitis, may afflict adult cancer patients with neutropenia and carries a grave prognosis. Management of neonatal and adult forms of NEC includes careful supportive care, including fluid management and administration of broad-spectrum antibiotics. Early surgical consultation is essential for this syndrome, and surgery is necessary for patients with evidence of significant ischemia or perforation.

### Appendicitis

**Etiology.** The most common cause of emergency surgery on the abdomen, **appendicitis** is an inflammation of the vermiform appendix. The classic hypothesis suggests that obstruction of the appendiceal lumen by a fecalith causes most cases of appendiceal inflammation. Less commonly, lymphoid hyperplasia or parasitic worms may lead to appendicitis. In an unknown number of cases appendiceal inflammation may be self-limited and may remit (e.g., with relief of the obstruction). If left unchecked, inflammation generally leads to necrosis of the appendix, with subsequent abscess formation and life-threatening peritonitis. Rarely appendicitis may occur in a subacute or stuttering fashion over several days or weeks.

**Clinical manifestations and treatment.** Appendicitis is two times more likely to occur in individuals younger than age 45 as compared to those 45 years and older, and it affects men somewhat more often than women. The peak incidence is between ages 10 and 19 years. The earliest manifestation of appendicitis is generalized periumbilical pain accompanied by nausea and, occasionally, diarrhea. The pain is often described as "migrating" or localizing to the lower right abdomen (**McBurney's point**) because of distention of the serosa from inflammatory edema, at which time fever usually manifests. Experienced surgeons generally operate in suspicious cases. Less typical cases should

**FIGURE 36-10** Colonic diverticula are evident as small outpouchings of colonic mucosa through the muscular tunicae (arrow). (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

be assessed with computed tomography (CT), or with ultrasound if the patient is a child or pregnant women or if CT is not readily available. Such an approach yields a relatively low false-positive surgical rate of around 5%.<sup>2</sup> Surgical removal of the appendix, either through an open procedure or laparoscopically, is the treatment of choice for appendicitis. Administration of antibiotics with replacement of fluid and electrolytes is usually necessary. Localized abscesses secondary to perforation may be managed with percutaneous tube drainage and antibiotics alone, if there are no signs of diffuse peritonitis.<sup>35</sup> Delayed appendectomy is usually carried out several weeks later, after the initial inflammation has subsided.

### Diverticular Disease

**Etiology.** The term diverticular disease generally refers to **diverticulosis**, or the presence of diverticula in the colon. Diverticula are acquired herniations of the mucosa and submucosa through the muscular coat of the colon (Figure 36-10) that probably result from a combination of structural and functional factors. In particular, areas of weakness in the bowel wall, especially where blood vessels enter, are subject to damage from high intraluminal pressures. Colonic diverticulosis is very common in Western countries and is associated with a diet low in fiber; this lack of fiber presumably fails to provide enough bulk to dampen pressure variations in the intestine. The prevalence of diverticulosis increases with age; about 30% of the general population at 60 years of age and about 80% at 80 years will have diverticula in the colon.<sup>1</sup> Most persons experience no manifestations of diverticulosis, and by itself diverticulosis is not considered a pathologic condition. However, when diverticula become inflamed, the condition is referred to as diverticulitis (see Box 36-1 for the terminology of diverticulosis).

**Clinical manifestations and treatment.** Inflammation of diverticula can lead to serious consequences such as the development of abscesses in the bowel wall, peritonitis, and intestinal obstruction. Manifestations of diverticulitis include acute lower abdominal pain (usually left lower quadrant in location), fever, and leukocytosis. Constipation is common, but 25% of patients may have diarrhea. During an acute episode of diverticulitis, the administration of broad-spectrum antibiotics is indicated, and on occasion percutaneous or surgical drainage of an abscess may be necessary. Recurrence of diverticulitis is common. Long-term complications include colonic strictures and fistulas, which may necessitate surgery. Surgery is also recommended for patients with one or more recurrences of diverticulitis.

### BOX 36-1 TERMINOLOGY OF DIVERTICULOSIS

**Diverticulum:** A single pouchlike herniation through the muscular layer of the colon

**Diverticula:** More than one diverticulum (Latin plural form)

**Diverticulosis:** The presence of one or more diverticula

**Diverticulitis:** Inflammation of one or more diverticula

**Diverticular disease:** Complications related to the presence of diverticula

### KEY POINTS

- Alterations in intestinal wall integrity are generally a result of infection, inflammation, or weakness of the muscular layers. General symptoms include pain, bleeding, and diarrhea.
- Gastritis may be acute or chronic. Acute gastritis is generally precipitated by the ingestion of irritating substances, including alcohol and aspirin. Chronic gastritis may lead to atrophy of the gastric mucosa and the subsequent decreased production of HCl and intrinsic factor. Acute gastroenteritis is usually due to the ingestion of pathogenic organisms or preformed bacterial toxins and is characterized by self-limited vomiting, diarrhea, and abdominal pain.
- PUD may affect the esophagus, stomach, and duodenum. Gastric ulcers are thought to be due to breakdown of the protective mucous layer that normally prevents the diffusion of acids into gastric epithelia. Duodenal ulcers are caused by excessive acid secretion that is mediated by increased vagal activity. The organism *H. pylori* has been implicated in the pathogenesis of both gastric and duodenal ulcers. PUD is characterized by epigastric pain that is relieved by food or antacids. Perforation and bleeding are the major complications of PUD. Management of PUD is aimed at minimizing acid secretion and eradicating *H. pylori*.
- Ulcerative colitis and Crohn disease are chronic inflammatory disorders of the bowel. Ulcerative colitis (inflammation and ulceration of the colon and rectal mucosa) is manifested as bloody diarrhea and abdominal pain. There is an increased risk for colon cancer in persons who have had ulcerative colitis for more than 7 to 10 years. Crohn disease generally affects the proximal portion of the colon or the terminal ileum. Involvement of all layers of the intestinal wall predisposes to fistula formation and malabsorption. Crohn disease may result from blockage and subsequent inflammation of lymphatic vessels. Chronic abdominal pain and diarrhea are common. Management of ulcerative colitis and Crohn disease is aimed at reducing inflammation and subsequently trying to maintain remission.
- Acute inflammation of the intestinal wall may manifest as pseudomembranous enterocolitis or necrotizing enterocolitis. Abdominal pain, diarrhea, fever, and sepsis may result. The use of broad-spectrum antibiotics has been implicated in the etiologic development of pseudomembranous enterocolitis. Necrotizing enterocolitis, which occurs most often in infants, is thought to be due to bowel ischemia.
- Appendicitis is characterized by right lower quadrant pain, nausea and vomiting, and systemic signs of inflammation. Surgical removal of the appendix is necessary. Untreated appendicitis may result in rupture of the appendix and subsequent peritonitis; localized abscesses may be managed with tube drainage and antibiotics alone.
- Diverticula of the colon are very common in Western society because of a low intake of dietary fiber. Low-bulk stools result in the development of high intraluminal pressure, which predisposes to diverticula formation. Diverticulosis is generally asymptomatic. Inflammation of the diverticula, or diverticulitis, is manifested as fever and lower abdominal pain. Antibiotics and surgery may be required for management of complicated diverticulitis.

## ALTERATIONS IN MOTILITY OF THE GASTROINTESTINAL TRACT

Disorders of the GI tract that alter its regular propulsive ability may have a negative effect on nutrient absorption. In the case of increased motility, the transit time of substances passing through the GI tract may be too fast to allow for adequate absorption. Conversely, a blockage or constriction of the GI tract may result in slowed or absent motility, which also prevents normal ingestion and processing of nutrient substances. As with alterations in the integrity of the GI tract wall, these alterations in GI motility may be acute or chronic, with many implications for the lifestyle of the patient.

### MOTILITY DISORDERS

#### Irritable Bowel Syndrome

**Irritable bowel syndrome** is a complex entity that remains incompletely understood despite decades of intensive research. A clear definition of this syndrome has not yet been decided by all authorities; nevertheless, certain defining characteristics have been established. Typically, IBS is the presence of alternating diarrhea and constipation accompanied by abdominal cramping pain in the absence of any identifiable pathologic process in the GI tract.<sup>2</sup> (Other terms that have been used for this syndrome include spastic colitis and irritable colon syndrome.) Many authorities emphasize that the quantity of symptoms is not as important as their effect on the normal lifestyle of an individual. Persons with IBS may miss work, curtail their social life, and avoid sexual intercourse. This is an extremely common disorder, affecting up to 20% of the U.S. population.<sup>2</sup> It is important to differentiate IBS, in which no pathologic process of the GI tract has been identified, from inflammatory bowel disease, in which a specific pathologic process is identifiable.

**Etiology and pathogenesis.** The etiologic factors and pathogenesis of IBS are presently obscure. Most evidence seems to show that IBS is primarily a disorder of bowel motility. Studies have demonstrated that the myoelectric activity of the colon in persons with IBS is altered. In particular, the slow wave activity of the colon, which usually occurs at a rate of three to six times per minute, is markedly increased in IBS.<sup>1,2</sup> Moreover, the sensory response to distention and stimulation seems to be heightened. Whether these findings are the result of genetic factors or such environmental factors as episodic infection, psychological stressors, or dietary patterns remains unknown. The role of sensitivity to substances in ingested foods such as gluten and the contribution of bacterial overgrowth to symptoms are among current areas of exploration.

**Clinical manifestations and treatment.** The manifestations of IBS may vary greatly, with some persons experiencing only diarrhea or constipation and others experiencing an alternating pattern of both. In addition to cramping abdominal pain, manifestations such as nausea and mucus in the stool may also be present. The severity of manifestations ranges from barely noticeable to incapacitating. Current therapy focuses on the use of antidiarrheal agents and antispasmodic medications as appropriate. The 5-hydroxytryptamine (serotonin, 5-HT)<sub>3</sub> receptor antagonist alosetron has shown favorable results for the diarrhea-predominant form of IBS, whereas the 5-HT<sub>4</sub> receptor agonist tegaserod has been useful for patients with constipation as the main manifestation. However, both of these products have been associated with significant side effects, necessitating the Food and Drug Administration (FDA) to restrict their use. Lubiprostone is a locally acting chloride channel activator that enhances chloride-rich intestinal fluid secretion and is useful for patients with primarily constipative IBS.

Ingestion of a diet with increased amounts of fiber has proved useful in many cases and is thought to promote a more normal pattern of myoelectric activity by providing a regular propulsive stimulus in the gut. Perhaps more than with most GI disorders, patients with IBS may benefit from support groups, Internet-based resources, and alternative therapies.

#### Intestinal Obstruction

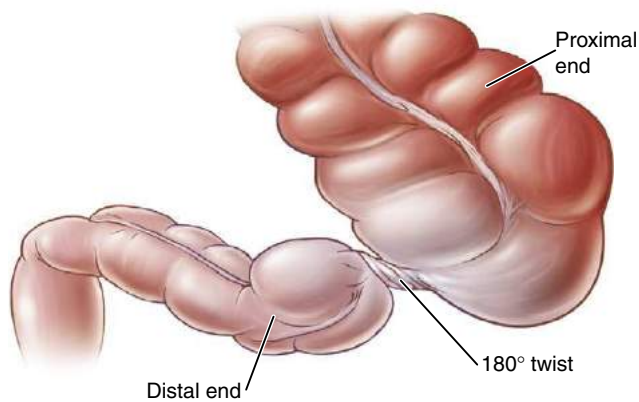

Intestinal obstruction is partial or complete blockage of the intestinal lumen of the small or large bowel. Mechanical obstructions are caused by blockage of the intestine by adhesions, hernia, tumor, inflammation, stricture (as in Crohn disease), impacted feces, volvulus, or intussusception. (Volvulus and intussusception are covered in more detail in the following sections.) Functional obstruction or ileus refers to the loss of propulsive ability by the bowel and may occur after abdominal surgery or in association with hypokalemia, peritonitis, severe trauma, spinal fractures, ureteral distention, and the administration of medications such as narcotics. Ogilvie syndrome is a rare severe motility problem characterized by recurrent bouts of ileus.

**Etiology and pathogenesis.** The most common location for gastrointestinal obstruction is the small bowel (90% of cases). The most frequent contributing factors are previous abdominal surgery with adhesions and congenital abnormalities of the bowel. Metastatic carcinoma, particularly cancer of the intestinal tract or female reproductive organs, is an important cause of obstruction and should be considered in patients with obstruction who have never had abdominal surgery. The severity and types of symptoms initially accompanying an intestinal obstruction vary with its cause and location.

With obstruction of the bowel lumen, fluid and gas begin to accumulate proximal to the obstructed location. The distention produced by trapped fluid and gas causes water and electrolytes to be secreted into the obstructed lumen of the small bowel. Distention also results in the impedance of venous return, and the bowel wall becomes edematous. The absorptive ability of the bowel wall is compromised, and fluid and gas continue to accumulate as additional water and electrolytes are secreted into the lumen. The pressure on the bowel wall exerted by the excess fluid and gas may result in leakage of fluid through the wall into the peritoneum, as well as necrosis of the bowel wall.

In addition to the process just described, other complications may be present with blockage of the intestinal lumen. Impairment of bowel circulation leads to ischemia, a process referred to as strangulation. Bacteria may translocate across the bowel wall into the bloodstream to produce fever and other signs of sepsis. As blood escapes from the engorged veins, significant loss of blood and plasma from the affected segment may result in the rapid development of shock. In addition, the strangulated segment may become gangrenous, with resulting peritonitis, or become perforated, with the leakage of highly toxic bacterial material into the peritoneal cavity.<sup>2</sup> If left untreated, a person with an intestinal obstruction of the small bowel has a high risk of death from shock and vascular collapse.

**Clinical manifestations and treatment.** The manifestations of an intestinal obstruction depend on its site and duration. Obstructions in the upper jejunal area usually result in vomiting, dehydration, and electrolyte depletion. In obstructions of the distal portion of the small bowel or ileum, constipation may be an early manifestation, with massive accumulation of fluid in the lumen occurring later. Dehydration may progress to hypovolemic shock if the obstruction is left untreated. In obstructions of the colon, massive gas distention may be present. The fluid and electrolyte losses associated with colonic obstruction may not be as severe as those seen in obstruction of the small bowel. Blockage of the colon by a tumor is the most common cause of colonic

**FIGURE 36-11** Volvulus. Intestine twists at least 180 degrees, causing obstruction and ischemia. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 714.)

obstruction, and perforation of the bowel wall adjacent to the tumor may occur in association with an obstruction.

Therapeutic strategies for intestinal obstruction include surgical intervention to correct or remove the source of a mechanical obstruction. Supportive therapy, including decompression of the bowel with specialized tubes or endoscopy, and fluid and electrolyte replacement therapy, may be needed during an acute obstructive episode.

### Volvulus

**Volvulus** is twisting of the bowel on itself, causing intestinal obstruction and blood vessel compression (Figure 36-11). The two most common sites for the development of volvulus are the cecum and the sigmoid colon.<sup>2</sup> A volvulus may be the result of an anomaly of rotation, an ingested foreign body, or an adhesion; however, the cause cannot always be determined. Volvulus tends to occur in elderly individuals with coexistent medical conditions. With the sudden tight twisting of the bowel on its mesentery, blood flow to the bowel is impeded. Gangrene, necrosis, and perforation may develop, resulting in a life-threatening situation. If both ends of a bowel segment are twisted, a closed-loop obstruction results, with the manifestations described earlier for intestinal obstruction. Treatment varies according to the severity and location of the volvulus and includes the therapeutic approaches described for intestinal obstruction.<sup>2</sup>

### Intussusception

**Intussusception** is a telescoping or invagination of a portion of the bowel into an adjacent distal portion (Figure 36-12). It is most common in infants and occurs three times more often in males than in females.<sup>2</sup> In most cases involving infants, the actual cause is unknown, although intussusception has been linked to viral infections<sup>36</sup> and the use of some forms of rotavirus vaccine. In older children, it may be associated with alterations in intestinal motility or a condition called Meckel diverticulum, in which a congenital abnormality consisting of a blind tube is present in the distal end of the ileum. In adults, intussusception usually results from the presence of benign or malignant tumors.

As a bowel segment undergoes intussusception, peristalsis acts to pull more bowel along with it. The resulting area of tightened, invaginated bowel becomes edematous; venous engorgement with hemorrhage may occur. Intestinal obstruction of the bowel may develop, with eventual gangrene, shock, and perforation of the bowel if surgical treatment is delayed.

**FIGURE 36-12** Intussusception. A portion of bowel telescopes into adjacent (usually distal) bowel. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 714.)

### Megacolon

Megacolon can be congenital or acquired at any age. Perhaps the most common cause in Western countries is prolonged constipation/obstipation, usually chronic in nature. This is particularly common in younger children who are dealing with the psychological aspects of toilet training and bowel control. Although most of these children are psychologically normal, a small number of children with **encopresis** have experienced sexual abuse, and its presence should be considered.<sup>37</sup> Significant voiding issues also plague the other end of the age spectrum, and constipation/obstipation in the elderly may lead to megacolon, particularly when the sufferer has relied on regular enemas or laxatives for many years.

Hirschsprung disease (see following section) is characterized by the congenital absence of autonomic smooth muscle ganglia. The aganglionic bowel segment contracts but without the reciprocal relaxation needed to propel the intestinal contents forward. Stasis of stool and dilation of the proximal end of the colon result in megacolon, or massive dilation of the colon. Chagas disease caused by infection with *Trypanosoma cruzi* is a common cause of acquired colon neuronal dysfunction and megacolon in Central and South America, but is rarely seen in the United States, except among immigrants from endemic countries. As discussed earlier in the chapter, antibiotic-associated colitis (pseudomembranous colitis) may result in acute megacolon, which is a surgical emergency. Finally, the idiopathic syndrome of intestinal pseudoobstruction (**Ogilvie syndrome**) may rarely result in megacolon.

### Hirschsprung Disease

**Hirschsprung disease** is a congenital disorder of the large intestine in which the autonomic nerve ganglia in the smooth muscle are absent or markedly reduced in number. In 90% of individuals with Hirschsprung disease, the aganglionic segment is in the rectosigmoid area, but occasionally the entire colon may be affected.<sup>2</sup> Hirschsprung disease occurs in approximately 1 in 5000 live births and is occasionally familial.<sup>38</sup> It is more common in males than in females, with a ratio of 3.8:1.<sup>2</sup> The disease often coexists with other anomalies, particularly Down syndrome. Although Hirschsprung disease is most commonly identified in infants and children, it may be present in adults as a long-standing undiagnosed condition.

In infants, Hirschsprung disease may have severe, life-threatening effects. Fecal stagnation may result in enterocolitis with bacterial overgrowth, profuse diarrhea, hypovolemic shock, and intestinal perforation. Interventions such as colonic lavage may be performed to empty the bowel until the infant is stable enough to withstand surgical intervention, which is the definitive treatment.

**KEY POINTS**

- IBS is manifested by bouts of alternating diarrhea and constipation in the absence of an identifiable GI pathologic process. The cause is unclear; however, the slow wave activity of the bowel is markedly increased. A high-fiber diet and antidiarrheal agents may be recommended.
- Intestinal obstructions may be mechanical or functional. Mechanical obstructions are due to adhesions, hernia, tumors, impacted feces, volvulus (twisting), or intussusception (telescoping). Mechanical obstructions are characterized by increased bowel sounds initially, accompanied by abdominal pain, nausea, and vomiting. Functional obstructions are due to conditions that inhibit peristalsis, such as use of narcotics, exposure to anesthetic agents, surgical manipulation, peritonitis, hypokalemia, and spinal cord injuries. Functional obstructions are characterized by the absence of bowel sounds. Uncorrected obstruction may lead to intestinal wall edema, ischemia, and necrosis. Bowel gangrene, sepsis, and shock can result. Surgical intervention or decompression with an intestinal tube is often required.
- Hirschsprung disease is a familial, congenital disorder of the large intestine in which the autonomic ganglia are reduced or absent. Stasis of stool and megacolon may occur in the abnormally innervated section of bowel. Megacolon can also be acquired as an adult.

**DISORDERS OF MALABSORPTION**

**Malabsorption** refers to failure of the GI tract to absorb or normally digest one or more dietary constituents.<sup>1</sup> It is typically manifested as diarrhea, with the passage of inappropriately processed intestinal contents resulting in impaired fluid absorption. A variety of pathologic processes produce malabsorption syndromes, including intestinal enzyme abnormalities (e.g., lactase deficiency), infection (e.g., AIDS enteritis), and radiation enteritis, among others. The types of malabsorption syndromes discussed here result from a mucosal disorder of the small bowel or from the surgical removal of portions of the stomach or small bowel.

**MUCOSAL DISORDERS**

Myriad disorders affect the mucosa of the small intestine. Because the small intestine is the principal site of digestion and absorption of nutrients, a defect in this area has the potential for causing malabsorption of fat, protein, carbohydrate, vitamins, and minerals. Crohn disease, described earlier, may result in damage to the mucosa of the distal portion of the ileum, which is the site of vitamin B<sub>12</sub> and bile acid absorption. Other important mucosal disorders of the small intestine are celiac disease and tropical sprue.

**Celiac Disease**

**Etiology.** **Celiac disease** (also called celiac sprue) is characterized by intolerance of gluten, a protein in wheat and wheat products. Current research suggests that celiac sprue is an immune disorder triggered by exposure to gliadin (a specific wheat gluten) in genetically predisposed persons.<sup>2,39</sup> Environmental, genetic, and immune factors play pivotal roles in determining the nature of symptoms. The main pathologic finding is villus atrophy, with a decrease in the activity and amount of surface epithelial enzymes. The resulting malabsorption of ingested nutrients may promote malnutrition and severe debilitation.

Celiac disease affects twice as many females as males and may have a familial inheritance pattern. More accurate serologic tests have shown the incidence in the general population to be much higher than previously believed; the current prevalence is about 1 in 300,

with those affected primarily of northwestern European ancestry. The onset of celiac disease may present in infancy, when gluten-containing products are first introduced into the diet, but is more common in the fourth and fifth decades.<sup>2</sup>

**Diagnosis and treatment.** In the past the diagnosis of celiac disease relied on intestinal biopsy showing the typical pathologic manifestations. New blood tests that assay for anti-tissue transglutaminase antibody (anti-ttG) and the more specific immunoglobulin A (IgA) endomysial antibody (EMA) have a high degree of sensitivity and specificity, although in general biopsy is still recommended for confirmation. Effective treatment includes the elimination of all gluten from the diet, which results in significant improvement in the intestinal mucosa, and the administration of supplemental iron, folate, and in specific cases vitamin B<sub>12</sub> and the fat-soluble vitamins (A, D, E, K). Refractory cases may be treated with oral corticosteroids or other immunomodulating agents.<sup>3</sup> Ulcerative jejunitis and lymphoma should be suspected among refractory patients who do not respond to corticosteroids. Importantly, although the overall risk for malignancy is no higher than the general population, the incidence of certain types of intestinal malignancy, especially lymphoma, is modestly increased among sprue patients.<sup>40</sup>

**Tropical Sprue**

**Etiology.** **Tropical sprue** or **enteropathy** is a malabsorptive syndrome of unknown cause prevalent in equatorial countries. Current theory suggests that bacterial overgrowth of the large intestine produces products of fermentation that damage intestinal mucosa, although the exact etiology is obscure. In tropical sprue, the mucosa of the small intestine atrophies, with resulting malabsorption, malnutrition, and B<sub>12</sub> and folic acid deficiency. Its incidence is high in persons living in or visiting tropical climates, and it appears to affect adults more often than children.<sup>2</sup> Although environmental factors seem pre-eminent, a genetic component may be present in some cases.

**Clinical manifestations and treatment.** The atrophy of the small intestinal mucosa may have severe effects. Massive malabsorption may result from failure of the mucosa to produce the enzymes needed for digestion. Manifestations include severe diarrhea with blood-tinged stools, abdominal distention, and steatorrhea (the presence of excess fat in the stool). In the Caribbean, tropical sprue is strongly linked to the presence of enterotoxin-producing coliforms and responds well to broad-spectrum antibiotics.<sup>2</sup> The response of patients from other areas (e.g., India) to treatment is less predictable than that of patients with Caribbean sprue. Treatment includes antidiarrheal medication and prolonged antimicrobial therapy as well as replacement of deficient vitamins, particularly folic acid.

**MALABSORPTION DISORDERS AFTER SURGICAL INTERVENTION**

Surgical procedures in which a portion of the stomach or small bowel is removed may result in loss of the ability to absorb nutrients properly, either through a loss of appropriate motility patterns or through a loss of the surface area of the small bowel needed for adequate absorption. Two types of disorders of malabsorption may occur after surgical intervention on the stomach or small bowel: dumping syndrome and short-bowel syndrome.

**Dumping Syndrome**

**Etiology.** **Dumping syndrome** is a term used to describe the literal dumping of stomach contents into the proximal portion of the small intestine because of impaired gastric emptying (Figure 36-13). This loss of normal, gradual pyloric emptying may occur after removal

**FIGURE 36-13** Dumping syndrome (postgastrectomy). (From Gould BE: *Pathophysiology for the health professions*, ed 4, Philadelphia, 2011, Saunders.)

of all or part of the stomach (gastrectomy), a procedure performed commonly for PUD in previous years, but more recently primarily for control of obesity. Interestingly, dumping seems to occur only with Roux-en-Y gastric bypass procedures.

**Pathogenesis and clinical manifestations.** With the normal reservoir function of the stomach now impaired, a large volume of hyperosmolar food is dumped rapidly into the small intestine, with consequences that may be severe. The hyperosmolar contents of the small intestine draw water into the lumen and stimulate bowel motility, with manifestations of diarrhea and abdominal pain. In addition, the rapid absorption of a large amount of glucose and a subsequent rise in blood glucose levels promote an excessive rise in plasma insulin level. The elevated insulin level then causes a rapid fall in blood glucose levels 1 to 3 hours after a meal. This sudden reversal is referred to as “rebound hypoglycemia.”<sup>2</sup>

**Treatment.** Persons who have undergone a gastrectomy procedure will require specific instruction regarding eating small meals six to eight times a day rather than three large meals. Restriction of carbohydrate intake may be needed to limit glucose absorption. Medications to

reduce bowel motility have been helpful in promoting a more normal pattern of bowel function in this population.

### Short-Bowel Syndrome

**Etiology.** Short-bowel syndrome refers to the severe diarrhea and significant malabsorption that develop after the surgical removal of large portions of the small intestine.

**Pathogenesis and clinical manifestations.** The severity of the manifestations depends on the amount and location of the bowel resected. In particular, removal of the distal two thirds of the ileum and the ileocecal valve may result in severe malabsorption. Because the ileocecal valve serves to regulate the transit time of intestinal contents, its removal may promote a transit time that is too rapid for adequate absorption of nutrients. In addition, loss of large portions of the small intestine will result in a diminished ability to absorb water, electrolytes, protein, fat, carbohydrates, vitamins, and trace elements.

**Treatment.** The small intestine displays an amazing ability to adapt after bowel resection. The remaining villi may enlarge and lengthen, thus increasing the absorptive surface area of the bowel. The presence

of orally ingested nutrients is needed for this adaptive process to occur, and a gradual increase in oral intake after bowel resection may promote gradual improvement in absorptive ability. Intravenous nutritional support may be required temporarily or indefinitely following surgical foreshortening of the gut.

#### KEY POINTS

- Malabsorption occurs when the small bowel fails to absorb one or more dietary components. Diarrhea and abdominal discomfort are the usual manifestations. Malabsorption may occur because of mucosal dysfunction (Crohn disease, celiac disease, tropical sprue), enzyme deficiencies, or surgical alterations that affect transit time and absorptive surface area.
- Celiac disease appears to be caused by a familial intolerance of gluten-containing foods. Ingestion of gluten leads to inflammation and atrophy of the intestinal villi. A reduced surface area and a decreased number of brush border enzymes impair nutrient absorption.
- Dumping syndrome occurs with loss of pyloric sphincter regulation, generally after gastric surgery for ulcers or cancer. Rapid dumping of chyme into the duodenum causes an osmotic shift of water into the lumen, and diarrhea. Glucose absorption may be rapid and lead to overshoot of insulin secretion and rebound hypoglycemia.
- Short-bowel syndrome follows surgical procedures involving removal of large sections of the small intestine. Rapid transit time and reduced surface area for absorption lead to diarrhea and malabsorption.

## NEOPLASMS OF THE GASTROINTESTINAL TRACT

Neoplasms may develop in every region of the GI tract. They vary in their severity and in their ability to disrupt normal GI functioning. The most common neoplastic processes of the GI tract are summarized here; the reader may wish to refer to Chapter 7 as a background for understanding these specific types of neoplasms occurring in the GI tract.

### ESOPHAGEAL, GASTRIC, AND SMALL INTESTINAL CANCERS

#### Esophageal Cancer

**Etiology.** Esophageal cancer accounts for 1% to 2% of all cancers and affects men three times more often than women.<sup>1</sup> It usually develops in men older than 60 years, with a 5-year survival rate of about 15%.<sup>41-45</sup> Although the cause of esophageal cancer is presently unknown, several predisposing factors have been identified, including genetic predisposition, dietary habits (especially ingestion of foods high in nitrosamine content), environmental exposures, and chronic irritation of the esophagus from heavy smoking and alcohol use. Chronic severe reflux, especially that associated with **achalasia**, is a prominent risk factor for adenocarcinoma as well.

Most esophageal tumors worldwide are squamous cell carcinomas. The incidence of adenocarcinoma of the gastroesophageal junction has been increasing steadily in the United States and is now more common than squamous cell cancer. This shift seems to reflect an increased prevalence of **Barrett esophagus** (discussed earlier in the chapter). Interestingly, infection with *H. pylori* seems to protect against development of this form of esophageal cancer.<sup>42</sup>

**Pathogenesis and treatment.** Tumors of the esophagus are usually infiltrating, and the disease may spread extensively to surrounding organs by way of the esophageal lymphatics at an early stage. Invasion of surrounding structures may lead to the formation of

esophagobronchial or esophagopleural fistulas, with subsequent pneumonia or abscess. The tumor may partially constrict the lumen of the esophagus, and surgery, radiation therapy, or other measures may be considered to maintain a patent esophagus. Endoscopic procedures of benefit include stent placement and ablation of the tumor through heat probe and laser techniques. If the individual survives the initial extension of the tumor, the liver and lungs are the usual sites of distant metastasis.<sup>45</sup> Regardless of the cell type, the prognosis is extremely poor. Selected patients may be candidates for surgical resection, with or without adjuvant chemotherapy and radiation treatment.

#### Gastric Carcinoma

Gastric carcinoma is common throughout the world; however, certain population groups appear to be at higher risk than others.<sup>1,41</sup> In Japan, the prevalence of gastric adenocarcinoma is about 10 times the prevalence in the United States. The incidence is higher in men older than 30 years than in other age and gender groups. The overall 5-year survival rate is approximately 10%, although the prognosis depends on the stage of the disease at the time of diagnosis. Early stage gastric cancer has not penetrated the major muscle layer of the stomach wall and is associated with a more favorable survival rate than seen in more advanced disease.

**Etiology.** The etiology of gastric cancer is a rapidly expanding area of research. A recent consensus Committee of the World Health Organization affirmed the role that *H. pylori* plays in development of gastric cancer, with a twofold increased risk for infected individuals compared to their uninfected peers.<sup>2</sup> In particular, the development of multifocal atrophic gastritis induced by persistent *H. pylori* infection is a critical step in the development of gastric cancer.<sup>7</sup> Epstein-Barr virus is another viral oncogene that has been identified as contributing to the global burden of gastric cancer.<sup>43</sup> Other risk factors are similar to those for esophageal cancer, with the exception that alcohol is not a significant contributor to gastric carcinoma.<sup>2</sup> Aspirin use seems to be protective against stomach cancer. Small numbers of gastric neoplasms may have different histologic characteristics, including lymphoma and carcinoid tumors, and have distinct clinical courses.

**Clinical manifestations and treatment.** Unfortunately, early gastric cancer typically has no manifestations and is rarely identified in countries that do not have a widespread screening program. Gastric carcinoma extends rapidly to the regional lymph nodes and surrounding organs by way of the lymphatic system and the bloodstream and by direct extension through the wall of the stomach. Advanced gastric cancer (Figure 36-14) has penetrated the muscle layer of the stomach and produces manifestations such as anorexia, weight loss, and GI bleeding.

Surgical resection of the tumor with appropriate surrounding margins remains the only effective treatment for this cancer, which, like esophageal cancer, has a dismal long-term survival.

#### Small Intestinal Neoplasms

Neoplasms of the small intestine may be benign or malignant. Fairly unusual, they account for fewer than 5% of GI tumors.<sup>1</sup> Tumors of the small intestine (usually adenocarcinomas) occur most often in persons older than 50 years. Carcinoid tumors, lymphoma, and sarcoma represent less common forms of intestinal tumors. Depending on the extent and type of tumor, partial or complete obstruction of the small bowel may occur.

**Clinical manifestations and treatment.** If the tumor is located near the ampulla of Vater, the common bile duct may become obstructed, with resulting biliary stasis and jaundice. Bleeding and ulceration of small intestinal tumors are common manifestations, as is obstruction and less commonly intussusception. Treatment may

**FIGURE 36-14** Ulcerating gastric cancer. (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders.)

include surgical intervention to remove the tumor and the affected portion of the small intestine, as well as chemotherapy for lymphomas and carcinoid tumors.

## COLONIC POLYPS AND COLON CANCER

Cancer of the colon and rectum is identified in more than 140,000 men and women in the United States each year, with the incidence equally distributed between men and women.<sup>3</sup> It is second only to lung cancer as a cause of cancer deaths. It is well accepted that adenomatous colon polyps represent the major precursor lesion in the development of colon cancer.<sup>2,41</sup>

### Colon Polyps

The term **polyp** refers to any protrusion into the lumen of the GI tract. Polyps may be benign or malignant, although most clinicians use the term polyp to refer to a benign or not-yet-malignant lesion. Polyps can have several forms; a sessile polyp is a raised protuberance with a broad base, whereas a pedunculated polyp is attached to the bowel wall by a stalk that is narrower than the body of the polyp. Benign adenomatous polyps of the colon predispose to malignant adenocarcinoma of the colon through dysplasia and neoplastic degeneration. In fact, some adenomatous polyps may already contain a focus of carcinoma (carcinoma in situ). Many people with polyps have no manifestations, although polyps may cause occult or gross bleeding and abdominal pain attributable to obstruction. Treatment will vary according to the size and type of polyp and its location in the colon. Biopsy and subsequent removal of polyps may be performed during sigmoidoscopy or colonoscopy. **Figure 36-15** shows various colonic polyps. Several benign colon polyps, including the common hyperplastic variety, may be found on endoscopic biopsy and carry no cancer risk.

### Colon Cancer

**Etiology and risk factors.** A number of risk factors have been identified for the development of colon cancer. The risk of colon cancer increases with advancing age. After age 40 the annual incidence of colon cancer accelerates, doubling every decade until age 80.<sup>1</sup> Dietary factors also seem to increase the risk; a high-fat, low-fiber diet has been proposed as an associated factor. Certain bowel conditions may predispose an individual to colon cancer, including ulcerative colitis and Crohn disease of the colon (see previous discussions). A hereditary predisposition may also be present; the probability of colorectal cancer

**FIGURE 36-15** Photographs of colonic polyps. (Courtesy LE Copstead.)

in a person who has a first-degree relative with the disease is greater than 15%, compared with a 5% risk in the general population.<sup>1</sup>

An important hereditary condition is familial adenomatous polyposis (FAP), one form of which is Gardner syndrome. More common are the so-called hereditary nonpolyposis colorectal cancer syndromes. Clues to a familial syndrome include at least three close relatives with colorectal cancer, colorectal cancer involving at least two generations, and one or more cases of colorectal cancer occurring before age 50 years.<sup>2</sup> Colon cancer screening guidelines have recently

**FIGURE 36-16** Barium enema demonstrating extensive mucosal destruction from a primary lymphoma of the right colon (arrowhead). (From Sleisenger MH, Fordtran JS, editors: *Gastrointestinal disease*, ed 5, Philadelphia, 1993, Saunders, p 1484.)

been updated; for the individual at average risk, colonoscopy every 10 years is recommended.<sup>44</sup> Persons with an increased risk for colon cancer based on family history should undergo more aggressive colon cancer screening.

**Clinical manifestations.** The manifestations of colon cancer depend on the anatomic location and function of the bowel segment containing the tumor. On the right side of the colon, the site of water and electrolyte absorption, tumor growth tends to extend along the bowel rather than surround the lumen (Figure 36-16). Although no signs of obstruction are present, black, tarry stools, which signify bleeding into the intestinal lumen, are a significant finding. On the left side of the colon, a tumor may cause manifestations of obstruction in the early stages of its growth. Feelings of intermittent abdominal cramping and fullness may be present, and “ribbon” or pencil-shaped stools may occur. Typically, the individual may note that the passage of stool or flatus relieves the abdominal pain. As tumor growth progresses, blood or mucus may be present in the stool. When the tumor is located in the rectum, early manifestations may include a change in bowel habits, often beginning with an urgent need to defecate upon awakening in the morning or alternating constipation and diarrhea. Later in the progression of tumor growth, a sensation of rectal fullness and a dull ache may be felt in the rectum or sacral region.

**Treatment.** The treatment and prognosis for colon cancer depend on several factors, including the extent of tumor invasion through the colon wall, cell type and degree of dysplasia, tumor genetics, and the presence or absence of local or distant tumor metastases.<sup>2,41</sup> The 5-year survival rate is directly related to the extent of tissue invasion. The traditional Dukes classification scheme (Table 36-1) has been modified and expanded over the last several decades; currently the tumor-node-metastasis (TNM) classification is accepted as the standard scheme. The most effective treatment is surgery to remove the malignant tumor

**TABLE 36-1 MODIFIED DUKES CLASSIFICATION FOR COLORECTAL CANCER**

DUKES CATEGORY	DEFINITION	5-YR SURVIVAL (%) AFTER TREATMENT
A	Cancer limited to mucosa or submucosa	90
B1	Cancer penetrates into but not through muscularis propria	80
B2	Cancer penetrates through muscularis	70
C1	Same as B1, plus lymph node metastases	50
C2	Same as B2, plus lymph node metastases	50
D	Distant metastases are present	<30

and adjacent tissue and lymph nodes that may contain cancer cells. The surgical formation of a **colostomy**, or an artificial opening of the colon on the abdominal wall, may be performed after removal of the affected bowel segment. Chemotherapy and radiation therapy are used as supportive measures in addition to surgical intervention. Chemotherapy in particular has advanced rapidly over the last 2 decades and has significantly improved the prognosis for moderately advanced (i.e., with nodal metastases) colon cancer.<sup>41,45</sup>

#### KEY POINTS

- Warning signs for cancer of the GI tract include black, tarry, bloody, or pencil-shaped stools and a change in bowel habits. Risk factors for GI cancer include a low-fiber, high-fat diet; polyps; and chronic irritation or inflammation.
- The prognosis for GI cancer is related to the extent of spread in the body. Surgical removal of tumors followed by chemotherapy, radiation therapy, or both is the usual treatment. Early detection is associated with a better prognosis.

## PSYCHOSOCIAL ASPECTS OF GASTROINTESTINAL DISORDERS

### STRESS OF LIFESTYLE CHANGES

GI disorders may have profound effects on the psychosocial functioning of the affected individual. Moreover, these disorders may place great stress on the family attempting to cope with the demands of that person’s illness. Nutrition and bowel elimination are behaviors that are dependent on cultural norms; changes in these basic areas of human activity caused by a GI disorder may have a variety of meanings to different individuals. A teenager affected by a chronic GI disorder such as Crohn disease may be unable to participate in social activities that revolve around eating and thus may feel isolated from peers. IBS in a young adult who is beginning the most productive years of life may curtail the ability to function fully in the roles of spouse, parent, and wage earner. Finally, the onset of GI disorders, particularly a neoplastic process, in a middle-aged or older individual not only may limit that person’s ability to perform activities of daily living but also may result in an increased awareness of aging and mortality.

In the past, much of the health care literature, including nursing texts, tended to stereotype individuals with chronic disorders of the GI tract as having behavioral disorders. Aberrant psychological characteristics, it was thought, were somehow associated with or even responsible for certain diseases of the GI tract, such as Crohn disease and UC. It is now recognized that the pathogenic process is almost never the result of primarily psychological causes, although

some chronic diseases of the GI tract may be aggravated by emotional factors.<sup>1,3</sup> The stress of coping with a chronic, disabling illness may result in psychological trauma; in addition, any type of illness represents a threat to the integrity of the person. Individuals experiencing a chronic GI disorder may exhibit the psychological effects of such threats and will benefit from a sensitive approach to meeting their needs.

## SUMMARY

This chapter has described the major alterations in the GI tract that may occur across the human life span. Because of the strong links between cultural and psychological functioning and activities associated with the GI tract, an in-depth understanding of these alterations is essential for health care professionals.

Disorders of the GI tract may have many manifestations, including dysphagia, pain, vomiting, gas, and alterations in bowel elimination patterns. Disorders may occur in any portion of the GI tract, from the mouth to the anus, and may be the result of alterations in the integrity of the GI tract wall (as in UC) or alterations in motility (as in IBS).

Disorders of malabsorption, such as celiac disease, may seriously limit the individual's ability to utilize dietary nutrients and are therefore potentially life threatening. Patients who have undergone surgery on the GI tract may also be at risk for malabsorption. Neoplasms of the GI tract are prevalent in the U.S. population, and the reader will want to review the associated risk factors for these neoplasms very carefully. Finally, readers who are preparing for a career in health care should carefully consider the information provided on the psychosocial aspects of GI disorders and identify ways to provide optimal care for patients with these disorders.

- Key Points Review

## KEY QUESTIONS

- How is bile produced, stored, and secreted?
- How is pancreatic enzyme secretion regulated?
- What factors predispose to formation of cholesterol gallstones?
- What is the relationship between cholecystitis and cholelithiasis?
- What clinical and laboratory findings are indicative of acute pancreatitis?
- What serious complications may result from acute pancreatitis?
- How do the etiologic factors, clinical presentation, and management of chronic pancreatitis differ from those of acute pancreatitis?
- What are the signs, symptoms, and treatment for pancreatic cancer?

