ACTIVATE THE COMPLETE LEARNING EXPERIENCE  
THAT COMES WITH YOUR BOOK BY REGISTERING AT

<http://evolve.elsevier.com/Copstead/>

- **Animations**  
More than 70 animations offer a visual tool for students to help learn difficult material.
- **Answers to Key Questions**  
Provides the answers to the Key Questions included in each chapter opener in the book in an effort to reinforce key concepts and allow self-study.
- **Audio Glossary**  
Enables students to confirm their pronunciation of important terminology
- **Case Studies**  
Patient case studies initiate the critical thinking process and assist in the application of pathophysiologic concepts in clinical situations.
- **Key Points**  
The Key Points boxes are provided for quick review of the main points from each chapter.
- **Student Review Questions**  
Provides more than 690 multiple choice and multiple response questions with rationales for students to use while studying for exams.

#### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Wilson, North Carolina

The scientific basis of pathophysiology is rapidly expanding and becoming increasingly well understood at the genetic and cellular levels. Progress in human genetics and epigenetics has transformed our understanding of physiology and disease. To be clinically relevant and useful to health care students and professionals, a text must be able to synthesize a vast amount of detailed knowledge into overarching concepts that can be applied to individual diseases. As in previous editions, the fifth edition of *Pathophysiology* gives attention to the development of practical, student-centered learning aids that support learning and mastery of content. Discussions of relevant biochemistry, genetics, and cell physiology are used to help students understand concepts at a deeper level. This fifth edition has been updated extensively with sensitivity to the unique needs of today's students to better prepare them as practitioners in an ever-changing health care environment.

## ORGANIZATION

*Pathophysiology* is a comprehensive text and reference that uses a systems approach to content, beginning with a thorough treatment of normal physiology, followed by pathophysiology and application of concepts to specific disorders. The text is organized into 15 units, each of which includes a particular system or group of interrelated body systems and the pertinent pathophysiologic concepts and disorders.

**Unit I: Pathophysiologic Processes (Chapters 1 and 2)** sets the stage for understanding major elements of the pathophysiologic processes in individuals and population groups. The purpose of these chapters is to give students an appreciation for the complex nature of disease and illness, including sociocultural influences, global health considerations, and the significant contributions of stress, adaptation, and coping. The unifying concepts of pathophysiologic processes—etiology, pathogenesis, clinical manifestations, and implications for treatment of disease—are explained. A new section on telomeres and telomerase and their relationship to stress and aging is presented in Chapter 2.

**Unit II: Cellular Function (Chapters 3 to 7)** addresses cellular mechanisms of physiology and disease. Chapter 3 describes normal cells to give students an insight into how cells function, with an emphasis on cellular signaling and communication. Chapter 4 discusses cellular pathology and the processes of injury, apoptosis, aging, and death. Chapters 5 and 6 describe gene structure, function and regulation, development, and genetic and congenital disorders. Chapter 7 describes the cellular biology of tumor growth, focusing on the roles of proto-oncogenes and tumor suppressor genes. Revisions reflect new knowledge about apoptosis, genetics, and cancer biology.

**Unit III: Defense (Chapters 8 to 12)** addresses key cellular defense mechanisms and the basic processes of infectious disease, inflammation, immunity, autoimmune disease,

hypersensitivity, hematologic malignancies, and HIV-AIDS. Unit III was revised to reflect new knowledge about immune mechanisms and therapy for HIV disease as well as global health considerations for HIV-AIDS.

**Unit IV: Oxygen Transport, Blood Coagulation, Blood Flow, and Blood Pressure (Chapters 13 to 16)** includes content pertaining to the transport of oxygen in the circulation, hemostasis, vascular regulation of flow, blood pressure regulation, and the pathologies relevant to these functions. Content on blood pressure was updated to reflect current practice recommendations.

**Unit V: Cardiac Function (Chapters 17 to 20)** includes concepts related to cardiac physiology and pathophysiology. Content has been updated to reflect new knowledge in the areas of apoptosis and regeneration of cardiac cells, heart failure, and shock.

**Unit VI: Respiratory Function (Chapters 21 to 23)** provides a thorough description of pulmonary anatomy and physiology including concepts of ventilation, perfusion, and gas exchange. Differences between obstructive and restrictive diseases are highlighted.

**Unit VII: Fluid, Electrolyte, and Acid-Base Homeostasis (Chapters 24 and 25)** describes concepts basic to understanding the alterations in fluid, electrolyte, and acid-base homeostasis that accompany many disease processes.

**Unit VIII: Renal and Bladder Function (Chapters 26 to 29)** provides a thorough description of renal anatomy and physiology, abnormalities of renal function, bladder dysfunction, and strategies for interpreting common laboratory values in the context of kidney or bladder diseases. Chapters on renal disorders, chronic kidney disease, and disorders of the urinary tract have been extensively revised.

**Unit IX: Genital and Reproductive Function (Chapters 30 to 34)** includes comprehensive, current information on male and female genital anatomy, embryology, and reproductive physiology as well as discussion of common disorders. Chapter 34 provides thorough coverage of common sexually transmitted infections.

**Unit X: Gastrointestinal Function (Chapters 35 to 38)** provides a review of normal gastrointestinal anatomy, physiology, and disorders, with separate chapters dedicated to pancreatic and biliary dysfunction and liver disease.

**Unit XI: Endocrine Function, Metabolism, and Nutrition (Chapters 39 to 42)** addresses alterations in endocrine control, metabolism, and nutrition. The chapter on normal endocrine physiology includes a detailed discussion of hormone synthesis, activity, and regulation. A separate chapter is dedicated to the growing problem of type 2 diabetes mellitus.

**Unit XII: Neural Function (Chapters 43 to 47)** includes a review of neurologic anatomy and physiology, acute and chronic neuronal disorders, disorders of special senses, and pain. Content has been updated to reflect new information on Alzheimer disease and Parkinson disease.

**Unit XIII: Neuropsychological Function (Chapters 48 and 49)** covers current concepts in the pathophysiology of psychobiology including anxiety, mood, thought, and personality disorders. New to the fifth edition is inclusion of global health considerations in mental health. Chapter 49 was completely rewritten to reflect current insights about disorders commonly seen in clinical practice and updated with a focused discussion of global health and pathophysiologic implications of depression.

**Unit XIV: Musculoskeletal Support and Movement (Chapters 50 to 52)** includes alterations in musculoskeletal support and movement, with separate chapters dedicated to normal bone and muscle anatomy and physiology, disorders of bone and muscle, and rheumatic disorders.

**Unit XV: Integumentary System (Chapters 53 and 54)** includes alterations affecting the largest system of the body—the integumentary system. Chapter 53 includes normal integumentary structure and function and a survey of common skin disorders. Chapter 54 covers burn injury, emphasizing the multiple stresses that are encountered in patients with these complex injuries.

## FEATURES

An understanding of normal structure and function of the body is necessary for any detailed understanding of its abnormalities and pathophysiology. The first chapter in most units includes a fully illustrated *review of normal physiology*. *Global Health Considerations*, where pertinent, are highlighted in separate boxes. Changes in structure and function as a result of normal development and aging are also addressed where appropriate. Age-related concepts are highlighted in boxes titled *Geriatric Considerations* and *Pediatric Considerations*.

Each chapter opens with *Key Questions*, which are designed to develop a strong pathophysiologic knowledge base and to serve as the foundation for critical thinking. These Key Questions integrate the essential information in each chapter, emphasizing *concepts* rather than small details. *Chapter Outlines* are also included at the beginning of each chapter to help the reader locate specific content. Within every chapter, *Key Points* are identified at the end of every major discussion and are presented in short bulleted lists. These recurring summaries help readers to focus on the main points.

Nearly 900 illustrations elucidate both normal physiology and pathophysiologic changes. The entire book is in *full color*,

with color used generously in the illustrations to better explain pathophysiologic concepts.

To help students master the new vocabulary of pathophysiology, key terms appear in boldface within each chapter, and these terms are defined in a comprehensive *Glossary*, which appears at the end of the text. Throughout this text, the nonpossessive forms of eponyms (e.g., Down syndrome) are used consistently when referring to the person for whom a disease is named. Clinical and laboratory values are provided in the *Appendix*.

## ANCILLARIES

### Student Learning Resources on Evolve

The student section of the book's website hosted on Evolve offers nearly 700 *Student Review Questions* in a variety of question formats, an *Audio Glossary*, *Animations* to help readers visualize pathophysiologic processes, *Case Studies with questions*, **Key Points** review, and answers to *Key Questions*. Visit the Evolve website at <http://evolve.elsevier.com/Copstead/>.

### Study Guide

Pathophysiology can be a daunting subject for students because of the large volume of factual material to be learned. The student **Study Guide** is designed to help students focus on important pathophysiologic concepts. Questions to check recall of normal anatomy and physiology are included for each chapter. A number of activities that help the student focus on similarities and differences between often-confused pathologic processes are included. More than 1500 *Self-assessment test questions* with answers are included to help students check their understanding and build confidence for examinations. *Case studies*, with more than 250 questions including rationales for correct and incorrect answers, are used to help students begin to apply pathophysiologic concepts to clinical situations.

### Instructor Learning Resources on Evolve

The **Instructor's Resources** on Evolve provide a number of teaching aids for instructors who require the text for their students. The materials include a *Test Bank* presented in Exam View with approximately 1200 test items, a *Teach for Nurses instructor manual* detailing the resources available to instructors for their lesson planning, a *PowerPoint lecture guide* with more than 4000 slides with integrated case studies and audience response questions to facilitate classroom presentations, and an *Image Collection* of more than 900 color images from the text.

# ACKNOWLEDGMENTS

Many creative and unique efforts grace the pages of this work. It is exceedingly difficult to know how to best recognize every one. Writing this text has been possible only because of the tremendous dedication of authors, artists, reviewers, and editors. Our sincere gratitude goes to all who helped with this and previous editions. In particular, grateful appreciation is extended to all of the contributing authors—recognized experts—who gave exhaustively of their time to write chapters and create illustrations. We are also indebted to the many thoughtful experts who gave of their time to read and critique manuscripts and help ensure excellence in chapter content throughout the text.

No project of this magnitude could be accomplished without wonderfully supportive colleagues and students who provided a source of continual motivation and encouragement. We are most keenly aware of the inspiration provided by the faculty, staff, and students of Washington State University College of Nursing and the University of Wisconsin—Eau Claire College of Nursing and Health Sciences. Thank you to Assistant Professor of Nursing, Dr. Angela Stombaugh, for her contribution to the *Pediatric Considerations* boxes. Undergraduate nursing students Rachel Nerison and Anja Meerwald, and honors economics student, Laurelyn Wieseman of the University of Wisconsin—Eau Claire, deserve mention for their enthusiastic support and scholarly review of the *Global Health Considerations* boxes included in the fifth edition.

Grateful recognition is made to the staff at Elsevier. In particular, Charlene Ketchum deserves our heartfelt thanks for helping us with developmental editing through two editions of the text. As our new senior content development specialist (who picked up the reins from Charlene), Karen Turner helped with the content, illustrations, and the many details to keep our

project on track; Jeanne Genz, our project manager, paid excellent attention to the copyediting, proofreading, and page layout. George Barile contributed extensively to the art program of the fifth edition. Assistant Brooke Kannady kept all of the details straight to help this edition run so smoothly. In addition, we owe grateful thanks to Nursing Editor Sandra Clark, who believed in the book and oversaw the revision of the fifth edition from beginning to end.

We would like to recognize those who provided a foundation for the revised text through their contributions to first editions: Mary Sanguinetti-Baird, Linda Belsky-Lohr, Tim Brown, Karen Carlson, Leslie Evans, Jo Annalee Irving, Debby Kaaland, Rick Madison, Maryann Pranulis, Edith Randall, Bridget Recker, Cleo Richard, Gary Smith, Pam Springer, Martha Snider, Patti Stec, Julie Symes, Lorie Wild, and Debra Winston-Heath. We also would like to thank those who contributed to the second and third editions of the book: Arnold A. Asp, Katherina P. Choka, Cynthia F. Corbett, Mark Puhlman, Barbara Bartz, Arnold Norman Cohen, Karen Groth, Christine M. Henshaw, Carolyn Hoover, Marianne Genge Jagmin, Linda Denise Oakley, Anne Roe Mealey, David Mikkelsen, Donna Bailey, Billie Marie Severtsen, and Jacqueline Siegel. Thank you also to the contributors of the fourth edition: Carolyn Spence Cagle, Lorri Dawson, Patricia Garber, Jane Georges, Naomi Lungstrom, Sheila Smith, and Angela Starkweather.