Stones have been discovered in the gallbladders of Egyptian and Chinese mummies, suggesting that gallbladder disease has been present in humans for thousands of years. More than 700,000 operations to remove the gallbladder (cholecystectomy) are performed annually in the United States, and the incidence of new gallstones is 1 million to 2 million cases per year.<sup>1,2</sup> The incidence of acute pancreatitis varies according to geographic area but has been reported to range from 5 to 24 per 100,000 population in the United States and Europe.<sup>1</sup> Many health care professionals will encounter diseases of the pancreaticobiliary system frequently and need an in-depth understanding of the mechanisms that promote them. This chapter describes the

pathophysiology of diseases of the gallbladder, the biliary tree, and the exocrine pancreas, and summarizes current treatments. Cancers of the pancreas and biliary tree will be discussed briefly.

## STRUCTURE AND FUNCTION OF THE PANCREATICOBILIARY SYSTEM

The pancreaticobiliary system is composed of the gallbladder and cystic duct; the intrahepatic, hepatic, and common bile ducts; and the endocrine and exocrine pancreas. The extrahepatic biliary tree and the gallbladder form a controlled system for delivering bile to the intestinal

**FIGURE 37-1** **A**, The pancreaticobiliary system showing the anatomic placement of the gallbladder and pancreas, the junction of the common bile duct and the pancreatic duct in the ampulla, and the ampulla of Vater. **B**, Exocrine acinar cells are arranged around pancreatic ducts and secrete enzymes and bicarbonate into the pancreatic juice that enters the duodenum, whereas endocrine cells of the pancreatic islets secrete hormones into the interstitial space where they diffuse into capillaries and enter the bloodstream. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 887.)

tract. (For additional background, refer to Chapter 35, which describes the physiology of digestion in the gastrointestinal lumen.)

The **gallbladder** is a distensible sack of about 30- to 50-ml capacity that connects via the cystic duct with the common hepatic duct to form the common bile duct. The common bile duct, which is about 3 inches long, extends behind the duodenum to terminate at the ampulla of Vater, a complex structure that also forms the terminating point of the main pancreatic duct. The pancreatic duct travels proximally in the pancreas and branches off dorsally to drain the tail of the pancreas. Thus, the ampulla of Vater forms the major aqueduct through which important digestive secretions enter the intestinal tract (Figure 37-1).

## EMBRYOLOGY OF THE PANCREATICOBILIARY SYSTEM

In about the third or fourth week of gestation, the hepatic diverticulum forms from the primitive foregut.<sup>3,4</sup> It is composed of specialized progenitor liver cells that will eventually develop into the entire liver, biliary tree, and ventral pancreas. The dorsal pancreas forms from a separate outcropping of cells lying on the opposite side of the primitive foregut.

At 5 weeks of gestation, three buds can be seen in the hepatic diverticulum. The cranial bud contains specialized liver cells (hepatoblasts),

which will form the liver. The liver sinusoids develop and feed into the developing bile canaliculi, which drain into intralobular ductules and then into interlobular ducts. The caudal bud develops into the gallbladder, which joins the common hepatic duct via the developing cystic duct to form the common bile duct. The gallbladder and the hepatic ducts are initially hollow, but they solidify with development and become solid cords. With further differentiation, they become hollow once again to become the tubes and reservoir for bile flow. During the second trimester, the fetus produces bile, which gives color to the fetal meconium. Finally, the basal bud transforms into the ventral pancreas (Figure 37-2).<sup>3,4</sup>

## PHYSIOLOGY OF BILE

Normal bile is composed primarily of water, electrolytes, and organic solutes. It has a low protein content, containing mainly bile acids, pigment, cholesterol, and phospholipids.<sup>1</sup> Bile acids consist mostly of primary bile salts (cholic and chenodeoxycholic acids) and secondary bile salts (deoxycholic, ursodeoxycholic, and lithocholic acids). Bile is formed in the liver and then modified and stored in the gallbladder and bile ducts before secretion into the intestinal tract. The major functions of bile are to aid in the digestion of lipids in the diet

## CHAPTER 37 Alterations in Function of the Gallbladder and Exocrine Pancreas

**FIGURE 37-2** Stages in the embryonic development of the liver, pancreas, and duodenum at 4 weeks (**A**), 5 weeks (**B** and **C**), and 6 weeks (**D**). (From Moore KL, Persaud TVN, Torchia MG: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders.)

and to transport waste products (particularly bilirubin), immunoglobulins (IgA), toxins, and cholesterol into the intestine for eventual disposal or reabsorption. After secretion into the bile canaliculi, bile flows through the canals of Hering, ductules, interlobular ducts, septal ducts, and right and left lobar ducts, and into the common bile duct (see Figure 37-1).<sup>5</sup>

The principal function of the gallbladder is the concentration and storage of bile. During the fasting state, the muscular sphincter at the ampulla of Vater is contracted, promoting flow of bile into the gallbladder. Only about half of the bile is stored during this time; the remainder flows into the duodenum. At the same time that bile is moving into the gallbladder, absorption is also occurring so that within 4 hours up to 90% of water in bile can be removed, leaving a very concentrated mixture of sodium, bile salts, and other electrolytes.<sup>5</sup>

With the first morning meal, a hormonally and neurally regulated contraction of the gallbladder occurs, releasing the concentrated bile into the duodenum. Bile acids eventually will be absorbed again in the terminal ileum and travel by the portal circulation to be secreted again into the bile. (Bile acids are reabsorbed on average two or three times daily.) A small amount of the bile acid pool (less than 5%) enters the colon, where primary bile salts undergo bacterial transformation into secondary bile salts (Figure 37-3).<sup>6</sup>

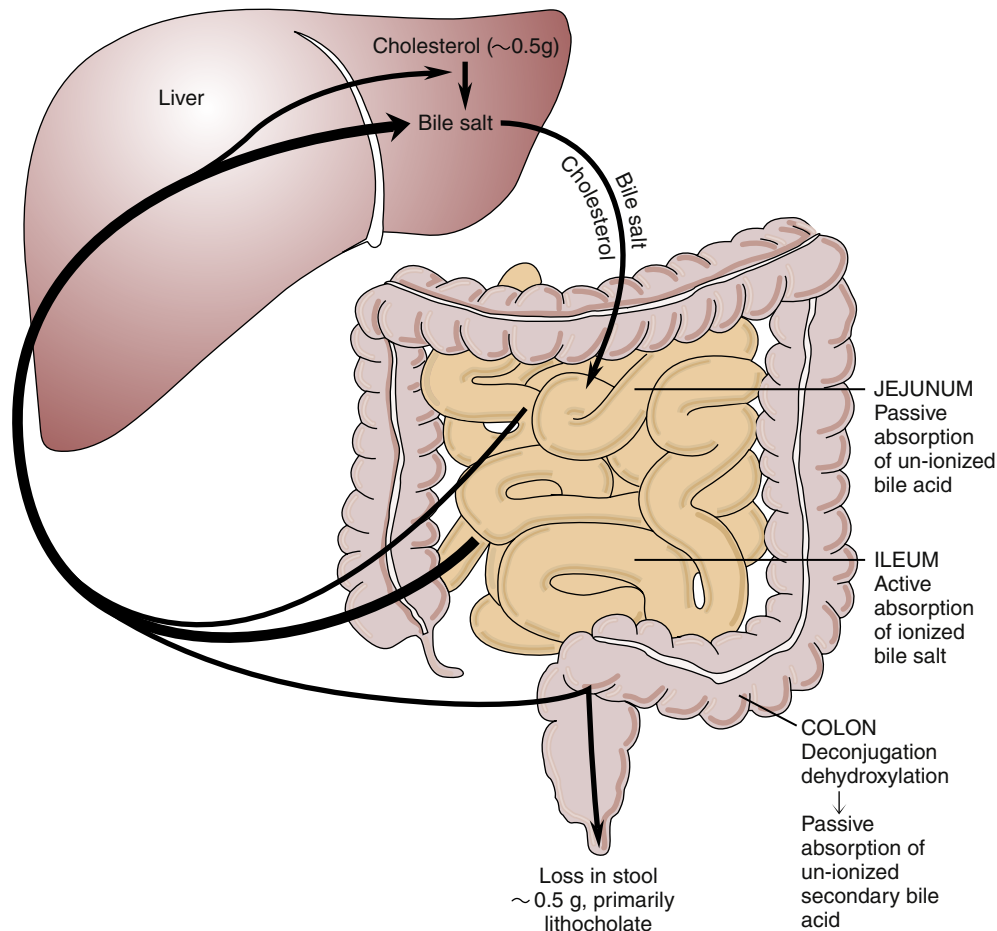

After secretion into the bile, bile salts have dual properties, being **hydrophilic** (soluble in water) at one end and **hydrophobic** (insoluble in water) at the other. Thus, these molecules tend to aggregate into clusters called micelles, which surround lipids such as cholesterol and allow them to solubilize (Figure 37-4). Micelles are not good stabilizers

of cholesterol alone, but another molecule, lecithin, also secreted in large amounts in the bile, is readily incorporated in the core of the micelle to greatly enhance the solubility of cholesterol. In this way, bile keeps cholesterol partly solubilized. Precipitation of cholesterol from bile occurs at high concentrations, predisposing to formation of gallstones.<sup>6</sup>

### FUNCTIONAL ANATOMY OF THE PANCREAS

The pancreas is really two organs in one: it functions as both an endocrine and an exocrine organ. On the one hand, hormones such as insulin, glucagon, and somatostatin are produced and secreted into the vascular system (characteristic of an endocrine organ). On the other hand, every 24 hours the pancreas secretes more than 1 L of digestive juice into the digestive tract (characteristic of an exocrine organ).<sup>5</sup>

Embryologically, the pancreas is composed of two fused organs: a dorsal and a ventral pancreas (Figure 37-5). Microscopically, the pancreas is somewhat lobular and arranged into exocrine glands. The pancreatic juices are secreted into the glandular acini, which eventually drain into the main pancreatic duct and then enter the intestinal tract. The juices themselves are composed of both active digestive enzymes (e.g., amylase, lipase) and precursor or proenzymes (e.g., trypsinogen). Their release during a meal is controlled by hormones secreted from the small intestinal mucosa: **cholecystokinin (CCK)** and **secretin**. When this regulation is deranged, enzymes may be released within the gland and produce **acute pancreatitis**.

**FIGURE 37-3** Enterohepatic bile salt recirculation is maintained by passive jejunal absorption of un-ionized bile salts, active ileal absorption of ionized bile salts, and colonic deconjugation and dehydroxylation of bile salts followed by passive absorption of lipid-soluble un-ionized secondary bile salt. The loss of unabsorbable bile salt is balanced by the de novo hepatic synthesis of bile salt from cholesterol. (From Cooper AD: Metabolic basis of cholesterol gallstone disease, *Gastroenterol Clin North Am* 20:34, 1991.)

**FIGURE 37-4** Bile acid-cholesterol-lecithin mixed micelle. Polar ends of bile acid and lecithin are oriented outward, whereas hydrophobic, nonpolar portions make up the interior. Cholesterol is solubilized within the hydrophobic, nonpolar center. (From Saunders KD et al: Pathogenesis of gallstones, *Surg Clin North Am* 70:1197-1216, 1990.)

#### KEY POINTS

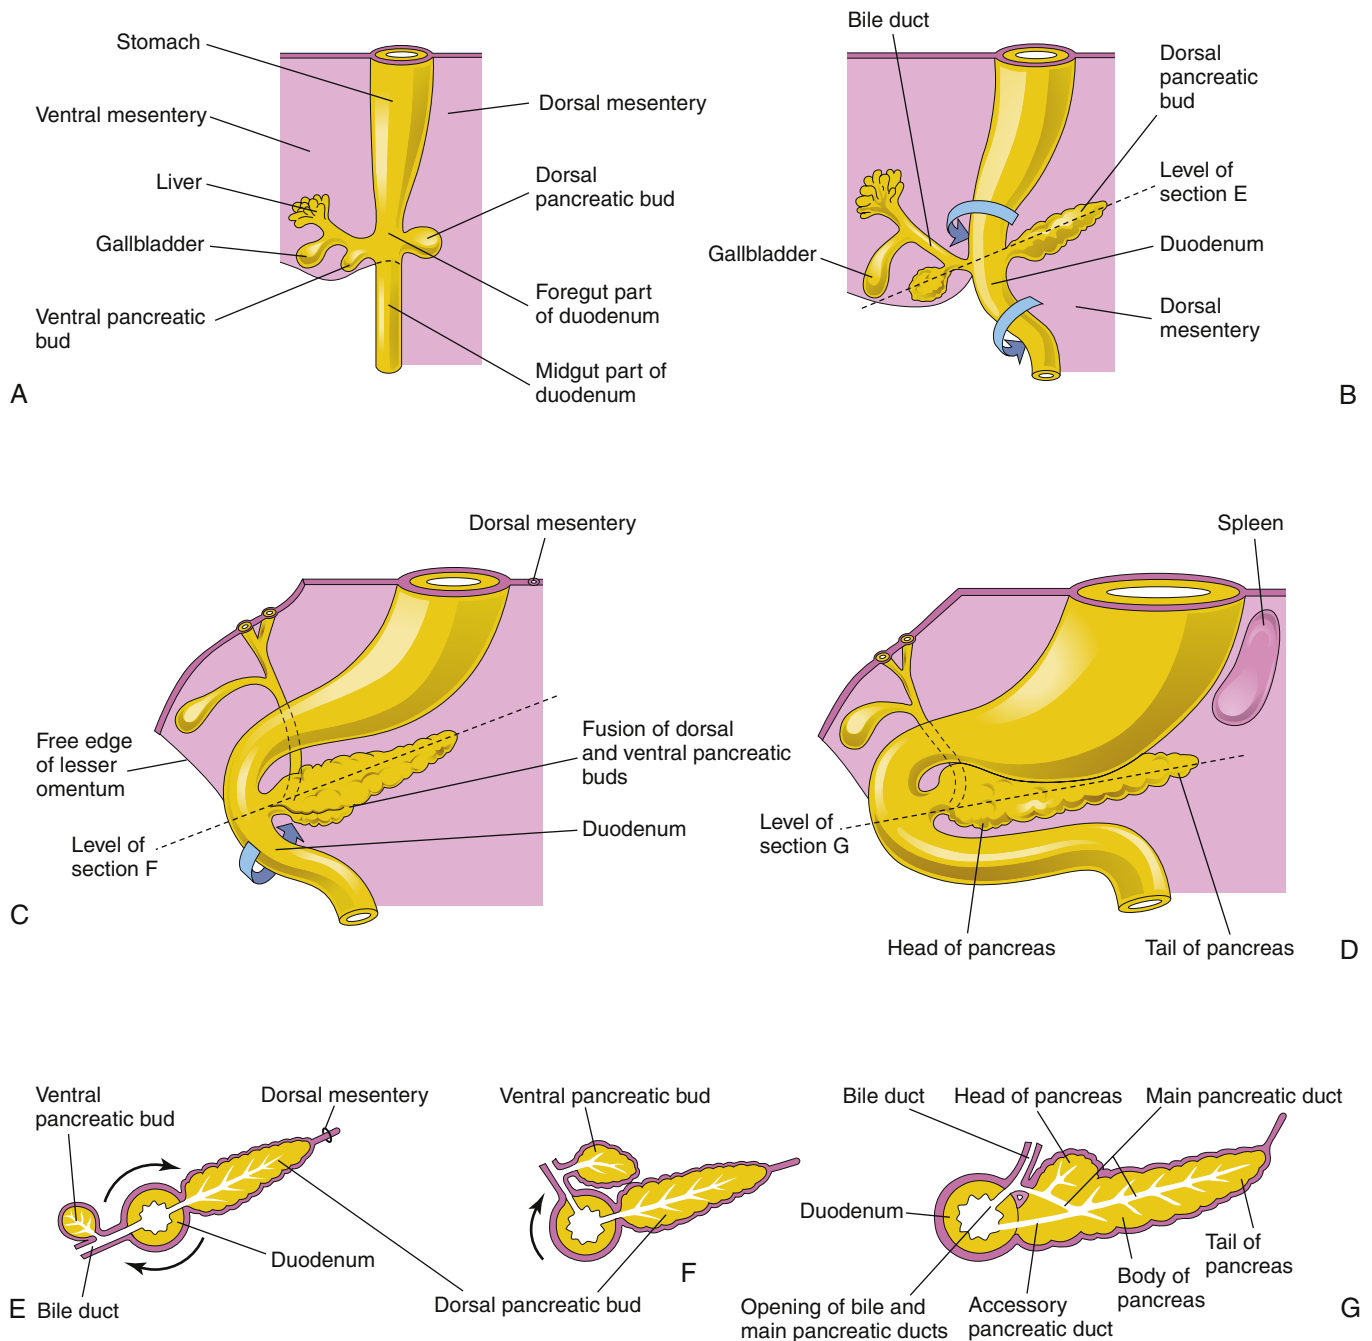

- Bile is produced by hepatocytes in the liver and stored in the gallbladder. The main components of bile are bile acids, pigment, cholesterol, and phospholipids. Bile salts are important for digestion and absorption of fats from the small bowel. Bile is an important route for excretion of waste products, particularly bilirubin. The gallbladder receives bile from the liver, concentrates bile by absorbing water, and then contracts to expel stored bile into the common bile duct, which terminates in the duodenum.
- The pancreas is both an endocrine organ (secreting insulin, glucagon, and somatostatin into the bloodstream) and an exocrine gland (secreting digestive juice into the duodenum). Some pancreatic enzymes are secreted in active form (amylase, lipase), whereas others are proenzymes that are activated in the duodenum (trypsinogen). Release of pancreatic enzymes is stimulated by cholecystokinin and secretin.

#### DISORDERS OF THE GALLBLADDER

##### PATHOPHYSIOLOGY OF CHOLESTEROL GALLSTONE FORMATION

The majority of gallstones among patients in the United States are cholesterol stones.<sup>1</sup> In general, the formation of cholesterol stones

## CHAPTER 37 Alterations in Function of the Gallbladder and Exocrine Pancreas

**FIGURE 37-5** Stages in the embryonic development of the pancreas from the fifth to eighth week (**A-D**), and a diagram of the progressive development of the bile duct and main pancreatic duct (**E-G**). (From Moore KL, Persaud TVN, Torchia MG: *The developing human: clinically oriented embryology*, ed 9, Philadelphia, 2013, Saunders.)

in the gallbladder (**cholelithiasis**) can be broken down into three phases: (1) supersaturation of bile with cholesterol; (2) nucleation of crystals; and (3) hypomotility allowing stone growth (**Figure 37-6**).

As described previously, cholesterol eventually precipitates from supersaturated bile. If conditions are right for the formation of cholesterol gallstones, nucleation occurs in which the cholesterol crystals aggregate together. Continued growth of the crystals then depends upon the balance between cholesterol growth-promoting factors and factors that tend to cause stone dissolution. A significant factor that promotes the continued growth of stones is hypomotility or stasis of bile within the gallbladder. Patients with high spinal cord injuries,

patients receiving total parenteral nutrition, and persons who undergo prolonged fasting or rapid weight loss have impaired emptying and are at particular risk for development of cholesterol gallstones. Other risk factors for cholelithiasis include pregnancy, oral contraceptives, obesity, diabetes mellitus, and octreotide (somatostatin analogue) therapy.<sup>1</sup>

About 25% of gallstones in Western countries are due to pigment stones, which contain a mixture of pigment polymers and calcium salts. “Black” pigment stones are most common and may be idiopathic or associated with cirrhosis or hemolysis. “Brown” pigment stones differ in their composition and are much more common in developing

**FIGURE 37-6** Three principal phases responsible for the formation of cholesterol gallstones illustrated with a Venn diagram. (From Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease: pathophysiology, diagnosis, management*, ed 7, Philadelphia, 2002, Saunders, p 1069.)

countries, where they are associated with biliary parasitosis and bacterial colonization and infection.<sup>1</sup>

## CHOLELITHIASIS AND CHOLECYSTITIS

Currently, about 20 million people in the United States have gallstones (cholelithiasis). The incidence of gallstones is related to age, gender, and a variety of medical factors. Gallstones are twice as common in women as in men. Native Americans, particularly the Pima Indians of North America, are markedly susceptible to gallstones, and American Caucasians somewhat less so. European Caucasians are intermediate in prevalence, and persons of Asian descent are at the lowest risk. Obesity correlates with the development of gallstones, but so does rapid weight loss in an obese individual. However, the presence of gallstones does not necessarily mean that an individual will have any symptoms. In many individuals, gallstones are completely asymptomatic and require no treatment. Cholelithiasis in children is usually associated with an underlying systemic disease such as cystic fibrosis or sickle cell disease. It is often symptomatic and requires treatment by gallbladder removal.

The term cholecystitis refers to inflammation of the gallbladder wall. The continued presence of gallstones in the gallbladder ultimately promotes inflammatory changes in the gallbladder wall, with fibrosis and thickening.<sup>7</sup> Cholecystitis is classified as acute or chronic, according to its clinical manifestations. The clinical manifestations of each are described, followed by diagnostic and treatment methods.

### Chronic Cholelithiasis

**Clinical manifestations.** The chief complication of chronic cholelithiasis is intermittent biliary colic, a persistent epigastric or right upper abdominal pain. Often the pain radiates to the back and is accompanied by nausea, vomiting, sweating, and flatus. A typical episode lasts several hours. Biliary colic is typically caused by periodic

obstruction of the cystic duct by a gallstone (Figure 37-7), although rarely spasm of the sphincter of Oddi may be etiologic.

Symptoms may be precipitated by a meal, but they often occur spontaneously and may manifest at night. The pain often increases steadily for 15 minutes and persists for 1 hour or more, and then slowly decreases. Attacks may recur on a frequent or infrequent schedule. Patients often describe additional symptoms, including fatty food intolerance, belching, flatus, bloating, and epigastric burning.<sup>1,7</sup>

**Diagnosis and treatment.** The diagnosis of chronic cholelithiasis depends on imaging studies, particularly ultrasonography, and is essentially the same as that described for acute cholecystitis.

In cases of chronic cholelithiasis with no or very few recurrent symptoms, “watchful waiting” may be considered.<sup>1,7</sup> However, patients with significant recurrences of biliary colic are candidates for one of the three current modes of treatment for cholecystitis: cholecystectomy (surgical removal of the gallbladder), chemical dissolution of gallstones, or lithotripsy (mechanical breaking up of gallstones within the gallbladder). These will be discussed in more detail in the Acute Cholecystitis section.

### Acute Cholecystitis

**Clinical manifestations.** Acute cholecystitis is defined as acute inflammation of the gallbladder wall. It is characterized by severe right upper abdominal pain that may radiate to the back. Abdominal tenderness and fever are often present. Cholelithiasis is present in about 90% of patients. Obstruction of the cystic duct occurs in almost all cases, suggesting that stasis of bile in the gallbladder is important in the pathogenesis of the disease. Bacterial infection commonly accompanies acute cholecystitis, although it is not thought to be the direct cause of the inflammatory process. Laboratory evaluation may reveal leukocytosis, mild elevations in the levels of bilirubin and serum transaminases, and, less often, elevated amylase levels.<sup>7</sup>

If left untreated, the inflammatory process often escalates, and gangrene of the gallbladder wall with rupture may occur. This can lead to peritonitis and septic shock, a localized abscess (**empyema**), or a **cholecystoenteric fistula** (fistula between the gallbladder and gastrointestinal tract).

**Acalculous cholecystitis** is an important subgroup of acute cholecystitis. As the name implies, it occurs in patients without preexisting gallstones. It tends to occur in the setting of major surgery, critical illness, trauma, or burn-related injury. Patients tend to be predominantly male and older than 50 years, and total parenteral nutrition (TPN) is a common cofactor. It carries a somewhat more serious implication than stone-associated cholecystitis, in part because of the associated medical conditions. In fact, gangrene of the gallbladder wall and perforation, **empyematous cholecystitis**, and **empyema** all develop more rapidly than in calculous cholecystitis.<sup>1</sup>

**Diagnosis.** Evaluation for possible cholecystitis includes an appropriate history and physical examination, laboratory studies, and imaging studies designed to evaluate the gallbladder and biliary tree. Ultrasound of the abdomen is the procedure of choice early in the diagnostic evaluation. Typically, the ultrasound scan reveals the presence of stones, occasionally in the cystic duct, as well as thickening of the gallbladder wall and distention of the lumen. It may also point to another diagnosis of right upper quadrant pain, such as a liver neoplasm or renal lesions. The sensitivity and specificity of ultrasound for stones larger than 2 mm in diameter approach 95%.<sup>7</sup> Sensitivity rates for acalculous cholecystitis are somewhat lower.

However, the presence of cholelithiasis and a thickened gallbladder wall may not be diagnostic, and other diagnostic tests are used

on occasion. Hepatobiliary scintigraphy (or cholescintigraphy) by hydroxyiminodiacetic acid (HIDA) scanning provides a good functional assessment of gallbladder excretion, which is markedly impaired with cholecystitis. Computed tomography (CT), magnetic resonance cholangiography (MRCA), and endoscopic retrograde cholangiopancreatography (ERCP) are useful for selected cases. The latter carries a risk of perforation and pancreatitis, and so is reserved for cases requiring intervention (stent placement, biopsy, or special contrast studies).

**Treatment.** Treatment for cholecystitis depends on the severity of symptoms and the patient's clinical status. Acute cholecystitis may necessitate intervention, but surgeons generally prefer to allow a "hot" gallbladder to "cool down" before performing surgery, particularly if the patient is considered a high surgical risk.<sup>7</sup> The benefit of antibiotics for uncomplicated cholecystitis remains unclear, but broad-spectrum antibiotics are generally administered in the setting of acute cholecystitis. Percutaneous catheter drainage or endoscopic drainage with stent placement may be performed to relieve obstruction, particularly if infection is involved. If the patient's condition precludes surgery, these may be the main treatments, and drains can be left in place indefinitely. Advanced acute cholecystitis complicated by empyema, gangrene, or emphysematous change is considered a surgical emergency.

**Laparoscopic cholecystectomy** was first performed in 1987 and has benefited from rapid improvements in video **laparoscopy** and instrumentation. Laparoscopic cholecystectomy is now the treatment of choice for symptomatic gallstones. The procedure is usually performed with four small incisions through which instruments are inserted. The gallbladder is freed either by electro-surgical or laser excision and is then withdrawn through one of the small incisions. Advantages of the laparoscopic technique include minimal scarring, less postoperative pain than after laparotomy, shortened hospital stays, and a rapid return to daily activities.<sup>7</sup>

**Open cholecystectomy** was first performed in the nineteenth century and remains an extremely safe operation with low morbidity and mortality. However, the length of the incision and accompanying postoperative pain render many patients immobile after the procedure. Altered anatomy or scarring from previous surgery or the presence of common bile duct stones may necessitate a traditional cholecystectomy. A laparoscopic procedure may be converted to an open one intraoperatively if necessary (e.g., upon finding a malignant tumor in the vicinity of the gallbladder). Complications of cholecystectomy (either laparoscopic or open) can include infection, inadvertent transection of the common bile duct, and the rare but debilitating syndrome of recurrent sclerosing cholangitis.

Some patients, such as elderly or debilitated persons, may be poor surgical risks and cannot undergo the stress of surgery. Nonoperative methods to manage gallstones, such as **chemodissolution** with a variety of bile acids or organic solvents and **lithotripsy**, have been tried as alternatives to surgery. Chemodissolution is the use of chemical substances, such as bile acids or organic solvents, to dissolve gallstones. Such agents as ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (CDCA) are administered orally.<sup>7</sup> However, this approach has several major drawbacks, including diarrhea in about 50% of patients and a low overall efficacy. CDCA is also quite expensive. Extracorporeal shock wave lithotripsy (ESWL), which involves the breaking up of gallstones using shock waves, is another nonsurgical approach. The objective is to fragment stones into pieces small enough to be passed through the cystic duct, or small enough to allow dissolving agents to function. ESWL is safe and relatively effective, under proper circumstances. The disadvantages include strict selection criteria (e.g., stones less than 2 cm in diameter), resulting in a low percentage of eligible patients. The

**FIGURE 37-7** Chronic cholecystitis demonstrated by a thickened gallbladder wall and luminal cholesterol gallstones. (From Cotran RS et al: *Robbins pathologic basis of disease*, ed 6, Philadelphia, 1999, Saunders, p 897.)

gallbladder also is left in place, allowing for possible recurrence of gallstones and necessitating the concurrent use of dissolving agents such as UDCA or CDCA to prevent new stone formation.

For the most part, in the near future the management of gallstone disease is likely to remain surgical, with traditional or laparoscopic cholecystectomy being the major forms of intervention.

### Chronic Cholecystitis

**Clinical manifestations.** Chronic cholecystitis is defined as chronic inflammation of the gallbladder wall attributable to persistent low-grade irritation from gallstones or to recurrent attacks of acute cholecystitis. Diabetes mellitus and obesity are important predisposing factors. Although many patients suffer from intermittent biliary colic or have symptomatic acute attacks, a surprising number of patients experience no symptoms.

Chronic cholecystitis may lead to many of the complications described earlier for acute cholecystitis, including biliary sepsis, as well as a specific type of scarring known as a calcified or porcelain gallbladder, which is associated with a higher risk of cancer.<sup>1</sup>

### Biliary Malignancy

Cancers of the biliary system are relatively rare; in the United States it accounts for only 1 to 2 cases per 100,000 per year.<sup>8-10</sup> Unfortunately, they tend to be asymptomatic and progress insidiously until well advanced. Chronic cholecystitis predisposes sufferers to the very uncommon gallbladder cancer, but is only a minor risk factor for cancer of the biliary tract. **Primary sclerosing cholangitis** is a significant risk factor, and among immigrants from endemic countries infestation with liver flukes such as *Clonorchis* species can lead to biliary cancer. Typical symptoms at presentation include right upper quadrant pain and jaundice associated with biliary obstruction.

Surgery for cure is a treatment option in fewer than 10% of cases. Chemotherapy and radiation therapy are indicated for palliation, and certain patients may benefit from stenting and other procedures to alleviate biliary obstruction.

### KEY POINTS

- Lecithin is an important component of bile that helps keep cholesterol from precipitating into crystals. Crystals of cholesterol may initiate gallstone formation. The relative concentrations of cholesterol, lecithin, and bile acids appear to determine the likelihood of cholesterol gallstone formation. Bile hypomotility or stasis contributes to growth of cholesterol stones.
- Gallstones occur more frequently in women than in men. Ethnicity, obesity, and rapid weight loss are predisposing factors. Gallstones may be asymptomatic or associated with symptomatic cholecystitis. Colicky pain attributable to intermittent obstruction of the cystic duct by a stone is the chief complaint. Symptoms of chronic cholecystitis include epigastric or right upper quadrant pain radiating to the back, nausea, vomiting, sweating, fat intolerance, bloating, and flatus.
- Acute cholecystitis is acute inflammation of the gallbladder associated with abdominal pain, leukocytosis, and fever. Cholelithiasis is present in about 90% of patients; obstruction of the cystic duct is present in nearly all patients.
- Treatment for cholecystitis includes surgical removal of the gallbladder (cholecystectomy), chemodissolution, ESWL (lithotripsy) for stones, antibiotics if indicated, and management of pain. Cholecystectomy is the mainstay of therapy.
- Biliary cancer is a rare malignancy with a poor prognosis. Surgery is the only curative therapy, but only available for a small minority of sufferers.

## DISORDERS OF THE PANCREAS

### PANCREATITIS

#### Acute Pancreatitis

**Etiology and pathogenesis.** Acute pancreatitis is an inflammatory process involving the pancreas that may range from mild and inconveniencing to severe and life threatening. After an attack, the exocrine and endocrine functions of the pancreas may remain impaired for a variable period. Pancreatitis affects between 1 and 5 per 10,000 individuals in the United States annually.<sup>1,7</sup> Predisposing factors for pancreatitis have been well-known for more than 100 years (Box 37-1); in the United States the most common causes are biliary tract disease, hypertriglyceridemia, and ethanol-associated pancreatitis. Although the exact mechanisms leading to pancreatitis are not fully understood, three possible pathways are known (Figure 37-8). The most prominent factor is obstruction of the pancreatic duct by a stone or other cause (usually unknown), with release of digestive enzymes within the parenchyma, followed by enzyme activation and then autodigestion of the pancreas.<sup>10</sup> Edema leading to vascular insufficiency and ischemic injury is a contributing factor. Other possible mechanisms include acinar cell injury from alcohol or drugs, trauma, or viral infection; and defective intracellular transport of proenzymes within acinar cells.

Up to 66% of first cases of pancreatitis are associated with alcoholism.<sup>1</sup> Although there is clearly an association of alcohol with pancreatitis, the causal mechanism has not been determined. Transient increases in pancreatic exocrine secretion, contraction of the sphincter of Oddi, and direct toxic effects on acinar cells have all been postulated from experimental studies.<sup>7</sup> Many authorities now believe that most cases of alcoholic pancreatitis are sudden exacerbations of chronic pancreatitis,

### BOX 37-1 CONDITIONS PREDISPOSING TO ACUTE PANCREATITIS

- Gallstones
- Biliary sludge and microlithiasis
- Other causes of mechanical ampullary obstruction
- Alcohol
- Hypertriglyceridemia
- Hypercalcemia

ERCP, Endoscopic retrograde cholangiopancreatography.

presenting as apparent de novo acute pancreatitis.<sup>10</sup> According to this view, chronic alcohol ingestion causes secretion of protein-rich pancreatic fluid, leading to deposition of inspissated protein plugs and obstruction of small pancreatic ducts, followed by the train of events described previously. However, other pathologic studies show no evidence of chronic pancreatitis in up to 40% of acute alcoholic pancreatitis patients.

**Clinical manifestations.** The presentation of acute pancreatitis usually begins with steady, boring pain in the epigastrium or left upper quadrant, which gradually increases in intensity. It often radiates or penetrates through to the back and is accompanied by nausea and vomiting. Tenderness on palpation may be exquisite. Bowel sounds are reduced but not absent. Abdominal distention may be present. Fever is common but is usually low grade initially. In more severe pancreatitis, this clinical picture is accompanied by signs of circulatory instability, respiratory insufficiency, and shock.<sup>11-12</sup>

**Diagnosis.** The laboratory evaluation of acute pancreatitis begins with measurements of serum pancreatic enzymes. Serum lipase and amylase levels rise more or less in tandem during the first 12 hours and remain elevated for several days. Lipase is more specific and persists longer, and therefore has become the preferred test for most clinicians. Levels of serum aminotransferases (aspartate aminotransferase, alanine aminotransferase) may also be elevated. Marked elevation of the alkaline phosphatase and bilirubin levels suggests the possibility of biliary disease or obstruction, particularly by gallstones. Associated laboratory findings include leukocytosis, hyperlipidemia (which may be marked), and hypocalcemia.<sup>1,7</sup>

The diagnosis of acute pancreatitis is based on the signs and symptoms, laboratory data, and imaging studies of the pancreas and surrounding organs. Radiographs of the abdomen may reveal an ileus pattern or the "sentinel loop" (a distended loop of small bowel in the area of the pancreas). Ultrasound can provide a convenient bedside technique to visualize the pancreas, gallbladder, common bile duct,

**FIGURE 37-8** Three proposed pathways in the pathogenesis of acute pancreatitis. Obstruction of the duct, extrinsic injury, and intrinsic metabolic mechanisms lead to injury of pancreatic cells. Injured cells release activated pancreatic enzymes that cause autodigestion and inflammation of the pancreas. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders.)

and other abdominal structures, but is limited by poor image resolution attributable to bowel gas. Computed tomography (CT) of the abdomen is the gold standard for evaluation of the pancreas and allows depiction of the pancreas in remarkable detail, including edema and abscess or cyst formation. The differential diagnosis of acute pancreatitis includes perforated peptic ulcer, acute cholecystitis, mesenteric vascular disease, and a variety of other illnesses (Box 37-2), most of which may be differentiated on the basis of biochemical and radiographic tests.

Grading systems allow prediction of the clinical course of acute pancreatitis. Ranson's criteria are a widely used benchmark for prognostic assessment, and are particularly useful with modifications based on CT scoring.<sup>13-18</sup> Early monitoring in the intensive care unit is indicated for patients with a high number of risk factors. One particularly important finding on contrast CT is the presence of significant pancreatic necrosis. Acute necrotizing pancreatitis carries a high risk for progression to infected pancreatic necrosis, a devastating complication with a high morbidity and mortality.

**Treatment.** Conservative management is indicated for mild to moderate cases of acute pancreatitis. In general, withholding oral feedings, providing nasogastric suction for significant adynamic ileus, and providing careful volume replacement with IV fluids are indicated.

Analgesics are administered parenterally. All narcotics should be used carefully because of the potential of sphincter of Oddi dysfunction, although recent studies show that no single agent is contraindicated.<sup>14</sup> This treatment is often sufficient when carried out for 3 to 7 days, after which the acute episode subsides and oral intake may gradually be resumed.

Severe pancreatitis, particularly in the setting of acute necrotizing pancreatitis, may result in multisystem organ dysfunction, requiring aggressive support in the intensive care unit setting. Nutritional deficits develop rapidly with extensive catabolism (tissue breakdown) and lack of caloric intake; total parenteral nutrition is usually indicated with pancreatitis of more than a few days' duration or if complications arise.<sup>6</sup> Additional supportive measures include calcium administration to reverse severe hypocalcemia, correction of magnesium deficiency, and control of hyperglycemia. Causes of death from severe pancreatitis include respiratory failure (usually associated with adult respiratory distress syndrome), acute renal failure, and acute intraabdominal sepsis. Mechanical ventilation and hemodialysis may be required in complicated cases.

Bacterial infection is a critical determinant of poor outcome in acute necrotizing pancreatitis. Although some authorities advocate broad-spectrum antibiotics (e.g., carbapenems) for all patients with

acute necrotizing pancreatitis, definitive studies are lacking.<sup>1</sup> In the patient with fever and signs of sepsis, empirical antibiotics should be administered, and any significant fluid collections found on CT scan should be aspirated for culture and sensitivity.

Abscess or hemorrhage may complicate pancreatitis with or without significant pancreatic necrosis and may necessitate surgical intervention. Open laparotomy with debridement of devitalized tissue (necrosectomy) and major pancreatic resection (pancreatectomy) are the main surgical options.<sup>8</sup> Drains are typically left in place postoperatively, and repeated debridement may be needed to remove infective debris and necrotic tissue. Pancreatic surgery is technically challenging and risky, and generally is only considered as a last resort.

Localized complications of acute pancreatitis may result in prolonged morbidity for the patient. The most common localized complication is pancreatic **pseudocyst**. This is a collection of fluid within or adjacent to the pancreas that often has a direct communication to the pancreatic duct. Unlike a true cyst, a *pseudocyst* contains no epithelial lining. It can develop rather acutely or more subacutely, as the patient recuperates from the acute illness. The presentation often includes fever, tachycardia, and an abdominal mass and tenderness. Complications of pseudocysts include infection (usually termed an infected pseudocyst, as opposed to the pancreatic abscess described earlier), spontaneous rupture, or hemorrhage. Management of pseudocyst includes endoscopic or surgical drainage of the cyst, either externally or internally, usually into the stomach or bowel.<sup>1,8</sup>

Pancreatic ascites may occur and may represent a persistent leak in the main pancreatic duct. It is usually painless and often massive. The fluid may find its way into unusual places, including the pleural space and mediastinum.<sup>1</sup> Pancreatic ascites may be detected by ultrasonography or CT, and diagnosis is confirmed by analysis of fluid obtained by aspiration, in particular the amylase level. Management is often conservative, with prolonged parenteral nutrition. Improvement may occur following the endoscopic placement of a stent (a thin-walled tube) into the main pancreatic duct.

Other complications of acute pancreatitis include common bile duct obstruction, portal or splenic vein thrombosis, peptic ulcer disease, and chronic fistula formation.

Endoscopic treatment may be carried out for gallstone pancreatitis in selected cases. Indications for urgent ERCP with ampullotomy (incision of the ampulla) include biliary sepsis, recalcitrant severe pancreatitis, and jaundice.<sup>1</sup> In milder cases, traditional conservative therapy followed by elective ERCP is acceptable. The risks of ERCP include exacerbation of pancreatitis, and therefore the need for this procedure must be carefully considered.

### Chronic Pancreatitis

**Etiology and pathogenesis.** Chronic pancreatitis is defined histologically as the presence of chronic inflammatory lesions in the pancreas, and in practice is the persistence of symptoms secondary to pancreatic dysfunction over weeks and months. Destruction of exocrine parenchyma and fibrosis precede the destruction of endocrine parenchyma. After a variable time, most patients with chronic pancreatitis develop calcifications that become visible on radiologic films of the abdomen or CT. Chronic pancreatitis is most often associated with alcohol consumption, although a small percentage of cases are idiopathic, hereditary, or associated with hyperparathyroidism (hypercalcemia), trauma, or various other factors.<sup>1-10</sup>

The association of alcohol ingestion with chronic pancreatitis is profound. Autopsy studies have shown that the changes of chronic pancreatitis are present in 45% of alcoholics, even those without symptoms, and that this rate is 40 to 50 times higher than that in nondrinkers.<sup>1,7</sup> Exactly how alcohol causes chronic pancreatitis is not known (see the previous discussion of alcohol and acute pancreatitis). One recent theory suggests that the initial factors include an increase in the protein concentration in pancreatic juice coupled with reduction in a specific “pancreatic stone protein” that inhibits the formation of pancreatic protein plugs.<sup>10</sup> This biochemical situation allows the formation of protein plugs that can later calcify, in addition to causing obstruction to the flow of pancreatic juice. A key element seems to be necrosis, followed by fibrosis, perhaps analogous to cirrhosis of the liver. Ischemic and antioxidant damage may occur as well. Another facet of alcohol-associated chronic pancreatitis is its tendency to progress after alcohol consumption is stopped.