To the late Dr. Michael J. Kirkhorn, we give acknowledgment and thanks for writing the first, second, and third edition's provocative and thoughtful essays that began each unit, and we thank Dr. Sheila Smith for her contribution to the fourth edition essays opening each of the units. We would also like to thank April Hart for her help with revising the glossary for this edition.

# CONTENTS

## UNIT I PATHOPHYSIOLOGIC PROCESSES

### 1. Introduction to Pathophysiology, 1

*Lee-Ellen C. Copstead*

#### Framework for Pathophysiology, 2

*Etiology, 2*

*Pathogenesis, 2*

*Clinical Manifestations, 3*

*Stages and Clinical Course, 3*

*Treatment Implications, 3*

#### Concepts of Normality in Health and Disease, 4

*Statistical Normality, 4*

*Reliability, Validity, and Predictive Value, 5*

*Individual Factors Influencing Normality, 5*

*Cultural Considerations, 5*

*Age Differences, 5*

*Gender Differences, 5*

*Situational Differences, 6*

*Time Variations, 6*

#### Patterns of Disease in Populations, 6

*Concepts of Epidemiology, 6*

*Endemic, Pandemic, and Epidemic Diseases, 6*

*Aggregate Factors, 6*

*Levels of Prevention, 9*

### 2. Homeostasis and Adaptive Responses to Stressors, 12

*Debra A. Jansen and Roberta J. Emerson*

#### Homeostasis and Allostasis, 12

*Homeostasis, 12*

*Allostasis, 13*

#### Stress as a Concept, 13

*The General Adaptation Syndrome and Allostasis, 14*

*Alarm Stage, 14*

*Resistance or Adaptation Stage, 16*

*Exhaustion Stage, 16*

*Stressors and Risk Factors, 16*

#### Neurohormonal Mediators of Stress and Adaptation, 17

*Catecholamines: Norepinephrine and Epinephrine, 17*

*Adrenocortical Steroids: Cortisol and Aldosterone, 17*

*Endorphins, Enkephalins, and Immune Cytokines, 19*

*Sex Hormones: Estrogen, Testosterone, and Dehydroepiandrosterone, 19*

*Growth Hormone, Prolactin, and Oxytocin, 19*

*Adaptation, Coping, and Illness, 20*

*Adaptation and Coping, 20*

*Allostatic Overload and Illness, 20*

## UNIT II CELLULAR FUNCTION

### 3. Cell Structure and Function, 25

*Jacquelyn L. Banasik*

#### Plasma Membrane, 26

*Membrane Structure, 26*

*Lipid Bilayer, 27*

*Membrane Proteins, 28*

#### Organization of Cellular Compartments, 29

*Cytoskeleton, 29*

*Nucleus, 30*

*Endoplasmic Reticulum, 30*

*Golgi Apparatus, 31*

*Lysosomes and Peroxisomes, 32*

*Mitochondria, 32*

#### Cellular Metabolism, 34

*Glycolysis, 34*

*Citric Acid Cycle, 34*

*Oxidative Phosphorylation, 37*

#### Functions of the Plasma Membrane, 38

*Membrane Transport of Macromolecules, 38*

*Endocytosis and Exocytosis, 38*

*Membrane Transport of Small Molecules, 38*

*Active Transport Pumps, 39*

*Membrane Transport Carriers, 41*

*Membrane Channel Proteins, 41*

*Cellular Membrane Potentials, 42*

*Resting Membrane Potential, 42*

*Action Potential, 44*

*Intercellular Communication and Growth, 45*

*Cell Signaling Strategies, 45*

*Cell Surface Receptor–Mediated Responses, 47*

*Intracellular Receptor–Mediated Responses, 50*

*Regulation of Cellular Growth and Proliferation, 50*

### 4. Cell Injury, Aging, and Death, 57

## UNIT IV OXYGEN TRANSPORT, BLOOD COAGULATION, BLOOD FLOW, AND BLOOD PRESSURE

### 13. Alterations in Oxygen Transport, 255

Marie L. Kotter and Susan G. Trevithick

#### Composition of Blood, 256

*Organic and Inorganic Components, 257*

*Cellular Components, 257*

*Erythrocytes, 259*

*Leukocytes, 259*

*Platelets, 259*

#### Structure and Function of Red Blood Cells, 261

*Hematopoiesis, 261*

*Hemoglobin Synthesis, 261*

*Hemoglobin Synthesis in Infants, 261*

*Nutritional Requirements for*

*Erythropoiesis, 262*

*Energy and Maintenance of Erythrocytes, 262*

*Red Cell Production, 263*

*Red Cell Destruction, 264*

#### Gas Transport and Acid-Base Balance, 265

*Oxygen Transport, 265*

*Carbon Dioxide Transport, 267*

*Alterations in Oxygen Transport, 267*

#### ANEMIA, 269

##### General Effects of Anemia, 270

##### Anemia Related to Decreased Red Cell

*Production, 273*

*Aplastic Anemia, 273*

*Anemia of Chronic Renal Failure, 274*

*Anemia Related to Vitamin B<sub>12</sub> (Cobalamin)  
or Folate Deficiency, 274*

*Iron Deficiency Anemia, 275*

##### Anemia Related to Inherited Disorders of the Red Cell, 276

*Thalassemia, 276*

*Sickle Cell Anemia, 277*

*Hereditary Spherocytosis, 279*

*Glucose-6-Phosphate Dehydrogenase  
Deficiency, 280*

##### Anemia Related to Extrinsic Red Cell

*Destruction or Loss, 280*

*Hemolytic Disease of the Newborn, 280*

*Antibody-Mediated Drug Reactions, 281*

*Acute Blood Loss, 282*

*Other Extrinsic Abnormalities, 282*

##### Transfusion Therapy, 282

#### POLYCYTHEMIA, 283

*Polycythemia Vera, 283*

*Secondary Polycythemia, 288*

*Relative Polycythemia, 288*

### 14. Alterations in Hemostasis and Blood Coagulation, 294

Robin Beeman and Roberta J. Emerson

#### The Process of Hemostasis, 294

*Stages of Hemostasis, 294*

*Platelets, 295*

*Blood Coagulation Factors, 295*

*Fibrin Clot, 296*

*Fibrinolysis, 297*

#### Evaluation of Hemostasis and Coagulation, 297

*Clinical Assessment, 297*

*Laboratory Tests, 299*

#### Vascular and Platelet Disorders, 301

*Vascular Disorders, 301*

*Vascular Purpura, 301*

*Hereditary Hemorrhagic Telangiectasia, 302*

*Platelet Disorders, 302*

*Thrombocytopenia, 302*

*Thrombocytosis, 303*

*Qualitative Platelet Disorders, 303*

#### Coagulation Disorders, 304

*Hemophilia, 304*

*von Willebrand Disease, 305*

*Vitamin K Deficiency Bleeding in Infancy, 305*

*Acquired Vitamin K Deficiency, 305*

*Disseminated Intravascular Coagulation  
(DIC), 306*

*Hepatic Disease, 307*

### 15. Alterations in Blood Flow, 309

Teresa Grigsby Loftsgaarden

#### Organization of the Circulatory and Lymphatic Systems, 311

*Vessel Structure, 311*

*Anatomy of Arteries and Veins, 312*

*Anatomy of Capillaries, 313*

*Lymphatic Structure, 313*

#### Principles of Flow, 314

*Hemodynamics of the Circulatory System, 314*

*Blood Flow, Pressure, and Resistance, 314*

*Velocity and Laminar and Turbulent Flow, 315*

*Wall Tension and Compliance, 316*

*Dynamics in the Microcirculation: Capillaries  
and Lymphatics, 317*

#### Control of Flow, 318

*Control of Blood Flow, 318*

*Extrinsic Mechanisms, 318*

*Intrinsic Mechanisms, 319*

*Control of Lymphatic Flow, 319*

#### General Mechanisms That Cause Altered Flow, 319

*Blood Vessels: Obstructions, 320*

*Thrombus, 320*

*Embolus, 320*

*Disseminated Intravascular Coagulation, 446*

*Acute Renal Failure, 447*

*Multiple Organ Dysfunction Syndrome, 447*

## UNIT VI RESPIRATORY FUNCTION

### 21. Respiratory Function and Alterations in Gas Exchange, 449

*Lorna L. Schumann*

**Functional Anatomy, 450**

*Development of the Pulmonary System, 450*

*Upper Airway Structures, 450*

*Lower Airway Structures, 452*

*Pulmonary Circulation, 455*

*Age-Related Variations, 456*

**Ventilation, 458**

*Lung Volumes and Capacities, 458*

*Dead Space, 458*

*Minute Ventilation, 459*

*Alveolar Ventilation/Oxygenation, 459*

*Mechanics of Breathing, 459*

*Airway Resistance, 459*

*Lung Compliance, 460*

*Distribution of Ventilation, 461*

*Neurologic Control of Ventilation, 461*

**Pulmonary Blood Flow, 463**

*Pulmonary Vasculature, 463*

*Distribution of Blood Flow, 463*

*Ventilation-Perfusion Ratios, 463*

*Hypoxic Vasoconstriction, 464*

**Diffusion and Transport of Respiratory**

**Gases, 464**

*Barriers to Diffusion, 464*

*Oxygen Transport, 465*

*Carbon Dioxide Transport, 466*

**Alterations in Pulmonary Function, 467**

*Hypoventilation and Hyperventilation, 467*

*Hypoxemia and Hypoxia, 467*

*Acute Respiratory Failure (ARF), 467*

**Alterations in Pulmonary Vasculature, 469**

*Pulmonary Hypertension, 469*

*Pulmonary Venous Thromboembolism, 470*

**Pulmonary Malignancies, 472**

### 22. Obstructive Pulmonary Disorders, 475

*Lorna L. Schumann*

**Obstruction from Conditions in the Wall of the**

**Lumen, 476**

*Asthma, 476*

*Acute Bronchitis, 482*

*Chronic Bronchitis, 483*

**Obstruction Related to Loss of Lung**

**Parenchyma, 487**

*Emphysema, 487*

**Obstruction of the Airway Lumen, 489**

**Bronchiectasis, 489**

*Bronchiolitis, 490*

*Cystic Fibrosis, 491*

*Acute Tracheobronchial Obstruction, 492*

*Epiglottitis, 493*

*Croup Syndrome, 493*

**Diagnostic Tests, 494**

*Pulmonary Function Testing, 494*

*Bronchial Provocation Tests, 495*

### 23. Restrictive Pulmonary Disorders, 497

*Lorna L. Schumann*

# Introduction to Pathophysiology

Lee-Ellen C. Copstead

## evolve WEBSITE

<http://evolve.elsevier.com/Copstead/>

- Review Questions and Answers
- Glossary (with audio pronunciations for selected terms)
- Animations
- Case Studies
- Key Points Review

## KEY QUESTIONS

- What is pathophysiology?
- How are etiology and pathogenesis used to predict clinical manifestations and response to therapy?
- How are normal and abnormal physiologic parameters defined?
- What general factors affect the expression of disease in a particular person?
- What kinds of information about disease can be gained through understanding concepts of epidemiology?

## CHAPTER OUTLINE

### Framework for Pathophysiology, 2

- Etiology, 2
- Pathogenesis, 2
- Clinical Manifestations, 3
  - Stages and Clinical Course, 3*
- Treatment Implications, 3

### Concepts of Normality in Health and Disease, 4

- Statistical Normality, 4
  - Reliability, Validity, and Predictive Value, 5*
- Individual Factors Influencing Normality, 5
  - Cultural Considerations, 5*

*Age Differences, 5*

*Gender Differences, 5*

*Situational Differences, 6*

*Time Variations, 6*

### Patterns of Disease in Populations, 6

- Concepts of Epidemiology, 6
  - Endemic, Pandemic, and Epidemic Diseases, 6*
- Aggregate Factors, 6
- Levels of Prevention, 9

Pathophysiology derives from the intersection of two older, related disciplines: pathology (from *pathos*, suffering) and physiology (from *physis*, nature). Pathology is the study and diagnosis of *disease* through examination of *organs, tissues, cells, and bodily fluids*. Physiology is the study of the mechanical, physical, and biochemical functions of living organisms. Together, as *pathophysiology*, the term refers to the study of abnormalities in physiologic functioning of living beings.