**Clinical manifestations.** The presentation of chronic pancreatitis may consist of bouts of acute pancreatitis with progressive signs of

persistent pancreatic dysfunction after the acute attack subsides. Alternatively, an insidious onset of pain in the epigastrium that radiates to the back may be the first symptom. About 10% to 15% of patients will not present with pain but rather with the sequelae of chronic pancreatitis, including diabetes mellitus, malabsorption, and weight loss.<sup>1,7</sup> The mortality is 3% to 4% per year. Interestingly, the incidence of pancreatic carcinoma does not appear to be substantially increased in patients with chronic pancreatitis.

The pain of chronic pancreatitis is often the major form of debility. Nerve fibers from the pancreas pass to the celiac plexus and then to spinal sympathetic ganglia. The events that actually trigger the pain are not well understood. There may be a relation to ductal pressures or possibly to ischemia in the pancreas. The pain is often accompanied by nausea and is steady and boring in nature. The pain is usually located in the upper abdomen, particularly in the epigastrium, and radiates to the back in more than half of cases. In alcoholic pancreatitis, continued drinking affords temporary anesthesia but may foster recurrences of pain. Cessation of drinking may allow for a better long-term prognosis. After about 5 years of continual pain, many patients note a decrease in the symptoms (i.e., the pain “burns out”).

Endocrine and exocrine pancreatic insufficiency lead to diabetes mellitus, malabsorption, and weight loss. Diabetes mellitus arises from progressive loss of endocrine cells in the pancreatic islets and usually requires exogenous insulin administration; diabetic ketoacidosis is an unusual finding. Weight loss may be aggravated by poor intake as a result of pancreatic pain. Malabsorption of fat does not occur until pancreatic enzyme output drops to 10% of normal. Along with the malabsorption of fat, the absorption of fat-soluble vitamins (A, D, E, and K) may be impaired, leading to such problems as coagulopathy and night vision impairment.<sup>1</sup>

Further complications of chronic pancreatitis are similar to those of acute pancreatitis and include pseudocyst, pancreatic ascites, and obstruction of the common bile duct. Obstruction of the bile duct may lead to elevated values on liver function tests and the need to intervene either surgically or endoscopically. Alkaline phosphatase and bilirubin levels may become markedly elevated if obstruction is severe. Unusual complications include thrombosis of the portal and splenic veins. This may lead to gastrointestinal hemorrhage from gastric varices.<sup>12</sup> Peptic ulcer disease is also increased in patients with chronic pancreatitis, although a definite causal relationship has not been established.

**Diagnosis.** The diagnosis of chronic pancreatitis is usually suggested by the clinical history, physical examination findings, and routine blood chemical analyses. Biochemical studies of pancreatic function may be helpful. Confirmation of the diagnosis is aided by plain radiographs showing calcifications in the area of the pancreas. Abdominal ultrasound, CT, or magnetic resonance cholangiopancreatography (MRCP) are usually performed with reasonable sensitivities and specificities. ERCP is reserved for suspicious cases that cannot be confirmed by other techniques, or for cases in which biopsy or cytologic examination is necessary to rule out malignancy.<sup>1</sup> It shows the pancreatic duct to range from almost normal in early cases, to markedly dilated or beaded—the “chain of lakes” appearance (Figure 37-9). A common finding is truncation of the secondary branches of the pancreatic duct.

**Treatment.** The treatment for chronic pancreatitis is directed toward controlling pain, addressing exocrine and endocrine insufficiency, and managing complications. By far the most challenging is the management of pain. Absolute abstention from alcohol is paramount to prevent worsening of symptoms. For almost 40 years, analgesics and surgical intervention have been the mainstay of pain control, and celiac plexus block is helpful for some patients. With the advent of ERCP,

**FIGURE 37-9** Endoscopic retrograde cholangiopancreatogram in a patient with chronic pancreatitis shows marked narrowing and irregularity of the main pancreatic duct body and tail (arrows). (From Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease: pathophysiology, diagnosis, management*, ed 6, Philadelphia, 1998, Saunders, p 952.)

less drastic forms of intervention are now possible. Pancreatic sphincterotomy is indicated for the management of single or multiple stones. Endoscopic drains may be placed for pseudocysts of the pancreas if they are adjacent to the stomach or duodenum. Obstruction of the common bile duct can be managed with endoscopically placed biliary stents. Strictures of the main pancreatic duct can be managed with indwelling pancreatic stents.<sup>1,7</sup>

If endoscopic management fails or is not appropriate in a given patient, surgery may be indicated. Various procedures, such as the pylorus-preserving Whipple procedure (pancreaticoduodenectomy), may be used, generally with favorable results regarding relief of pain.<sup>8</sup> Complete and distal pancreatic resections are rarely used for this condition. As with management of acute pancreatitis, the judgment of the surgeon is paramount to prevent the catastrophic complications that can result from surgery on the pancreas.

Pancreatic enzyme replacement has become a standard therapy for chronic pancreatitis, both for its effects on steatorrhea and for the management of chronic pain.<sup>1</sup> Because proteases (e.g., trypsin, chymotrypsin, and elastase) exert a controlling influence on pancreatic secretion, feedback regulation should result in relief of pain following oral administration of pancreatic enzymes. Unfortunately, only 20% to 30% of patients with the typical alcohol-induced type of disease respond to such therapy. Responses seem to be higher in patients with small-duct disease. Acid suppression with an H<sub>2</sub>-blocker or proton pump inhibitor is indicated to reduce inactivation of the enzymes from gastric acid. Medium-chain triglycerides (MCTs) can provide extra calories in patients with weight loss. Research on octreotide, a synthetic long-acting analogue of somatostatin that has been shown to inhibit CCK release and both basal and neural-stimulated pancreatic secretion, has generally been disappointing.<sup>1,18</sup>

Management of exocrine insufficiency can usually be accomplished with low-fat diets and pancreatic enzyme supplementation. Likewise, endocrine insufficiency in the form of diabetes mellitus is managed with diet and either oral hypoglycemic agents or insulin.<sup>6</sup>

### Pancreatic Cancer

Pancreatic cancer is a challenging malignancy with a generally dismal prognosis, which has been unfortunately increasing in incidence, particularly among non-white populations. The current incidence is about 9 per 100,000, or about 2% of all cancers, but this cancer ranks fourth among deaths from all malignancies.<sup>9</sup> Cigarette smoking and obesity are risk factors for pancreatic cancer, both increasing the risk by about 50% compared to the general population.<sup>1,10</sup> The vast majority of pancreatic tumors are adenocarcinomas, but an important subset of neoplasms are neuroendocrine tumors.

Lesions of the head of the pancreas outnumber those in the body and tail 3 to 1. Symptoms of pancreatic head tumors include jaundice, malabsorption, and weight loss, whereas those of the tail generally include abdominal pain and nausea. The distinction between chronic pancreatitis, autoimmune pancreatitis, or benign cystic adenomas and pancreatic cancer may be difficult, and even a negative needle biopsy does not preclude cancer.<sup>10</sup> Most cancers are advanced at the time of presentation, with only 15% to 20% of cases being candidates for surgical resection.<sup>8</sup> Patients presenting with painless jaundice attributable to an obstructing pancreatic head lesion have the best prognosis. Even with surgery, most patients die of their disease. Chemotherapy plays a role in both attempts at surgical cure and palliation. The median survival among all patients is only 1 year, though there is some evidence that the cure rate may be improving somewhat because of new therapeutic modalities being employed at major medical centers.<sup>9</sup>

### KEY POINTS

- Acute pancreatitis is commonly associated with biliary tract disease and excessive ethanol ingestion. Activation of pancreatic proenzymes to active forms within the pancreas leads to autodigestion and inflammation of the gland. The manifestations of acute pancreatitis may be mild or severe and include a steady, boring pain in the epigastrium or left upper quadrant, nausea, vomiting, a tender abdomen, reduced bowel sounds, and fever. In severe cases, circulatory shock may occur. Elevated serum amylase and lipase levels are indicative of pancreatitis.
- Management of acute pancreatitis is aimed at reducing pancreatic secretion. Because chyme entering the duodenum is the primary stimulus for pancreatic secretion, food is withheld and nasogastric suctioning may be instituted. Complications of acute pancreatitis include hyperglycemia, nutritional deficit, and pancreatic hemorrhage, infection, abscess formation, or necrosis. Antibiotics, fluid management, total parenteral nutrition, and insulin may be indicated to manage complications.
- Chronic pancreatitis is closely associated with alcohol use. Acute pancreatitis attributable to biliary obstruction rarely progresses to chronic pancreatitis. Chronic pancreatitis results in progressive destruction of endocrine and exocrine function. Manifestations of chronic pancreatitis are more insidious than those of acute pancreatitis. Epigastric pain, diabetes mellitus, malabsorption, and weight loss may be the presenting problems.
- The complications of chronic pancreatitis are similar to those of acute pancreatitis. Therapy is directed to controlling pain, ameliorating endocrine and exocrine deficiency, and monitoring and managing complications. Surgery to correct obstruction of the pancreatic duct may be performed. Pancreatic enzyme therapy may be helpful in reducing pain by providing negative feedback, which reduces pancreatic secretion.
- Pancreatic cancer is a highly fatal cancer that can be difficult to diagnose and treat. Median survival is 12 months.

### SUMMARY

The pancreaticobiliary system is central to the digestion of food because it provides necessary digestive enzymes and lipid-emulsifying agents that allow the intestine to absorb nutrients. This chapter has considered alterations in the function of the gallbladder and exocrine pancreas. A major disease of the pancreaticobiliary system is the formation of cholesterol gallstones, which can lead to acute and chronic

cholecystitis and acute and chronic pancreatitis. New forms of surgical and nonsurgical interventions for the management of gallstone disease have become available in the past few years, with conventional open surgery remaining a useful option. These interventions, as well as interventions for acute and chronic pancreatitis, are currently the focus of much clinical research.

The liver is a vital but vulnerable organ. Its role in digestion of fats, storage of carbohydrates, detoxification of blood, and production of proteins makes it indispensable; in contrast to the kidney and heart, there are no “artificial livers.” Nevertheless, the liver is susceptible to a wide variety of metabolic, circulatory, toxic, microbial, and neoplastic insults. In some instances the disease is primary to the liver, as in viral hepatitis and hepatocellular carcinoma (HCC). More often the hepatic involvement is secondary, a consequence of some of the more common diseases of humans, such as cardiac decompensation, metastatic cancer, alcoholism, and infections. This chapter will focus on primary diseases of the liver.

**STRUCTURE AND FUNCTION OF THE LIVER**

The liver, the largest parenchymal organ of the body, averages 1500 grams (g). It is located in the right upper quadrant of the abdomen,

beneath the diaphragm, and is anatomically divided into right and left lobes and then further subdivided according to the pattern of its blood supply and biliary drainage. It is covered by a connective tissue capsule, the Glisson capsule, which in turn is covered by visceral peritoneum, reflections of which form the various suspensory hepatic ligaments. These structures demarcate the bare area of the liver directly in contact with the diaphragm (**Figure 38-1**).<sup>1-3</sup>

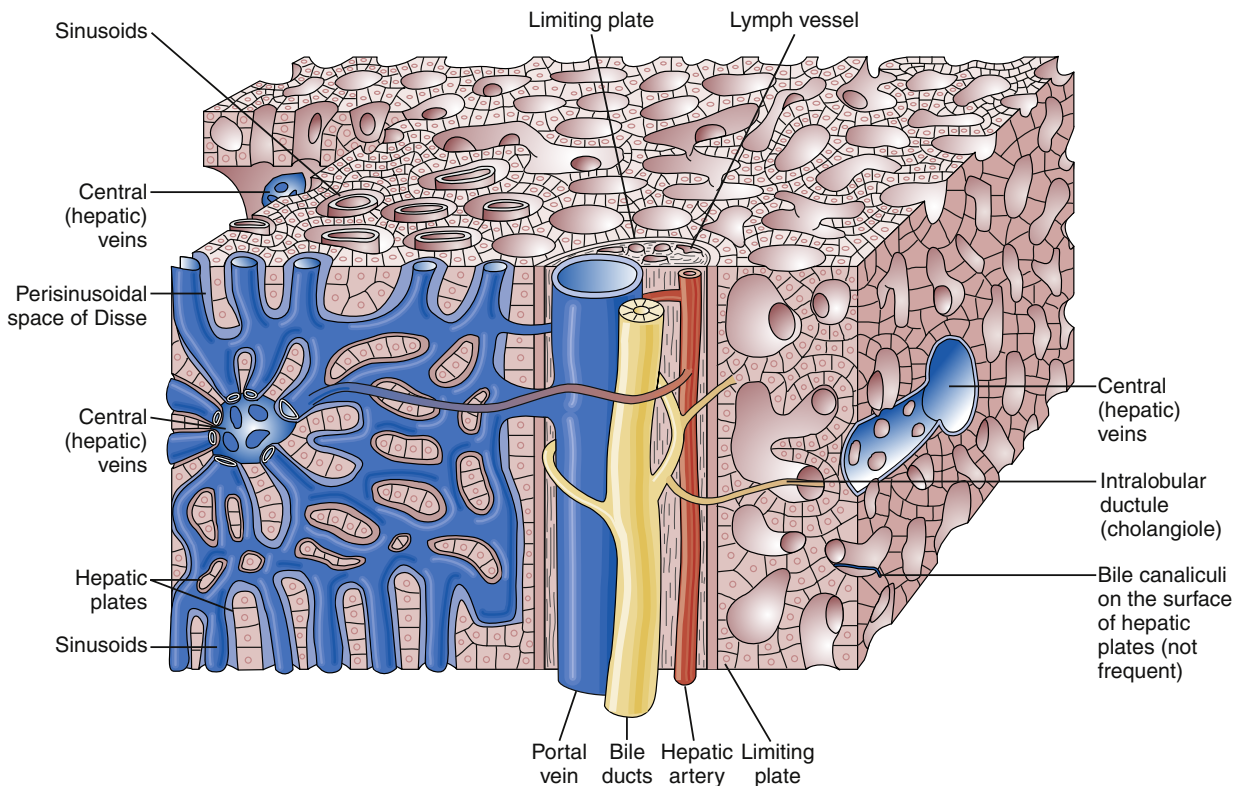

The liver has a dual blood supply. Arterial inflow from the aorta via the celiac trunk and hepatic artery provides 25% of the organ’s blood supply, with the remainder from the portal vein, which drains the capillary bed of the alimentary canal and pancreas (**Figure 38-2**). This oxygen-depleted venous blood is rich in substances absorbed and secreted by the gut. These afferent blood vessels then branch throughout the liver in association with the bile ducts and form the portal triads (consisting of the portal veins, hepatic arteries, and bile ducts).

**FIGURE 38-1** The liver and its peritoneal relations. Stippled areas represent surfaces not covered with peritoneum. **A**, Superior view. **B**, Anterior view. **C**, The diaphragm, viewed from the front, showing the position of the bare area of the liver. **D**, Visceral surface of the liver, viewed from behind. (Redrawn from Gardner E et al: *Anatomy: a regional study of human structure*, ed 3, Philadelphia, 1969, Saunders, p 414.)

**FIGURE 38-2** Schematic diagram of the portal circulation. Blood from the aorta supplies the alimentary canal. Venous blood from the intestine reaches the sinusoids of the liver by way of the portal vein. Venous blood from the liver reaches the inferior vena cava by way of the hepatic veins.

**FIGURE 38-3** Liver lobule.

Eventually, blood from both the hepatic artery and the portal vein drains into the hepatic sinusoids, which surround sheets of liver cells, or hepatic plates (Figure 38-3). The sinusoids are lined by endothelial cells and Kupffer cells (a type of phagocytic macrophage). This blood drains into the central veins, which finally coalesce into the hepatic vein and empty into the inferior vena cava. Any obstruction to the flow of blood may result in a rise in portal venous pressure proximal to the level of blockage. This condition is called **portal hypertension** and is a central pathophysiologic event in many liver diseases. The liver also has a rich and complex lymphatic drainage system.

The liver is one of the most metabolically active organs in the body and functions simultaneously as a digestive organ, an endocrine organ, a hematologic organ, and an excretory organ (Box 38-1). All of these functions are elegantly interwoven with such redundancy that more than 80% of the liver may be destroyed before life is threatened.

## GENERAL MANIFESTATIONS OF LIVER DISEASE

Whether primary or secondary, all hepatic derangements tend to cause similar signs and symptoms that are directly attributable to loss of hepatocellular function or disruption of blood flow through the liver. Because of the liver's considerable reserve, however, manifestations appear only when the injury is significant and diffuse or so strategically located that it obstructs biliary outflow.

### Hepatocellular Failure

Hepatocellular failure results in a number of typical manifestations, including jaundice, muscle wasting, ascites, excessive bleeding, deficiencies of important blood proteins and vitamins, glucose imbalance, and impaired hormone production (Table 38-1). At its most basic the liver is a sophisticated biochemical factory, and these conditions all derive from problems with processing the essential molecules of the body. Inadequate protein metabolism leads to decreased production of clotting factors and hypoalbuminemia. Decreased serum albumin level in turn leads to generalized edema as a result of low serum oncotic pressure. Abnormal storage and release of glucose in the form of glycogen may result in bouts of either hyper- or hypoglycemia. Reduced production of bile salts by the liver impairs absorption of the fat-soluble vitamins A, D, E, and K from the gastrointestinal (GI) tract. Lack of vitamin D may lead to osteomalacia (impaired bone homeostasis); lack of vitamin K contributes to poor blood clotting factor production. Altered lipoprotein processing leads to dyslipidemias, particularly hypertriglyceridemia.

Hepatocellular failure is associated with impaired processing of endogenous steroid hormones and the by-products of protein metabolism, as well as decreased clearance of exogenous drugs and toxins. Impaired metabolism of estrogen leads to feminization in men

(gynecomastia, impotence, testicular atrophy, female hair distribution), irregular menses in women, palmar erythema, and spider telangiectasia. Impaired conversion of ammonia to urea is associated with hepatic encephalopathy, which will be discussed later in this chapter.

### Jaundice

**Etiology and pathogenesis.** Jaundice, the green-yellow staining of tissues by bilirubin, results from impaired bilirubin metabolism and is one of the most characteristic signs of liver disease. A study of the mechanisms of bilirubin metabolism is essential to an understanding of liver disease and may serve as a paradigm for other hepatic processes (Figure 38-4).<sup>4-6</sup>

As red blood cells age or are damaged by disease, they lyse and release oxygen-carrying hemoglobin molecules. These are taken up by the reticuloendothelial system, which separates heme from globin, and through the action of heme oxygenase opens the heme ring to release the central iron atom. This process yields biliverdin, which in turn is converted by the enzyme bilirubin reductase to bilirubin. (A small percentage of bilirubin is derived from the premature destruction of immature cells in the bone marrow and spleen and from heme proteins such as myoglobin and the cytochromes in the liver.) Bilirubin is released into the plasma and transported to the liver tightly bound to the plasma protein albumin. The free unconjugated bilirubin is lipid soluble and can be displaced from albumin by fatty acids and certain organic anions (e.g., sulfonamides, salicylates). The neonate is particularly sensitive to free unconjugated bilirubin, which can diffuse into the brain and cause a type of encephalopathy known as **kernicterus** (see the Liver Diseases and Pediatric Considerations section).

Liver cells are able to extract unconjugated bilirubin from the plasma with special transport proteins. In the cytosol, bilirubin is quickly bound, or conjugated, to water-soluble derivatives of glucuronic acid by the action of the enzyme uridine diphosphate glucuronosyltransferase (UDPGT) located in the endoplasmic reticulum. This process yields water-soluble bilirubin monoglucuronide and diglucuronide, which is then actively excreted into microscopic bile ducts (canaliculi). Bilirubin is then transported through the biliary system as a component of bile to the small intestine. Because it cannot be absorbed in the small intestine, it passes to the colon where bacterial  $\beta$ -glucuronidase enzymes convert it to urobilinogen. A small fraction of urobilinogen is absorbed from the colon and re-excreted by the kidneys and the liver. In the presence of liver disease, the hepatic fraction decreases and the urinary fraction increases, thus accounting for the rise in urinary urobilinogen concentration seen with liver dysfunction. With complete obstruction to bile flow or with intestinal obstruction above the colonic level, urinary urobilinogen level falls to zero, since

## BOX 38-1 SUMMARY OF NORMAL LIVER FUNCTION

### The Liver as a Digestive Organ

Bile salt secretion for fat digestion  
Processing and storage of fats, carbohydrates, and proteins absorbed by the intestines  
Processing and storage of vitamins and minerals

### The Liver as an Endocrine Organ

Metabolism of glucocorticoids, mineralocorticoids, and sex hormones  
Regulation of carbohydrate, fat, and protein metabolism

### The Liver as a Hematologic Organ

Temporary storage of blood  
Removal of bilirubin from the bloodstream  
Hematopoiesis in certain disease states  
Synthesis of blood clotting factors

### The Liver as an Excretory Organ

Excretion of bile pigment  
Excretion of cholesterol via bile  
Synthesis of urea  
Detoxification of drugs and other foreign substances

no bilirubin reaches the colon. (The function of bile salts and the other components of bile flow are discussed in Chapter 37.)

Therefore, jaundice may result from dysfunction anywhere along this complex pathway. Classically, it is divided into prehepatic, hepatic, and posthepatic or cholestatic, but much overlap occurs.

**Prehepatic.** The most common causes of prehepatic jaundice are hemolysis and ineffective erythropoiesis. The resorption of large hematomas in patients with mild liver disease is a frequent and harmless cause of mild jaundice attributable to unconjugated hyperbilirubinemia.

**Hepatic.** Dysfunction of each of the hepatic steps in bilirubin metabolism may cause jaundice. In the neonate, immature UDPGT levels may result in physiologic jaundice of the newborn. Various genetic disorders of UDPGT synthesis are characterized by high levels of unconjugated bilirubin in the blood. Mutant UDPGT enzymes can produce the common and benign Gilbert syndrome, in which low levels of unconjugated bilirubin may be increased by fasting or illness (e.g., viral gastroenteritis). Other UDPGT mutations cause the Crigler-Najjar type I and II syndromes with severe neonatal unconjugated hyperbilirubinemia (see the Liver Diseases and Pediatric Considerations section). Most of the liver diseases to be discussed later, such as viral hepatitis, alcoholic liver disease, and autoimmune hepatitis, result in jaundice because dysfunction within the liver cells result in elevated levels of conjugated bilirubin.

**Posthepatic.** At the level of canalicular bilirubin transport, the rare inherited Dubin-Johnson and Rotor syndromes cause conjugated hyperbilirubinemia. Both conditions have an excellent prognosis. At

the canalicular posthepatocytic level, many drugs such as the phenothiazines and the sex hormones may cause jaundice.<sup>1</sup> In susceptible women, the high sex hormone levels of normal pregnancy can cause benign cholestasis of pregnancy.<sup>1</sup> This condition is also associated with defective transport of bile salts and is characterized by jaundice and intense pruritus (i.e., itching).

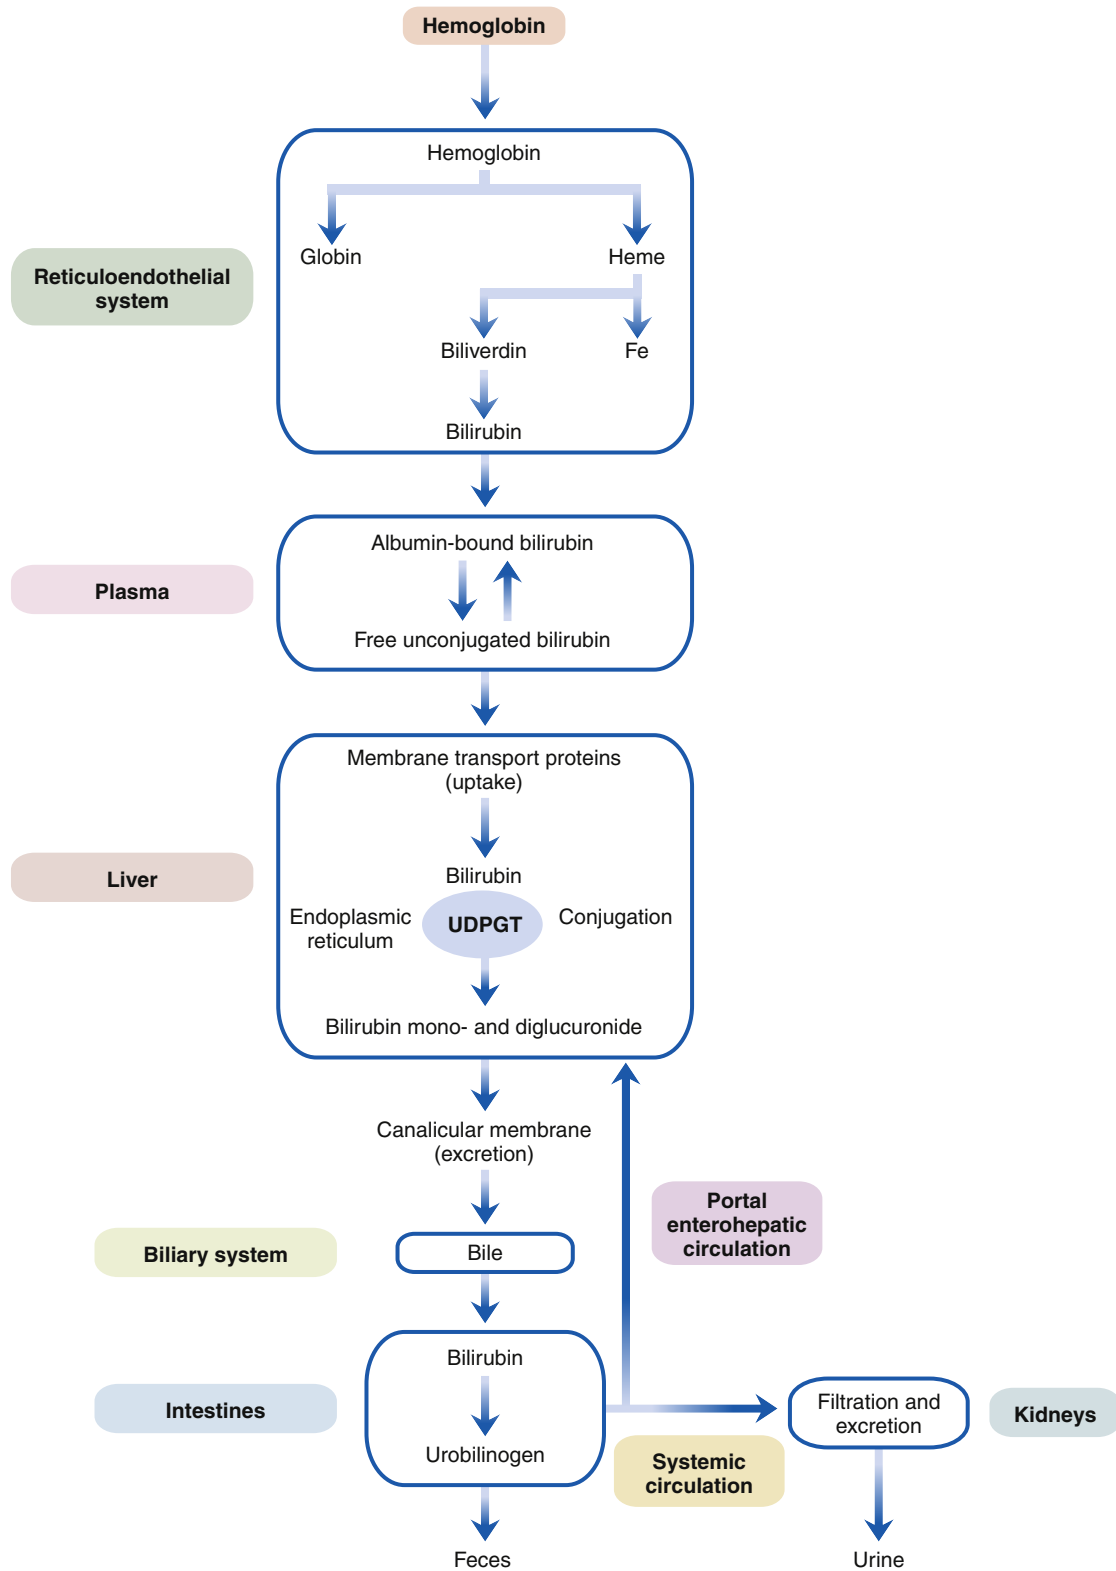

Mechanical obstruction of the bile ducts from obstructing tumors, strictures, or gallstones is the most common cause of cholestatic jaundice. Some experts differentiate obstructive jaundice caused by a gross mechanical blockage to bile flow in the biliary tract from intrahepatic cholestatic jaundice, the latter implying a defect at the microscopic level.

**Evaluation.** Evaluation of a jaundiced patient may be used as a model for investigation of any patient with liver disease. After a complete history and physical examination are obtained and routine laboratory data reviewed, specific liver-related tests may be performed (Table 38-2). The underlying cause, such as alcoholic liver disease, a drug reaction, or metastatic or primary malignancy, is often suggested by the history and physical examination. Physical stigmata of chronic liver disease include telangiectasia, ascites, palmar erythema, gynecomastia, testicular atrophy, hair loss (in men), and central obesity with peripheral muscle wasting.

**Diagnostic tests.** Biochemical test abnormalities usually fall into one of several categories. A significant elevation in the levels of transaminases out of proportion to the other liver enzymes indicates a primarily hepatocellular disorder (i.e., hepatitis). Alcoholic and other toxic hepatitides virtually always show the aspartate aminotransferase

**TABLE 38-1 PATHOPHYSIOLOGY UNDERLYING THE SYMPTOMS AND SIGNS OF LIVER DISEASE**

SYMPTOMS/SIGNS	PATHOPHYSIOLOGIC MECHANISM
Weakness, fatigue, anorexia, weight loss, muscle wasting	Failure of multiple metabolic functions
Fever	Liver inflammation, decreased reticuloendothelial function with increased risk of infection
Bruising, increased bleeding	Thrombocytopenia secondary to splenic enlargement, decreased synthesis of clotting factors I, II, V, VII, VIII, IX, and X
Palmar erythema, cutaneous spider telangiectases, irregular menses, gynecomastia, impotence, female body hair distribution in men, testicular atrophy	Altered metabolism of sex hormones, chronic debilitation
Hepatic encephalopathy	Abnormal protein metabolism
Fetor hepaticus	Decreased detoxification
Pruritus	Decreased bile salt excretion
Cyanosis	Arteriovenous shunts in lungs, liver
Jaundice	Biliary obstruction, decreased bilirubin synthesis, decreased bilirubin excretion
Hyperdynamic circulation, wide pulse pressure, tachycardia	Generalized vasodilation (? Hormonally mediated)
Ascites, peripheral edema	Portal hypertension, sodium and water retention, low serum albumin secondary to decreased hepatic synthesis
Splenomegaly	Portal hypertension
Hepatomegaly	Cirrhosis (liver may be small), hepatitis, vascular congestion, bile duct obstruction, infection, benign infiltrative disease (e.g., fatty liver, amyloidosis, hemochromatosis), malignant infiltrative disease (e.g., metastatic cancer, lymphoma, large space-occupying lesions such as neoplasm, abscess)
Varices (esophageal, gastric, rectal, ectopic) or abnormal abdominal vascular pattern (caput medusae, umbilical bruit)	Portal hypertension with collateral blood flow around hepatic blockage
Osteomalacia, hypocalcemia, night blindness, coagulopathy	Fat-soluble vitamin malabsorption and loss of fat-soluble vitamin reserves A, D, and K; loss of vitamin K metabolism (a cofactor for I, II, VII, VIII, IX, and X)
Anemia	Multifactorial: blood loss, chronic disease, vitamin B <sub>12</sub> deficiency, splenic sequestration
Leukopenia	Hypersplenism secondary to portal hypertension
Hypoglycemia	Altered glycogenolysis, gluconeogenesis
Hyperglycemia	Portosystemic shunting with delayed hepatic uptake of absorbed glucose
Hypercholesterolemia	Obstructive jaundice with decreased cholesterol excretion

**FIGURE 38-4** Summary of bilirubin metabolism (see text for explanation). *UDPGT*, Uridine diphosphate glucuronosyltransferase.

TABLE 38-2 COMMON LABORATORY TESTS IN LIVER DISEASE

TEST	NORMAL RANGE	SIGNIFICANCE
AST/SGOT	5-40 units/ml	Elevated levels indicate hepatocellular inflammation or necrosis
ALT/SGPT	5-35 units/ml	AST much greater than ALT in alcoholic liver disease AST less specific; may be of skeletal muscle, myocardial, kidney, or liver origin ALT more specific for liver disease
Alkaline phosphatase	35-150 units/ml	Elevated in cholestasis, infiltrative liver disease (e.g., cancer, granulomas) May be of bone origin
$\gamma$ -Glutamyltranspeptidase	10-48 units/ml	Elevated in cholestasis and hepatocellular disease Used to confirm that elevated alkaline phosphatase is of hepatic origin Disproportionately elevated in alcoholic liver disease May be induced by many drugs (e.g., phenobarbital)
5'-Nucleotidase	2-11 units/ml	Elevated in cholestasis Very specific to liver
Total bilirubin	<1.0 mg/dl	Elevated levels diagnose jaundice
Indirect bilirubin	<0.8 mg/dl	Elevated in hemolysis, Gilbert disease
Prothrombin time	11.5-14 sec	Prolongation suggests decreased hepatic synthetic function
Serum albumin	3.5-5.5 gm/dl	Decreased level suggests decreased hepatic synthesis
Serum globulin	2.5-3.5 gm/dl	Elevated in autoimmune hepatitis
Urine bilirubin	0	Increased with elevation of serum conjugated (direct) bilirubin, zero in unconjugated (indirect) hyperbilirubinemia
Urinary urobilinogen	0-4 mg/24 hr; spot test $\pm$ on urine dipstick	Zero in complete biliary or proximal bowel obstruction Increase may suggest liver disease Nonspecifically insensitive Primary utility because its presence on urine dipsticks allows simple office/bedside testing or screening with one-time urinalysis

(AST) concentration markedly elevated in comparison with the alanine aminotransferase (ALT) concentration, whereas in viral hepatitis the reverse is usually true. Predominant elevations of alkaline phosphatase (ALP) level indicate intrahepatic cholestasis and are often due to an infiltrative process (e.g., metastatic carcinoma, sarcoidosis). Elevated levels of bilirubin can result from either direct (conjugated) or indirect (unconjugated) causes. Although an overwhelming liver process in an adult will produce elevations of both forms of bilirubin, as a practical matter unconjugated hyperbilirubinemia points to significant hemolysis. Predominant conjugated bilirubin level elevation points to extrahepatic cholestasis attributable to biliary obstruction. It is noteworthy that jaundice in patients with cirrhosis often shows elevations in all parameters, reflecting the widespread liver dysfunction and obstruction of the bile canals and small vessels caused by scarring.

Evaluation of hepatocellular and cholestatic disorders may include assessment for viral hepatitis (Table 38-3), performance of various biochemical assays (see the specific disorders discussed later), or conduction of a needle biopsy of the liver. Needle biopsies may be carried out “blind” or may be directed by ultrasound or computed tomography (CT), allowing examination of a specific target such as a mass lesion.

Radiologic imaging with ultrasonography is often helpful for significant liver disease. This is particularly true given the fact that structural liver abnormalities such as tumors may present with any of the aforementioned enzyme patterns or with a mixed picture. CT provides more information and has a special role in evaluating the content of iron in the liver in cases of suspected hemochromatosis. Specific visualization of the bile ducts may necessitate percutaneous transhepatic cholangiography or endoscopic retrograde cholangiopancreatography (ERCP; see Chapter 37), although magnetic resonance cholangiopancreatography (MRCP) has rapidly gained acceptance as a noninvasive way of evaluating the liver and biliary tree in great detail.

### Portal Hypertension

Manifestations of liver disease not attributed to hepatocellular failure are mainly due to impaired blood flow through the liver as a result of increased resistance from fibrosis and degeneration of liver tissue. Sluggish blood flow through the liver results in increased pressure in the portal circulation (**portal hypertension**) (Figure 38-5). In this condition, venous drainage of much of the gastrointestinal tract is congested. Symptoms are surprisingly few early in the course, but as abnormal vascular patterns progress anorexia may result. The end results of elevated venous pressure are varices, particularly esophageal, but also gastric and hemorrhoidal. A pathognomic feature of advanced liver disease is superficial periumbilical varices, known as caput medusae, or the head of Medusa. Portal hypertension may present as an accumulation of peritoneal fluid, or **ascites**. A serious consequence of portal hypertension is uncontrolled bleeding from esophageal varices, which are prone to rupture.

### Gastroesophageal Varices

**Etiology.** Esophageal varices result mainly from portal hypertension, which in Western society is generally the result of cirrhosis attributable to the chronic effects of alcoholism or viral hepatitis. In developing tropical countries, chronic infection with the *Schistosoma* species of liver fluke is a major cause of portal hypertension. Recently, it has been recognized that vasoactive hormones, as well as increased splanchnic blood flow and increased vascular resistance in the liver, have a prominent role in the formation of variceal esophageal veins.<sup>1</sup> Gastric varices may occur in conjunction with or independently from esophageal varices, the latter if splenic vein obstruction or thrombosis occurs.

**Pathogenesis.** Gastroesophageal varices are merely one of a number of collateral venous pathways that dilate in response to elevated portal pressure in an attempt to transport blood from the

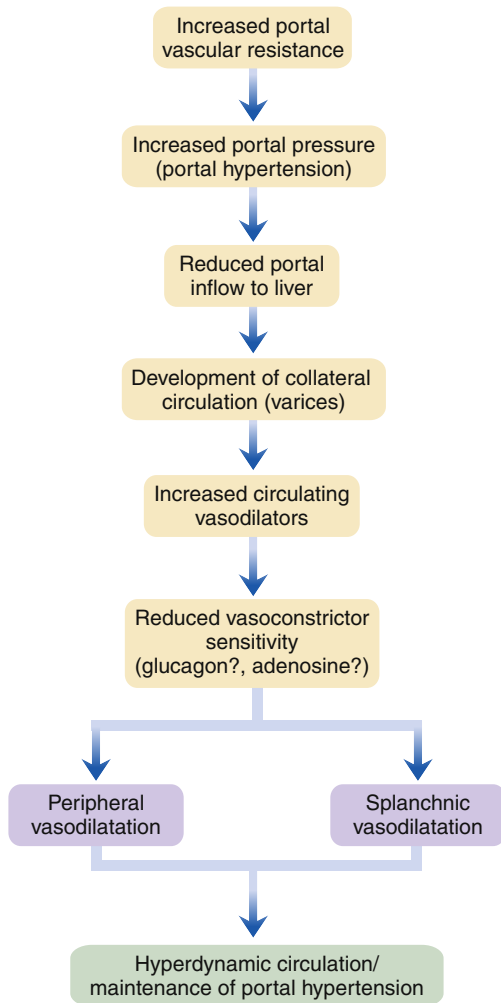

TABLE 38-3 IMMUNOLOGIC MARKERS IN VIRAL HEPATITIS

MARKER	DESCRIPTION
<b>Hepatitis A</b>	
Anti-HAV IgM	Acute infection with HAV, but may persist for months
Anti-HAV IgG	Past infection with HAV Implies immunity to the virus
<b>Hepatitis B</b>	
Hepatitis B surface antigen (HBsAg)	Surface protein coat of HBV Implies active infection Detectable 2-6 wk after infection Remains present as long as infection is active
Hepatitis B surface antibody IgM (HBsAb IgM)	Antibody to surface protein of HBV Detectable shortly after or with clearance of HBsAg Implies resolution of infection and immunity to HBV
Hepatitis B core antibody IgM (HBcAb IgM)	Antibody to inner core protein of HBV Detectable 3-5 wk after infection Implies recent infection
Hepatitis B core antibody IgG (HBcAb IgG)	Same as for HBcAb IgM, but implies past infection
Hepatitis Be antigen (HBeAg)	Soluble fraction of HBV Detectable 2-6 wk after infection Implies ongoing infection with high infectivity May resolve independently of HBsAg
Hepatitis Be antibody (HBeAb)	Antibody to soluble fraction of HBV Detectable when HBeAg clears Implies decreased infectivity
HBV DNA polymerase activity	Same significance as HBV DNA
<b>Hepatitis C</b>	
Anti-HCV	Antibody to HCV antigens May not be detectable early in infection Does not indicate immunity to the virus Rapidly evolving area; many commercially available assays of different sensitivity and specificity
HCV RNA by PCR	Many false-positive and false-negative results Assay for level of viremia Correlates positively with activity of infection Clears with resolution of infection Technically difficult; available through reference laboratories
<b>Hepatitis D (Delta)</b>	
Hepatitis delta antigen (HDAg)	Assay for 35-nm RNA virus Detectable 2-10 wk after infection Implies early infection
Anti-HDV	Implies past or chronic infection Does not indicate immunity to the virus
<b>Hepatitis E</b>	
HEV RNA by PCR	Detects presence of virus
HEV antibody IgG and IgM	Not well standardized
<b>Hepatitis G</b>	
HGV by PCR	Measures level of viremia

PCR, Polymerase chain reaction.

splanchnic bed around the cirrhotic obstructed liver and back to the heart. Other common pathways include a variety of spontaneous deep and usually entirely asymptomatic portosystemic shunts, such as splenorenal shunts; dilated veins in the small intestine, colon, and rectum are also not uncommon.<sup>1</sup> Unfortunately, part of the very

complex venous network that surrounds the proximal part of the stomach and esophagus lies just beneath the mucosa, rendering it especially liable to rupture when portal pressures reach a critical level. Rupture often results in massive, life-threatening upper GI bleeding (Figure 38-6).

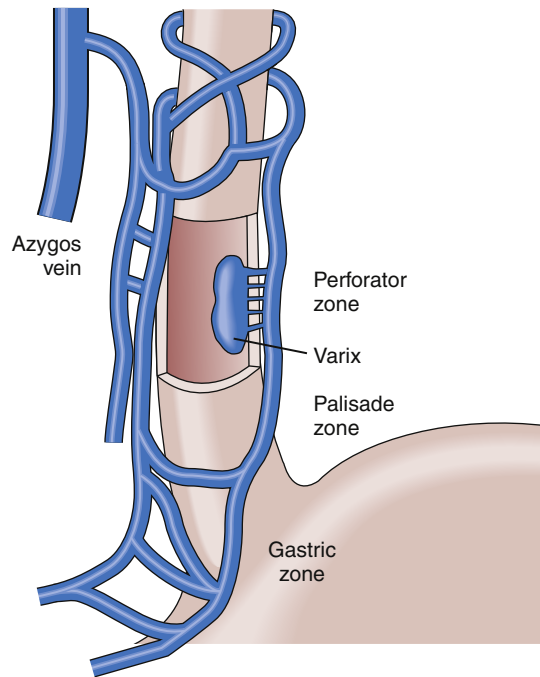

**FIGURE 38-5** Pathophysiologic process of portal hypertension. (Redrawn from MacMathuna P: The pathogenesis of variceal rupture, *Gastrointest Endosc Clin North Am* 2[1]:1-8, 1992.)

**Clinical features.** Varices will affect more than half of cirrhotic patients, and approximately 30% of them experience an episode of variceal hemorrhage within 2 years of the diagnosis of varices.<sup>1</sup> Variceal size is the main determinant of risk for bleeding, which is one of the main causes of death (20% to 33%) in persons with long-standing cirrhosis. The mortality after an episode of significant variceal bleeding is as high as 50%. The diagnosis is made mainly endoscopically, but varices may be seen on CT scans of the abdomen, as well as on upper GI barium examinations.

The initial symptoms and signs of bleeding from gastroesophageal varices include hematemesis, melena, and even bright red rectal bleeding. These characteristics may be associated with profound anemia and symptoms and signs of shock. In most cases, concomitant evidence of chronic liver disease and portal hypertension is seen on physical and laboratory examination. There are two distinct phases of the variceal hemorrhage process: one, coincident with and shortly after the bleeding; and two, a period of 6 to 8 weeks following the initial bleed, when there is a high risk of rebleeding. The greatest risk of rebleeding occurs in the first 72 hours.

**Treatment.** Initial treatment is directed at performing fluid resuscitation, correcting the coagulopathy, and stopping further bleeding. Large-bore intravenous lines are placed, and fluid resuscitation is carried out with normal saline. Blood components and clotting factors are

**FIGURE 38-6** Gastroesophageal venous anatomy. (Redrawn from MacMathuna P: The pathogenesis of variceal rupture, *Gastrointest Endosc Clin North Am* 2[1]:1-8, 1992.)

replaced as needed. Any coagulopathy may necessitate administration of parenteral vitamin K, fresh frozen plasma, and platelet infusions if profound thrombocytopenia is present. Recombinant factor VIIa is helpful in reversing the coagulopathy associated with advanced liver disease and may be considered for patients whose prothrombin time (PT) fails to normalize after the previously stated measures have been performed.<sup>7-9</sup>

Primary acute pharmacologic management rests on drugs that can effectively lower portal pressure by dilating alternative collateral pathways, reducing splanchnic blood flow, or both. Until recently, the agent of choice in the United States was vasopressin, an analogue of antidiuretic hormone, administered by continuous intravenous infusion along with nitroglycerin. Although effective in controlling variceal bleeding, vasopressin use may be associated with angina pectoris, severe abdominal cramping, and hyponatremia, side effects that limit its usefulness.<sup>3</sup>

In recent years, octreotide acetate, a synthetic analogue of the naturally occurring hormone somatostatin, has been effectively used as a replacement for vasopressin.<sup>1</sup> It is administered as an initial intravenous bolus followed by continuous infusion, which may be administered for as long as 3 to 5 days. In the doses used, the drug is remarkably free of side effects and more effective than vasopressin. However, it should be noted that no drug treatment has shown a mortality benefit for this condition.

Metoclopramide and  $\beta$ -blockers have been used as ancillary treatments in the past and may be considered for selected patients. Intravenous  $H_2$ -blockers or proton pump inhibitors are also often administered. The use of prophylactic antibiotics is recommended by the American Association for the Study of Liver Diseases; intravenous ceftriaxone or an oral quinolone for a 1-week course is the preferred regimen.<sup>8</sup>

Emergency esophagogastroduodenoscopy (EGD) is crucial in determining the site of bleeding, as well as excluding other causes of

upper GI bleeding. In addition to its diagnostic role, EGD actively addresses bleeding varices. **Endoscopic sclerosis** of esophageal varices is accomplished by passing a flexible needle through the gastroscope and injecting various sclerosant solutions into and around the bleeding varix (Figure 38-7). Such treatment results in initial thrombosis of the vein with hemostasis. Repeated injections cause fibrosis and obliteration of the varix and fibrosis of the overlying mucosa. This process can effectively obliterate all of the varices at risk of bleeding. Unfortunately, this treatment may be associated with a variety of acute and chronic complications, including drug reactions to the sclerosing solutions, exacerbation of bleeding, perforation, ulceration, infection, and stricture formation.<sup>5</sup>

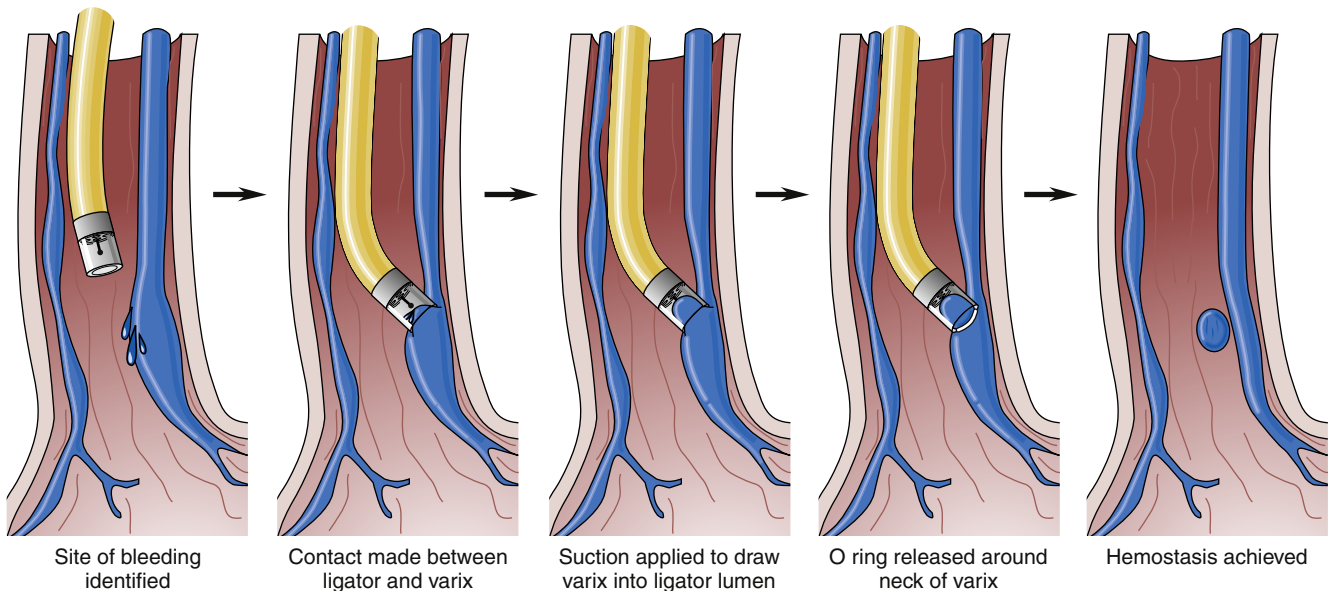

**FIGURE 38-7** Endoscopic sclerosis of varices.

An alternative treatment method is endoscopic ligation of esophageal varices (Figure 38-8). In this technique, a special apparatus is preloaded onto the gastroscope so that the endoscopist can suction a varix into a special chamber at the end of the gastroscope and then ligate the varix with a small rubber band. This technique also results in immediate loss of flow in the varix and eventually leads to thrombosis and fibrosis. The area ligated simply sloughs off over the next few weeks without significant residual ulceration or scarring. This method requires fewer sessions than endoscopic sclerosis to completely obliterate the varices, seems to be associated with a lower complication rate, and may be more effective in the management of bleeding gastric varices.<sup>1</sup> However, it is technically more challenging and is generally reserved for elective use.

Endoscopic techniques have shown a mortality benefit relative to treatment with drugs alone but fail to control acute bleeding in 10% to 20% of patients. Unfortunately, both of these methods may result in an increase in venous pressure proximal to the area treated, perhaps resulting in an increased risk of bleeding from congestive gastroenteropathy (a diffuse venous congestion that may result in both chronic and acute severe blood loss).

Balloon tamponade of varices was widely used before the availability of endoscopic treatment.<sup>1</sup> This treatment consists of a gastric balloon that is passed orally or transnasally into the stomach, inflated, and held in gentle traction against the gastric varices in the fundus, thus tamponading bleeding vessels and restricting blood flow from the fundus up into the esophageal varices (Figure 38-9). Suction of oropharyngeal and gastric secretions is accomplished with integral or separate drainage tubes. Balloon tamponade carries frequent risks, including aspiration of stomach contents, migration of the tube with airway compression, pressure necrosis of the esophagus and stomach, rupture of the balloon, and rebleeding after the maximal inflation period of 24 hours. These limit the usefulness of balloon tamponade to a temporizing role until definitive treatment.

Chronic pharmacologic management of portal hypertension is frequently successful with nonselective  $\beta$ -blockers such as propranolol or nadolol. The drug is carefully titrated to reduce the initial resting heart rate by 25%. These drugs may be used prophylactically in patients with known portal hypertension and are often prescribed following

**FIGURE 38-8** Endoscopic band ligation of varices.

endoscopic therapy as part of a combined approach to variceal bleeding prevention. It should be noted that studies have not yet shown a consistent survival benefit for this intervention, however. In addition to  $\beta$ -blockers, oral long-acting nitrates such as isosorbide mononitrate act synergistically with  $\beta$ -blockers to reduce portal pressure and have been studied for prevention of variceal hemorrhage.<sup>9,10</sup> Side effects limit use of nitrates as primary prophylaxis, but these agents could be considered for secondary prophylaxis in patients who do not respond to  $\beta$ -blockers alone.

If the aforementioned measures are ineffective, a number of surgical and radiologic procedures are possible. Although rarely used in the United States, esophageal transection and reanastomosis with ligation of other collateral channels has been used in other countries.<sup>1</sup> Surgery to reduce portal pressure is very effective in decreasing the rate of rebleeding, but it may not alter overall survival. A variety of surgical techniques are used, all of which create an alternative connection between the splanchnic and systemic circulations. These techniques include portacaval, mesocaval, splenorenal, and distal splenorenal shunts (Figure 38-10). A discussion of the specific indications and technical aspects of these shunts is beyond the scope of this text, but each has certain specific indications, advantages, and disadvantages.<sup>1</sup>

In recent years a radiographic procedure called transjugular intrahepatic portosystemic shunting (TIPS) has been developed that combines angiographic and ultrasonographic techniques.<sup>1</sup> The hepatic vein is cannulated by the transjugular route. A needle is then passed into a main portal vein branch. Catheters are passed over this guidewire along with balloon dilation of the tract just created. This step is then followed by placement of an expandable metallic stent, thus creating a portosystemic shunt (portal vein to hepatic vein) within the liver itself. This procedure is technically very demanding and may be complicated

by hemorrhage, infection, stent migration, stent stenosis, and occlusion, both acute and chronic. In addition, hepatic encephalopathy and congestive heart failure may result. The primary use of this modality is as a bridge to allow stabilization of patients who are candidates for liver transplantation.<sup>17</sup>

Treatment of esophageal varices is often unsatisfactory. Ideally, the underlying condition for varices (i.e., portal hypertension) should be reversed. The only consistently effective way to accomplish this goal is by liver transplantation (see the Transplantation section), which is limited in its application to a select group of patients.

## Portal Systemic Encephalopathy

### Hepatic Encephalopathy

**Pathogenesis.** Hepatic encephalopathy is a complex neuropsychiatric syndrome characterized by symptoms ranging from mild confusion and lethargy to stupor and coma. Some patients exhibit dementia, psychotic symptoms, spastic myelopathy, and cerebellar or extrapyramidal signs. The classic physical finding is asterixis, or “liver flap,” a spastic jerking of the hands held in forced extension. Hepatic encephalopathy is associated with fulminant hepatic failure or severe chronic liver disease, conditions in which liver function is severely depressed and blood is shunted around the liver. The arterial ammonia level correlates positively with the level of encephalopathy in most patients, consistent with its central role in the pathogenesis of hepatic encephalopathy as one of the primary causes of neuronal dysfunction. The exact cause is unclear, and other contributing factors such as elevated mercaptan levels, enhanced activation of certain neurotransmitter receptors (including  $\gamma$ -aminobutyric acid and benzodiazepine receptors), and elevated levels of aromatic amino acids (false neurotransmitters) remain under investigation.<sup>1,18</sup>

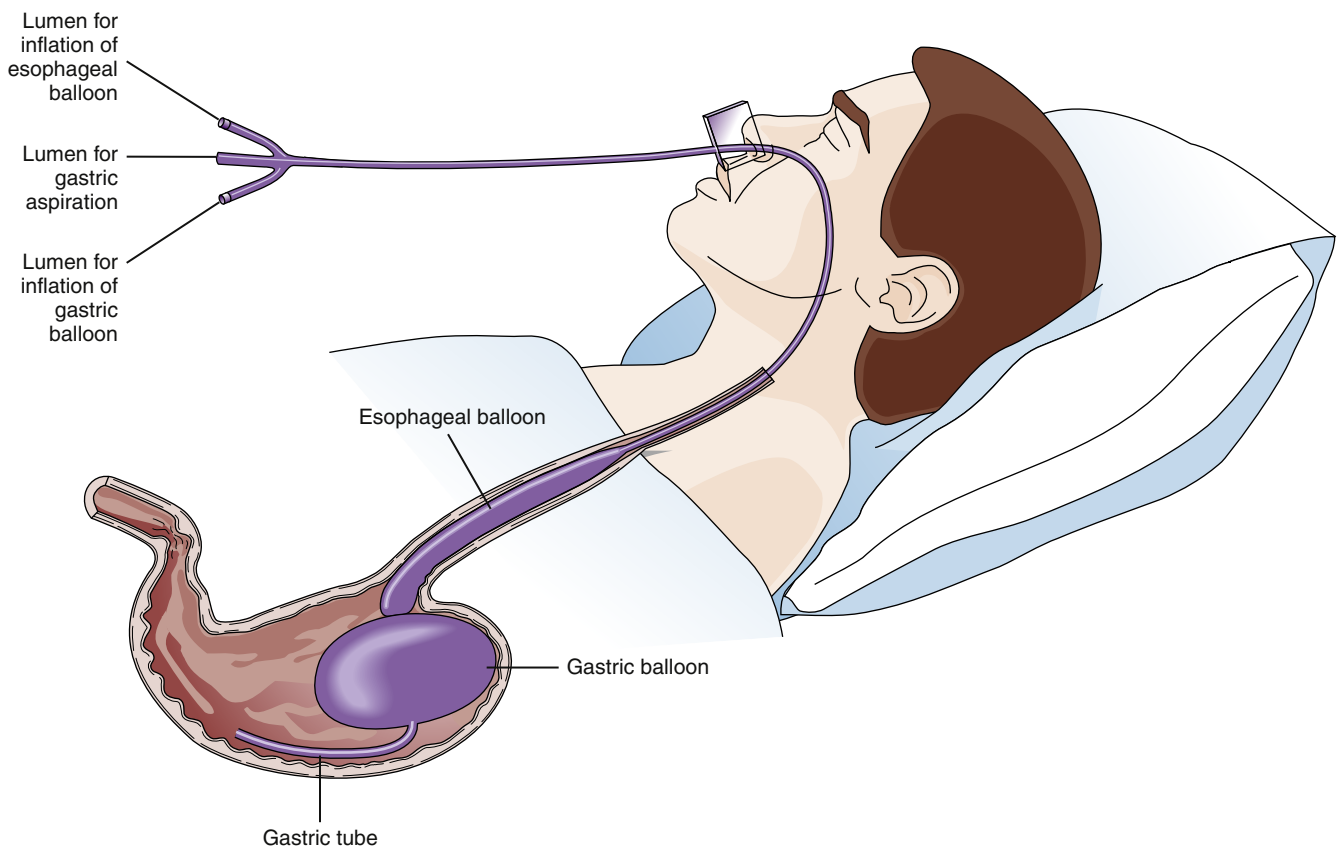

FIGURE 38-9 Sengstaken-Blakemore tube.

FIGURE 38-10 Portosystemic shunt operations.

**Clinical manifestations.** Hepatic encephalopathy is usually precipitated by certain well-defined clinical developments, including hypokalemia, hyponatremia, alkalosis, hypoxia, hypercarbia, infection, use of sedatives, GI hemorrhage, protein meal gorging, renal failure, and constipation. In some patients, progressive liver failure leads to chronic encephalopathy without other exacerbating factors.

Hepatic encephalopathy is graded 1 to 4:

**Grade 1:** Confusion, subtle behavioral changes, no flap

**Grade 2:** Drowsy, clear behavioral changes, flap present

**Grade 3:** Stuporous but can follow commands, marked confusion, slurred speech, flap present

**Grade 4:** Coma, no flap

**Treatment.** The first step in treatment of hepatic encephalopathy consists of correcting any identifiable precipitating factors, such as gastrointestinal bleeding. Restriction of dietary protein to 60 g or less daily is indicated for patients with chronic encephalopathy, along with enhanced elimination of the toxic nitrogenous substances produced by intestinal digestion (see following paragraph). Critically ill patients should receive peripheral or central glucose infusions along with vitamins, especially thiamine. As the patient's ammonia levels drop, protein may be reintroduced into the diet. The initial amount of 20 g/day is increased by 10 or 20 g/day every few days to an ultimate 0.75 to 1.0 g of protein per kilogram of body weight daily.<sup>13</sup> Observation for worsening encephalopathy is crucial at this time. When protein is restricted, it is essential to provide at least 400 g of carbohydrate daily.

Vegetable protein may be better tolerated than animal protein. High dietary fiber intake may help by decreasing constipation. If dietary measures fail, oral defined-formula feedings containing essential amino acids and enriched with branched-chain amino acids may be indicated.

Osmotic diuretics or antibiotics are used to enhance elimination of nitrogenous wastes. Lactulose is the standard osmotic cathartic and may be given orally or rectally by enema. (Standard precautions must be taken before any cathartic is administered, including ruling out bowel obstruction and monitoring electrolyte levels, particularly in patients with renal insufficiency.) Some evidence suggests that a lactulose-related change in pH also inhibits ammonia production by the gut flora, possibly by selecting for bacterial populations that are less ammoniagenic. No serious adverse reactions have been reported with lactulose therapy, although flatulence and abdominal cramping may occur. The dosage should be individually titrated so that two soft, acidic stools are passed daily.

Oral antibiotics have been used for many years to suppress the intestinal flora that break down dietary protein and release ammonia. Amoxicillin and rifaximin are currently used for this purpose. Bacterial overgrowth is one of the complications that limit the long-term use of antibiotics; therefore, this treatment is reserved for persons who cannot tolerate lactulose. Neomycin, the first antibiotic widely used in hepatic encephalopathy, is no longer recommended because of side effects.<sup>1</sup>

## Cerebral Edema

**Pathogenesis.** Swelling of the brain (cerebral edema) often develops in patients with grade 3 or 4 hepatic encephalopathy and results in an increase in intracranial pressure. Both vascular and toxic mechanisms have been implicated as etiologic factors. With increasing intracranial pressure, blood perfusion of the brain is decreased (cerebral perfusion pressure = carotid artery pressure – intracranial pressure) with resulting cerebral hypoxia. Cerebral edema is a major cause of death in patients with acute hepatic failure.<sup>1</sup>

**Clinical manifestations.** Clinically, cerebral edema is suggested by deepening coma, systolic hypertension, and extensor rigidity (decerebrate posture), followed by pupillary dilation and, if brainstem herniation occurs, respiratory arrest. Some highly specialized referral centers monitor patients with advanced hepatic encephalopathy by extradural pressure monitors to permit early detection. Unfortunately, complications of extradural monitors occur up to 20% of the time and include infection and intracranial bleeding.<sup>1</sup>

**Treatment.** Cerebral edema is managed primarily by the intravenous infusion of mannitol, which by increasing serum osmolarity draws water from the brain and thus reduces the swelling. Patients should be kept in the semi-Fowler position (head and trunk elevated 30 degrees). The barbiturate sodium pentothal is used as a second-line agent for patients with recalcitrant intracranial hypertension and those who cannot tolerate the fluid volume component of mannitol therapy (e.g., those in heart or kidney failure). Moderate hypothermia with the use of cooling blankets has looked promising in preliminary trials as well.<sup>14</sup> Aggressive treatment allows patient survival in 60% of cases, until liver failure resolves or liver transplantation can be accomplished.

## Complications of Advanced Liver Disease

### Ascites

**Etiology, pathogenesis, and clinical manifestations.** Ascites, or the pathologic accumulation of fluid in the peritoneal cavity, can occur in patients with advanced liver disease complicated by portal hypertension and hypoalbuminemia (Figure 38-11). Abdominal distention results from an inappropriate osmotic gradient across the pleura, with the intraabdominal accumulation of sodium, water, and protein.<sup>1,15</sup> Other causes of ascites are malignancy, infection, pancreatitis, hypothyroidism, vasculitis, nephrosis, cardiac failure, constrictive pericarditis, Budd-Chiari syndrome, and portal vein thrombosis. The specific chemical and cellular composition of the ascites varies with its cause.

Abdominal paracentesis should be performed in all patients with new ascites and in those with known ascites who have experienced significant worsening of their condition.<sup>1</sup> The fluid should be examined for total protein level, albumin level, and cell count. Optional tests include culture for bacteria, fungi, and mycobacteria; cytologic studies; and measurement of amylase, glucose, and lactate dehydrogenase levels. A small amount of ascites may not require specific therapy. However, with increasing volumes, abdominal discomfort, abdominal or umbilical herniation, respiratory embarrassment, or infection may occur.

**Treatment.** Dietary sodium should be restricted to 88 mEq (2000 mg) per day in patients with ascites. In motivated patients, this is perhaps the most helpful intervention that can be undertaken. Bed rest is useful, although strict bed rest can result in decubitus ulcers, deconditioning, and other problems. Diuretics are necessary for the majority of patients. The aldosterone antagonist spironolactone works in the distal nephron as a weak diuretic that also inhibits potassium secretion, thus sparing serum potassium. A delay of 2 to 3 days may occur before the full effect of the drug is seen, and the dosage should not be increased more frequently. Many authorities suggest adding a loop diuretic such as furosemide from the beginning and increasing

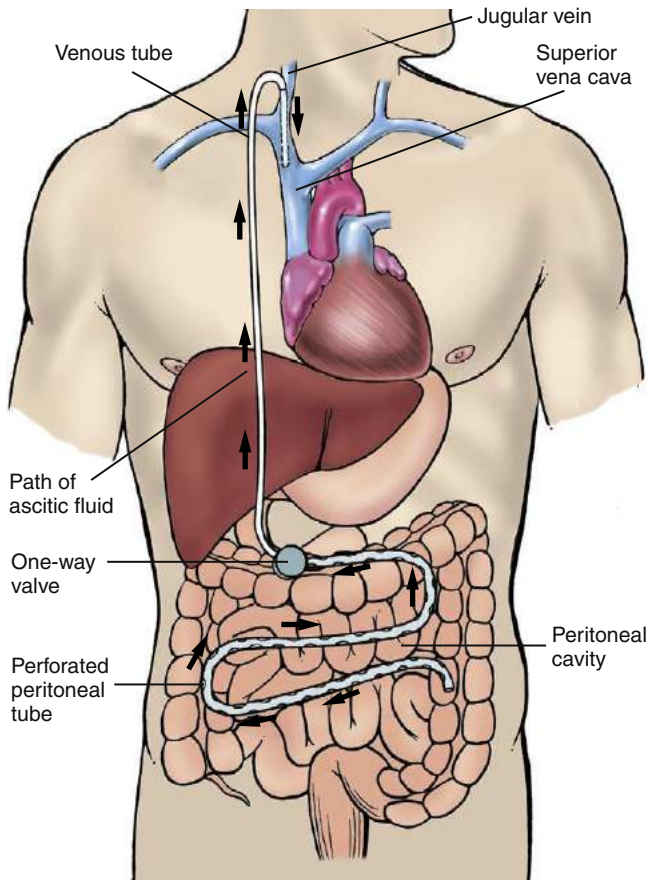

**FIGURE 38-11** Pathophysiologic process of ascites. (Redrawn from Dudley FJ: Pathophysiology of ascites formation, *Gastroenterol Clin North Am* 21:215-235, 1992.)

the dose at a ratio of 4:10 with spironolactone.<sup>1</sup> It is helpful to monitor both urinary sodium and potassium levels periodically. When the urinary sodium level exceeds the urinary potassium level, spironolactone is exerting its maximal effect. Serum potassium levels must be carefully controlled.

The goal is the loss of approximately 0.5 kg of body weight daily, although in patients with peripheral edema, slightly more rapid weight loss is tolerable. More rapid losses may result in diuretic-induced renal impairment, intravascular volume depletion and severe electrolyte abnormalities, and hepatic encephalopathy. Diuresis should be continued until the ascites is barely detectable. Free water restriction is prescribed if hyponatremia is present or develops during treatment, although compliance with a strict regimen is unlikely.

In patients who do not respond to both diuretic therapy and sodium restriction, the use of 25% albumin infusions may help initiate diuresis. However, the effect of this treatment is often short lived and not without a risk of overexpansion of the intravascular volume, with congestive heart failure, pulmonary edema, and precipitation of variceal hemorrhage all possible. Alternatively, large volumes of ascitic fluid can be removed from the peritoneal space through paracentesis. This “large-volume therapeutic paracentesis” is a very rapid and effective treatment that can be safely instituted if the intravascular volume is maintained by appropriate measures.<sup>1</sup> Diuretic and dietary treatment should be continued, but in severe cases, large-volume paracentesis may be repeated as needed.

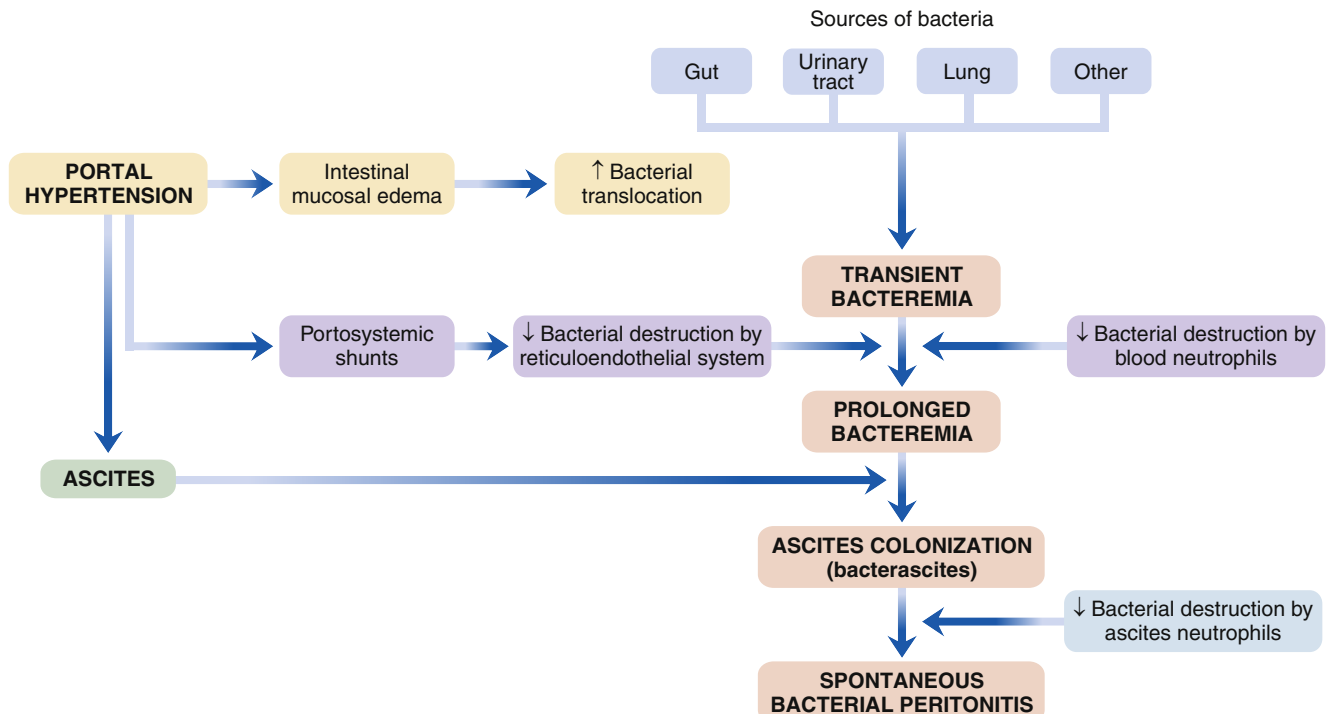

**FIGURE 38-12** LeVein shunt. Arrows show direction of flow of ascitic fluid out of the peritoneal cavity, through the shunt, into the superior vena cava. (From Monahan FD, Neighbors M: *Medical-surgical nursing: foundations for clinical practice*, ed 2, Philadelphia, 1998, Saunders, p 1146.)

Shunting procedures such as the LeVein (Figure 38-12) and Denver shunts have been used. These one-way valves connect the peritoneal space with the venous system, usually at the jugular vein. These shunting procedures, although useful, carry significant risks and are best reserved for a small subset of ascites patients who have refractory ascites and are not candidates for liver transplantation.<sup>1</sup> The use of transjugular intrahepatic portosystemic stenting (TIPS) has largely replaced traditional surgical procedures for treatment of refractory ascites (see earlier discussion). Diuretic-resistant ascites is also an indication for liver transplantation in the patient who meets other criteria.

### Spontaneous Bacterial Peritonitis

**Pathogenesis and clinical manifestations.** Patients with cirrhosis and ascites suffer from a variety of defects in host defense that predispose to infection in the peritoneal cavity. This observation is especially true in patients who have ascites with a low protein concentration. These defects include diminished opsonic activity of the ascitic fluid, diminished reticuloendothelial function, and transmigration of gut bacteria across the intestinal wall and into the ascites.<sup>1</sup> Chronic alcoholics demonstrate abnormal white blood cell function as well (Figure 38-13).

Typically, patients with spontaneous bacterial peritonitis (SBP) have a single infecting organism of gut origin in the fluid. This pattern is in marked distinction to patients with secondary infection of the ascites, as may occur after traumatic gut perforation, for instance, in which a polymicrobial infection is typical. The onset of spontaneous bacterial peritonitis may be subtle, with only mild abdominal discomfort or general clinical deterioration, including worsening hepatic encephalopathy, renal failure, or a nonspecific “septic” picture. Significant fever may be lacking. The most important diagnostic study is abdominal paracentesis. An ascitic polymorphonuclear leukocyte count greater than  $250/\text{cm}^3$  suggests the diagnosis, although it should be noted that a low count does not rule out the diagnosis, and bacterial culture remains the gold standard.

**FIGURE 38-13** Pathophysiologic process of spontaneous bacterial peritonitis. (Redrawn from Garcia-Tsao G: Spontaneous bacterial peritonitis, *Gastroenterol Clin North Am* 21:257-275, 1992.)

**Treatment.** Antimicrobial therapy should be initiated promptly in suspected cases of spontaneous bacterial peritonitis pending culture results. Third-generation cephalosporins and quinolone antibiotics are effective empirical therapy. Use of long-term oral antibiotics for prophylaxis in at-risk patients with cirrhosis is controversial but may be considered for selected patients. Use of a narrow-spectrum agent such as trimethoprim-sulfamethoxazole therapy is preferable to agents of the quinolone class.<sup>1</sup> Overall, the occurrence of spontaneous bacterial peritonitis is a poor prognostic sign, because it is typically associated with end-stage liver disease.

### Hepatorenal Syndrome

**Etiology and pathogenesis.** Patients with liver failure may experience acute kidney failure with rising serum creatinine levels and oliguria. The kidney itself is normal, but intrarenal blood flow is seriously disturbed. This disturbance in blood flow appears to be due to an imbalance between vasoconstricting and vasodilating mechanisms related to the liver disease.<sup>1,16</sup> The course is usually acute and progressive, but chronic cases are occasionally seen. Differentiation from reversible causes of renal failure is essential. Hepatorenal syndrome may be precipitated by overly vigorous diuretic therapy or paracentesis, severe diarrhea, nonsteroidal antiinflammatory drugs, variceal bleeding, and sepsis.

**Prognosis and treatment.** The prognosis depends on the severity of the liver disease and is generally poor.<sup>17</sup> Treatment is primarily preventive and supportive; hemodialysis should be considered only as a bridge to definitive therapy. Fortunately, liver transplantation generally results in return of normal renal function, providing no undue delay has occurred.

#### KEY POINTS

- The liver is a vital, multifunctional organ located in the right upper quadrant beneath the diaphragm. Blood is supplied to the liver by the hepatic artery and the portal vein. The portal vein drains the capillaries of the alimentary canal and pancreas. Arterial and portal blood flows into the hepatic sinusoids, which have direct contact with hepatic cells.
- The functions of the liver are multiple and include metabolism of fats, proteins, and glucose; synthesis and secretion of bile salts; storage of vitamins and minerals; metabolism and detoxification of endogenous and exogenous substances; and synthesis of urea.
- Manifestations of liver disease are attributable to hepatocellular failure and portal hypertension. Jaundice, decreased levels of clotting factors, hypoalbuminemia, decreased levels of vitamins D and K, and feminization are attributed to hepatocellular failure. Portal hypertension may result in GI congestion with the development of esophageal or gastric varices, hemorrhoids, splenomegaly, and ascites. Bleeding from varices is often massive and life threatening; various pharmacologic, endoscopic, and surgical treatments are now available.
- Symptoms of hepatic encephalopathy range from confusion and lethargy to coma. A spastic flapping tremor of the hands, called asterixis, is a classic finding. The severity of the encephalopathy correlates positively with serum ammonia levels. Encephalopathy may be precipitated by conditions that increase protein metabolism, such as GI hemorrhage and increased protein consumption, and by conditions that further impair hepatocyte function. Treatment may include restriction of protein intake, administration of antibiotics to reduce ammonia production by intestinal organisms, and utilization of lactulose to enhance ammonia excretion in the stool. Cerebral edema is a common cause of death in patients in deep hepatic coma.

- Ascites is a pathologic accumulation of fluid in the peritoneal cavity. It occurs commonly in liver disease because of the increased fluid transudation that occurs with portal hypertension and hypoalbuminemia. In severe ascites, treatment may be instituted to ameliorate pain and respiratory difficulty. Sodium restriction, diuretics, and intermittent paracentesis are commonly prescribed. Surgical shunting procedures that allow accumulated peritoneal fluid to flow back into the circulation through a one-way valve may be effective.
- Spontaneous bacterial peritonitis is infection of ascites by a single organism unrelated to bowel perforation or surgical procedures. Antibiotic therapy alone is usually curative.
- Hepatorenal syndrome is a type of functional renal failure caused by severe liver disease. The prognosis is poor and is contingent on the outcome of the liver disease.

## DISORDERS OF THE LIVER

### HEPATITIS

#### Acute Viral Hepatitis

Hepatitis is inflammation of the liver parenchyma. Acute hepatitis may be caused by many viruses, among them cytomegalovirus and Epstein-Barr virus. However, the term viral hepatitis is usually applied to illnesses caused by hepatitis A, hepatitis B, and hepatitis C viruses (Table 38-4). A fourth virus, known as the delta agent, is a defective RNA virus that requires the helper function of hepatitis B virus and so occurs only as a coinfection with that agent. Hepatitis E virus is a recently described agent common mainly in developing countries.

Despite variation in the symptoms, signs, and epidemiologic progression of these diseases, it is often clinically impossible to differentiate them in a given patient without appropriate serologic tests (Figure 38-14) (see Table 38-2).

#### Hepatitis A

**Pathogenesis and clinical manifestations.** Hepatitis A virus (HAV) is an RNA virus that is usually spread by the fecal-oral route. The infection has a 2- to 7-week incubation period (see Figure 38-14). The illness may be asymptomatic or mildly symptomatic without jaundice (anicteric); the latter occurs especially in children, with the patient exhibiting nonspecific GI symptoms. The majority of adults develop hepatitis with jaundice. The prodromal symptoms of icteric hepatitis consist of malaise, anorexia, nausea, low-grade fever, and right upper quadrant pain. This is followed by jaundice lasting 2 weeks on average. The clinical course is generally self-limited, although fulminant and fatal attacks occur rarely, particularly in patients with preexisting chronic active hepatitis B or C infection. Two uncommon prolonged syndromes are recognized: prolonged cholestasis and relapsing hepatitis.<sup>1</sup>

**Diagnosis, treatment, and prevention.** HAV infection is diagnosed through serologic testing. The presence of anti-HAV immunoglobulin G (IgG) indicates previous infection, and the presence of immunoglobulin M (IgM) indicates acute infection. The test is highly reliable within several weeks of exposure.

Treatment does not change the course of acute HAV infection. Supportive management includes rest and a nutritious diet. Alcohol, acetaminophen, and other potential hepatotoxins should be avoided. HAV is a common infection control concern, particularly in the community setting. The usual fecal-oral precautions, such as careful hand washing, segregation, and cleaning of laundry and personal items, should be undertaken by patients and contacts.

TABLE 38-4 COMPARISON OF HEPATITIS VIRUSES

VIRUS	HEPATITIS A	HEPATITIS B	HEPATITIS C	HEPATITIS D	HEPATITIS E
Type of virus	ssRNA	Partially dsDNA	ssRNA	Circular defective ssRNA	ssRNA
Viral family	Hepatovirus; related to picornavirus	Hepadnavirus	Flaviviridae	Subviral particle in Deltaviridae family	Calicivirus
Route of transmission	Fecal-oral (contaminated food or water)	Parenteral, sexual contact, perinatal	Parenteral; intranasal cocaine use is a risk factor	Parenteral	Fecal-oral
Mean incubation period	2-4 weeks	1-4 months	7-8 weeks	Same as HBV	4-5 weeks
Frequency of chronic liver disease	Never	10%	≈80%	5% (coinfection); ≤70% for superinfection	Never
Diagnosis	Detection of serum IgM antibodies	Detection of HBsAg or antibody to HBcAg	PCR for HCV RNA; third-generation ELISA for antibody detection	Detection of IgM and IgG antibodies; HDV RNA serum; HDAG in liver	PCR for HEV RNA; detection of serum IgM and IgG antibodies

From Washington K: Inflammatory and infectious diseases of the liver. In Kumar V et al, editors: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 640.

dsDNA, Double-stranded DNA; ELISA, enzyme-linked immunosorbent assay; HBcAg, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; HDAG, hepatitis D antigen; HDV, hepatitis D virus; HEV, hepatitis E virus; PCR, polymerase chain reaction; ssRNA, single-stranded RNA.

Active immunization is indicated for risk groups (e.g., foreign travelers, persons with chronic active hepatitis B or C, persons in institutions) using an inactivated whole-virus vaccine that is highly immunogenic and effective in preventing acute hepatitis A.<sup>18</sup> An intramuscular dose is followed by a booster 6 to 12 months later, providing lifelong immunity in at least 98% of recipients.<sup>19</sup> The vaccine is ideally administered at least 2 weeks preexposure (e.g., before travel to a developing country) but can also be administered in the setting of a community outbreak. It is effective even among persons with advanced chronic liver disease. Hepatitis A vaccination was added to the routine childhood vaccination schedule by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) in 2006.

Patients exposed to HAV who are anti-HAV antibody negative should receive passive immunization with pooled human immunoglobulin, in addition to active vaccination. An intramuscular dose should be given within 2 weeks of exposure. Passive immunity lasts 4 to 6 months and does not diminish vaccine effectiveness. However, subclinical or symptomatic but attenuated infections may develop in some exposed patients.