Pathophysiology seeks to reveal physiologic responses of an organism to disruptions in its internal or external environment. Because humans exhibit considerable diversity, healthy structure and function are not precisely the same in any two individuals. However, discovering the common and expected responses to abnormalities in physiologic

functioning is useful, and it allows a **general prediction of clinical progression**, identification of possible causes, and selection of interventions that are most likely to be helpful. Thus, **pathophysiology is studied in terms of common or “classic” presentations of disorders**.

Historically, **descriptions of diseases** were based on observations of those individuals who attracted medical attention because they **exhibited abnormal signs or complained of symptoms**. Over time, cases with **similar presentations** were noted and treatments that had been successful before were used again. In some cases, similarities among individuals pointed to possible **common causes**. With the advent of more sophisticated measurements of physiologic and biochemical function, such as **blood pressure measurements, blood chemistry values, x-ray**

images, and DNA analysis, the wide variability in the expression of diseases and disorders in the population became apparent, as did the opportunity to discover diseases at earlier stages, before they were clinically obvious. Screening programs that evaluated large segments of the population revealed the complexity and diversity of disease expression, even in persons with the same genetic defect. Thus, although the study of pathophysiology is necessarily a study of the usual and expected responses of the body to a given disruption, individuals often vary significantly from a classic presentation, making the diagnostic process complex and challenging.

Advances in genomic and epigenomic characterization, innovative technologies, and revolutionary approaches to the analysis of genetic variation and function have made studies and treatments possible that were not even imaginable just a few years ago. As a result, definitions of the living world have been virtually transformed and permeate every branch of biological science. Benefits of this new biology include a deeper understanding of evolution, greater insights into immune mechanisms, and nearly every advance against cancer and acquired immunodeficiency syndrome (AIDS).

Genetic manipulation also raises sensitive and complex ethical and moral questions that did not exist half a century ago. Scientists are able to experiment with genetic manifestations and their mechanisms of action, dramatically altering medical practice, especially the management of inherited diseases. New capabilities have led to experimental treatments such as gene therapy—molecular surgery powerful enough to cure and alter the next generation. The study of pathophysiology assumes even greater significance as genetic research shows fresh insights and hopeful new treatments for human diseases.

Pathophysiology examines disturbances of normal mechanical, physical, and biochemical functions, either caused by a disease or resulting from a disease or abnormal syndrome or condition. For example, the study of a toxin released by a bacterium has evolved from the science of infectious diseases, as well as the harmful effects of that toxin on the body, one possible result being sepsis. Another example is the study of the chemical changes that take place in body tissue as the result of inflammation.

Although individual study of specific diseases undertaken in medical pathology textbooks helps students identify subtle differences between similar diseases, the study of pathophysiology is dynamic and conceptual, seeking to explain processes and relationships common to a number of pathologies. For example, the pathophysiology of inflammation, hypotension, fluid volume deficit, hypoxia, and ischemia is important to the understanding of a large number of different pathologies, but each separate process is not necessarily a specific disease.

Pathophysiology includes four interrelated topics: etiology, pathogenesis, clinical manifestations, and treatment implications—the framework used throughout this textbook. Specific diseases will be used as illustrative examples of conditions in which particular pathophysiological processes may occur.

## FRAMEWORK FOR PATHOPHYSIOLOGY

### Etiology

Etiology, in its most general definition, is the study of the causes or reasons for phenomena.<sup>1</sup> A description of etiologic process includes the identification of those causal factors that, acting in concert, provoke a particular disease or injury. When the cause is unknown, a condition is said to be idiopathic. If the cause is the result of an unintended or unwanted medical treatment, the resulting condition is said to be iatrogenic. Most disorders are multifactorial, having several different etiologic factors that contribute to their development. For example, coronary

## BOX 1-1 ETIOLOGIC CLASSIFICATION OF DISEASES

- Congenital (inborn) diseases or birth defects
- Degenerative diseases
- Iatrogenic diseases
- Idiopathic diseases
- Immunologic diseases
- Infectious diseases
- Inherited diseases
- Metabolic diseases
- Neoplastic diseases
- Nutritional deficiency diseases
- Physical agent–induced diseases
- Psychogenic diseases

heart disease is a result of the interaction of genetic predisposition, diet, exposure to cigarette smoke, elevated blood pressure, and perhaps numerous other lifestyle and hormonal factors acting in concert. None of these individual factors can be said to cause the disease. When the link between an etiologic factor and development of a disease is less than certain, but the probability is increased when the factor is present, it is termed a risk factor. The identification of risk factors is important for disease prevention and various levels of prevention provide focus for the epidemiology section at the end of this chapter.

Some diseases are closely linked with etiologic factors, such that they are said to be the causative agents in the disease. For example, microbial pathogens are considered to be causative agents for infectious diseases: human immunodeficiency virus causes HIV disease, influenza viruses cause the flu, and *Mycobacterium tuberculosis* causes pulmonary tuberculosis. These diseases do not occur unless the pathogen is present in the body; however, this does not mean that the infection will have the same consequences in each case, because many host factors affect the clinical course. Even when the link between disease and etiologic agent is strong, only a portion of the population exposed to the factor may develop the disease. For example, in persons who consume large quantities of alcohol and develop liver cirrhosis, it is the alcohol consumption that is considered to be the cause, yet only a portion of persons who drink heavily will develop cirrhosis.<sup>2</sup> Thus categorizing the probable etiologies for diseases is a long, difficult research process and, not surprisingly, the exact causes of most disorders remain incompletely understood. Several classification schemes have been proposed to categorize diseases according to etiology. Box 1-1 summarizes an example of an etiologic classification system. No classification system is truly comprehensive and some diseases fall into multiple categories. Some diseases may receive different designations in the future, as further research reveals new data.