## Hepatitis B

**Pathogenesis and clinical manifestations.** Hepatitis B virus (HBV) is a partially double-stranded DNA virus that is highly prevalent worldwide. Probably 300 million persons, or 5% of the world population, have chronic HBV infection. Chronic infection in the United States affects approximately 1 to 1.25 million people, most of them immigrants from endemic countries. In contrast to HAV, HBV is spread by parenteral contact with infected blood or blood products, including contaminated needles, and by sexual contact. Perinatal infection is a major route in endemic (mainly developing) countries. Other risk factors for HBV infection include working in a health care setting (3% of cases in the United States), undergoing transfusions and dialysis (1% each), having acupuncture treatments, tattooing, traveling for extended time overseas, and residing in an institution.<sup>1</sup>

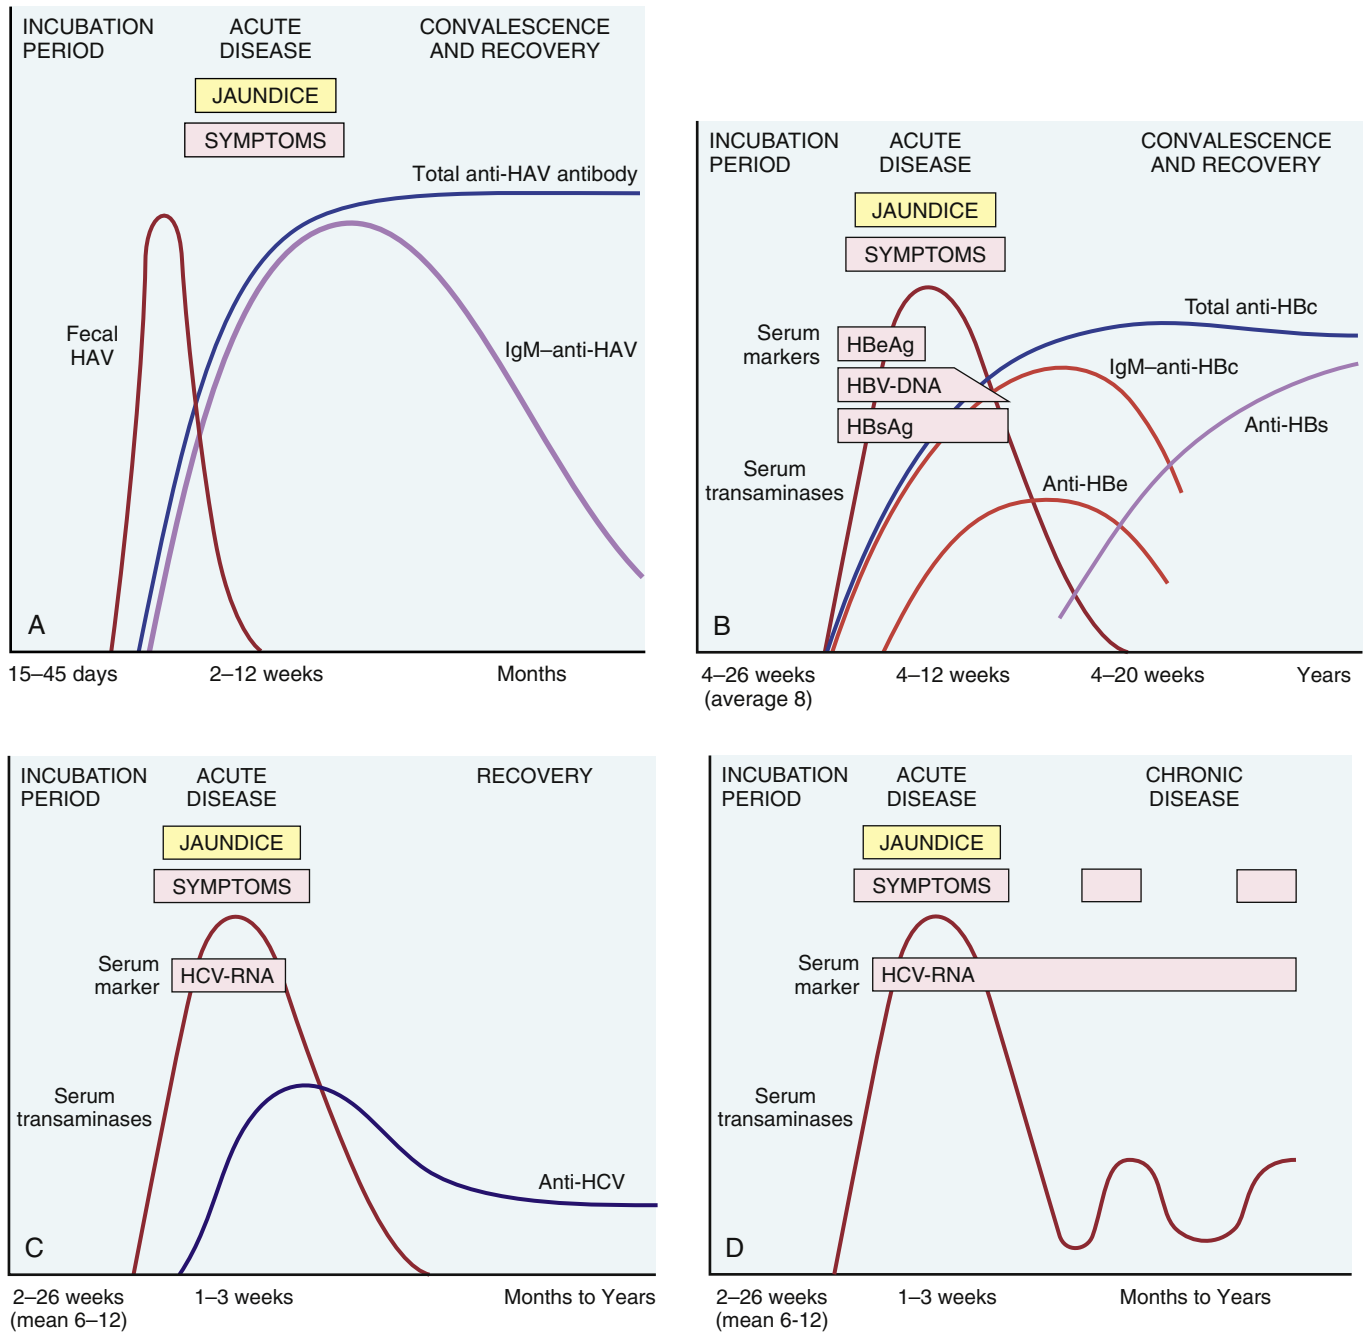

HBV has an incubation period of 2 to 6 months. The prodrome of HBV infection is often longer and more insidious than that of HAV infection and may involve a variety of immune complex-related phenomena, including urticarial (i.e., hives) and other rashes, arthralgia

and arthritis, angioedema, serum sickness, and glomerulonephritis. Severity of illness ranges from no symptoms to moderate illness to fulminant hepatitis (1% of cases). The jaundice phase for most HBV infections is similar in degree and duration to that of HAV infections, although serious extrahepatic illness occurs more frequently.

**Diagnosis.** The serologic diagnosis is somewhat complicated (see Figure 38-14). A typical screening panel for HBV infection includes surface antigen (HBsAg), surface antibody (HBsAb), core antigen (HBcAg), and core antibody (HBcAb). In brief, with acute infection HBV core antigen (HBcAg) appears first, followed by seroconversion to core antibody (HBcAb). Presence of HBV surface antigen (HBsAg) shows up early and may persist, indicating active infection; development of surface antibody (HBsAb) points to resolution and immunity. (It should be noted that conversion from surface antigen to surface antibody positivity can take as long as 1 year after acute infection, so treatment should not be considered immediately after infection.) In chronic infection, hepatitis B e antigen (HBeAg) is associated with viral replication and infectivity, whereas hepatitis B e antibody (HBeAb) indicates minimal replication and infective potential.

Chronic infection is indicated by HBsAg positivity. There are two important features of chronic infection: ongoing liver inflammation and active viral replication. Liver damage may be deduced from persistently elevated levels of liver enzymes and confirmed by liver biopsy. Viral replication can be measured by molecular testing (HBV DNA by quantitative polymerase chain reaction) and is associated with a positive HBeAg. Persons who have a detectable virus and are HBeAg positive can readily transmit the virus to their contacts, and should be counseled regarding appropriate sexual and blood exposure precautions (including no blood donation). Patients with chronic HBV and cirrhosis are at risk for development of hepatocellular carcinoma (HCC), and periodic screening (e.g., at 6- to 12-month intervals) with ultrasound and  $\alpha$ -fetoprotein determinations is recommended. Screening for other blood-borne pathogens such as human immunodeficiency virus (HIV) and hepatitis C virus (HCV) is recommended.

**Treatment.** Fulminant hepatitis is a life-threatening illness with high mortality. Care for patients with acute hepatitis is largely supportive, and those with fulminant hepatitis may require aggressive treatment for coagulopathy, encephalopathy, cerebral edema, and other manifestations. Liver transplantation is the only definitive treatment

**FIGURE 38-14** Comparison of clinical course and serologic tests in viral hepatitis. **A**, Hepatitis A only occurs in an acute form. **B**, The acute phase of hepatitis B—a small number of patients may not clear the virus during this stage and become chronic carriers. **C**, Acute hepatitis C is often not diagnosed because the symptoms tend to be mild. **D**, Most patients with hepatitis C infection are unable to clear the virus and develop chronic hepatitis C. (From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, pp 641, 642, 644.)

for progressive liver failure in acute hepatitis. Most nonfulminant HBV infections resolve spontaneously, although about 5% of acute hepatitis cases progress to chronic infection. Management of acute HBV infection is similar to that of HAV infection in terms of supportive care.

Management of chronic HBV infection has advanced dramatically over the last decade.<sup>20-22</sup> Endpoints are defined as elimination of hepatitis B DNA from the blood and conversion from E antigen positivity to E antibody positivity. Currently available therapies are interferon- $\alpha$ , lamivudine, adefovir, entecavir, tenofovir, and telbivudine. Interferon- $\alpha$

was the first effective treatment available and may be given daily or weekly (in the pegylated form) for 24 to 48 weeks with a response rate of about 33%. A significant proportion of patients experience a flare-up of acute hepatitis, and therefore this treatment cannot be used for patients with advanced liver disease (e.g., cirrhosis) or significant comorbidities. Lamivudine, emtricitabine, adefovir, entecavir, tenofovir, and telbivudine are oral nucleoside analogues that are generally given for several years. Lamivudine has the advantage of being significantly cheaper than the other options and is safe during pregnancy, but increasing

drug resistance limits its role as primary therapy. Entecavir is the treatment of choice for most patients, with a response rate of about 67% and E antibody seroconversion rate of 21%. It can be used in patients with cirrhosis as well. The drawback is the cost, because the treatment is extremely expensive (\$20 to \$25 per day). Telbivudine has a higher durable response rate, but it cannot be used for lamivudine-resistant strains of HBV. Adefovir has significant nephrotoxicity, and its use is reserved for patients with resistant strains, though tenofovir has greater activity and has generally supplanted adefovir in such cases.

Treatment of patients coinfecting with HIV is more complicated. Early treatment of HIV with an appropriate antiretroviral agent should include one or more of the nucleoside analogues noted previously (i.e., tenofovir, lamivudine, emtricitabine) that has activity against both agents. If HIV treatment is not deemed necessary at the time HBV treatment is begun, adefovir or pegylated interferon can be used, because these will not induce HIV resistance.

Patients with chronic active hepatitis B infection are at risk for fulminant hepatitis with a superimposed hepatitis A infection and should be vaccinated against hepatitis A using the killed, two-dose vaccine. They are also at risk for fulminant hepatitis or more rapid progression of liver disease if they contract hepatitis D virus (see Hepatitis D [Delta] section), so they should avoid risk factors for this virus such as injection drug use and unprotected sex.

**Prevention.** HBV vaccine is a recombinant vaccine that is highly immunogenic with no material of human origin. (Thus, there is no risk of transmission of other agents such as HIV.) Adults are vaccinated intramuscularly with three doses of HBV vaccine given at birth and at 1 and 6 months of age. Simultaneous administration of hepatitis B immunoglobulin (HBIG) and other vaccines has no effect on efficacy. After the full course, the antibody response rate is 95% for normal hosts.<sup>1</sup> The response rate is slightly lower in obese individuals, smokers, and men, and significantly lower in patients with cirrhosis or chronic renal failure, organ transplant recipients, children with celiac disease, and immunosuppressed patients. The effect of vaccination is considered long-lasting, and booster shots are not required. Postvaccination testing is not recommended but could be considered for certain high-risk groups (e.g., sexual partners of chronic carriers).

Universal immunization is indicated for neonates in this country and has been suggested for individuals of any age, but especially for the following high-risk groups: sexually active individuals with multiple sex partners, male homosexuals, users of illicit drugs, household contacts of HBV carriers, hemodialysis patients, residents of institutions, health care workers, patients needing frequent transfusions, and individuals planning to reside in high-risk areas (e.g., the Far East and sub-Saharan Africa).<sup>18</sup> If exposed to HBV, a susceptible person should receive one dose of HBIG and HBV vaccine as soon as possible after exposure and then complete the vaccination program. The issue of how to deal with persistent nonresponders, especially health care workers, is unsettled, but most authorities recommend a full three-injection course according to the usual schedule.<sup>23-26</sup>

The administration of immunoglobulin containing high levels of hepatitis B surface antibody (HBIG) affords effective postinoculation prophylaxis if given within 7 days of exposure. The indications for HBIG are as follows: (1) neonates born to HBsAg-positive mothers; (2) prophylaxis after needlestick or sexual exposure in nonimmune persons; and (3) after liver transplantation in patients who are HBsAg positive before transplantation.<sup>1,37</sup> The usual dose is 0.05 to 0.07 ml/kg given intramuscularly, with the same dose repeated 25 to 30 days later. (See Foster and colleagues for dosing recommendations for perinatal vaccination.<sup>37</sup>) The immune status of the recipient may be determined before treatment to avoid unnecessary administration. HBV vaccine should be given concomitantly with HBIG in most cases.

## Hepatitis C

**Pathogenesis and clinical manifestations.** Hepatitis C virus (HCV; previously categorized as non-A, non-B hepatitis virus) is a single-stranded RNA virus that belongs to the Flaviviridae family. Our knowledge of HCV is evolving rapidly but has lagged behind that of HAV and HBV for two important reasons: lack of a suitable cell line for replication in the laboratory and an extremely high mutation rate. Worldwide about 3% of the population is chronically infected, with a somewhat lower rate in the United States. The mode of transmission of HCV closely resembles that of HBV, although sexual and perinatal transmission is much less likely. The main pool of infected U.S. individuals acquired HCV through intravenous drug use or blood transfusions before the availability of the screening test in 1990. HCV remains an important occupational risk for health care workers, with the risk after a single needlestick being about 3%, as opposed to 30% for HBV or 0.3% for HIV. A significant number of seropositive persons have no known risk factors for HCV.

Acute HCV infection is usually asymptomatic. Clinical illness, when it occurs, is usually mild, with transaminase levels rarely exceeding 1000 IU/L. Only a minority of acute infections resolve, with the remainder progressing to chronic active infection (see Figure 38-14). The course is erratic, with wide fluctuations in the concentrations of liver enzymes (primarily ALT). A number of extrahepatic manifestations occur, the most prominent of which are a medium-vessel vasculitis (polyarteritis nodosa), essential mixed cryoglobulinemia, and membranoproliferative glomerulonephritis.<sup>1</sup> Chronic infection seems to progress to significant liver disease about 20% of the time, although there are no reliable noninvasive ways to predict who will progress. HCV infection is currently one of the most common causes of end-stage liver disease with cirrhosis in the United States. If untreated, as with hepatitis B, chronic active HCV infection with cirrhosis predisposes to HCC. Of the six recognized serotypes, type 1 is most common in the United States but has a lower response rate to treatment. Types 2 and 3 are also common in the North America, whereas types 4 to 6 predominate overseas.

As with hepatitis B, screening for other blood-borne pathogens including HIV and HBV is recommended.

**Treatment.** Management of acute HCV infection is the same as for other acute viral strains (i.e., supportive and expectant unless complications or subacute hepatic failure develops). Treatment of acute HCV infection with antiviral agents is not currently recommended, and immunoglobulin is not helpful in preventing infection in the acute exposure setting. Between 20% and 40% of acute seropositive patients will convert to seronegativity and an undetectable viral load during the first 6 months after infection, so early treatment is not recommended. Chronic infections should be assessed by determination of viral load and viral genotype, and a liver biopsy to stage disease activity should be considered for those with a type 1 virus.<sup>1</sup>

The current standard of treatment for chronic HCV infection depends on virus type. Treatment of type 1 consists of pegylated interferon- $\alpha$ , given intramuscularly once weekly, and ribavirin orally twice daily. Treatment of acute HCV infection with antiviral agents is recommended two times daily.<sup>1,24</sup> Since the advent of effective protease inhibitor therapy the response rate for type 1 virus has improved from 45% to as much as 80%.<sup>25,26</sup> Important factors influencing a sustained virologic response include baseline viral load (i.e., a viral load greater than 800,000 copies per milliliter indicates a poorer response) and presence of the TT genotype of the *IL28B* gene. The latter is much more common among African Americans (and to a lesser extent Hispanics) than other ethnic groups and likely accounts for a significantly poorer response rate among these groups.<sup>27</sup>

For the less common types 2 and 3, the response rate is 85%. Side effects of interferon-based therapy are significant and include

cytopenias, malaise, and flulike symptoms, as well as induction or aggravation of depression and anxiety. In fact, in many patients the latter side effects are severe and have resulted in suicides. About 5% to 10% of recipients drop out of treatment because of side effects. The expense is considerable—from \$10,000 to \$50,000 for a treatment course. Treatment for type 1 virus lasts 48 weeks, and for other types 24 weeks. New treatments for HCV infection are currently a burgeoning area of research.

Patients with chronic active hepatitis C infection should be vaccinated against hepatitis A and hepatitis B and counseled regarding blood-borne precautions. Because the issue of sexual transmission is unsettled, the Centers for Disease Control and Prevention does not currently recommend barrier methods for patients with long-term sexual partners because of the apparent low risk of infection.

Coinfection with HIV significantly complicates the treatment of both conditions. Optimal treatment of HIV is recommended, along with standard therapies for hepatitis C as discussed previously. Treatment responses are similar, though side effects and drug interactions are significant. Use of the newer anti-HCV protease inhibitors boceprevir and telaprevir has not been well studied in coinfecting patients.

### Hepatitis D (Delta)

**Pathogenesis and clinical manifestations.** Hepatitis D virus (HDV) is an incomplete viral organism that requires the presence of HBV for replication. It may occur coincident with or subsequent to initial infection with hepatitis B. The disease is primarily transmitted by parenteral routes and by intimate personal contact, like hepatitis B.<sup>1</sup> In the United States and northern Europe, HDV infection is most prevalent in persons exposed to blood and blood products (e.g., drug addicts and hemophiliacs). HDV infection tends to accelerate the progress of liver disease associated with HBV infection. In fact, fulminant hepatitis may result from HDV infection superimposed on chronic HBV infection. Because HDV is a deficient virus, its persistence is determined by the duration of the HBV infection. Diagnosis is by anti-HDV IgM and IgG enzyme-linked immunosorbent assays (ELISAs).

**Treatment and control.** HDV infection is controlled through the same measures used to prevent transmission of other hepatitis viruses: following safe sexual practices, screening blood products, avoiding intravenous drug use, and vaccinating susceptible persons with the HBV vaccine. There is no specific vaccine or treatment for HDV.

### Hepatitis E

**Pathogenesis and clinical manifestations.** Hepatitis E virus (HEV) is one of the most common causes of acute hepatitis in developing countries. Cases in developed countries are usually related to recent travel. HEV is an RNA virus spread via the fecal-oral route, especially through contaminated water. Parenteral transmission may occur.

The incubation period is 2 to 9 weeks. The prodrome and icteric illnesses are similar to those of HAV infection but usually last only 2 weeks. It is assumed that many subclinical cases occur, but in the absence of widely available serologic testing, subclinical infection is difficult to determine. Fulminant hepatic failure may occur, especially in pregnant women (see the Liver Diseases and Pediatric Considerations section).

**Treatment.** Treatment is supportive. Because no vaccine is available, the only prophylaxis is avoiding undercooked foods, performing careful hand washing, and drinking safe water and beverages (i.e., canned, bottled, or purified through the usual means). The antiviral drug ribavirin has been studied as a potentially effective treatment but is not currently recommended.

## Chronic Hepatitis

**Chronic hepatitis** encompasses a group of diseases characterized by inflammation of the liver that lasts 6 months or longer. The most prominent of these conditions is chronic active viral hepatitis, but chronic hepatitis may be due to toxic, autoimmune, or metabolic causes as well.

### Chronic Persistent Hepatitis

**Chronic persistent hepatitis**, often called triaditis or transaminitis, is an archaic term for a chronic, low-grade liver inflammation of any cause. The inflammation is confined to the portal triads without destruction of normal liver structures, but serum transaminase levels are elevated. The condition may be asymptomatic or may be associated with mild, nonspecific symptoms. Progressive liver disease does not usually develop, and no drug treatment is indicated. The illness has an excellent prognosis. However, other more serious liver diseases may pass through a phase that is histologically indistinguishable from chronic persistent hepatitis and may progress (e.g., chronic viral hepatitis).

Current classification schemes emphasize (1) etiologic factor, (2) histologic grade, and (3) stage in terms of fibrosis. Therefore, chronic persistent hepatitis would generally correspond to a liver condition with mild disease activity and minimal or no fibrosis by biopsy.

### Chronic Active Hepatitis

**Pathogenesis and clinical manifestations.** On the other hand, **chronic active hepatitis** is a progressive, destructive inflammatory disease that extends beyond the portal triad to the hepatic lobule (piecemeal necrosis). In current nomenclature, grade and stage span the spectrum from mild to severe. The natural history of chronic active hepatitis (CAH) is variable, since the disease could spontaneously arrest with any degree of fibrosis or could progress to cirrhosis and end-stage liver disease.

Symptoms typical of acute hepatitis are often seen, including fatigue, malaise, nausea, anorexia, ascites, hepatomegaly, abdominal pain, and jaundice.

Patients with chronic active hepatitis may be grouped into several categories based on etiology. First, as discussed earlier, a minority of newly infected HBV patients but a majority of those with HCV will progress to chronic active hepatitis. The second subgroup (mainly young women) manifests autoimmune hepatitis and exhibits a variety of immunologic markers, including antinuclear antibodies and anti-smooth muscle antibodies. In addition, these patients frequently suffer from a second autoimmune disease such as Hashimoto thyroiditis. In the third subgroup are patients with chronic hepatitis induced by alcohol or other toxins, including therapeutic agents such as minocycline or nitrofurantoin. In the fourth subgroup are patients with a metabolic liver disorder such as Wilson disease or hemochromatosis. A small number of patients have neither a suggestive history nor any detectable markers to suggest an etiology; advanced liver disease in this group is usually termed **cryptogenic cirrhosis**.

**Diagnosis.** The diagnosis of chronic hepatitis is made on the basis of the clinical setting and abnormal values for liver enzymes. Serologic studies are indicated to screen for viral hepatitis and autoimmune hepatitis. Serum iron and ferritin studies are performed to diagnose hemochromatosis, and a serum ceruloplasmin level is determined to screen for Wilson disease. A liver biopsy may be performed to confirm the diagnosis and to exclude other specific causes, if the etiology is not forthcoming. Biopsy also allows for grading and staging, as discussed earlier in the chapter.

**Management of chronic active hepatitis.** Treatment of CAH depends on the cause; management of HBV and HCV infection has

already been discussed. Managing toxic hepatitis involves discontinuing the offending drug, including alcohol. Specific antidotes or treatments are available for some of these conditions.<sup>1</sup> Specific treatments for Wilson disease and hemochromatosis are discussed later in the chapter in the Metal Storage Diseases section.

**Diagnosis.** Autoimmune hepatitis is characterized by the presence of several autoantibodies as well as a polyclonal hypergammaglobulinemia. Antinuclear antibody (ANA) is generally positive at a high level. Anti-smooth muscle antibodies (ASMAs) are a less sensitive indicator than ANA level but highly specific for autoimmune hepatitis. The finding of highly positive autoimmune markers in the presence of significant hepatitis, in the absence of other tests indicative of viral or metabolic liver disease, is pathognomonic for this condition. There is some overlap between conditions, however, and in questionable cases a liver biopsy is indicated.

**Management of autoimmune hepatitis.** Corticosteroids and immunosuppressive drugs have been used since the early 1960s for the management of autoimmune chronic active hepatitis. Their use is based on the assumption that immunologic mechanisms either cause or maintain ongoing hepatic inflammation. Corticosteroids alone or in combination clearly lower mortality in chronic active hepatitis, most noticeably in symptomatic patients and those with very severe pathologic lesions demonstrated on liver biopsy. Current guidelines recommend prednisone with azathioprine until a remission is induced (usually within 18 to 24 months, as indicated by significant improvement in liver function test results).<sup>28</sup> Subsequently, steroids can be tapered over 6 weeks or more, with azathioprine tapered more slowly; 65% to 80% of patients will respond to this initial regimen. Cyclosporine is another treatment option for nonresponders. Treatment with corticosteroids is generally accompanied by well-known complications: arterial hypertension and fluid retention, hypokalemia, glucose intolerance, mental status changes, cataracts, thinning of skin and bones, suppression of the adrenal gland, avascular necrosis of the joints, rounding of the face (moon facies), loss of muscle mass, and central adiposity, as well as increased risk for certain infections. Suddenly stopping long-term treatment with corticosteroids may result in acute adrenal insufficiency with hypotension and shock.

#### KEY POINTS

- Acute viral hepatitis is generally classified as hepatitis A, B, C, D (delta), and E infection. Modes of transmission and severity of symptoms differ among types.
- HAV infection is also known as enteric hepatitis because it is generally transmitted by ingestion of contaminated substances. Symptoms are flulike and tend to be less severe than those of HBV infection. Early treatment with  $\gamma$ -globulin and vaccination after exposure may be effective in preventing disease.
- HBV infection is also known as serum hepatitis because its usual route of transmission is through infected blood. The incubation period is longer and the severity of symptoms (particularly jaundice) is greater than in HAV infection. Hepatitis B immunoglobulin (HBIG) is effective after inoculation if given within 7 days of exposure. HBV vaccine is recommended as part of the childhood vaccination regimen and for high-risk individuals, and after exposure. Treatment is with intramuscular interferon- $\alpha$  for 6 to 12 months, or with one of several nucleoside analogues for 1 to several years.
- HCV, also known as non-A, non-B hepatitis virus, resembles HBV in its routes of transmission. Chronic HCV infection develops in 85% of cases and is usually asymptomatic until advanced liver disease intervenes. Immunoglobulin does not protect against HCV infection. Treatment is with intramuscular pegylated interferon and oral ribavirin for 6 to 12 months, with the addition of one of two recently approved protease inhibitors for type 1 virus.

- HDV coinfects with HBV and requires the presence of HBV to be active. Infection appears to accelerate and worsen HBV infection symptoms. Prevention of HBV infection also prevents HDV infection.
- HEV is a common virus in the developing world that causes an illness similar to HAV infection but has a relatively high mortality in pregnant women.
- Chronic hepatitis is characterized by persistent inflammation of the liver lasting 6 months or more. Autoimmune disease, viral hepatitis (B and C), toxins, and metabolic diseases may result in chronic hepatitis. Chronic active hepatitis may progress to cirrhosis. Corticosteroids (prednisone) and immunosuppressants (azathioprine) are common therapeutics for autoimmune hepatitis.

## CIRRHOSIS

**Cirrhosis** represents the irreversible end stage of many different hepatic injuries, including severe acute hepatitis, chronic hepatitis, the metal storage diseases, alcoholism, and toxic hepatitis. It is characterized by diffuse hepatic fibrosis surrounding nodules of liver tissue and results in permanent alteration in hepatic blood flow and liver function. The pathophysiology of cirrhosis and its complications have been reviewed earlier in this chapter. We will discuss briefly the sequelae of chronic biliary disease and alcoholic liver disease.

### Biliary Cirrhosis

**Etiology and pathogenesis.** **Biliary cirrhosis** represents the end result of continuous, ongoing inflammation of the bile ducts, which may be due to macroscopic or microscopic biliary obstruction. Persistent biliary obstruction results in inflammation and scarring of the liver, with obliteration of the bile ductules. The consequence is diffuse and widespread fibrosis with regenerative nodule formation (islands of healthy liver tissue within a background of fibrosis), and the consequences of portal hypertension described earlier. The prototypical form of microscopic biliary disease is **primary biliary cirrhosis (PBC)**, an autoimmune condition often associated with systemic lupus erythematosus and other autoimmune illnesses. It is usually associated with positive tests for ANA and antimitochondrial antibodies (AMAs).

Examples of large-duct obstruction include gallstone disease, chronic biliary fluke infestation, and primary sclerosing cholangitis (PSC). The biliary flukes endemic in Asia, *Opisthorchis* and *Clonorchis* species, are acquired by eating raw fish that carry larval cyst forms.<sup>29</sup> *Fasciola hepatica* is found in all sheep-producing and cattle-producing areas of the world and infects humans as accidental hosts; it is acquired by eating fecally contaminated watercress and other aquatic plants that harbor the immature cysts. Immigrants from infected areas may be at risk for these chronic infestations.

**Diagnosis and treatment.** The diagnosis of PBC depends upon appropriate serologic and liver biopsy results. Ursodeoxycholic acid (ursodiol, UDCA) is the only approved treatment for PBC and may delay development of end-stage liver disease. Methotrexate and colchicine are other therapies whose efficacy has yet to be elucidated in studies, but which may be added to UDCA in certain cases. Supportive care is similar to that for other conditions with impaired bile metabolism, including supplementation with fat-soluble vitamins. In spite of these measures, most patients will eventually require liver transplantation for prolonged survival.

The diagnosis of biliary flukes in immigrants and (less commonly) foreign travelers can usually be made by serial stool examinations for parasitic ova, and serologic testing is often helpful. Treatment with antiparasitic agents (praziquantel, mebendazole, or albendazole) will eliminate the live worms but will not necessarily prevent recurrent episodes of cholangitis and other consequences.

### Primary Sclerosing Cholangitis

**Etiology and pathogenesis.** Primary sclerosing cholangitis (PSC) is an autoimmune condition generally seen in patients with ulcerative colitis; 80% of PSC patients have coexistent ulcerative colitis, whereas 3% to 5% of ulcerative colitis patients develop PSC.<sup>1</sup> It is characterized by recurrent episodes of cholangitis, with progressive biliary scarring and obstruction. Secondary forms of sclerosing cholangitis, such as that following bile duct injury during surgery, behave in a similar fashion.

**Diagnosis and treatment.** A majority of patients with PSC will have a positive perinuclear antinuclear cytoplasmic antibody (p-ANCA) test, though this is not necessarily pathognomonic. Diagnosis is primarily by means of endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) showing the typical beaded and atrophic appearance of the biliary tree; liver biopsy is often performed for staging reasons. Although a variety of treatments have been investigated, medical and endoscopic treatments (for relief of strictures) are merely palliative, and the only effective recourse is liver transplantation.<sup>30</sup> The end result of recurrent cholangitis of any cause is cirrhosis, and such patients are predisposed to cholangiocarcinoma.

### Alcoholic Liver Disease

**Alcoholic liver disease** is manifested by fatty liver, hepatitis, and cirrhosis. One or more of these manifestations may be found in alcoholic patients.

#### Alcoholic Fatty Liver

**Etiology.** **Alcoholic fatty liver** (alcoholic steatohepatitis) is an accumulation of fat in the liver cells. It is caused by more fat being delivered to the hepatocyte than it can normally metabolize or by a defect in fat metabolism within the cell.

**Diagnosis and treatment.** Steatohepatitis is not exclusively alcohol-related. Indeed, diabetes mellitus, obesity, protein malnutrition, total parenteral nutrition, drugs, and many other factors may result in a similar pathologic process. It is usually mild and asymptomatic, and is often diagnosed incidentally on ultrasound or CT examination or by liver biopsy for another reason. Levels of liver enzymes are often mildly abnormal, generally serum transaminases. Hypertriglyceridemia is commonly found and at times may be dramatically elevated (e.g., greater than 1000 mg/dl). Occasionally, there is significant liver enlargement, abdominal discomfort, and even portal hypertension. Treatment involves stopping alcohol intake and providing appropriate nutrition. Nonalcoholic steatohepatitis (NASH) may be managed with reduction of weight, control of diabetes and hyperlipidemia, or other treatment directed at the underlying cause. Although the exact risk is unclear, it has been estimated that between 3% and 15% of persons with untreated NASH will eventually develop progressive liver fibrosis and cirrhosis.<sup>1</sup>

#### Alcoholic Hepatitis

**Pathogenesis and clinical manifestations.** **Alcoholic hepatitis** is an active inflammation of the centrilobular region of the liver. The liver cells show pathologic changes of hepatocyte necrosis with neutrophilic infiltration and intracellular inclusions known as Mallory bodies. This form of liver disease often occurs in chronic alcoholics who “go on a bender” and binge on quantities much greater than their usual intake. Clinically the illness ranges from mild to very severe, with the worst cases characterized by hepatomegaly, fever, signs of acute liver failure, and encephalopathy. Hepatitis may be complicated by acute alcohol withdrawal and delirium tremens. Mortality rates as high as 33% are seen with this condition.<sup>1</sup>

**Diagnosis and treatment.** The diagnosis is supported by the history, if the patient is reliable. The finding of a serum AST (SGOT) level markedly higher than a serum ALT (SGPT) level strongly suggests a toxic etiology, rather than acute viral hepatitis. Viral serologies, serum acetaminophen levels, and tests for certain metabolic disorders (e.g., determination of serum ceruloplasmin level for Wilson disease) may help sort diagnostic dilemmas.

Because one of the pathogenetic factors in alcoholic hepatitis is malnutrition and vitamin deficiencies, special attention should be given to nutrition. Thiamine 100 mg daily and a multivitamin should be administered routinely, and vitamin B<sub>12</sub> and folate levels should be measured and replenished as necessary. Patients with an elevated prothrombin time or International Normalized Ratio (INR) should receive subcutaneous vitamin K. Corticosteroid therapy with prednisolone is recommended for seriously ill patients, especially those with declining liver function and coma.<sup>28-32</sup>

## TOXIC LIVER DISORDERS

### Metal Storage Diseases

#### Hereditary Hemochromatosis

**Pathogenesis and diagnosis.** **Hereditary hemochromatosis (HH)** is one of the most common autosomal recessive disorders in the world. In European populations, approximately 1 in 10 persons is a heterozygous carrier, and 0.5% are homozygous persons with disease.<sup>45</sup> Studies in the United States show a prevalence of HH homozygosity of 0.44% for Caucasians, 0.027% for Hispanics, and 0.014% for African Americans.<sup>33</sup> The prevalence among Asians is extremely low. However, despite the high prevalence of the gene, the number of persons with clinical hemochromatosis is considerably smaller—less than 1% of homozygotes. This is due to incomplete penetrance of the gene and environmental factors.

The disease is caused by the activity of a mutant gene called *HFE*, which allows excessive and uncontrolled iron absorption by the GI tract. The usual *HFE* mutation has been identified as C282Y, but other mutations can occur and act in a similar way. A small number of patients with HH are heterozygotes for *HFE*; disease in this population may result from as-yet-unidentified mutations or other factors. The result of these mutations is iron deposition in numerous organs; in advanced disease, the body may contain 20 g or more of iron, mainly in the liver, pancreas, and heart. Because of menstruation and perhaps endocrinologic factors, hemochromatosis is much less common in women than in men (ratio of 1:5 to 1:10 female to male ratio).<sup>1</sup>

The liver is usually the first organ to show evidence of involvement, with hepatomegaly and elevated levels of liver enzymes. Specific manifestations in organ systems other than the liver include diabetes mellitus, hyperpigmentation, polyarthritides, hypogonadism, and heart failure. (Archaically the condition was known as bronze diabetes, polyarthritides, hypogonadism, heart failure and bronze discoloration of the skin.) In advanced disease, fibrosis and macronodular cirrhosis of the liver develop insidiously and represent the major cause of death. Splenomegaly is common, although portal hypertension and its complications (see earlier discussion) occur less frequently than with other forms of liver disease. HCC develops in about 30% of persons with hemochromatosis, exclusively in the setting of cirrhosis.<sup>1</sup> Therefore, early diagnosis and treatment are critical.

**Clinical manifestations and diagnosis.** The diagnosis is suggested by clinical features and family history. Plasma iron and transferrin saturation is increased, and serum ferritin level is dramatically elevated, often to several thousand micrograms per liter (normal 10 to 200 mcg/L). The diagnosis of hereditary hemochromatosis is confirmed by genetic analysis for the *HFE* gene. In selected cases liver

biopsy may be performed, demonstrating iron deposition in periportal hepatocytes.<sup>1</sup> The diagnosis of hereditary hemochromatosis should prompt investigation of other family members for carriage and expression of the *HFE* gene.

It should be noted that a second large category of iron overload syndromes exists—that of secondary hemochromatosis. This may occur with chronic hereditary dyserythropoietic states (e.g., sideroblastic anemia and thalassemia), in alcoholic patients with liver disease, and in patients with excessive iron ingestion over a period of many years. Hemochromatosis related to anemias is generally the result of repeated blood transfusions and iron intake. Of mainly historical interest is an interesting condition called Bantu siderosis, which occurred among South African tribesmen who imbibed beer fermented in iron pots. All of these secondary forms of hemosiderosis are not associated with the *HFE* gene.

**Treatment.** Recently, observational studies have shown that asymptomatic patients with a relatively low iron load have an essentially normal lifespan.<sup>34</sup> Therefore treatment is reserved for those patients with a ferritin level greater than 1000 mcg/L. The mainstay of treatment for hemochromatosis is repeated phlebotomy. The typical protocol is weekly phlebotomy of 500 ml (1 unit) of whole blood until the hematocrit drops below 37%, at which time maintenance phlebotomy of 1 unit is carried out every 2 to 3 months. Patients who do not tolerate phlebotomy may be treated with subcutaneous or intramuscular deferoxamine, a drug that chelates iron and facilitates its renal excretion. Deferoxamine is much less efficient than phlebotomy and requires adequate renal function. If identified early, hereditary and acquired hemochromatosis carries an excellent prognosis in terms of preventing heart failure and liver disease. Diabetes may still develop, however, and iron removal does not change hypogonadism or arthritis. Liver transplantation is available for patients with irreversible cirrhosis whose heart involvement does not preclude surgery.

### Wilson Disease (Hepatolenticular Degeneration)

**Etiology.** Wilson disease, or hepatolenticular degeneration, is a rare autosomal recessive disorder in which excessive amounts of copper accumulate in the liver and other organs. As with hereditary hemochromatosis, it has now been linked to a specific abnormal protein mutation in the Wilson disease protein ATP7B gene, which results in retention of copper in the liver as well as impaired incorporation of copper into ceruloplasmin. Most patients are compound heterozygotes with more than one of several mutations involving the *ATP7B* gene. The condition may present at any time before age 30, generally with either significant hepatic dysfunction or neuropsychiatric illness. Patients with a neuropsychiatric presentation virtually always have occult compensated cirrhosis at the time of diagnosis.

**Clinical manifestations.** Hepatic disease is more common in children than adults and begins as hepatomegaly, fatty infiltration of the liver, and elevated levels of liver enzymes. Great variability in liver disease is seen, and Wilson disease may manifest as acute hepatitis progressing to fulminant hepatic failure, a condition very similar to autoimmune hepatitis with numerous extrahepatic symptoms, or insidious development of macronodular cirrhosis with portal hypertension. Neurologic involvement presents as a movement disorder or rigid dystonia, or occasionally as primarily psychiatric symptoms. Other manifestations include renal tubular acidosis with a Fanconi-like syndrome, cardiomyopathy, hypogonadism, metabolic bone disease (i.e., vitamin D-resistant rickets), and arthritis.

**Diagnosis.** Clinical signs and symptoms suggest the diagnosis, in particular the finding on slit-lamp examination of the brownish Kayser-Fleischer rings at the margin of the cornea. However, lack of Kayser-Fleischer rings does not exclude the diagnosis. Unlike hereditary

hemochromatosis, genetic analysis is not the primary diagnostic pathway; it should be reserved for those with proven metabolic abnormalities because of variability in the genetic mutations that cause copper overload syndromes. The combination of low serum ceruloplasmin level and elevated 24-hour urinary copper excretion is highly suggestive of Wilson disease.<sup>1</sup> Results of 24-hour urinary copper excretion after penicillamine administration provide additional diagnostic proof in ambiguous cases. The liver biopsy technique for copper determination is technically demanding and is not routinely performed. As with hereditary hemochromatosis, genetic screening of close relatives should be carried out.

**Treatment.** Treatment involves dietary modification and copper removal therapy. Patients should try to eliminate copper-rich foods from their diet, including organ meats, shellfish, nuts, chocolate, and mushrooms.<sup>1,13</sup> (Vegetarians require specific dietary counseling.) Dietary measures include testing home water sources and filtering water with a high copper content. Oral chelation therapy is the mainstay of treatment for Wilson disease, and the currently preferred agent is trientine. Alternative agents include penicillamine and zinc. Patients receiving this treatment early in the course of the disease will show marked improvement and protection against liver and neurologic disease.<sup>1</sup> Even patients with advanced Wilson disease may expect some functional recovery. Treatment is lifelong, and noncompliance leads to definite progression.

Side effects are less common with trientine than with the older therapy, penicillamine. A mild anemia and gastritis may occur with this medication, also a transient worsening of neurologic symptoms. Finally, ammonium tetrathiomolybdate is occasionally used for severe neurologic Wilson disease because, unlike penicillamine, it is not associated with early transient neurologic deterioration.<sup>35</sup> As with hemochromatosis, liver transplantation has a limited but useful role.

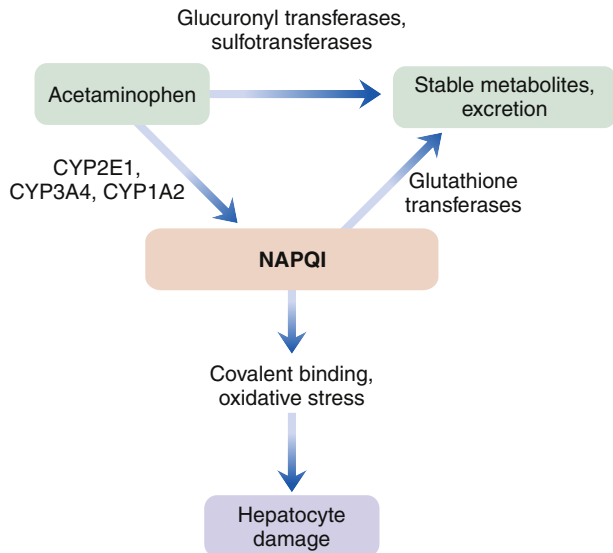

### Toxic Metabolic Agents

#### Acetaminophen Poisoning

**Etiology.** Many drugs and toxins cause liver damage. Unfortunately, treatment is often limited to withdrawal of the offending agent and administration of supportive care. Standard measures, including gastric lavage, induced emesis, and activated charcoal, are used in cases of acute ingestive poisoning. Specific antidotes are few, although heavy metal intoxication may be managed with chelating drugs. Acetaminophen overdose is an important exception that bears further discussion.

**Pathogenesis and clinical manifestations.** Acetaminophen (paracetamol in Britain and Europe) is a widely used, nonprescription analgesic and antipyretic that is frequently implicated in suicide attempts and accidental poisonings. In fact, a multicenter study recently showed that acetaminophen overdose was responsible for 39% of cases of acute hepatic failure in the United States.<sup>36</sup> Oral acetaminophen is rapidly absorbed and metabolized (Figure 38-15). A toxic metabolite, *N*-acetyl-*p*-benzoquinone imine, is formed and rapidly detoxified by reaction with glutathione. However, acute ingestion of at least 140 mg of acetaminophen per kilogram of body weight may expose the liver to high levels of the toxic metabolite with resultant hepatic necrosis. Importantly, repeated ingestion of smaller amounts may cause harm in children, the elderly, patients with pre-existing liver disease, persons abusing alcohol, and persons taking other possibly hepatotoxic drugs. Significant liver damage is rare if serum acetaminophen levels are less than 150 and 37 g/ml, respectively, 4 and 12 hours after ingestion. Given the many variables affecting acetaminophen toxicity, it is imperative for clinicians evaluating a suspected case to refer to a published nomogram and obtain periodic drug levels of acetaminophen.<sup>37</sup> (Screening for ingestion of other drugs, such as tricyclic antidepressants, should also be done.)

**FIGURE 38-15** Mechanism of acetaminophen toxicity. The majority of an administered dose of acetaminophen is conjugated with sulfate or glucuronic acid to form stable metabolites that are promptly excreted in urine. Under most circumstances, only a minority of the total acetaminophen dose undergoes bioactivation to the reactive intermediate *N*-acetyl-*p*-benzoquinone imine (NAPQI). This species is capable of binding to intracellular proteins and mediating cell injury or death. The liver enzymes capable of bioactivating acetaminophen to NAPQI are CYP2E1, CYP3A4, and CYP1A2. Accumulation of NAPQI in the liver does not generally occur because the liver has sufficient ability to detoxify this metabolite through glutathione conjugation. (Redrawn from Fontana RJ, Watkins PB: Genetic predisposition to drug-induced liver disease, *Gastroenterol Clin North Am* 24:811-823, 1995.)

Within several hours of ingestion, the patient generally experiences nausea, vomiting, and diarrhea. After these symptoms, there is often a temporary “window” period, in which the patient feels well and may wish to withdraw from medical care. Within 24 to 48 hours, signs of hepatic injury occur, including abnormal liver enzyme levels. If untreated, progressive liver failure with jaundice, encephalopathy, hypoglycemia, coagulopathy, and even death may occur, generally within the first week. Patients surviving 1 week generally experience complete recovery of normal liver function without sequelae.

**Treatment.** Initial treatment, as for any poisoning, involves decontamination with induced emesis or lavage and activated charcoal (which will not interfere with use of acetylcysteine). The proper use of acetylcysteine for patients with clearly toxic levels can effectively prevent hepatic necrosis and its fatal consequences if started in a timely fashion. Acetylcysteine, a mucolytic solution often used in patients with bronchial diseases, stimulates liver production of reduced glutathione, which can then keep up with blood levels of toxic metabolites.<sup>37</sup> Acetylcysteine is nontoxic but may cause rash and frequently induces vomiting because of its foul odor and taste. It is often given by nasogastric tube in conjunction with antiemetic medications. It can also be given intravenously, although this preparation is associated with a 10% incidence of anaphylactic-type reactions requiring immediate attention.

## OTHER STRUCTURAL LIVER CONDITIONS

### Liver Abscess

**Pathogenesis, clinical manifestations, and diagnosis.** Pyogenic liver abscess is a very common condition worldwide. In the United States it represents most commonly a complication of ascending

cholangitis with or without gallstones, from anaphylactic-type reactions associated with intestinal infection (e.g., appendicitis, through the portal vein), or from hematogenous seeding caused by an endovascular infection.

Liver abscess should be considered in any patient with fever and right upper abdominal pain. Nausea and vomiting are common, and jaundice from biliary obstruction may rarely be present. Frequently, tender hepatosplenomegaly and sometimes a palpable mass are noted. Typical signs of pyogenic infection are usually present, including leukocytosis, an elevated erythrocyte sedimentation rate, and elevated levels of liver enzymes, usually in a “mixed” pattern. Because the primary diagnostic considerations include acute cholecystitis, cholangitis, or liver tumor, imaging of the liver with ultrasonography or CT is usually carried out. Ultrasound-guided or CT-guided thin-needle aspiration of abscesses is recommended to provide the necessary material for Gram stain and cultures; blood cultures should also be obtained.

Pyogenic liver abscess from abdominal sources generally contains enteric aerobic and anaerobic gram-negative bacteria. *Escherichia coli*, *Klebsiella* species, and *Bacteroides fragilis* are particularly important. Abscesses of hematogenous origin are more heterogeneous. *Streptococcus viridans* and related streptococcal species are commonly seen. *Staphylococcus aureus* is seen in the setting of endocarditis or widespread bacteremia.

Other uncommon causes of cystic liver abnormalities should be considered, in particular hydatid liver cysts secondary to *Echinococcus* species and amebic liver abscess. These conditions are virtually always seen among persons who have lived in developing countries for many years. Their appearance on ultrasound and CT is usually characteristic, and serologic values are available to assist with diagnosis. (Aspiration of probable echinococcal cysts is contraindicated because of the possibility of anaphylactic shock attributable to leakage of immunogenic cyst material.) Fungal and mycobacterial infections of the liver are usually granulomatous and diffuse, but in certain settings, such as in neutropenic patients, localized infection with an organism such as *Aspergillus* may be seen.

**Treatment.** Large (2.0 cm) solitary or multiple liver abscesses require drainage, formerly a surgical procedure. However, at present CT-guided and ultrasound-guided percutaneous drainage tubes are the standard of care and may be placed with minimal morbidity and discomfort. These should be kept in place until drainage has essentially resolved.

Antibiotic coverage should be directed at likely organisms. A third-generation cephalosporin such as ceftriaxone can be used alone or in combination with metronidazole, if anaerobic bacteria are likely. A  $\beta$ -lactam with  $\beta$ -lactamase inhibitor (e.g., ampicillin/sulbactam) is an excellent choice, but it must be given four times daily. Ertapenem is a once-daily carbapenem with broad aerobic and anaerobic coverage and is a good choice for outpatient administration. Since 3 to 4 weeks of antibiotic administration is generally required, the latter part of the treatment course could be given orally, using an oral quinolone such as levofloxacin with or without oral metronidazole. Therapy should be adjusted depending on culture results.

### Trauma

**Etiology and clinical manifestations.** The liver is the most common solid organ to be injured by penetrating abdominal trauma (such as gunshot wounds, stab wounds, or rib fractures) and the second most commonly injured organ in blunt trauma. Damage or injury to the liver should be suspected when any upper abdominal or lower chest trauma is sustained. The liver is frequently injured by steering wheels in vehicular accidents. Common injuries to the liver include simple lacerations, multiple lacerations, avulsions, and crush injuries.

The gravity of liver wounds arises from the fact that the liver is a highly vascular organ receiving approximately 29% of the body's cardiac output. When hepatic trauma occurs, blood loss can be massive. The patient generally exhibits the typical signs of hemorrhagic shock: hypotension, tachycardia, tachypnea, pallor, diaphoresis, and confusion. Hemoglobin/hematocrit levels may be normal early following the trauma but eventually will reflect significant blood loss. Clinical manifestations include right upper quadrant pain with abdominal tenderness, distention, guarding, and rigidity. Abdominal pain exaggerated by deep breathing and referred to the shoulder may indicate diaphragmatic irritation.

**Treatment.** Treatment entails the administration of fresh whole blood or packed red blood cells and fresh frozen plasma, as well as massive fluid infusion to maintain adequate intravascular volume and hematocrit. Most patients require surgical management, although some may be treated angiographically or expectantly with medical support. Postoperatively, a patient with hepatic trauma is usually admitted to a critical care unit and monitored for persistent bleeding. The complete blood cell count and coagulation parameters must be closely monitored for trends in changes.

### Malignancy

**Etiology.** Malignancy in the liver usually develops as a metastatic process. Because of the vascularity and lymphatic drainage of the liver, the organ is a common site for metastasis from primary cancers of the esophagus, stomach, colon, rectum, breast, and lung—among many other possibilities.

Primary hepatic malignancy (cancer originating within the liver) is rare in the United States, though increasing in frequency.<sup>38</sup> However, in other parts of the world such as Africa, it is one of the most common sites of malignancy because of a high prevalence of chronic hepatitis B virus infection. Primary liver tumors include HCCs (discussed in the next section), cholangiocarcinoma, and angiosarcoma. Hepatoblastoma is the most common malignant tumor in children. Lymphoma, especially T-cell lymphoma, may occasionally arise primarily in the liver. Benign liver tumors are much less common, with the exception of cavernous hemangioma.

**Clinical manifestations and diagnosis.** The most common form of primary hepatic malignancy is **hepatocellular carcinoma (HCC)**, often referred to as hepatoma. HCC is a malignancy of middle-aged persons, more frequent in men than in women. The incidence is increasing in the United States, in part as a result of increasing HBV and HCV prevalence. (It is always preceded in these situations by cirrhosis.) Approximately 28,000 cases were diagnosed in the United States last year. Signs and symptoms of HCC include hepatomegaly, abdominal pain, weight loss, nausea, and, in advanced cases, jaundice and ascites. HCC has an extraordinary number of paraneoplastic syndromes, including hypercalcemia, erythrocytosis, hypoglycemia, thyrotoxicosis, and hypertrophic osteoarthropathy (finger clubbing).<sup>1</sup>

Space-occupying masses of the liver may first be suggested by abnormal measurements of liver-related enzymes, especially alkaline phosphatase.  $\alpha$ -Fetoprotein level is often dramatically elevated in cases of HCC, although some false-positive results can occur. Definitive diagnosis requires imaging of the liver with ultrasonography, CT, or magnetic resonance imaging, although on occasion the tumor may be diffuse and difficult to image. These studies also allow guided needle biopsy of the liver lesion.

**Treatment.** The only treatment for HCC is hepatic resection. Unfortunately, because of advanced diffuse liver disease or multifocal tumors, such treatment is not usually possible. Partial resection is preferred, but complete hepatectomy followed by liver transplantation is a radical option for tumor localized to the liver. Other treatments

## BOX 38-2 CONDITIONS TREATED WITH LIVER TRANSPLANTATION

### Cirrhosis Secondary to

- Viral hepatitis
- Alcoholic hepatitis
- Autoimmune hepatitis
- Cryptogenic source (no cause determinable)

### Metabolic Liver Diseases

- Wilson disease
- $\alpha_1$ -Antitrypsin deficiency
- Hemochromatosis, neonatal
- Glycogen storage disease
- Tyrosinemia
- Byler disease
- Crigler-Najjar syndrome
- Other miscellaneous

### Cholestatic Liver Diseases

- Primary biliary cirrhosis
- Sclerosing cholangitis
- Biliary atresia
- Other miscellaneous

### Acute Liver Failure

- Drug reactions
- Toxins (e.g., mushroom poisoning)
- Viral hepatitis
- Acute Budd-Chiari syndrome, other ischemic insult

include systemic chemotherapy and chemotherapy directed selectively to the liver via portal vein or hepatic artery cannulation.<sup>1</sup> Other novel palliative treatments include hepatic artery ligation, direct percutaneous injection of alcohol into hepatic tumors, cryotherapy, and other thermal techniques. A new drug, sorafenib, has been approved for treatment of HCC not amenable to curative surgery and has shown a modest survival benefit. Nevertheless, the 5-year survival for this cancer is only 14%.

## TRANSPLANTATION

Patients with end-stage liver disease that has not responded to conventional medical or surgical intervention are potential candidates for **liver transplantation** (Boxes 38-2, 38-3, and 38-4). In adults, diseases currently managed by orthotopic (in-place) liver transplantation (OLT) include end-stage cirrhosis from chronic active hepatitis, alcoholic liver disease, primary biliary cirrhosis, and primary sclerosing cholangitis; and hepatic metabolic diseases such as hemochromatosis and Wilson disease.<sup>1,39</sup> Liver transplantation is rarely performed for patients with malignant neoplasms, although there is clearly a subset of patients with HCC who are candidates for this procedure.<sup>40</sup> The major indication for pediatric OLT is biliary atresia following a failed Kasai procedure (portoenterostomy) or delayed recognition of the diagnosis. Other major pediatric indications include  $\alpha_1$ -antitrypsin deficiency and other metabolic disorders. Currently about 5000 liver transplantations are performed yearly, although the waiting list contains about three times that number.

### Evaluation of the Transplantation Patient

Potential transplantation patients undergo extensive physiologic and psychological evaluation by physicians, nurses, psychologists, and

**BOX 38-3 INDICATIONS FOR LIVER TRANSPLANTATION****Acute Liver Disease**

Fulminant liver failure with progressive encephalopathy  
 Prothrombin time >10 sec above control  
 Bilirubin <15 mg/dl and rising

**Chronic Liver Disease**

Bilirubin >15 mg/dl  
 Intractable hepatic encephalopathy  
 Intractable ascites  
 Serum albumin <2.5 mg/dl  
 Prothrombin time ≥20 sec  
 Hepatorenal syndrome

**BOX 38-4 CONTRAINDICATIONS TO LIVER TRANSPLANTATION****Absolute Contraindications**

End-stage cardiopulmonary disease  
 Metastatic cancer  
 Active sepsis  
 Acquired immunodeficiency syndrome  
 Psychiatric illness preventing compliance with treatment

**Relative Contraindications (Vary Greatly Among Transplant Centers)**

Renal failure  
 Hepatitis B infection  
 Liver cancer  
 Portal vein thrombosis  
 Active alcoholism

social workers to identify potential contraindications to the procedure. Conditions that would normally preclude OLT include uncontrolled bacterial sepsis, failure of other major organ systems, extrahepatic malignancy, and more. Additional identified risk factors include portal vein thrombosis, previous portosystemic shunt operations, current alcohol or drug addiction, a poor psychosocial support system, and psychological instability. Many of these conditions are relative contraindications that diminish the chance of a successful outcome, but they do not always preclude transplantation. One group whose numbers are growing is patients with HIV and end-stage liver disease, and this group is increasingly being considered for OLT.<sup>1</sup>

Patients with viral hepatitis are particularly susceptible to recurrence in the transplanted organ and must be managed with care. Recent data show that patients transplanted for HBV who are treated indefinitely with high-dose HBIG have low recurrence rates, with acceptable survival and quality of life.<sup>41</sup> In contrast to HBV, it has not been possible to develop an effective regimen to prevent recurrent HCV infection. A promising approach is preemptive antiviral therapy started shortly after OLT but before histologic recurrence is established; in particular, the use of long-acting pegylated interferons is currently the focus of ongoing clinical trials.<sup>42</sup>

After the patient has been identified as a candidate and a donor organ has been procured, the actual surgical procedure can take 8 to 22 hours to complete. The procedure involves five anastomoses between recipient and donor organs, including the following vascular anastomosis sites: suprahepatic inferior vena cava, infrahepatic vena cava,

portal vein, hepatic artery, and biliary tract. The biliary anastomosis site varies, depending on the patient's extrahepatic biliary tract.

**Posttransplantation Management**

A cornerstone of posttransplantation management is immunosuppression to prevent rejection of the transplant graft. The rejection response after liver transplantation most often occurs between postoperative days 4 and 10. Clinical manifestations of acute rejection include tachycardia, fever, right upper quadrant or flank pain, diminished bile flow through the T tube drain or a change in bile color, and increasing jaundice. Laboratory findings include elevated serum bilirubin, transaminase, and alkaline phosphatase levels and increased prothrombin time. Following the successful use of cyclosporine, a number of immunosuppressive drugs have appeared and provide several choices for improving outcome. Immunosuppressives may be broadly categorized into three groups: initial immunosuppression, maintenance immunosuppression, and management of acute cellular rejection.<sup>1</sup> Prednisone is the primary posttransplantation immunosuppressive and is steadily tapered in favor of maintenance drugs. The calcineurin inhibitors cyclosporine or tacrolimus are begun during anesthesia induction and represent the mainstays of maintenance therapy. In most centers, tacrolimus has supplanted cyclosporine as the preferred immunosuppressive. Adjunctive maintenance agents include either mycophenolate mofetil or the older drug azathioprine. Acute rejection is generally managed with high-dose corticosteroids. Patients who fail to respond to steroids can be treated with infusion of one of several agents, including muromonab (OKT3), mycophenolate mofetil (MMF), or an interleukin-2 receptor blocker (e.g., basiliximab).

Side effects limit the usefulness of all these drugs and are a main source of morbidity and mortality among transplant recipients. The main nonimmunologic side effects of cyclosporine and tacrolimus are hypertension and renal insufficiency. Blood levels must be carefully monitored. Side effects of mycophenolate mofetil and azathioprine include bone marrow suppression with cytopenias. Problems with the acute antirejection infusions include hypersensitivity and cytokine reactions, and a heightened risk of opportunistic infection, especially cytomegalovirus, immediately after use. Among the many side effects of prednisone are hypertension and hyperglycemia. The main consequence of all these treatments is immune suppression and increased risk for infection.

Early infections are generally due to issues involving surgical technique and pre-existing infection (e.g., cholangitis) and have declined significantly in recent years.<sup>1</sup> They usually represent nosocomially acquired pathogens. Infections in the middle period from 1 to 6 months often represent viral infection or reactivation. Trimethoprim-sulfamethoxazole (TMP-SMX) is usually prescribed for prophylaxis against bacterial infection and *Pneumocystis jiroveci* for the first year. Of particular concern and the focus of several prophylactic strategies is cytomegalovirus. Cytomegalovirus occurs at a high rate among seronegative recipients who receive a liver from a seropositive recipient, and reactivation rates are significant as well. In the middle and late periods fungal infection is important, especially *Aspergillus* species, and lymphoproliferative disorder attributable to Epstein-Barr virus is seen. OLT recipients should be instructed to avoid exposure to environmental or food-borne mold, which could increase their risk for fungal infection. Another important preventive strategy is appropriate vaccination, particularly annual influenza shots. (Live virus vaccinations, such as varicella and yellow fever, should be avoided.)

Critical issues in the posttransplantation period include the following: hypertension, renal dysfunction, hyperlipidemia and cardiovascular disease, obesity, osteoporosis, and increased risk for cancer. Psychological issues are especially prominent, and caregivers and

family should be alert for signs of depression and anxiety. Many of the antirejection medications exacerbate these symptoms. With careful follow-up, OLT recipients can live productive lives for many years after transplantation. Chronic rejection, often in the setting of progressive ductopenia, and recurrence of primary pretransplantation liver disease tend to cause graft failure with time. Actuarial survival at 5 years is approximately 88% for persons with cholestatic liver disease, 78% for patients with noncholestatic liver disease who are HCV negative, and 70% for persons with HCV.<sup>43</sup>

## AGE-RELATED LIVER DISORDERS

### LIVER DISEASES AND PEDIATRIC CONSIDERATIONS

Liver disease in infants and children not only encompasses pediatric variations of adult liver diseases but also includes conditions unique to that age group. Many of these conditions present at birth or shortly thereafter, although several may appear in later life.

#### Abnormal Bilirubin Metabolism in the Neonatal Period

**Physiologic jaundice of the newborn** is a harmless condition lasting no longer than 2 weeks after delivery. (Bilirubin metabolism in the neonatal period has already been discussed; see earlier Jaundice section.) Immature bilirubin conjugation and transport mechanisms are the primary causes, along with increased gut absorption of bilirubin. Hyperbilirubinemia is not considered physiologic or normal if the bilirubin level is greater than 5 mg/dl on the first postpartum day, 10 mg/dl on the second day, or 13 mg/dl at any time.<sup>44</sup> It should be noted that breast-fed babies have a higher incidence of hyperbilirubinemia than do bottle-fed babies because the  $\beta$ -glucuronidase in breast milk results in increased unconjugated bilirubin in the gut, which can be absorbed. If significant hyperbilirubinemia occurs, breast feeding can be stopped.

Pathologic bilirubin levels should lead to an immediate evaluation to exclude congenital hemolytic disorders, Crigler-Najjar syndrome, hypothyroidism, congenital pyloric stenosis, sepsis, resorbing hematomas, and other conditions associated with an elevated serum bilirubin level.

**Kernicterus** refers to brain injury as a result of hyperbilirubinemia. It is a serious complication of the neonatal period, generally occurring in the setting of premature birth, neonatal jaundice, and especially hemolytic disease of the newborn.<sup>45</sup> In brief, the immature blood-brain barrier allows free unconjugated bilirubin to enter the brain, leading to encephalopathy. The term kernicterus refers to yellowish staining of permanently damaged brain tissue, primarily in the basal ganglia and thalamus. Despite decades of research, the exact pathophysiologic mechanisms by which elevated levels of bilirubin cause brain damage have not been elucidated, although evidence points toward premature programmed cell death (i.e., apoptosis). Unfortunately, most infants die of this condition, and survivors often suffer from cerebral palsy, movement disorders, and mental retardation. Drugs that displace bilirubin from albumin seriously worsen the condition.

If recognized early, treatment with exchange transfusions, phenobarbital (to increase the levels of UDPGT; see previous discussion), and phototherapy (“bili-lights”) may prevent these catastrophic consequences.<sup>46</sup> Phototherapy with light in the 450-nm wavelength band is used to treat unconjugated hyperbilirubinemia in infants. Light at this wavelength converts unconjugated lipid-soluble bilirubin into water-soluble photoisomers that can be excreted by the kidneys, thus lowering the bilirubin level.

### Infectious and Acquired Hepatitis in Children

**Acute hepatitis A virus infection** is often mild or asymptomatic in children. The prevalence of childhood infection correlates inversely with the quality of sanitation and hygiene. Treatment is supportive, and prevention guidelines parallel those for adults. Universal childhood vaccination is recommended in the United States and in many countries around the world.

Globally, **hepatitis B virus infection** is a common childhood disease, with vertical transmission from an HBsAg-positive mother to the infant being the most common mechanism of dissemination. Infected blood products and drugs are modes of infection in less developed areas. Features suggesting immune complex disease such as arthritis, fever, papular acrodermatitis (a rash not seen in adults), renal disease, and hematologic complications are more common in children. The incidence of chronic infection is also much higher after neonatal or childhood infection, which has grave long-term consequences because of the late sequelae of cirrhosis and HCC.

Passive immunization with HBIG should be given within 12 hours of birth to children of HBsAg-positive mothers. Active immunization with HBV vaccine should be administered as a series of intramuscular injections at birth and at 1 and 6 months of age. Identical prophylaxis should be given to children of high-risk mothers even if not screened for HBsAg and to children otherwise exposed to HBV. In 1991 the U.S. Public Health Service recommended universal childhood HBV vaccination.<sup>22</sup> Strategies include infant vaccination, possibly with a booster dose in young adulthood, or adolescent vaccination.

Unlike HBV, **hepatitis C virus** is less commonly spread vertically, and effective screening of blood products has greatly reduced the risk of childhood infection. **Hepatitis delta virus** may be transmitted by the intrafamily route as a coinfectant with hepatitis B.

Acute **hepatitis E virus** is especially virulent in adolescents and young adults, with a high mortality in pregnant women. In endemic regions, it is the most common cause of childhood hepatitis and is indirectly a cause of infant mortality.

Many systemic viruses may cause biochemical or clinical hepatitis in the pediatric population, including Epstein-Barr virus, cytomegalovirus, herpesvirus, and adenovirus. Neonatal hepatitis is part of the so-called TORCH syndrome and may be caused by a variety of congenital infections, including cytomegalovirus, herpesvirus, varicella, *Toxoplasma*, and syphilis. Encephalitis and retinitis may accompany these conditions, with lifelong sequelae. An enlarged liver and elevated levels of transaminases in the newborn should necessitate a search for congenital infection.

**Reye syndrome** is primarily a disease of children, although adult cases are reported. The syndrome usually occurs shortly after a viral illness such as influenza or chickenpox, and begins with nausea and vomiting rapidly progressing to coma. The exact pathophysiologic mechanism is unknown, but significant mitochondrial dysfunction of hepatocytes occurs.<sup>47-63</sup> Reye syndrome is characterized by fatty infiltration of the liver with severe hepatic dysfunction, including encephalopathy, coagulopathy, and elevated levels of hepatocellular enzymes. Mortality may be as high as 40%. A strong association with aspirin use during the preceding viral illness has been noted, but other drugs may be causative as well.<sup>47</sup> (Because of the risk of Reye syndrome, aspirin is contraindicated for childhood viral illnesses.) Treatment of Reye syndrome is supportive, and if the child survives, recovery is complete. As with other toxic hepatitis, liver transplantation is reserved for irreversible disease.

### Congenital Liver Disease

Many heritable diseases of the liver occur in childhood. These may be broadly characterized as enzyme deficiencies affecting multiple organ

systems including the liver (e.g.,  $\alpha_1$ -antitrypsin deficiency), disorders of bilirubin metabolism (e.g., Crigler-Najjar syndrome), inborn errors affecting other metabolic pathways, intrahepatic ductopenic conditions, and extrahepatic ductopenia (biliary atresia).

### Multisystem Enzyme Deficiencies

**$\alpha$ -Antitrypsin deficiency** is an autosomal recessive condition that commonly affects children and young adults, although it may not become obvious until later in life.  $\alpha_1$ -Antitrypsin is an enzyme inhibitor found in many tissues that prevents normal enzymes, such as elastase and collagenase, from causing damage to those tissues. Production of this enzyme is genetically controlled by a gene that has many allelic variations (gene types). Although numerous abnormal alleles have been identified, the most common pathologic form, which causes both liver and lung disease, is the protease inhibitor Z variant PiZZ, which produces  $\alpha_1$ -ATZ protein.<sup>1</sup> This defective  $\alpha_1$ -antitrypsin protein accumulates in the liver and produces the diagnostic granules seen microscopically, although the exact mechanism of liver damage is unclear. A characteristic centrilobular emphysema, pancreatic insufficiency, and cirrhosis may occur. Treatment by liver transplantation is often precluded by these other problems. Gene therapy for  $\alpha_1$ -antitrypsin deficiency is an area of active investigation.<sup>1</sup>

**Cystic fibrosis (CF)** is an autosomal recessive condition primarily known as a cause of lung disease in children. CF results from one of many mutations in a single large gene on chromosome 7 that encodes the cystic fibrosis transmembrane conductance regulator (CFTR) protein. Clinical disease requires disease-causing mutations in both copies of the *CFTR* gene.

In addition to pulmonary disease, this relatively common genetic condition (1 in 3000 Caucasian births; 1 in 15,000 African-American births) may also cause pancreatic insufficiency, intestinal obstruction, gallstone disease, neonatal giant cell hepatitis, bile duct obstruction, and biliary cirrhosis. Treatment is directed at complications.<sup>1</sup> Administration of ursodeoxycholic acid improves the biochemical indices of liver injury; however, conclusive evidence that the drug halts the progression to cirrhosis is lacking. Gene therapy for CF is in the experimental phase.

**Wilson disease** and **hemochromatosis** are single gene mutation illnesses with significant liver involvement and have been discussed earlier in the chapter.

### Disorders of Bilirubin Metabolism

Inherited defects in bile acid metabolism can manifest as impaired synthesis or transport. The first group includes **cerebrotendinous xanthomatosis**, a steroid hydroxylase deficiency that leads to premature atherosclerosis and encephalopathy. However, manifestations do not generally include liver disease. Children treated with chenodeoxycholic acid have shown marked improvement. Peroxisomes are responsible for  $\beta$ -oxidation in the final steps of bile acid synthesis, and numerous hereditary peroxisomopathies have been described. The most well-known of these conditions is X-linked adrenal leukodystrophy, which is manifested by progressive neurologic dysfunction and adrenal insufficiency. Treatments for this and related conditions remain generally ineffective, but investigational therapies, including bone marrow transplantation and gene therapies, continue to be developed.<sup>48</sup> One interesting if controversial therapy for X-linked adrenal leukodystrophy is dietary therapy with the so-called “Lorenzo’s oil”—a mixture of glycerol trioleate and glycerol trierucate.<sup>49</sup>

Disorders of bile acid transport include **Gilbert syndrome**, a very common (about 10% of the Caucasian population in the United States), entirely benign, autosomal dominant condition that results in mild unconjugated (indirect) hyperbilirubinemia. It is caused by

decreased bilirubin glucuronidation. Awareness of this disorder is important to avoid inappropriate evaluation of these patients.

**Crigler-Najjar syndrome** is a rare autosomal recessive disorder marked by significant unconjugated hyperbilirubinemia.<sup>50</sup> In type I Crigler-Najjar syndrome, the near-total absence of bilirubin conjugation results in high levels of unconjugated bilirubin crossing the immature blood-brain barrier. This condition presents shortly after birth, and neonates usually die of kernicterus or suffer irreversible neurologic damage. Liver transplantation following phototherapy and plasma exchange transfusion has been lifesaving in rare instances. In type II Crigler-Najjar syndrome, some conjugating capability exists, and it is enhanced by the administration of phenobarbital. These patients rarely experience bilirubin encephalopathy and can lead normal lives. Treatment consists of phototherapy, phenobarbital administration, and potentially liver transplantation. Gene therapy is an active area of research for Crigler-Najjar syndrome.

**Progressive familial intrahepatic cholestasis (PFIC)** is a rare autosomal recessive disorder involving severe jaundice, pruritus, and malabsorption attributable to a defect in bile salt excretion. PFIC type I, or **Byler syndrome**, is caused by a single-gene mutation and traces back to an Amish kindred descended from Jacob Byler. Other genetic defects cause different types of PFIC with similar manifestations. Medical therapy with ursodeoxycholic acid is helpful in some children, and biliary diversion procedures have given symptomatic relief to some patients by decreasing the bile acid pool.<sup>1</sup> In the past the disease was uniformly fatal, but liver transplantation has been shown to normalize bile acid synthesis and growth in selected patients.<sup>51</sup>

Other rare disorders of bile salt transport exist and are generally fatal in infancy. These chronic cholestatic diseases, such as North American Indian childhood cirrhosis and cholestasis-lymphedema syndrome (Aagaens syndrome), are undergoing investigation at the molecular genetic level and are generally linked to single-gene mutations.

### Inborn Errors of Metabolism

A very broad range of enzyme abnormalities resulting from single-gene mutations, generally autosomally recessive, may appear in children. These result in abnormal processing of lipids, glycogen, amino acids and proteins, lipopolysaccharides, and other substances. The pathologic process generally results from excessive accumulation of precursor substances in target organs, such as the brain and spinal cord. The liver is often the primary site of processing and may be the target of toxic accumulation as well. The latter may result in signs of liver disease, including hepatomegaly, elevation in levels of liver enzymes, and jaundice. Inborn errors that manifest in the neonatal period are usually fatal unless immediate treatment is undertaken. Inborn errors presenting in infancy and later years may be amenable to specific therapies. Liver or bone marrow transplantation may be effective for some of these conditions, and many of these conditions are foci of intense research regarding gene therapy.<sup>52</sup> The diagnosis of any inborn error of metabolism should prompt a thorough investigation of family history and the provision of appropriate genetic counseling and testing of family members.

As noted previously, given the heterogeneity and rarity of these conditions, they will not be discussed further in this chapter, and the interested reader is referred to a standard text on the subject.

### Intrahepatic Cholestatic Conditions

Intrahepatic cholestasis may be defined as cholestatic liver disease in which the pathologic process is confined to the liver (i.e., the extrahepatic biliary system is normal).<sup>53</sup> One cause of this condition is neonatal hepatitis, which can be idiopathic, viral, or secondary to an inborn error of metabolism. (Viral hepatitis and inborn errors were discussed

earlier in this chapter.) The second category of these illnesses includes conditions in which the number of bile ducts is decreased and inadequate to accommodate normal bile metabolism and transport.

**Alagille syndrome**, or arteriohepatic dysplasia, is the most common form of inherited intrahepatic cholestasis. This autosomal dominant condition has incomplete penetrance and expressivity, and is associated with typical bony and cardiovascular malformations, as well as a paucity of intrahepatic bile ducts. The disease generally progresses slowly; pruritus, hypercholesterolemia, xanthomas, and neurologic complications due to vitamin E deficiency may occur if untreated. Patients may be maintained on ursodeoxycholic acid until liver transplantation, which is the current treatment of choice.<sup>54</sup>

Several other conditions manifest a paucity of intrahepatic bile ducts. Some of these arise from defective bile transport mechanisms and are discussed in the Inborn Errors of Metabolism section.

### Extrahepatic Cholestatic Conditions (Biliary Atresia)

Extrahepatic ductopenia is often referred to as **biliary atresia**. Biliary atresia or, as some authors prefer, progressive obliterative cholangiopathy can be either congenital or acquired. The latter occurs in the setting of certain autoimmune illnesses and is one of the principle forms of chronic rejection of a transplanted liver allograft. Biliary atresia is a rather common birth defect, occurring in 1:10,000 to 1:15,000 live births (and is therefore much more common than intrahepatic cholestatic conditions).<sup>1</sup> Distinguishing between this disorder and idiopathic neonatal hepatitis can be challenging, but the liver biopsy findings are usually characteristic. Infants and children with biliary atresia have progressive cholestasis with all the usual concomitant features: pruritus, malabsorption with growth retardation, fat-soluble vitamin deficiencies, hyperlipidemia, and eventually cirrhosis with portal hypertension. Some children have recurrent episodes of bacterial cholangitis as well. A cholangiogram should be obtained to assess the possibility of a correctable obstruction. The Kasai procedure is often performed to create a hepatopertoenteric connection, which may allow adequate bile drainage. This procedure is not usually curative but ideally does “buy time” for growth of the child until an appropriate time for liver transplantation.

#### KEY POINTS

- Cirrhosis is the irreversible end stage of many different hepatic injuries. The liver is fibrotic, scarred, and nodular. Symptoms of cirrhosis are due to hepatocellular failure and portal hypertension.
- Biliary cirrhosis is associated with chronic bile duct obstruction with resultant accumulation of bile in the liver. Gallstones and extrahepatic and intrahepatic bile duct inflammation are common causes.
- Alcoholic cirrhosis is associated with chronic alcohol ingestion, which may precipitate fatty liver, hepatitis, and, finally, cirrhosis.
- The liver is subject to damage because of its role in storing and detoxifying potentially injurious substances. Metal storage diseases are genetic disorders in which excessive minerals are absorbed and subsequently deposited in the liver. Hemochromatosis is characterized by excessive iron absorption and is manifested by elevated serum ferritin and iron levels. Phlebotomy is the usual treatment. Wilson disease is due to excessive accumulation of copper in the liver and other organs. Copper chelators are effective in preventing liver damage.
- Acetaminophen is converted to a toxic metabolite in the liver that is normally rapidly detoxified by liver enzymes. In acetaminophen overdose, the detoxification reaction may be overwhelmed and liver necrosis results. Treatment is with acetylcysteine.

- Liver abscesses are suspected in patients with fever, nausea, vomiting, and right upper quadrant pain. Ascending biliary infection, abdominal infections transported by the portal vein, and direct extension of infection from neighboring structures are usual sources of infection. Antibiotics and drainage are commonly prescribed.
- The liver commonly sustains injury during penetrating and blunt trauma to the abdomen. Because the liver is highly vascular, trauma may produce extreme blood loss and hemorrhagic shock. Liver trauma is manifested by abdominal tenderness, distention, guarding, and rigidity.
- In the United States, cancer of the liver is usually metastatic and rarely primary. Tumors of the esophagus, stomach, colon, rectum, breast, and lung commonly seed in the liver. HCC is more common in other parts of the world but its incidence is increasing in the United States, with HBV and HCV as important contributing factors.

## LIVER DISEASES AND GERIATRIC CONSIDERATIONS

Liver size and blood flow decrease with aging, but this observation has little functional significance. Drugs whose metabolism is primarily related to hepatic blood flow and drugs processed by the mixed-function oxidase system (cytochromes) may have a prolonged serum half-life requiring careful monitoring and dose adjustment. Routine blood test results of liver-related enzymes are not changed by aging.

In the United States, HCC is usually the result of years of injury from alcohol or chronic viral hepatitis and is therefore more often seen in older people. The prognosis is unfortunately dismal (see discussion earlier in the chapter).

**Ischemic hepatitis** is usually associated with underlying cardiovascular disease and episodes of hypotension, as during surgery or sepsis, and is more common in older patients. Typically, the levels of serum transaminases rise rapidly and the prothrombin time is prolonged. Recovery may be rapid, but the prognosis depends on the severity of the underlying disorder. Ischemic hepatitis alone is rarely a cause of death in such patients. Right-sided heart failure may result in passive hepatic congestion with ascites and (rarely) liver failure. In developing countries, constrictive pericarditis and uncorrected valvular heart disease attributable to rheumatic fever are still significant causes of intractable ascites and should be considered in the differential diagnosis.

Metabolic liver diseases rarely present in the geriatric population. **Hemochromatosis** in women often occurs after menopause and may present as new-onset diabetes mellitus, heart failure, arthritis, cirrhosis, or HCC. Typically, **autoimmune liver diseases** are seen in young to middle-aged people. However, autoimmune chronic active hepatitis may be a cause of “cryptogenic” cirrhosis in older women. **Primary biliary cirrhosis** is uncommon in later life. **Primary sclerosing cholangitis (PSC)** may afflict older persons with long-standing ulcerative colitis, even those who had colectomies many years, even decades, earlier.

Because **alcohol abuse** generally starts early in life, older patients bear the cumulative injury of years of exposure and are likely to show signs of advanced liver disease. Treatment is the same as in younger patients, but attention must be given to the older patients’ social circumstances and intercurrent medical problems. Symptoms and signs of alcohol intoxication and hepatic encephalopathy may be confused with senile dementia and made worse by concomitant drug use (e.g., minor tranquilizers, opiates).

The diagnosis of **acute viral hepatitis** may be more difficult in older people because of nonspecific symptoms in mild cases and decreased clinical suspicion. Acute HAV infection is less common as a result of

the higher incidence of immunity, but it may be more severe with higher mortality rates in the elderly. The end results of HBV and HCV infection often become evident in elderly persons, and in the United States the increased prevalence of persons living with these viruses will mean more elderly patients with liver disease in coming decades.

Older patients with chronic HBV and HCV infection may be treated with the standard treatments, but comorbid medical problems,

intolerance to the side effects of treatment, and advanced liver disease may preclude treatment in many persons. The indications for **liver transplantation** do not change with advancing years, and no arbitrary age limits have been set on transplantation. However, there may be subtle barriers in effect, and the allocation of organs remains a highly controversial issue. Each patient must be evaluated individually regarding the propriety of transplantation and the likelihood of success.

## SUMMARY

Disorders of the liver are diverse and complex. Because the liver is vital to most life processes, even mild disorders can cause life-threatening alterations. Health care professionals need a good understanding of hepatobiliary anatomy and physiology to appreciate the effects of these disorders on patients.

Many liver disorders are the consequence of lifestyle choices such as alcoholism and drug abuse. Health care professionals are in a position to explain the risks of detrimental lifestyles and their relationship to liver diseases so as to prevent occurrence of these diseases.

Medical treatment entails the use of drugs from many different classes. Because the liver is central to the metabolism of many of these drugs, their use requires special attention. Before any drug is given to a patient with liver disease, it is essential to become completely familiar with it by consulting a good pharmacology text or drug information source.

## KEY QUESTIONS

- How does the lipid or water solubility of hormones affect their transport in the circulation?
- What are the general mechanisms of action of lipid-soluble and water-soluble hormones on target cells?
- How do target cells regulate their responsiveness to endocrine hormones?
- How do feedback mechanisms control the secretion of hormones?
- What are the anterior and posterior pituitary hormones, their target tissues, and their negative feedback mechanisms?
- How are thyroid and steroid hormones synthesized?
- What are the normal actions on target cells of antidiuretic hormone, growth hormone, thyroid hormone, and steroid hormones?

## CHAPTER OUTLINE

### Hormone Structure and Action, 784

Chemical Structure of Hormone Classes, 784

Mechanisms of Hormone Action, 784

*Hormones with Cell Membrane Receptors, 784*

*Amplification of Hormone Activity, 785*

*Hormones with Intracellular Receptors, 785*

### Hormone Regulation, 786

Hormone Synthesis, Secretion, and Metabolism, 786

*Factors Affecting Hormone Secretion, 787*

*Feedback Control of Secretion, 787*

*Hormone Metabolism and Excretion, 787*

*Pharmacologic Hormone Concentrations, 787*

Regulation of Receptor Responses, 787

*Receptor Specificity and Affinity, 787*

*Receptor Down-Regulation and Up-Regulation, 788*

*Permissiveness, 788*

*Hormone Agonists and Antagonists, 788*

### Hypothalamic-Pituitary Endocrine System, 788

Hormones of the Posterior Pituitary Gland, 788

*Antidiuretic Hormone, 789*

*Oxytocin, 790*

Hormones of the Hypothalamus and Anterior Pituitary Gland, 790

The endocrine system is composed of cells and organs that are specialized to synthesize and secrete hormones into the bloodstream to act at distant target cells. The nervous and endocrine systems are closely integrated, and many of their actions are coordinated at the level of the hypothalamus. Endocrine systems are particularly suited for regulating complex functions that involve numerous tissues and organs such as growth, metabolism, fluid balance, responses to stress, and reproduction.<sup>1</sup> It is now appreciated that all cells in an organism are involved in cell-to-cell communication, not just the specialized endocrine cells; therefore the term *classical* endocrine systems is sometimes used to designate specialized endocrine glands. This chapter describes general principles of endocrine communication systems and explores the details of hypothalamic-pituitary regulation of antidiuretic hormone, oxytocin, growth hormone, prolactin, gonadotropins, thyroid hormone, and corticosteroid hormones. Disorders of these systems are discussed in Chapters 40 and 41. Reproductive function and disorders can be found in Unit IX.

## HORMONE STRUCTURE AND ACTION

An endocrine **hormone** may be defined as a blood-borne chemical messenger that has an effect on target cells anatomically distant from the secreting cell (Figure 39-1). Chemical messengers may also act in a **paracrine** or **autocrine** fashion; the hormone molecule is secreted by one cell and affects adjacent cells, or the original secreting cell. Paracrine and autocrine actions of hormones are not traditionally included in endocrine system physiology; however, the same signaling molecules can have autocrine, paracrine, and distant actions. As an example, estrogen acts locally within the ovary potentiating maturation of ova but is required systemically for outward female sexual differentiation.<sup>2</sup> Secretion of hormones into the bloodstream by neurons may be termed **neurocrine** signaling, a process common to the hypothalamic-pituitary communication system.