### Pathogenesis

Pathogenesis refers to the development or evolution of a disease, from the initial stimulus to the ultimate expression of the manifestations of the disease.<sup>3</sup> The sequence of physiologic events that occurs in response to an etiologic agent is a dynamic interplay of changes in cell, tissue, organ, and systemic function. As the ways in which intricate intercellular communication networks control physiologic function are discovered, pathogenesis is being increasingly understood on the cellular level. One of the best examples of this communication network is the immune system and its interactions with essentially every other cell in the body. A disruption in the delicate system of checks and balances between immune tolerance of normal cells and immune surveillance

for abnormal cells and foreign antigens is at the root of a large number of degenerative and inflammatory diseases.

Pathologic disruptions in cellular behavior lead, in turn, to changes in organ and system function that may be detected by clinical or laboratory examination. Most pathophysiology texts take a systems approach to presenting information. This approach builds on the way in which students learn anatomy and physiology and has its roots in medical specialization. Usually the clinical examination of a patient is also conceptualized by a systems approach. Although the division into systems is useful for dividing the content into conceptual pieces, it is important to remember that the organism functions as an integrated whole and the intercellular communication networks are not confined within single systems. In summary, pathogenesis is a description of how etiologic factors are thought to alter physiologic function and lead to the development of clinical manifestations that are observed in a particular disorder or disease.

### Clinical Manifestations

Manifestations of disease that are observed are termed *signs of disease*. Such objective data may be gathered by clinical examination or by biochemical analysis, diagnostic imaging, and other laboratory tests. The subjective feelings of an abnormality in the body are termed *symptoms*. By definition, symptoms are subjective and can only be reported by the affected individual to an observer. For example, the feeling of nausea is a symptom, whereas vomiting is objectively observed and is a sign. Some signs and symptoms, such as fever and headache, are nonspecific and, although they designate that something is amiss, they do not indicate a specific cause. In this case further examination and, often, laboratory tests are needed to focus on the possible causes of the signs and symptoms. Many diseases and disorders are characterized by a particular constellation of signs and symptoms, the knowledge of which is essential for accurate detection and diagnosis. When the etiology of a particular set of signs and symptoms has not yet been determined, the disorder may be termed a *syndrome*. For example, AIDS was originally detected as a set of signs and symptoms related to a deficiency of helper T cells of unknown cause, now known to be a late stage of HIV infection.<sup>4</sup>

The clinical manifestations of some diseases may change significantly over time, resulting in a completely different clinical presentation at different stages. Knowledge of the possible stages of a disease is helpful in making an appropriate diagnosis and anticipating the clinical course.

### Stages and Clinical Course

Early in the development of a disease, the etiologic agent or agents may provoke a number of changes in biological processes that can be detected by laboratory analysis, although no recognition of these changes by the patient has occurred. The interval between exposure of a tissue to an injurious agent and the first appearance of signs and symptoms may be called a latent period or, in the case of infectious diseases, an **incubation period**. The **prodromal period**, or prodrome, refers to the appearance of the first signs and symptoms indicating the onset of a disease. Prodromal symptoms often are nonspecific, such as headache, malaise, anorexia, and nausea. During the stage of **manifest illness**, or **the acute phase**, the disease reaches its full intensity, and signs and symptoms attain their greatest severity. Sometimes during the course of a disease, the signs and symptoms may become mild or even disappear for a time. This interval may be called a silent period or latent period. For example, in the total-body irradiation syndrome, a latent period may occur between the prodrome and the stage of

manifest illness. Another example is syphilis, which may have two latent periods: one occurring between the primary and secondary clinical stages and another occurring between the secondary and tertiary stages.<sup>5</sup>

A number of diseases have a subclinical stage, during which the patient functions normally, although the disease processes are well established. It is important to understand that the structure and function of many organs provide a large reserve or safety margin, so that functional impairment may become evident only when organ damage has become advanced. For example, **chronic renal disease** can completely destroy one kidney and partly destroy the other before any symptoms related to a decrease in renal function are perceived.<sup>6</sup>

The clinical course of a disease is often classified as acute or chronic. An acute condition has relatively severe manifestations but runs a short course measured in hours, days, or a few weeks. A chronic condition lasts for months to years. Sometimes chronic disease processes begin with an acute phase and become prolonged when the body's defenses are insufficient to overcome the causative agent or stressor. In other cases, chronic conditions develop insidiously and never have an acute phase.

Some diseases (e.g., some types of autoimmune diseases) follow a course of alternating exacerbations and remissions. An exacerbation is a relatively sudden increase in the severity of a disease or any of its signs and symptoms. A remission is an abatement or decline in severity of the signs and symptoms of a disease. If a remission is permanent (sometimes defined as longer than 5 years), the person is said to be cured.

Convalescence is the stage of recovery after a disease, injury, or surgical operation. Occasionally a disease produces a subsequent pathologic condition called a sequela (plural: sequelae). For example, the sequela of an inflammatory process might be scarring. The sequelae of acute rheumatic inflammation of the heart might be scarring and deformation of cardiac valves. In contrast, a complication of a disease is a new or separate process that may arise secondarily because of some change produced by the original problem. For example, bacterial pneumonia may be a complication of viral infection of the respiratory tract.

### Treatment Implications

An understanding of the etiology, pathogenesis, and clinical consequences of a particular disorder may suggest, or "imply," that certain treatments could be helpful. For example, understanding that a person with septic shock has excessive dilation of blood vessels that contributes to hypotension implies that fluid administration would likely be helpful. In contrast, most patients with cardiogenic shock have fluid overload, and hypotension in this case is unlikely to improve with fluid administration. Care must be taken not to rely on theoretical implications when evidence-based treatment recommendations are available. When subjected to evaluation by rigorous randomized clinical trials, many treatments that seem as though they should help based on pathophysiology fail to pass the test of application.

The treatment implications discussed in pathophysiology texts usually are general statements rather than specific prescriptions. For example, the pathophysiology of heart failure is characterized by fluid overload, which implies that diuretic therapy would be useful; however, the exact selection of a drug and the dosing schedule would depend on a number of factors particular to the individual patient. Specific treatment recommendations are beyond the scope of a pathophysiology text and can be found in pharmacology and clinical practice textbooks.