### Chemical Structure of Hormone Classes

Hormones may be classified according to chemical structure as peptides, tyrosine-derived catecholamines and thyroid hormones, and steroids (Box 39-1). The great majority of endocrine hormones are peptides (small proteins) and are water-soluble and easily transported through the circulation to target cells.<sup>3</sup> The catecholamines (dopamine, epinephrine, and norepinephrine) are also water-soluble. Water-soluble hormones usually travel free in solution in the plasma, although some are partially protein-bound. Water-soluble hormones are unable to cross the plasma membrane to enter cells and therefore must exert their actions by binding to receptors located on the surface of target cell membranes.<sup>1</sup>

Thyroid hormones ( $T_3$  and  $T_4$ ) are derived from tyrosine amino acids to which iodine has been attached. The steroid hormones are derived from cholesterol. Thyroid and steroid hormones require transport proteins (globulin) to convey them through the circulation because they are poorly soluble in the blood. In some cases these transport proteins are specialized to carry a certain hormone (thyroxine-binding globulin, cortisol-binding globulin), but hormones can also be carried by nonspecific proteins, such as albumin.<sup>1</sup> Transport proteins are manufactured by the liver. At the target cell, the hormone detaches from the transport protein and moves through the cell membrane to activate intracellular receptors in the cytoplasm or nucleus.<sup>1</sup>

### Mechanisms of Hormone Action

#### Hormones with Cell Membrane Receptors

Hormones exert their actions by binding to target cell receptor proteins. The target cell receptors for water-soluble hormones have a

## BOX 39-1 CHEMICAL CLASSIFICATION OF HORMONES

### Water-Soluble Peptides

Adrenocorticotropic hormone (ACTH)  
 Angiotensin II  
 Atrial natriuretic hormone  
 Antidiuretic hormone (vasopressin) (ADH)  
 Calcitonin  
 Cholecystokinin  
 Follicle-stimulating hormone (FSH)  
 Growth hormone (GH)  
 Glucagon  
 Hypothalamic-releasing hormones  
 Insulin  
 Insulin-like growth factor-1 (IGF-1)  
 Luteinizing hormone (LH)  
 Oxytocin  
 Parathyroid hormone (PTH)  
 Prolactin  
 Secretin  
 Thyroid-stimulating hormone (TSH)

### Tyrosine-Derived Amines

Dopamine  
 Epinephrine  
 Norepinephrine

### Lipid-Soluble

### Tyrosine-Derived Thyroid Hormones

Triiodothyronine ( $T_3$ )  
 Thyroxine ( $T_4$ )

### Steroids

Aldosterone  
 Cortisol  
 Corticosterone  
 Estrogen  
 Progesterone  
 Testosterone  
 Vitamin D

hormone-binding site located on the external portion of a specific cell-surface receptor. Once hormone-receptor binding takes place, a change in the conformation of the receptor protein conveys a signal to the interior of the cell. Some receptors generate second messengers, such as cyclic adenosine monophosphate (cAMP), within the cell whereas others become activated enzymes. The intracellular activities occurring after hormone-receptor binding may include changes in cell membrane permeability; activation or inactivation of enzymes; cellular maintenance, growth, and differentiation; protein synthesis; and genetic expression via RNA and DNA synthesis in the cell nucleus.<sup>4</sup> A more detailed explanation of receptor mechanisms can be found in Chapter 3.

**G-protein-linked receptors.** Hormones can be described as “first messengers”; the hormone carries a message from the secreting cell to the target cell. A **second messenger** is generated within the cell

**FIGURE 39-2** Mechanism of G-protein-linked receptor signaling in endocrine cells. Activation of the receptor by a hormone on the outside of the cell changes the conformation of the receptor and activates its target G-proteins. Common G-proteins in endocrine systems are  $G_s$  (which activates adenylyl cyclase to produce cAMP) and  $G_q$  (which activates phospholipase C to produce DAG and IP<sub>3</sub>).

in response to the first message. The term *second messenger* is usually applied to the products generated by a class of receptors called G-protein-linked (or G-protein-coupled) receptors. These receptors undergo a conformational change upon binding to a hormone that allows them to interact with a class of proteins, called G-proteins, located on the inner side of the cell membrane (Figure 39-2). G-Proteins have three subunits ( $\alpha$ ) binds to a GTP molecule and then dissociates from the other subunits ( $\beta$ ,  $\gamma$ ).<sup>3</sup> The activated  $\alpha$  subunit is able to move along the inner membrane and interact with target enzymes, inducing them to produce the second messenger. There are several different forms of G-proteins that have different target enzymes and produce different sets of second messengers (see Chapter 3). The most important of these for endocrine systems are the  $G_s$  and the  $G_q$  subtypes. Hormones that bind to receptors that are linked to  $G_s$  increase the production of cAMP within the cell. The usual downstream target of cAMP is an enzyme called protein kinase A. Kinases are enzymes that attach phosphates (phosphorylation) to target proteins to change their activity. Enzymes within the cell called phosphatases work to remove the attached phosphates. Phosphorylation-dephosphorylation is a common strategy for controlling enzyme activity in cells. Activation of protein kinase A causes varied cellular effects depending on the cell type. Important examples of hormones that are linked to increased cAMP production through activation of the  $G_s$  pathway include adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), epinephrine ( $\beta$  receptors), parathyroid hormone, antidiuretic hormone (ADH), and glucagon.<sup>1</sup>

The  $G_q$  pathway is linked to production of two second messengers, diacylglycerol (DAG) and inositol trisphosphate (IP<sub>3</sub>). Norepinephrine and epinephrine can activate the  $G_q$  pathway by binding to  $\alpha_1$  receptors on target cells. DAG and IP<sub>3</sub> work together to increase the activity of protein kinase C, which then phosphorylates downstream target proteins to change cell behavior.

**Protein kinase receptors.** A second class of surface receptors important in endocrine signaling is the protein kinase receptor family. These receptors either become activated kinases themselves or are associated with cytoplasmic kinases on their inner domain (Figure 39-3). Both types of receptors phosphorylate their target proteins upon binding of the hormone to an external binding site. An important example of a receptor kinase is the insulin receptor that phosphorylates tyrosine amino acids in its targets and activates several different intracellular signaling cascades (Chapter 41). Growth hormone and prolactin receptors are associated with Janus kinase (JAK) on the cytoplasmic side and become activated when the hormone binds to the outside of the receptor, causing a conformational change that pulls two JAK enzymes closer together.<sup>1</sup> The JAK enzymes become activated and phosphorylate their target proteins, initiating a signaling cascade.

### Amplification of Hormone Activity

The process of intracellular activation by secondary signals occurs via a cascade effect. Progressively larger numbers of chemical reactions occur at each step, so that activation of one receptor at the cell surface can activate numerous G-proteins.<sup>3</sup> Each activated G-protein may interact with 100 or more target enzyme molecules, such as adenylyl cyclase. Each activated enzyme produces many molecules of a second messenger (cAMP), and each second messenger molecule activates many molecules of protein kinase, and so forth. This mechanism of signal *amplification* explains why minute amounts of circulating hormone cause significant and rapid cellular and systemic effects.

### Hormones with Intracellular Receptors

Receptors for thyroid and steroid hormones are located in the cytoplasm or the nucleus of the target cell (Figure 39-4). For decades the transport of thyroid hormone across the cell membrane was thought to be a passive process of diffusion through the bilayer; however, recent discoveries indicate that special protein carriers in the

**FIGURE 39-3** Some endocrine receptors have intrinsic kinase activity, whereas others have kinases associated with their inner domain. In either case, hormone binding to the outer part of the receptor triggers a conformational change in the receptor that initiates kinase activities. Kinases phosphorylate target proteins and alter their activity.

**FIGURE 39-4** Thyroid and steroid hormones are transported through the plasma membrane and bind to intracellular receptors (located in the cytoplasm or nucleus). The hormone-receptor complexes are DNA-regulatory proteins that regulate messenger RNA transcription, processing, and translation into proteins.

membrane are necessary to transport thyroid hormone into the cell.<sup>5</sup> Steroid hormones are still believed to be able to pass directly across the plasma membrane to interact with intracellular receptors.<sup>6</sup> However, they may also bind cell-surface receptors as evidenced by the discovery that estrogen can bind to a G-protein-linked receptor on some cells. These G-protein receptors achieve a more rapid change in cell behavior than those associated with intracellular receptors. Binding of the hormones to intracellular receptors causes a change in affinity of the receptor for binding sites on DNA in the cell nucleus.<sup>4</sup> Gene expression is changed by binding of the hormone-receptor complex to specific DNA-binding sites. The events that result from the interaction between nuclear DNA and the receptor include messenger RNA transcription, processing, and translation into specific proteins (see Chapter 5 for a review of protein synthesis). In general, the onset of action of thyroid and steroid hormones is slow compared with that of the water-soluble hormones described previously, and there is no amplification cascade. Changes in DNA transcription and protein synthesis occur over hours to days.

### KEY POINTS

- Endocrine hormones are chemical messengers that travel via the bloodstream to exert effects on target cells distant from the secreting glands. Hormones regulate complex functions including reproduction, growth and development, fluid homeostasis, and metabolism.
- Hormones may be classified according to chemical structure as water-soluble or lipid-soluble. Receptors for water-soluble hormones are located on the cell surface (catecholamines, peptides), and most thyroid and steroid hormone receptors are located intracellularly.
- Activation of G-protein-linked receptors on the cell surface leads to the production of second messengers within the cell and alteration in intracellular functions. Most endocrine hormones affect their targets through G-protein-linked receptors.
- Some endocrine hormones, such as insulin, growth hormone, and prolactin, interact with receptors on the cell surface that are protein kinases or directly associated with kinases. Activation of kinase receptors results in phosphorylation of target proteins, which changes their activity and initiates intracellular signaling cascades.
- Steroid and thyroid hormones are carried in the circulation by transport proteins. Carriers in the cell membrane transport thyroid hormone into the cell, whereas steroid hormones are able to diffuse through the membrane. Their best characterized receptors are in the cytoplasm or nucleus. Some steroid receptors are associated with the cell membrane. Intracellular hormone-receptor complexes bind to specific targets on nuclear DNA and alter gene expression.

## HORMONE REGULATION

### Hormone Synthesis, Secretion, and Metabolism

Hormone synthesis and secretion may take place in several different cell types, but one site is generally considered to be the primary endocrine tissue and is responsive to feedback about the need for the hormone or its effects. For example, endothelial cells throughout the vascular system produce small amounts of angiotensin II (AII); however, the primary endocrine control is through the renin-angiotensin-aldosterone cascade in which specialized cells in the kidney trigger AII production in response to changes in extracellular volume and pressure.

Most endocrine hormones are polypeptides manufactured on the rough endoplasmic reticulum and stored in vesicles within the cells. A review of protein synthesis can be found in Chapter 5. The initial forms of the polypeptide hormones are usually larger molecules called *prohormones* or *pre-prohormones*. These must be cleaved by specific enzymes to release the active form of the hormone.<sup>1,3</sup> Sometimes this cleavage occurs after the hormone is packaged into vesicles and the fragments are released into the bloodstream along with the hormone. In some cases, such as with insulin secretion, this is clinically useful as a marker of hormone synthesis. Insulin and its C-peptide fragment are produced in a 1:1 ratio and the concentration of C-peptide, which is more stable in the circulation, can be used as a measure of insulin production.

Because they are water-soluble, peptide hormones can be contained within the lipid bilayer of the vesicles and stored until a trigger results in exocytosis of the hormone into the extracellular space. Catecholamines are also water-soluble and stored in vesicles until they are released by exocytosis. However, they are formed by enzymes within the cytoplasm that begin with tyrosine and through a series of steps convert it first to dopamine; depending on the cell type, dopamine may be the final hormone or it can be converted to norepinephrine and then to epinephrine.

Steroid and thyroid hormones are not stored within vesicles because they are lipid-soluble and might leak from the vesicle. The strategy for

synthesis and storage is much different for each of these hormones. When a steroid hormone is needed, increased production of the hormone closely precedes hormone release into the circulation.<sup>2</sup> Steroid hormones are formed on demand from cholesterol that is either stored in the cell or retrieved from the circulating lipoproteins. The stimuli that trigger steroid secretion induce the enzymes in the pathway to synthesize the necessary hormones from cholesterol. Once formed, steroid hormones can simply diffuse through the plasma membrane and into the circulation. The strategy for trapping thyroid hormones within the thyroid gland until they are needed is quite different. Hormone synthesis precedes secretion by weeks or months. Triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ) are synthesized in the thyroid follicle, bound to a protein called *thyroglobulin*.<sup>7</sup> Thyroglobulin is a large water-soluble protein that is trapped within the thyroid follicle. Secretion occurs via cleavage of the thyroid hormone from thyroglobulin in response to systemic needs determined by the hypothalamus and the pituitary gland. Free  $T_3$  and  $T_4$  are released from the thyroid cells through membrane carrier proteins. Thyroid and steroid synthesis and release are detailed later in this chapter.

### Factors Affecting Hormone Secretion

Secretion of endocrine hormones is dependent on the interplay of many factors. Most of the hormones controlled by the anterior pituitary gland are secreted in cyclical patterns. These cycles are regulated by the hypothalamus and may occur in response to feeding-fasting cycles, light-dark cycles, sleep-wake cycles, or in a 24-hour (circadian) period. Cycles also occur over longer periods (e.g., the 28-day menstrual cycle) or over years (e.g., the hormones that control reproductive differentiation and maturity).<sup>1,2</sup> Acute systemic needs or stressors can partially override cyclical patterns and modify hormone secretion. An example of this is activation of the stress response that alters the normal circadian pattern of cortisol secretion. Knowledge of the cyclical nature of hormone release is important when comparing measured serum concentrations to normal ranges and when attempting to provide hormone replacement therapy that mimics the normal physiologic pattern.

### Feedback Control of Secretion

The most common mechanism regulating hormone production and secretion is *negative feedback* control in which some aspect of the secreted hormone is sensed and regulates further secretion.<sup>4</sup> An example of negative feedback is the interaction between the hypothalamic-pituitary system and the respective hormone-releasing glands controlled by this system. For example, thyrotropin-releasing hormone (TRH) is secreted by the hypothalamus when the central nervous system senses an inadequate supply of thyroid hormones in the circulation. TRH stimulates the synthesis and release of thyroid-stimulating hormone (TSH) from specific cells in the anterior pituitary gland; TSH then stimulates the synthesis and release of the thyroid hormones  $T_3$  and  $T_4$  from the thyroid follicle. The resulting increase in plasma thyroid hormone concentration exerts an inhibitory effect, or negative feedback, on the release of TSH by the anterior pituitary gland and TRH from the hypothalamus.<sup>7,8</sup> The negative feedback loop is a mechanism for maintaining hormone activity within a normal range or *set point* of normal activity. The set point is genetically determined and influenced by age, gender, circadian cycles, and current internal and environmental conditions. The regulatory influences are multiple and complex, but often there is a particular variable that is influenced by the hormone's activity and provides most of the feedback regulation. These feedback systems are detailed for the hormones of the pituitary system in later sections of this chapter. Knowledge of feedback controls is helpful when evaluating patients for endocrine diseases (see Chapter 40).

### Hormone Metabolism and Excretion

The plasma concentration of a hormone depends not only on the rate of synthesis and release of the hormone but also on how rapidly the hormone is metabolized and excreted. Like other compounds, hormones are frequently degraded and excreted by the liver and kidneys. Water-soluble hormones may be excreted in the urinary filtrate. Lipid-soluble hormones, which are bound to plasma proteins and stored in adipose tissue, are less readily metabolized and remain in the circulation for a more prolonged period.<sup>4</sup> In addition to metabolism by the kidneys and liver, hormones are often degraded by the target cell after binding to receptors. *Half-life* is a term used to describe the duration of hormone activity in the circulation and may be expressed in minutes, hours, or days. The half-life is the time for a hormone to reach half of its original concentration in the blood and is influenced by the rate of uptake by cells, degradation, and excretion.

### Pharmacologic Hormone Concentrations

It is important to differentiate between physiologic and pharmacologic hormone activity. Physiologic hormone concentrations are extremely low in most cases, and pharmacologic levels of hormones are usually several-fold greater than would normally be secreted by endocrine tissues. Pharmacologic levels occur as a consequence of either pathologic processes or the administration of large doses of hormones. The tissue response to pharmacologic hormone concentrations may be significantly different from that caused by physiologic levels of hormones.<sup>4</sup>

### Regulation of Receptor Responses

Tissue response to circulating hormone is only partially determined by the amount of hormone present in the circulation. Although virtually all body tissues are exposed to circulating hormones, specific hormones elicit a response only from certain cells and tissues. The ability of a cell to respond to a particular hormone depends on the presence of specific receptors for that hormone on or in the cell. Target cells are able to regulate their responsiveness to hormones by altering the receptor number, affinity, and efficiency of coupling to intracellular responses.<sup>3</sup>

### Receptor Specificity and Affinity

The concept of *receptor specificity* is important for understanding the targeted responses of the endocrine system. Specificity refers to the molecular “fit” of a hormone within a receptor-binding pocket. Specificity cannot easily be separated from the concept of *affinity*. Affinity describes the degree of “tightness” of the hormone-receptor bond, or the inclination of the hormone to remain bound to the receptor. Specificity and affinity determine whether a cell with a receptor will respond to a hormonal stimulus and the hormone concentration at which the receptor effectively can bind the hormone. The potency of the hormone, or the amount of hormone required to elicit a cellular response, is dependent in part on the affinity of the receptor for a particular hormone. The higher the affinity of the receptor for a hormone, the lesser the amount of hormone needed to produce a response.<sup>3</sup> Therefore, hormones that circulate in very minute amounts may have a large effect on cellular activity because of the tightness of the hormone-receptor bond.

“Cross-specificity” between hormones of similar structure may occur. For example, prolactin and growth hormone both can bind to the prolactin receptor, but with differing affinities. Under normal circumstances, the plasma concentration of growth hormone is not adequate to bind a significant number of prolactin receptors. However, in the condition called *acromegaly*, in which excessive concentrations of growth hormone lead to massive bone and tissue overgrowth, milk may be secreted from the mammary glands secondary to growth hormone stimulation of prolactin receptors.<sup>9,10</sup>

### Receptor Down-Regulation and Up-Regulation

A factor determining the degree of response to a circulating hormone is the number of cell receptors available for hormone binding. When cells are exposed to high concentrations of hormone for a prolonged period, a common result is that the cell decreases the number of receptors. This phenomenon is known as *down-regulation*. An example of down-regulation occurs with insulin receptors in obese individuals. An increase in the plasma insulin level commonly occurs in obese individuals. This increased concentration of insulin does not result in an increase in cellular activities in most cells because the number of insulin receptors is down-regulated in response to the high plasma insulin concentration.<sup>3</sup> Down-regulation probably serves a protective function: the cells are protected against excessive activity despite pathologic processes that cause excessive hormone levels. *Up-regulation*, or an increase in the number of receptors in response to chronically low hormone concentrations, may also occur. Up-regulation would make the cell more sensitive to the hormone, and hormone-dependent cellular activity could occur at normal or nearly normal levels despite a lower than normal hormone concentration.<sup>3</sup>

Another mechanism for altering hormone responsiveness is through regulation of the coupling mechanism between receptor activation and its intracellular responses.<sup>3</sup> For example, the cytoplasmic domain of a receptor can be phosphorylated or otherwise altered so that it cannot effectively interact with its target G-protein. Additionally, enzymes such as phosphorylases, which remove phosphates from proteins, and phosphodiesterases, which degrade cyclic nucleotides, can be up-regulated or down-regulated to turn off the cellular responses more or less quickly. Many of these regulatory mechanisms are not fully understood.

### Permissiveness

One effect that hormones may have on target cells is to increase the number of receptors for other hormones, thus enhancing the effect of the second hormone. This phenomenon is known as *permissiveness*. For example, one effect of thyroid hormone on adipose cells is to increase the number of receptors for epinephrine. When the adipose tissue is subsequently exposed to epinephrine, a greater release of fatty acids (used in providing energy for cellular processes) takes place than would occur in the absence of thyroid hormone.<sup>4</sup> Permissiveness also allows cellular events to occur in sequence. One effect of estrogen, secreted early in the menstrual cycle, is to increase the number of uterine receptors for progesterone. The uterus is therefore sensitive to progesterone when it is present during the last part of the menstrual cycle, and normal proliferative changes take place.<sup>2,11</sup>

### Hormone Agonists and Antagonists

To produce a cellular effect, a hormone must bind to the receptor and initiate a series of events that lead to a change in cellular activity. A chemical may bind to a receptor without initiating the typical intracellular changes; this chemical is described as a hormone **antagonist** or **blocking agent**. **Agonists**, on the other hand, bind hormone receptors and cause the same intracellular events that would occur with hormone-receptor binding. A large number of pharmacologic agents have agonist or antagonist effects on receptors for hormones. For example, hormone antagonists that compete with epinephrine and norepinephrine for receptor sites are frequently used to block the cardiac stimulatory properties of these hormones and thus decrease cardiac workload. Conversely, agonist medications that mimic hormone activity are frequently given as hormone replacement therapy in deficiency syndromes.

### KEY POINTS

- Hormone concentration in the bloodstream depends on the rate of secretion and on the rate of degradation by the liver, kidneys, and target tissues. Lipid-soluble hormones are less readily metabolized than peptides and usually have a longer half-life.
- The secretion of most hormones is regulated by negative-feedback mechanisms. Target gland hormones provide feedback to inhibit secretion of the initial hormone and keep the response within a normal range or set point.
- Only target cells producing the specific receptor for a hormone will respond to a particular hormone. High-affinity receptors enable hormone binding at very low physiologic concentrations of hormone.
- The number of hormone receptors on a cell's surface may adapt to changes in cell environment. Down-regulation refers to a decrease in the number of receptors in response to excessive amounts of hormone. Up-regulation refers to an increase in receptor number in response to low hormone concentration. Receptors may also be uncoupled from their intracellular signaling cascades.
- In the phenomenon known as permissiveness, receptor number and responsiveness may be enhanced by the presence of other hormones.
- Chemicals other than the usual hormone may be able to bind to the hormone's receptors. Chemicals that bind receptors and block activity are antagonists; those that bind receptors and activate them are agonists.

## HYPOTHALAMIC-PITUITARY ENDOCRINE SYSTEM

The pituitary gland is located beneath the hypothalamus in the sella turcica, a pocket of bone at the base of the skull (Figure 39-5).<sup>12</sup> In adults, the pituitary gland is composed of distinct anterior and posterior lobes. The pituitary gland is connected to the hypothalamus by the pituitary stalk, which contains a portal system that transports capillary blood from the hypothalamus to the capillaries of the anterior pituitary gland. Neurons whose cell bodies lie within the hypothalamus send their axons down the pituitary stalk and terminate in the posterior pituitary gland. Synthesis and secretion of the various pituitary hormones are controlled, directly or indirectly, by the hypothalamus. Release of posterior pituitary hormones occurs when action potentials generated in the hypothalamic neurons travel down the axons of the pituitary stalk and trigger exocytosis of hormone from the nerve terminals in the posterior pituitary gland. The hypothalamus regulates endocrine function of the anterior pituitary gland by secreting releasing hormones and inhibiting hormones from hypothalamic neurons that are subsequently carried to anterior pituitary endocrine cells by the pituitary portal system.

The pituitary gland is also called the *hypophysis*, and the anterior and posterior lobes are sometimes referred to as the *adenohypophysis* and the *neurohypophysis*, respectively. The posterior pituitary gland secretes two important peptide hormones: antidiuretic hormone (vasopressin) and oxytocin. The anterior lobe of the pituitary gland has five endocrine cell types that secrete six different peptide hormones: (1) somatotropes, which secrete growth hormone (GH); (2) gonadotropes, which secrete gonadotropins (luteinizing hormone [LH], follicle-stimulating hormone [FSH]); (3) thyrotropes, which secrete thyroid-stimulating hormone (TSH, thyrotropin); (4) corticotropes, which secrete adrenocorticotropic hormone (ACTH); and finally (5) lactotropes, which secrete prolactin (PRL).<sup>9,10</sup> The hormones produced by the anterior pituitary gland have direct actions on other endocrine tissues and the liver (Table 39-1).

### Hormones of the Posterior Pituitary Gland

The posterior pituitary gland consists of nerve axons whose neuronal cell bodies originate in the supraoptic and paraventricular nuclei of the

**FIGURE 39-5** Cross section showing anatomic relationship of the hypothalamus and pituitary gland. (From Koeppen BM, Stanton BA, editors: *Berne & Levy physiology*, ed 6 [updated edition], Philadelphia, 2010, Mosby, p 707.)

<sup>‡</sup>Inhibin selectivity inhibits FSH release from the gonadotrope.

hypothalamus (Figure 39-6). Posterior pituitary hormones, oxytocin and antidiuretic hormone, are produced in the neurons of the hypothalamus and, packaged in vesicles, travel along the length of the nerve axons to the posterior pituitary gland. Release of antidiuretic hormone or oxytocin occurs as a result of depolarization of the appropriate hypothalamic neurons and conduction of action potentials to the nerve terminals in the posterior pituitary gland. Antidiuretic hormone is released in response to altered serum osmolality and hypotension and

causes water retention by increasing water reabsorption by the renal collecting duct. Oxytocin is released during sexual activity, childbirth, and breast feeding and causes uterine and milk duct contractions.<sup>10</sup>

### Antidiuretic Hormone

Antidiuretic hormone is a 9–amino acid peptide that differs by 2 amino acids from oxytocin, another 9–amino acid peptide. The circulating half-life of ADH is about 15 to 20 minutes, and it is destroyed by

**FIGURE 39-6** Axons from the paraventricular and supraoptic nuclei in the hypothalamus project down the pituitary stalk, and the axon terminals lie within the posterior pituitary gland. Oxytocin and antidiuretic hormone are produced in the hypothalamic neuron cell bodies and then transported to the axon terminals, where they are released into the bloodstream in response to action potentials. (From Porterfield SP, White BA: *Endocrine physiology*, ed 3, Philadelphia, 2007, Mosby, p 110.)

proteolysis in the kidney and liver.<sup>10</sup> The most important regulator of ADH release is the osmolality of plasma, which is detected by specialized neurons called *osmoreceptors* that are found in the hypothalamus. The osmoreceptors have a set point that influences the stimulation and suppression of ADH. When body fluids become too concentrated, ADH is released, leading to increased reabsorption of water in the kidneys. ADH secretion is also stimulated by the baroreceptors in response to hypovolemia and low arterial blood pressure.

The primary targets for ADH are vasopressin 2 (V2) G-protein-linked receptors on the basolateral membrane of distal renal tubule cells. ADH causes pores, called *aquaporins*, to move from the cytoplasm to the cell membranes of apical tubular epithelial cells (Figure 39-7). These pores allow free diffusion of water from the tubular fluid into the cell. Water then flows out the basolateral membrane and into the interstitium. The enhanced reabsorption conserves water in the body, creates concentrated urine, and reduces serum osmolality (see Chapter 26).

### Oxytocin

Oxytocin is structurally similar to ADH, and there is some overlap in biological activity. Oxytocin can inhibit diuresis. Oxytocin has a half-life of 3 to 5 minutes. Oxytocin is known for its actions on the breast and uterus. Sexual intercourse can stimulate oxytocin release in men and women. Its role in men is not well understood, but in women it is proposed to affect sperm motility through uterine contractions. Oxytocin also stimulates uterine contractions during labor. It is not thought to initiate labor, but once labor has begun, stretching of the cervix increases oxytocin release, which increases the intensity of uterine contractions.<sup>10</sup> This is an example of a positive feedback loop in which stretching of the cervix induces oxytocin release, resulting in

**FIGURE 39-7** Antidiuretic hormone (ADH) acts on renal tubule G<sub>s</sub>-protein-linked receptors to trigger movement of water channels (aquaporins) to the apical cell membrane. The aquaporins increase membrane permeability to water, allowing it to be absorbed through the process of osmosis. ADH thus decreases the osmolality of the extracellular fluids and creates a more concentrated urine. ATP, Adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

more forceful uterine contractions and further stretching of the cervix. Oxytocin has been characterized as the “tend and befriend” hormone because of its effects on social interaction and its participation in the stress response in men and women.

Oxytocin release is triggered by stimulation of the nipple and areola, which have sensory receptors that send neuronal signals to the hypothalamic nuclei. Oxytocin then binds to myoepithelial cells surrounding the milk ducts, causing them to contract and eject milk during breast feeding. This reflex can be triggered centrally without breast stimulation as a conditioned response to the sight or sound of an infant.

### Hormones of the Hypothalamus and Anterior Pituitary Gland

The hypothalamic-pituitary endocrine system is a three-tiered axis that includes hypothalamic releasing and inhibiting hormones, anterior pituitary hormones, and target organ hormones (Figure 39-8). Releasing and inhibiting factors are secreted into a capillary bed that is contained within the hypothalamus by hypothalamic neurons having short axons. Hypothalamic hormones diffuse into the capillary network, travel down the portal vein, and then diffuse from the anterior pituitary capillary network into the tissue where they bind receptors on pituitary cells.<sup>12</sup> All of the hypothalamic releasing and inhibiting factors are peptides, with the exception of dopamine, and all are water-soluble. Therefore all releasing and inhibiting factors interact with cell-surface receptors on the target pituitary cells.

The three-tiered hypothalamic-pituitary-target system provides an opportunity for fine modulation of hormone action on target tissues. The hypothalamic and pituitary hormones exemplify the complexity of endocrine interactions. In addition to feedback from target organ hormones, the hypothalamus processes numerous neuronal signals into an integrated response by the anterior pituitary gland. The hypothalamic releasing and inhibiting hormones are typically secreted in

**FIGURE 39-8** Relationship of the hypothalamic releasing and inhibiting hormones, anterior pituitary hormones, and target gland hormones. *ACTH*, Adrenocorticotropic hormone; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *IGF-1*, insulin-like growth factor-1; *LH*, luteinizing hormone; *TSH*, thyroid-stimulating hormone; *T<sub>3</sub>*, triiodothyronine; *T<sub>4</sub>*, thyroxine.

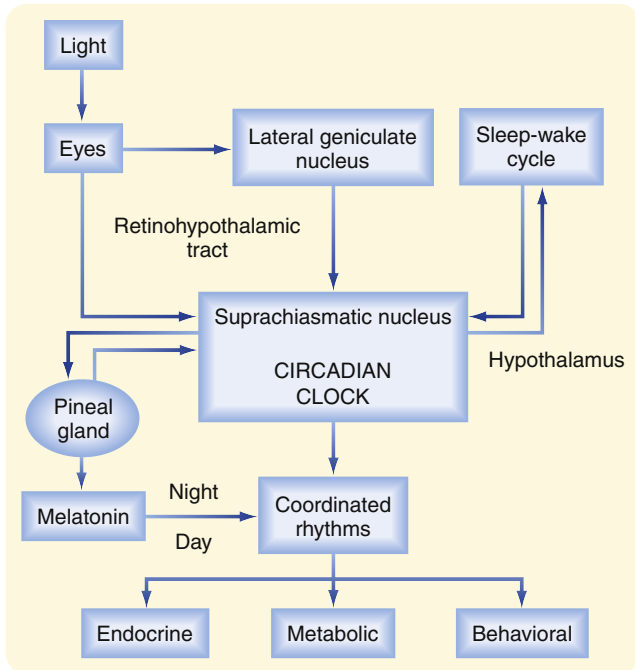

a pulsatile and circadian rhythm. Two structures thought to modulate this activity are the suprachiasmatic nucleus (SCN) and the pineal gland. Changes in light and dark patterns influence the SCN and pineal gland, resulting in a diurnal (daily) pattern of hormone secretion (Figure 39-9).<sup>9</sup> Each of the major anterior pituitary hormones is briefly described next.

### Growth Hormone

Pituitary GH secretion is controlled by hypothalamic release of growth hormone–releasing hormone (GHRH) and growth hormone–inhibiting hormone (somatostatin). GHRH binds to receptors on pituitary somatotropes and stimulates release of GH, whereas somatostatin inhibits GH release. Under normal physiologic conditions, the anterior pituitary gland secretes small pulsatile amounts of GH each day. Sleep studies indicate a circadian pattern to GH secretion, with secretion being greatest during deep, slow-wave sleep (stage 3 or 4). GH secretion is greatest during adolescence and decreases in the elderly.<sup>10</sup>

GH is a 191–amino acid protein that is similar in structure to prolactin. A major target for GH is the liver, where it affects liver metabolism and also induces the production of another endocrine hormone called *insulin-like growth factor-1* (IGF-1). Previously, IGF-1 was called *somatomedin*. IGF-1 is an anabolic hormone that increases the growth of bone and cartilage tissues of the body. GH is not the only stimulus for the production of IGF-1, nor is the liver the only source. Insulin is an important costimulator of IGF-1 along with GH.<sup>10</sup> GH also has direct effects on some cells and binds to receptors on muscle and adipose tissue, increasing muscle mass and decreasing fat mass by inducing lipolysis. It affects metabolic processes by increasing the rate of protein synthesis, decreasing protein catabolism, slowing carbohydrate utilization, and increasing mobilization of fats and the use of fats for energy (Figure 39-10).<sup>4</sup> An insufficient level of GH is exhibited as short stature in children, whereas excesses may lead to increased height in children and excessive growth of nonadipose tissues in adults (see Chapter 40).

Feedback regulation of GH release is complex and is affected by several hormones including estrogen, testosterone, and thyroid hormone, which stimulate GH release. Perhaps the most important negative feedback is through IGF-1. Hypoglycemia and a rise in the concentration of amino acids in the blood stimulate the release of GH as does starvation and exercise.

**FIGURE 39-9** Origin of circadian rhythms in endocrine gland secretion. (From Koeppen BM, Stanton BA, editors: *Berne & Levy physiology*, ed 6 [updated edition], Philadelphia, 2010, Mosby, p 656.)

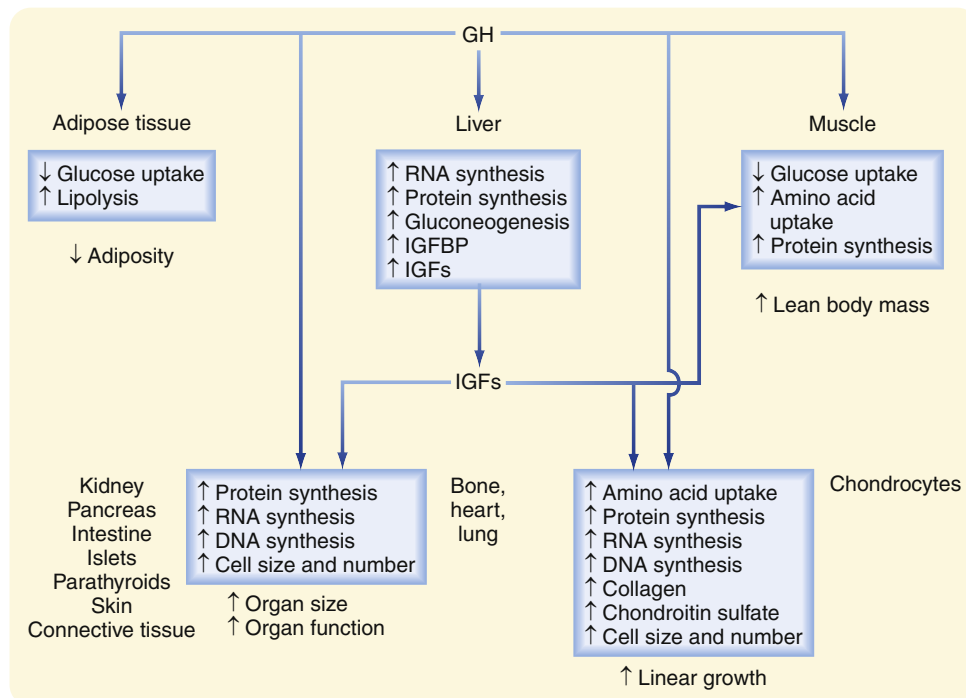

## Prolactin

The lactotropes that secrete prolactin are the second most numerous cell type in the anterior pituitary gland, after the somatotropes. Prolactin is a 199–amino acid protein that acts directly on numerous cell types.<sup>10</sup> Prolactin is best known for its trophic effects on breast tissue development and lactation and its ability to suppress reproductive function in both men and women. Prolactin exerts its inhibitory effects on fertility through suppression of hypothalamic gonadotropin-releasing hormone. Numerous other functions for prolactin have been proposed, and it has been noted that its level increases during sexual orgasm, stress, and exercise.

Prolactin secretion is normally under tonic (constant) inhibition by prolactin-inhibiting factor. The prolactin-inhibiting factor is dopamine produced in the hypothalamus. Drugs that block dopamine receptors can release prolactin from its normal inhibition, resulting in abnormal breast development in males (gynecomastia) or inappropriate milk secretion (galactorrhea). During pregnancy, the number of pituitary lactotropes increases under the influence of placental estrogen. Estrogen production and nipple stimulation increase prolactin synthesis and release from the anterior pituitary gland.

## Gonadotropins

The gonadotropins, FSH and LH, are produced together within the gonadotropes in the anterior pituitary gland; however, they are segregated into different packaging vesicles and are not necessarily released in equal amounts.<sup>2,10</sup> FSH and LH are proteins and bind to their specific respective receptors on target cells in the ovary or testes. In general, FSH and LH stimulate testosterone production in men (see Chapter 30) and estrogen and progesterone production in women.<sup>11</sup> These relationships are complex in women and change over the menstrual cycle (see Chapter 32). Release of FSH and LH is stimulated by hypothalamic gonadotropin-releasing hormone in a pulsatile fashion, and inhibited by negative feedback from sex steroids (except for the

**FIGURE 39-10** Biological actions of growth hormone (GH). *IGF*, Insulin-like growth factor; *IGFBP*, insulin-like growth factor binding protein. (From Koeppen BM, Stanton BA, editors: *Berne & Levy physiology*, ed 6 [updated edition], Philadelphia, 2010, Mosby, p 721.)

midcycle positive feedback LH surge induced by estrogen at the time of ovulation in women).

### Thyroid-Stimulating Hormone

Thyrotropes release TSH in response to hypothalamic thyrotropin-releasing hormone (TRH). TSH is a glycoprotein that binds to TSH receptors on follicle cells of the thyroid gland. TRH is released according to a diurnal (daily circadian) rhythm with its lowest period in the evening. Stress, starvation, and infection reduce the secretion of TRH. Negative feedback regulation of TRH and TSH is achieved primarily by the concentration of circulating  $T_3$ . TSH regulates all aspects of thyroid function, including growth of the gland and synthesis and secretion of hormone.<sup>8,10</sup> The details of thyroid hormone synthesis and action on target tissues are described later in this chapter.

### Adrenocorticotropic Hormone

ACTH is produced by corticotropes in the anterior pituitary gland in response to hypothalamic corticotropin-releasing hormone (CRH). ACTH is a 39–amino acid peptide that is derived from cleavage of a large pre-prohormone called pro-opiomelanocortin (POMC). Although POMC has the protein sequences for melanocyte-stimulating hormone and endorphin in its structure, human corticotropes express only the enzyme for cleaving ACTH as the sole hormone from this pre-prohormone.<sup>6,10</sup> ACTH circulates unbound in the circulation and has a half-life of about 10 minutes. It binds to  $G_s$ -coupled receptors on cells in the adrenal cortex and stimulates the production of cortisol and adrenal androgens. ACTH also has trophic effects on the adrenal cortex and supports the structure and synthetic enzymes of the gland. Withdrawal of ACTH results in adrenal cortical atrophy. ACTH in high concentration stimulates darkening of the skin by stimulating melanocyte receptors on skin cells. Normally keratinocytes in the skin produce melanocyte-stimulating hormone (MSH) in response to ultraviolet light, which can bind to MSH receptors on neighboring skin melanocytes in a paracrine fashion. ACTH can cross-react with melanocyte MSH receptors, and in high concentrations ACTH can produce abnormal skin pigmentation.

CRH and ACTH secretion demonstrate a significant diurnal pattern, with a peak upon waking and a valley during the usual time of sleep (Figure 39-11). The diurnal pattern can be altered when there are chronic changes in sleep-wake patterns. Negative feedback regulation of ACTH is accomplished by the actions of cortisol, which suppress CRH and ACTH release. Regulation of the hypothalamic-pituitary-adrenal (HPA) axis is complex and is affected by acute and chronic stress (see Chapter 2). The adrenal cortex produces three types of steroid hormones: glucocorticoids, mineralocorticoids, and androgens. The details of adrenocortical steroid hormone synthesis and action on target tissues are described later in this chapter.

**FIGURE 39-11** Typical pattern of cortisol secretion showing a diurnal (circadian) rhythm, with highest secretion occurring in the morning upon awakening and lowest levels in the late evening. The pattern can change when the usual wake and sleep times are altered, for example, in night-shift workers. (In Hall JE, editor: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 933.)

## THYROID HORMONES

### Thyroid Hormone Synthesis and Secretion

The thyroid gland, a two-lobed gland, lies in the neck region on either side of and anterior to the trachea. It secretes the thyroid hormones thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ).<sup>7,12</sup> The thyroid gland is composed of microscopic follicles made up of a single layer of epithelial cells forming a ball, with their apical surfaces toward a pocket in the middle filled with colloid and their basal surfaces facing the interstitial fluid and capillary system (Figure 39-12). Follicular cells perform all the functions required to make and secrete thyroid hormones.<sup>7,8</sup> They trap dietary iodine and transport it into the colloid, synthesize thyroglobulin protein, and transport it into the colloid along with the enzyme thyroid peroxidase. Thyroid peroxidase acts on thyroglobulin to produce thyroid hormones (Figure 39-13). First it oxidizes iodide and couples it to tyrosine amino acids in thyroglobulin. Some tyrosines receive two iodides (diiodotyrosine, DIT) and others have only one (monoiodotyrosine, MIT). Two iodotyrosines are then attached to each other by thyroid peroxidase to form  $T_4$  (two DIT) or  $T_3$  (one DIT and one MIT). Approximately 90% of the thyroid hormone is in the form of  $T_4$ , and 10% is in the form of  $T_3$ . The thyroid hormones remain attached to thyroglobulin, a storage protein, which accumulates in the thyroid follicles. By remaining attached to thyroglobulin,  $T_3$  and  $T_4$  are trapped within the water-soluble colloid. When stimulated by TSH, the follicular cells endocytose a portion of the colloid containing thyroglobulin with its attached thyroid hormones. The endocytic vesicle combines with a lysosome, and the thyroid hormones are cleaved from thyroglobulin. Released  $T_4$  and  $T_3$  are transported from the follicle and into the circulation through carriers on the basal membrane.