**KEY POINTS**

- Pathophysiology includes four interrelated topics: etiology, pathogenesis, clinical manifestations, and treatment implications.
- Etiology refers to study of the proposed cause or causes of a particular disease process. Etiology is a complex notion because most diseases are multifactorial, resulting from interplay between genetic constitution and environmental influences.
- Pathogenesis refers to the proposed mechanisms whereby an etiologic stimulus leads to typically observed clinical manifestations. Pathogenesis describes the direct effects of the initiating event, as well as the usual physiologic responses and compensatory mechanisms.
- Clinical manifestations describe the signs and symptoms that typically accompany a particular pathophysiologic process. Manifestations may vary depending on the stage of the disorder, individual variation, and acuity or chronicity.
- An understanding of the etiology, pathogenesis, and clinical consequences of a particular disorder may imply that certain treatments could be helpful.

## CONCEPTS OF NORMALITY IN HEALTH AND DISEASE

The ability to measure numerous structural, physiologic, biochemical, and genetic parameters in an individual allows the evaluation of information that is helpful in the diagnosis and monitoring of clinical diseases. Many of these same measures are commonly used to screen for disease or to evaluate the risks of a disease occurring in the future. To determine whether a certain finding is indicative of disease or “abnormal,” it must be compared with what is “normal.” The obviousness of this statement belies the difficulty in determining what is normal and the degree of deviation from normal that would be considered abnormal. Many clinical parameters are evaluated by direct observation by the examiner. Skin color and warmth, quality of pulses, briskness of pupil reactions to light, mental acuity, muscle strength, joint mobility, heart sounds, lung sounds, bowel sounds, balance, psychological affect, and level of consciousness are but a few examples of assessments that are subjectively interpreted based on the examiner’s observations. Deciding whether a clinical finding is normal, a normal variation, or an abnormality indicative of a disorder is essential.

Reliability of data obtained from observation is dependent upon the examiner’s skill and experience. Often the clinical examination is not sufficient to determine definitively the underlying pathophysiologic processes, and diagnostic testing is undertaken to provide more information.

### Statistical Normality

Some of the variables that are measured to diagnose disease are relatively easy to declare as normal or abnormal because they occur in only two states; for example, a bone is either broken or not broken on x-ray examination. However, most diagnostic variables occur in the population according to a “bell curve” or normal distribution.<sup>7</sup> This means that a large enough sample taken from the population should give a good estimate of the range of values in the population. Statistics are often used to determine the standard deviation of the variable in question, and then a normal range is suggested as the mean  $\pm 2$  standard deviations. This means that 95% of the values in the population are expected to fall in the normal range and 5% will be either higher or lower (Figure 1-1). The “population” chosen to serve as the normal reference population must be carefully selected to represent the individual to be tested for disease, because many variables are influenced by age and gender.

For example, bone density can be measured in the population by radiologic imaging and then a mean and standard deviation can be calculated. Women typically have lower bone density than men, and older women have lower bone density than younger women. If an elderly woman’s bone density is compared to women of her own age group, it may fall within the normal range, but when compared to a group of younger women, it is more than 2 standard deviations below the mean. Which is the right comparison group to use to determine if she has osteoporosis? There is controversy on this point because, in this situation, it is difficult to determine the difference between disease and the effects of normal aging.

Often, when assessing a person’s health status, a change in some value or factor is more significant than the actual value of the factor. A blood pressure of 90/70 mm Hg may not be significant if that is the usual value. However, if a person usually has a blood pressure of 120/80 mm Hg, a reading of 90/70 mm Hg could indicate a significant change. Individuals are typically evaluated more than once—generally two or three times—to establish deviation from their usual value.

**FIGURE 1-1** Representative example of a normal bell curve for a physiologic variable. Many physiologic variables are normally distributed within the population, so the mean  $\pm 2$  standard deviations include 95% of the normal values in the sample. Approximately 2.5% of values will be above the normal range and 2.5% will be below it. There may be overlap between the values in a normal sample and those in the population with a disease, making interpretation difficult in some cases.

### Reliability, Validity, and Predictive Value

The accurate determination of whether a specific condition is present or absent depends on the quality and adequacy of the data collected, as well as the skill of interpretation. Decisions about the data needed are based on the initial clinical presentation and a working knowledge of pathophysiology, which guide hypothesis generation about probable etiologies. During the clinical examination, data are analyzed and a number of likely explanations for the clinical presentation may emerge. These possible explanations are “probabilities” based on knowledge and past experience with similar cases. The purpose of further data collection, particularly laboratory and diagnostic testing, is to refine the initial probability estimates and identify the most likely diagnosis. The success of this approach depends on the selection of appropriate tests based on the pretest probabilities, as well as on the validity, reliability, and predictive value of the tests.

Validity, or accuracy, is the degree to which a measurement reflects the true value of the object it is intended to measure. For example, a pulse oximeter is designed to measure arterial oxygen saturation, and the closeness of the reading to a direct measurement of oxygen saturation in an arterial blood sample reflects its accuracy. Reliability, or precision, is the ability of a test to give the same result in repeated measurements. An instrument or laboratory test can be reliable, yet inaccurate. Repeated measurements with the pulse oximeter could give the same result each time, but if those values are significantly different from the “gold standard” of an arterial blood sample, the oximeter data would have poor validity.

Some measurements vary according to the reagents and laboratory methods used. For example, prothrombin time (PT) is sensitive to the reagent used. In one method of determining PT, the reagent—a substance composed of thromboplastin and calcium—is added to decalcified plasma to create a reaction resulting in clot formation. The PT is then determined by measuring the length of time it takes for clotting to occur after this reagent is added and compared to the normative average. Portions of the same blood sample sent to several different laboratories could return significantly different PT results. In fact, this is such a problem that laboratories now use a correction procedure to normalize the PT values across labs. The corrected PT value is reported as the International Normalized Ratio (INR), which has higher reliability than the PT.<sup>8</sup>

The predictive value of a test is the extent to which the test can differentiate between the presence or absence of a condition in an individual. The positive predictive value is an estimate of the probability that disease is present if the test is positive. The negative predictive value is an estimate of the probability that disease is absent if the test is negative. The predictive value of a test depends in part upon the sensitivity and specificity of the test and in part upon the probability of the disease being present before the test is obtained. Most tests are not perfectly specific and sensitive so the results must be interpreted probabilistically in view of the diagnostic hypotheses being tested.