### Thyroid Action on Target Cells

Thyroid hormones are carried in the circulation bound to thyroid-binding proteins. Ninety percent of the circulating thyroid hormone is  $T_4$ , and 10% is  $T_3$  (Figure 39-14). A small percentage of thyroid hormone (less than 1%) is dissolved in the plasma as free hormone and is able to

#### KEY POINTS

- Oxytocin and antidiuretic hormone (vasopressin) are synthesized in hypothalamic neurons that send axons to the posterior pituitary gland. Oxytocin is released during childbirth and suckling. Antidiuretic hormone is released in response to increased serum osmolality and decreased blood pressure.
- Major hormones of the anterior pituitary gland are GH, TSH, prolactin, ACTH, and gonadotropins (FSH, LH). The release of anterior pituitary hormones is regulated by releasing and inhibiting hormones secreted into pituitary portal blood by the hypothalamus. Many factors influence the secretion of releasing and inhibiting hormones, including circadian rhythms, hormone release from target cells, stress, and pain.

**FIGURE 39-12** Histology of thyroid follicle demonstrating single layer of epithelial follicular cells (*FC*) surrounding a core of colloid (*C*). The parafollicular cells (*P*) produce another hormone called *calcitonin*, which is involved in calcium regulation. (From Porterfield SP, White BA: *Endocrine physiology*, ed 3, Philadelphia, 2007, Mosby, p 142.)

**FIGURE 39-13** The follicular cells in the thyroid gland perform all of the functions required for thyroid hormone synthesis. Iodide is transported from the circulation into the inner core along with the protein thyroglobulin, which is synthesized within the cells. Follicles also produce a thyroid peroxidase enzyme and secrete it from the apical surface next to the colloid. Thyroid peroxidase activates and attaches iodides to tyrosine amino acids in the thyroglobulin. Two iodotyrosines are then coupled together, but remain attached to thyroglobulin. Stimulation by TSH initiates a cascade that induces the follicle cell to endocytose some of the colloid, followed by combining it with a lysosome that cleaves the  $T_3$  and  $T_4$  from the thyroglobulin.  $T_3$  and  $T_4$  can then leave the cell into the circulation.

cross into the target cells through specific membrane carrier proteins. Once in the cell,  $T_3$  is able to bind to its receptor and exert its actions.  $T_4$  is acted upon by cellular enzymes that cleave one of the iodine molecules to form either the active  $T_3$  or a mirror image of  $T_3$  called *reverse  $T_3$* . This stereoisomer of  $T_3$  has no known biological activity. The ratio of production of  $T_3$  and reverse  $T_3$  is normally about 1:1, but is influenced by altered metabolic states such as starvation.<sup>8</sup> Most of the actions of thyroid hormone on target cells are mediated through alterations in gene transcription. The nuclear thyroid receptor has much higher affinity for  $T_3$  than  $T_4$  and primarily binds  $T_3$  to form a complex that binds to specific DNA sequences and alters gene activity. Many of these genes influence the metabolic rate of the cell. The general physiologic effects of thyroid hormones are shown in Table 39-2. Excesses and deficits of thyroid hormone are exhibited by alterations in growth, development, and metabolic rate (see Chapter 40).

#### KEY POINTS

- Follicular cells in the thyroid gland perform all the functions required to make and secrete thyroid hormones. They trap dietary iodine and transport it into the colloid, synthesize thyroglobulin protein, and transport it into the colloid along with the enzyme thyroid peroxidase.
- Thyroid peroxidase oxidizes iodide and couples it to tyrosine amino acids in thyroglobulin. Two iodotyrosines are then attached to each other to form  $T_4$  (two DIT) or  $T_3$  (one DIT and one MIT). Approximately 90% of the thyroid hormone is in the form of  $T_4$ , and 10% is in the form of  $T_3$ .
- When stimulated by TSH, the follicular cells endocytose a portion of the colloid. The endocytic vesicle combines with a lysosome, and the lipid-soluble  $T_4$  and  $T_3$  are released and leave the follicle where they are more than 99% bound to proteins in the circulation. Only free hormone is physiologically active.
- Actions of thyroid hormone on target cells are mediated through alterations in gene transcription. The nuclear thyroid receptor binds  $T_3$  to form a complex that binds to specific DNA sequences and alters gene activity.
- Thyroid hormone increases metabolic rate and is essential for normal growth and development.

## STEROID HORMONES

### Steroid Hormone Synthesis and Secretion

The adrenal glands are located atop the kidneys and are composed of an inner medulla and an outer cortex. The adrenal medulla secretes epinephrine and norepinephrine in response to sympathetic nervous system stimulation and is discussed in Chapter 40. The hormones produced by the adrenal cortex are called **steroids** and include (1) glucocorticoids (cortisol), (2) mineralocorticoids (aldosterone), and (3) sex steroids (DHEAS, androgen).<sup>13,14</sup> The synthesis and secretion of these hormones, especially cortisol, are considered essential for life, regulating the body's response to normal and abnormal levels of physiologic and psychological stress. The activities of these three hormones can be remembered as regulating the “three S’s”: sugar, salt, and sex.

The adrenal cortex has distinct zones that differ in histologic appearance, hormonal regulation, and enzyme pathways available for steroid synthesis (Figure 39-15). The outer *zona glomerulosa* produces the mineralocorticoid (aldosterone) in response to stimulation by AII. The middle *zona fasciculata* produces the glucocorticoid (cortisol) in response to stimulation by ACTH from the pituitary gland.<sup>14</sup> The inner *zona reticularis* is adjacent to the adrenal medulla and produces the androgen (DHEAS). All of these hormones are synthesized from cholesterol, and some of the cholesterol-derived precursors feed enzymatic pathways in all three zones (Figure 39-16). This is an important concept because it explains why an enzyme deficiency in one pathway (e.g., cortisol synthesis) may lead to an overproduction in another pathway (e.g., DHEAS) as precursors are shunted. This is what happens in a disorder called *congenital adrenal hyperplasia* (see Chapter 40).

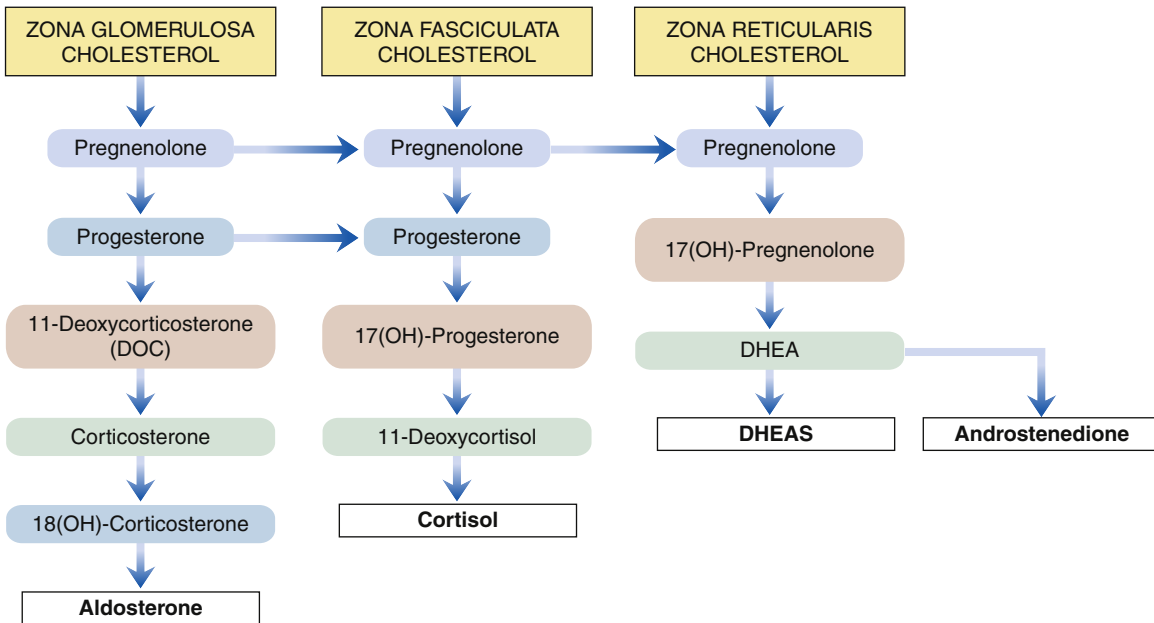

FIGURE 39-15 The adrenal gland is composed of the adrenal medulla at the innermost core, surrounded by the cortex. The adrenal cortex is composed of three anatomically and physiologically distinct layers: the zona glomerulosa, the zona fasciculata, and the zona reticularis. Each zone produces a different adrenocortical hormone.

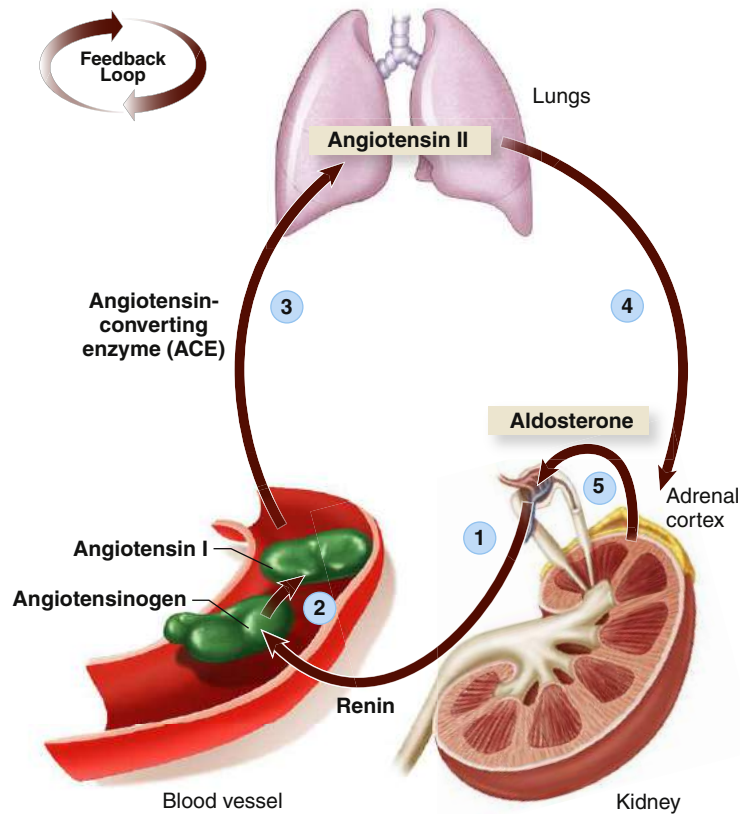

As previously noted, steroid hormones are lipid-soluble and diffuse from the adrenocortical cells as they are synthesized, so they are made on demand and not stored in the cells. The stimulus for both cortisol and androgen synthesis and secretion is ACTH, whereas aldosterone synthesis and secretion is under control of AII (Figure 39-17). The activity of aldosterone synthase, the enzyme that performs the last step to produce aldosterone, is stimulated by AII binding to G<sub>q</sub> receptors on adrenocortical cells in the zona glomerulosa.<sup>6</sup>

### Steroid Action on Target Cells

Steroid hormones travel in the circulation bound to proteins, including corticosteroid-binding globulin (transcortin) and albumin. Cortisol

**FIGURE 39-16** Adrenal cortex steroid hormone synthesis. Steroid hormones are synthesized from cholesterol and have some common precursors. *DHEAS*, Dehydroepiandrosterone.

**FIGURE 39-17** Renin-angiotensin mechanism for regulating aldosterone secretion. (1) When the incoming blood pressure in the kidneys drops below a certain level, the juxtaglomerular apparatus secretes **renin** into the blood. (2) Renin, an enzyme, causes **angiotensinogen** (a normal constituent of blood) to be converted to **angiotensin I**. (3) Angiotensin I circulates to the lungs, where converting enzymes in the capillaries split the molecule, forming **angiotensin II**. (4) Angiotensin II circulates to the adrenal cortex, where it stimulates the secretion of **aldosterone**. (5) Aldosterone causes increased reabsorption of sodium, which causes increased water retention. As water is retained, the volume of blood increases. The increased volume of blood creates higher blood pressure, which then causes the renin secretion to stop. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 7, St Louis, 2010, Mosby, p 561.)

**BOX 39-2 BIOLOGIC ACTIONS OF CORTISOL**

Hyperglycemic  
 Gluconeogenic  
 Lipolytic  
 Protein catabolic  
 Insulin antagonist in muscle and adipose tissue  
 Inhibits bone formation, stimulates bone resorption  
 Necessary for vascular response to catecholamines  
 Antiinflammatory  
 Suppresses immune system  
 Inhibits antidiuretic hormone secretion and action  
 Stimulates gastric acid secretion  
 Necessary for integrity and function of gastrointestinal tract  
 Stimulates red blood cell production  
 Alters mood and behavior  
 Permissive for calorogenic, lipolytic effects of catecholamines

Adapted from Porterfield SP, White BA: *Endocrine physiology*, ed 3, Philadelphia, 2007, Mosby, p 175.

and androgens bind tightly with their binding proteins, but aldosterone does not and has a shorter half-life in the circulation. Steroids have long been known to diffuse through their target cell membranes and bind with their respective cytoplasmic receptors, and then the hormone-receptor complex rapidly translocates into the nucleus. The complex binds to specific DNA sequences to alter responsive genes. In addition to this classic pathway, steroid hormones may also bind to receptors already located in the nucleus or to cell membrane-associated receptors. Membrane-associated receptors mediate more rapid changes in cell function than the classic DNA-binding pathway.

*Glucocorticoids*, principally cortisol, are named for their primary effect on glucose metabolism. Cortisol affects nearly every tissue in the body and exhibits a broad range of manifestations (Box 39-2). Glucocorticoids oppose the effects of insulin and raise the blood glucose level. This is accomplished by decreasing glucose uptake by many body cells, and increasing glucose synthesis in the liver from glycogen and amino acid and glycerol substrates in protein and fat stores. Glucocorticoids also contribute to protein catabolism by releasing muscle stores of proteins, providing amino acids for glucose production in the liver. Glucocorticoids promote lipolysis and increased blood cholesterol level. Glucocorticoids protect against the damaging physiologic effects of stress (see Chapter 2) and regulate the inflammatory and immune responses.<sup>13,14</sup>

*Mineralocorticoids*, principally aldosterone, function to maintain normal salt and water balance by promoting sodium retention and potassium excretion at the distal renal tubules. Aldosterone production is regulated primarily by the renin-angiotensin system associated with the juxtaglomerular cells of the kidney in response to a reduction in renal perfusion, and by a high serum potassium level (see Chapter 26).

**KEY POINTS**

- The hormones produced by the adrenal cortex are called steroids and include (1) glucocorticoids (cortisol), (2) mineralocorticoids (aldosterone), and (3) sex steroids (androgens).
- The adrenal cortex has distinct zones. The outer *zona glomerulosa* produces aldosterone, in response to stimulation by *Ang II*. The middle *zona fasciculata* produces cortisol in response to stimulation of ACTH from the pituitary gland. The inner *zona reticularis* is adjacent to the adrenal medulla and produces androgens.

- Steroids diffuse through their target cell membranes and bind with their respective cytoplasmic (or nuclear) receptors. The hormone-receptor complex rapidly translocates into the nucleus where it binds to specific DNA sequences to alter responsive genes. More rapid actions of steroid hormones have been noted and are mediated by cell membrane-associated receptors.
- Cortisol affects nearly every tissue in the body and exhibits a broad range of effects on metabolism including increasing plasma glucose level, regulating immune and inflammatory reactions, and inhibiting bone and collagen synthesis. Cortisol is an important hormone in the response to acute and chronic stress.
- Aldosterone secretion increases in response to low blood pressure and reduced perfusion of the kidney, which stimulate the renin-angiotensin-aldosterone cascade. Aldosterone increases sodium and water reabsorption in the distal tubule of the kidney and promotes the excretion of potassium in the urine.

**CATEGORIES OF ENDOCRINE DISEASE**

Endocrine pathologic processes can be divided into three general categories: disorders of hyposecretion, hypersecretion, and target cell hyporesponsiveness. These are discussed in relation to specific endocrine diseases in Chapter 40.

**Hyposecretion**

Primary hyposecretion occurs when an endocrine gland, such as the thyroid or adrenal cortex, releases an inadequate amount of hormone to meet physiologic needs. Secondary hyposecretion occurs when secretion of a tropic hormone, such as TSH or ACTH, is inadequate to cause the target gland to secrete adequate amounts of hormone. The diagnosis of hormone deficiency is complex because knowledge of tropic and releasing hormone levels, as well as the deficient hormone level, is necessary. For example, in a *primary* thyroid hormone deficiency (common), serum thyroid hormone level would be low but TSH levels would be high because the anterior pituitary gland would not be receiving negative feedback from thyroid hormone. However, in *secondary* thyroid hormone deficiency (rare), both thyroid hormone and TSH concentrations would be abnormally low.

**Hypersecretion**

Hypersecretion disorders can also be either primary or secondary.<sup>14</sup> When a diseased endocrine gland secretes an abnormally high amount of its hormone, the tropic pituitary hormone will be at an unusually low plasma level because of excessive negative feedback. Alternatively, if hypersecretion is secondary to elevated tropic hormone levels (rare), the plasma concentration of both hormones will be elevated. For example, in Cushing disease, the pituitary gland becomes hyperactive and oversecretes ACTH, which induces the adrenal cortex to produce too much cortisol (causing symptoms of cortisol excess). Excessive plasma hormone levels can also occur from hormone secretion by an ectopic source, as sometimes occurs with malignancies.

**Hyporesponsiveness**

Hyporesponsiveness (hormone resistance) of the target tissues will cause the same set of clinical symptoms as hyposecretion. The usual reason for hyporesponsiveness is lack of or a deficiency in cellular receptors, although postreceptor mechanisms such as second-messenger dysfunction can also cause decreased cellular response. If the target cell does not have appropriate receptors for a hormone, the

clinical symptoms will be the same as if inadequate hormone levels were reaching the target cells. However, plasma concentrations of hormone would be expected to be normal or high because of the lack of negative feedback to hormone-secreting organs. Nephrogenic diabetes insipidus is an example of kidney tubule resistance to the effect of ADH because of defective receptors on the tubular cells.<sup>15</sup> Some forms of diabetes mellitus also are characterized by tissue resistance to the effects of insulin (see Chapter 41).

#### KEY POINTS

- Endocrine disorders occur because of hyposecretion, hypersecretion, or lack of responsiveness by target cells. Hyporesponsiveness is clinically similar to hyposecretion and usually results from a lack of functional receptors or a defect in postreceptor signaling.
- Endocrine disorders may be due to abnormal tropic signals from the pituitary gland (secondary disorder) or to dysfunction of target glands (primary disorder).

## SUMMARY

The endocrine system, together with the nervous system, is responsible for coordination of cellular activity between many body systems and organs. Hormone secretion occurs in response to a variety of stimuli, including psychological or physiologic stress, electrolyte and metabolite levels, and normal circadian cycles. Increases or decreases in the

quantity of a particular circulating hormone tend to regulate levels of that hormone through negative feedback mechanisms. The cellular responses to hormones are complex and controlled by many other factors in addition to the circulating hormone levels.

Together with the nervous system, the endocrine system (the glands and the hormones they secrete) regulates body processes involving growth, maturation, metabolic functions, fluid balance, responses to stress, and reproduction.<sup>1,2</sup> This regulation is carried out through the actions of the hormones produced and secreted by the endocrine cells. **Endocrine hormones** are chemical messengers that travel through the bloodstream to exert physiologic effects on specific target cells and tissues. In the healthy state, hormones are released by endocrine glands when their action is needed and inhibited when their effect is attained.

Endocrine disease is marked by either hyperfunction (excessively high blood concentrations of a hormone, or conditions that mimic high hormone levels) or hypofunction (depressed levels, or conditions that mimic low hormone levels). Some endocrine disorders have such striking characteristics that recognition is obvious. Other symptoms of endocrine disease may be nonspecific and more difficult to detect. Observing and interviewing skills are important because, with the exception of the thyroid and testicles, the endocrine glands cannot be directly examined. Laboratory diagnostic tests are especially important in assessing the endocrine system.

This chapter describes alterations in the anterior pituitary regulatory system, including growth hormone, thyroid hormone, and adrenal hormones, as well as parathyroid hormone disorders and posterior pituitary disorders of antidiuretic hormone (vasopressin) secretion. Disorders of prolactin and the gonadotropins (follicle-stimulating hormone and luteinizing hormone) are discussed in Unit IX. Disorders of insulin secretion are discussed in Chapter 41.

## BASIC CONCEPTS OF ENDOCRINE DISORDERS

### Etiology of Endocrine Disorders

Dysfunction, either hyposecretion or hypersecretion, may originate in the hypothalamus/pituitary, the hormone-producing gland, or the target tissue (Figure 40-1). The etiology of endocrine disorders may be congenital, infectious, autoimmune, neoplastic, idiopathic, or iatrogenic. The onset of the disorders can be slow and insidious or abrupt and life threatening. The age at onset may range from birth to old age.

Abnormal hormone production occasionally results from an inborn genetic defect. Such defects may cause excessive production of hormone precursors because of an enzymatic block in the synthetic pathway, and enzyme deficiencies that impair hormone synthesis. An important example is congenital adrenal hyperplasia in which infants develop enlarged adrenal glands, but have a deficiency of cortisol production. If genetic defects do not cause a complete block of synthesis, increased pituitary stimulus may compensate by causing glandular hyperplasia, resulting in near-normal hormone levels.

Autoimmune disorders commonly cause endocrine dysfunction, particularly in women. The pathogenesis of autoimmunity is incompletely

understood, but involves both a genetic predisposition and an environmental trigger (see Chapter 10). Antibodies are produced against certain antigens on self tissue cells, resulting either in hyperfunction of the endocrine gland (e.g., hyperthyroidism of Graves disease) or in immune destruction of the gland, eventually leading to hypofunction (e.g., adrenal insufficiency of Addison disease).

Hormones may be produced by abnormal tissue sites. Such *ectopic* hormone production is usually associated with a malignant tumor. Although different tumors can produce hormones, some cell types are more commonly associated with specific tumors. For example, some lung tumors produce antidiuretic hormone (ADH), leading to water intoxication and hyponatremia. Endocrine disorders can also be classified as functional disorders caused by nonendocrine disease such as chronic renal failure, liver disease, or heart failure.

In some cases endocrine disease occurs when the target tissue fails to respond to a hormone. The presence of normal or elevated hormone levels without normal hormonal action indicates target tissue resistance. This problem is also demonstrated by diminished or absent response to the administration of exogenous hormones. The mechanisms of hormone resistance may be genetic or acquired and may include defects at receptor sites, antibody reaction to hormone receptors, and defective postreceptor hormone action.

Finally, some endocrine disorders may be induced by medical treatments, such as therapy for a nonendocrine disorder. These iatrogenic disorders can be caused by chemotherapy, radiation therapy, or surgical removal of glands. Commonly, a treatment for endocrine hyperfunction involves removal or destruction of glandular tissue with resultant chronic hypofunction. Long-term hormone replacement therapy may then be needed.

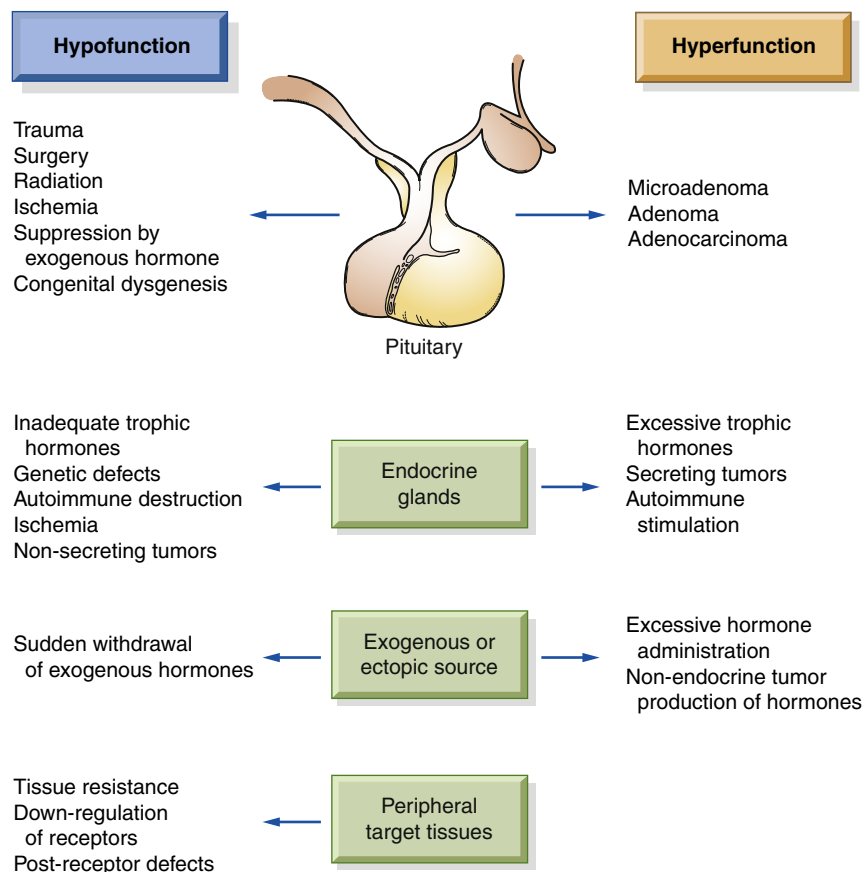

FIGURE 40-1 Common etiologies of endocrine disorders.

## Classification of Endocrine Disorders

Endocrine disorders involving control by the anterior pituitary gland commonly are classified as *primary* (intrinsic malfunction of the hormone-producing target gland) or *secondary* (malfunction of the hypothalamus/pituitary cells that control the hormone-producing target gland). The clinical presentation of an endocrine disorder of primary or secondary etiology is similar; however, diagnosing the source of the problem may be important in determining the best treatment. Measurement of serum concentrations of pituitary and target gland hormones allows differentiation between primary and secondary endocrine etiologies.

Clinically useful laboratory measures are available for diagnosing and monitoring hormone disorders including those affecting thyroid and adrenal function. Laboratory diagnosis is based on an understanding of the feedback loop communication between the hypothalamic-pituitary system and the target gland. When the *primary* gland fails, inadequate hormone is produced and low levels of hormone are present in the circulation, but blood levels of the corresponding trophic pituitary hormone become very elevated (Figure 40-2). For example, in primary hypothyroidism, the thyroid fails to secrete thyroid hormones and serum levels of thyroxine ( $T_4$ ) become lower. Thyroid-stimulating hormone (TSH) levels rise as the pituitary gland attempts to stimulate the malfunctioning thyroid. In contrast, in secondary hypothyroidism, the pituitary gland fails to release TSH, secondarily reducing thyroid gland production, so both thyroxine and TSH levels are abnormally low in the circulation. It is important to recall that the hormones released by the target gland are the ones that produce clinical signs and symptoms and that they are the starting point for interpretation of laboratory test results.

### KEY POINTS

- Endocrine disorders occur because of hypersecretion, hyposecretion, or nonresponsiveness by target cells.
- *Hypersecretion* is usually due to secreting tumors, autoimmune disease, or excessive stimulation of the gland by trophic signals.
- *Hyposecretion* may be due to failure or congenital absence of glandular tissue, autoimmune destruction, surgical removal of the gland, or lack of normal trophic signals.
- *Hyporesponsiveness* is clinically similar to hyposecretion and is due to target tissue dysfunction. This phenomenon is called *tissue resistance*.
- Endocrine disorders involving the hypothalamic-pituitary system are often classified as primary or secondary.
- Primary endocrine disorders result from intrinsic defects within the hormone-secreting gland.
- Secondary disorders result from abnormal hypothalamic-pituitary secretion of trophic signals. Manifestations of an endocrine disorder are due to abnormal target gland function and are therefore similar whether the etiologic classification is primary or secondary.

## GROWTH HORMONE DISORDERS

Growth hormone (GH) is produced in the anterior pituitary gland under the influence of hypothalamic releasing (growth hormone-releasing hormone) and inhibiting (somatostatin) factors. Its primary target organ is the liver, but GH also has direct effects on several tissue types. In general, GH increases lean body mass, reduces fat mass, and induces the liver to release glucose under conditions of hypoglycemia. Many of the effects of GH are mediated by a peptide called IGF-1 (insulin-like growth factor-1) that is released from the liver when stimulated by GH. Please refer to

Chapter 39 for details of GH synthesis, regulation, and activity. The major signs and symptoms of GH imbalance are summarized in Box 40-1.

### Growth Hormone Deficiency

**Etiology and pathogenesis.** Deficiencies in GH secretion can be classified into several major categories: (1) decreased GH secretion, (2) defective GH action (structurally abnormal GH or defective GH receptor), and (3) defective IGF-1 (somatomedin) generation.

Growth hormone deficiency is most clinically relevant in children. A birth history of prolonged labor or breech delivery is common, but GH deficiency may also be present in children who are born with mid-line craniocerebral defects, most likely attributable to congenital malformations or as sequelae of a chromosomal anomaly. Deficiencies in

**FIGURE 40-2** Diagnosing endocrine disorders as primary or secondary is based on the hypothalamic-pituitary and target tissue feedback loops. In this example, the low  $T_3$  and  $T_4$  levels are indicative of hypothyroidism. The elevated TSH level indicates that the pituitary gland is responding appropriately and is not the source of the hypothyroidism. A diagnosis of primary hypothyroidism would be made on the basis of these laboratory results.

### BOX 40-1 SIGNS AND SYMPTOMS OF GROWTH HORMONE IMBALANCE

#### GROWTH HORMONE EXCESS

##### Children

Increased linear growth and tall stature

##### Adults

Soft-tissue hyperplasia  
Increased bone density  
Large hands, feet  
Coarse facial features  
Thick, leathery skin  
Weight gain  
Glucose intolerance

#### GROWTH HORMONE DEFICIENCY

Delayed growth  
Fine features  
Short stature, proportionate

May be associated with hyposecretion of other pituitary hormones

GH and other pituitary hormones should be considered in any child with nystagmus, retinal abnormalities, and other midline or midfacial abnormalities, such as cleft lip or palate. The association between GH deficiency and other midline abnormalities appears to occur because the pituitary gland is developing during the same stage of fetal life as the other midline structures.

Children with GH deficiency have a variety of presentations, depending on the cause of the deficiency, the age at onset, and the severity of the disorder. The basis for this defect may be failure of the hypothalamus to stimulate pituitary GH secretion or failure of the pituitary to produce GH.

The most common tumors to influence hypothalamic-pituitary function are midline brain tumors. These include gliomas of the optic nerve and craniopharyngiomas. Craniopharyngiomas arise from cells at the junction of the anterior and posterior pituitary gland, are believed to be present at birth, and are slow growing. Craniopharyngiomas may grow to a large size without producing typical signs of increased intracranial pressure (vomiting, headache, oculomotor abnormalities). In older children, delayed growth may be the first symptom of a craniopharyngioma. Radiation therapy for brain tumors or leukemia may cause damage to hypothalamic and pituitary function. Traumatic insult to the skull or sella turcica may damage the pituitary gland, interrupting vascular connections and hypothalamic stimulation.

**Clinical manifestations.** GH-deficient infants usually have normal birth length and weight. They may manifest hypoglycemia because GH and cortisol are necessary to maintain the euglycemic state. Hypoglycemia may present after fasting, which could be as brief as 3 hours in an infant. Recurrent episodes of hypoglycemia may lead to seizures and permanent cerebral damage. Boys developing GH deficiency in utero may have micropenis and undescended testicles.

GH-deficient children fall below the third percentile of growth in comparison with their peers. Dental eruption is delayed, and the development and setting of the permanent teeth are irregular. The hair is thin, and the nail growth is poor. Older children have greater fat mass and decreased muscle mass, with delayed bone formation. Delayed puberty is common if other anterior pituitary hormones are also affected.

Children's growth should be evaluated annually. If growth velocity is abnormal, an endocrinologic evaluation and physiologic tests to stimulate GH release can be planned. Many pharmacologic agents are available that stimulate GH secretion in children, including insulin, arginine, levodopa, and clonidine. Children's neurosecretory GH patterns can be studied by obtaining timed serum GH samples during a normal nighttime sleep cycle.

**Treatment.** Hormonal replacement therapy for GH-deficient children has been available for several decades. The most obvious effect of GH replacement is stimulation of linear growth in children whose bones have not fused. With treatment, children experience an increase in growth velocity as well as depletion of the excess fat stores noted in GH-deficient children.

Acquired GH deficiency in adults has only recently been recognized and treatment approved by the Food and Drug Administration.<sup>3</sup> Adults may become GH deficient after resection of pituitary tumors or after traumatic head injuries. There is controversy regarding the manifestations of GH deficiency acquired in adulthood. There appears to be increased mortality attributable to cardiovascular causes when adults do not receive GH replacement following pituitary damage. GH-deficient adults may have diminished lean body mass, hypercholesterolemia, and decreased bone density.

### Growth Hormone Excess

**Etiology and pathogenesis.** GH excess is nearly always due to uncontrolled production of the hormone by a benign somatotropic

tumor in the pituitary gland adenoma. GH stimulates the liver to produce IGF-1, and these two hormones act in concert to cause up-regulated growth of soft and bony tissues. Because GH secretion varies significantly over the course of the day, the serum level of IGF-1, which is more stable, may be measured as an indicator of GH secretion. An elevated IGF-1 level is a useful indicator of GH hypersecretion. If the tumor presents in childhood before the skeletal epiphyses are closed, rapid growth results in *pituitary gigantism*. These children experience markedly accelerated growth velocity and quickly exceed the 95th percentile on pediatric growth charts. When the disorder is allowed to progress untreated, some of these children may grow to 8 feet or more in height and usually suffer an early cardiovascular death related to cardiomegaly and heart failure.

In adults, GH excess is called *acromegaly* and may be clinically subtle. Acromegaly occurs with equal frequency in men and women during the fourth and fifth decades of life. After the skeletal epiphyses close, bony growth increases bone density and thickening of the short bones, such as the hands and feet.

**Clinical manifestations of acromegaly.** Patients usually notice increased ring and shoe size, which progressively advances over several years. Enlargement of the frontal sinus causes a prominent brow, and growth of the mandible results in progressive underbite (*prognathism*) (Figure 40-3). Soft tissues also slowly hypertrophy, causing coarsening of facial features and skin tags. Internal organs increase in size, resulting in goiter (thyroid enlargement) and cardiomegaly. Other manifestations include deepening of the voice secondary to vocal cord thickening and enlargement of the tongue, resulting in sleep apnea. Colonic polyps become more common, with the potential for malignant degeneration. It is estimated that the average patient with acromegaly has an active pituitary tumor for 7 or more years before seeking evaluation. Most often the changes are attributed by the patient and his or her family as "just growing older." Abnormalities in bone and soft-tissue growth are mostly irreversible. Patients may develop symptoms of increased intracranial pressure if the pituitary tumor enlarges significantly, including headache and visual disturbances. Some patients may develop glucose intolerance or hyperglycemia, and GH has been called a *diabetogenic* hormone for this reason.

**Treatment.** Effective therapy for acromegaly involves surgically removing the tumor while counteracting the effects of excess GH. Octreotide, a synthetic form of somatostatin, suppresses production of GH. Surgery is usually performed using a transsphenoidal approach, but often the tumor is too large to completely resect. Radiation may be used postoperatively in these cases.

**FIGURE 40-3** Progressive development of facial features of acromegaly. (From Lewis SM et al: *Medical-surgical nursing*, ed 8, St Louis, 2011, Mosby. Courtesy Linda Haas, Seattle, WA.)

**KEY POINTS**

- Hyposecretion of GH results in decreased linear growth in children. In some cases decreased linear growth occurs despite normal GH levels, and abnormalities of IGF-1 generation or responsiveness are suspected.
- GH deficiency may be idiopathic or related to tumors, radiation, or trauma. The diagnosis is confirmed by a finding of decreased GH levels in the blood and deficient GH release in response to hypoglycemia or other stimulants.
- Excessive GH production is usually due to pituitary adenoma. Excess GH during childhood results in increased linear growth and gigantism. Excess GH secretion after closure of bone epiphyses results in increased bulk and acromegaly.
- Features of acromegaly include a protruding jaw, increased bone density, increased growth of soft tissues (e.g., nose, ears), and large hands and feet. Excessive GH secretion causes persistent hyperglycemia and increased insulin production in some individuals.
- Serum IGF-1 measurement is used to assess for acromegaly. High IGF-1 concentration and an elevated GH level that is not suppressed by administration of oral glucose aid in the diagnosis. Treatment entails surgical removal or pharmacologic palliation of the pituitary tumor.

**THYROID HORMONE DISORDERS**

Secretion of the thyroid hormones, triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ), is under control of thyroid-stimulating hormone (TSH) secretion from the anterior pituitary gland. In turn, TSH secretion from the pituitary is under control of thyroid-releasing hormone (TRH) from the hypothalamus. Thyroid hormones are important for normal growth and development of tissues throughout the body and an important regulator of metabolism. The details of thyroid hormone synthesis, regulation, and activity are described in Chapter 39.

**Hypothyroidism**

**Etiology and pathogenesis.** Hypothyroidism may be congenital in origin or acquired later in life. The great majority of cases of hypothyroidism are primary, due to intrinsic dysfunction of the thyroid

gland. Congenital hypothyroidism may result from a variety of causes. Thyroid dysgenesis (lack of thyroid gland development) accounts for most of the cases of congenital hypothyroidism. Abnormal TSH receptors and defective synthesis of thyroid hormone are other mechanisms causing congenital hypothyroidism.<sup>4</sup> Congenital hypothyroidism that results in significant defects in mental and physical development may be referred to as cretinism.

Lymphocytic thyroiditis (Hashimoto thyroiditis, or autoimmune thyroiditis) is the most common cause of acquired hypothyroidism. Lymphocytic thyroiditis is characterized by an enlarged thyroid gland (Figure 40-4) caused by lymphocytic infiltration. Thyroid hormone production decreases, stimulating the release of TSH from the pituitary gland and resulting in elevated serum TSH levels. Hypothyroidism and its clinical symptoms progress as the gland becomes fibrotic.

Other causes of acquired hypothyroidism include irradiation of the thyroid gland, surgical removal of thyroid tissue, and iodine deficiency. Iodine is essential for the formation of  $T_4$  and  $T_3$ . Lack of iodine prevents production of both  $T_4$  and  $T_3$  but does not stop the formation of thyroglobulin. As a result, insufficient hormone is available to inhibit production of TSH by the anterior pituitary gland. The elevated TSH level then causes the thyroid cells to secrete excessive amounts of thyroglobulin (colloid) into the follicles, and the gland grows larger and larger, producing a **goiter** (see Figure 40-4). An enlarged thyroid (goiter) is not always associated with hypothyroidism and can be present in euthyroid and hyperthyroid states.

Some foods contain “goitrogenic” substances that interfere with thyroid hormone synthesis. Such goitrogenic substances occur in some varieties of turnips and cabbage, but the clinical significance of these goitrogens is considered to be minimal. The drug lithium inhibits thyroid hormone synthesis and secretion and causes hypothyroidism in up to 20% of patients.<sup>5</sup>

Secondary hypothyroidism is caused by defects in TSH production and is uncommon. Individuals who have been exposed to severe head trauma, cranial neoplasms, brain infections, cranial irradiation, and neurosurgery can be left with secondary hypothyroidism.

**FIGURE 40-4** An enlarged thyroid gland (goiter) can be present in hypothyroid, hyperthyroid, and euthyroid states. Note enlargement at the base of the neck. (From Wilson JD, Foster DW, editors: *Williams textbook of endocrinology*, ed 8, Philadelphia, 1992, Saunders, p 425.)

## BOX 40-2 TYPICAL SIGNS AND SYMPTOMS OF THYROID IMBALANCE

## HYPERTHYROIDISM

Sleeplessness, nervousness  
 Muscle weakness, fatigue  
 Susceptibility to infection  
 Skin texture warm, silky, damp  
 Heat intolerance  
 Increased appetite with weight loss  
 Increased gastric emptying, increased intestinal motility  
 Tachycardia, narrow pulse pressure, palpitations, angina  
 Dyspnea  
 Enlarged thyroid, may be diffuse or nodular  
 Hair silky, nail loose or detached from nail bed  
 Hyperreflexia, fine tremor  
 Eye symptoms: burning, tearing, diplopia, lid lag, prominent eyes (exophthalmia with Graves disease), stare, eyelid tremors when closed  
 Absence of forehead wrinkling on upward gaze  
 Decreased or absent menses

## HYPOTHYROIDISM

Lethargy  
 Weakness  
 Dry, pale, cool, coarse skin  
 Cold intolerance  
 Weight gain  
 Constipation  
 Bradycardia, wide pulse pressure  
 Dyspnea, chest pain  
 Thyroid may be diffusely enlarged (goiter) or may not be palpable  
 Hair coarse  
 Sluggish return of reflexes; mental impairment: slowed cognitive ability, poor memory, forgetfulness, depressed affect; deafness (in one third of population)  
 Facial edema (especially periorbital); thinned lateral aspect of eyebrows  
 Heavy, prolonged menses; infertility; decreased libido

**Clinical manifestations.** Routine screening of newborns has resulted in early treatment of most infants with congenital hypothyroidism. Few clinical manifestations are present at birth. In untreated infants, symptoms appear in the first months of life and include a dull appearance; a thick, protuberant tongue; and thick lips (leading to feeding difficulties). Other signs include prolonged neonatal jaundice, poor muscle tone, bradycardia, mottled extremities, umbilical hernia, and a hoarse cry. Thyroid hormone is essential for normal central nervous system development; significant and irreversible intellectual disability will occur unless thyroid hormone replacement therapy is started early in infancy. Older children who acquire hypothyroidism have essentially the same clinical manifestations as seen in adults. In addition, growth retardation, delayed bone development, and delayed or precocious puberty may occur.