Sensitivity and specificity are measures of how well a given test can discriminate between persons with and without a given condition. Sensitivity is the probability that the test will be positive when applied to a person with the condition. For example, if a kit for testing a throat swab for the presence of streptococcal infection has a sensitivity of 80%, then 20% of a group of people with streptococcal throat infection would erroneously test negative for the condition (false negative rate). Another example is the blood test for HIV antibodies, which has a sensitivity of 99% and would fail to detect the condition in only 1% of a group of individuals who had HIV antibodies in their blood. Specificity is the probability that a test will be negative when applied to a person who does not have a given condition. If the streptococcal throat swab kit has a specificity of 95%, then 5% of those tested who do not actually have the condition would erroneously test positive (false positive rate).

The importance of evaluating the accuracy and precision of data is paramount because inappropriate diagnoses and clinical management could occur if decisions are predicated on invalid or unreliable data.

The positive predictive value of a test is improved when sensitivity and specificity are high and the test is applied to individuals who have a high probability of having the condition being tested. If the likelihood of a condition in the population being tested is low (e.g., a 2% prevalence rate), then a positive result in a test with 99% specificity and 99% sensitivity would only have a 67% positive predictive value.<sup>9</sup> This means that testing low-likelihood or low-risk individuals would produce a high percentage of false positive results (33% in the preceding example). Therefore deciding who to test for a given condition based on the probability of the condition being present is as important as the sensitivity and specificity of the test. A good working knowledge of pathophysiology is necessary to generate the hypotheses that guide collection of appropriate data and facilitate the diagnostic process.

### Individual Factors Influencing Normality

Variations in physiologic processes may be a result of factors other than disease or illness. Age, gender, genetic and ethnic background, geographic area, and time of day may influence various physiologic parameters.<sup>10</sup> Care must be taken to interpret “abnormal” findings with consideration of these possible confounding factors. In addition, the potential for spurious findings always exists. Thus, trends and changes in a particular individual are more reliable than single observations. Single measurements, observations, or laboratory results that seem to indicate abnormality must always be judged in the context of the entire health picture of the individual. One slightly elevated blood glucose level does not mean clinical diabetes, a single high blood pressure reading does not denote hypertension, and a temporary feeling of hopelessness does not indicate clinical depression.

### Cultural Considerations

Each culture defines health and illness in a manner that reflects its experience. Cultural factors determine which signs, symptoms, or behaviors are perceived as abnormal. An infant from an impoverished culture with endemic chronic diarrhea and a degree of malnutrition would be viewed as abnormal in a progressive culture, such as a well-baby clinic in Sweden. Given cultural variations that affect definitions of normal and abnormal, the resulting pattern of behaviors or clinical manifestations affects what the culture labels as illness.<sup>11</sup>

### Age Differences

Many biological factors vary with age, and the normal value for a person at one age may be abnormal at another. Physiologic changes, such as hair color, skin turgor (tension), and organ size, vary with age. In general, most organs shrink; exceptions are the male prostate and the heart, which enlarge with age.<sup>12</sup> Special sensory changes, such as severely diminished near-sight, high-tone hearing loss, and loss of taste discriminations for sweet and salty, are normal in an elderly adult and abnormal in a middle-aged adult or child. There are fewer sweat glands and less thirst perception in an elderly person than in a young adult or child. Elderly persons have diminished temperature sensations and can therefore sustain burn injuries—from a heating pad or bath water—because they do not perceive heat with the same intensity as do middle-aged adults. A resting heart rate of 120 beats per minute is normal for an infant but not for an adult.

### Gender Differences

Some laboratory values, such as levels of sex and growth hormones, show gender differences. The complete blood cell count shows differences by gender in hematocrit, hemoglobin, and red blood cell (RBC)

count.<sup>13</sup> For example, the normal range of hemoglobin concentration for adult women is lower than that for adult men—for adult women, the normal hemoglobin range is 12 to 16 g/100 ml of blood whereas for adult men the normal range is 13 to 18 g/100 ml of blood.<sup>13</sup> There are also gender differences in the erythrocyte sedimentation rate (ESR). Normally, in males, the ESR is less than 13 mm/hr; it is slightly higher in females.<sup>13</sup> There are differences by gender in creatinine values. For females, the normal serum creatinine level is 0.4 to 1.3 mg/dl; for males, the normal range is 0.6 to 1.5 mg/dl.<sup>13</sup> Research into gender differences also suggests that, on average, males snore more; have longer vocal cords, better daylight vision, and higher metabolic rates; and are more likely to be left-handed than females.<sup>14</sup> Research suggests, too, that females and males have different communication styles and respond differently to similar conditions.

### Situational Differences

In some cases, a deviation from the usual value may occur as an adaptive mechanism, and whether the deviation is considered abnormal depends on the situation. For example, the RBC count increases when a person moves to a high altitude.<sup>15</sup> The increase is a normal adaptive response to the decreased availability of oxygen at a high altitude and is termed *acclimatization*. A similar increase in the RBC count at sea level would be abnormal.

### Time Variations

Some factors vary according to the time of day; that is, they exhibit a circadian rhythm or diurnal variation. In interpreting the result of a particular test, it may be necessary to know the time at which the value was determined. For example, body temperature and plasma concentrations of certain hormones (such as growth hormone and cortisol) exhibit diurnal variation. Reflecting fluctuation in plasma levels, the peak rate in urinary excretion for a particular steroid (17-ketosteroid) occurs between 8 AM and 10 AM for persons who customarily rise early in the morning and is about two to three times greater than the lowest rate in the same people, which occurs between midnight and 2 AM, usually during sleep.<sup>16</sup> The urinary excretion of ions (e.g., potassium) also exhibits diurnal variation. Figure 1-2 illustrates circadian rhythms of several physiologic variables for persons living on a standard day-active schedule.

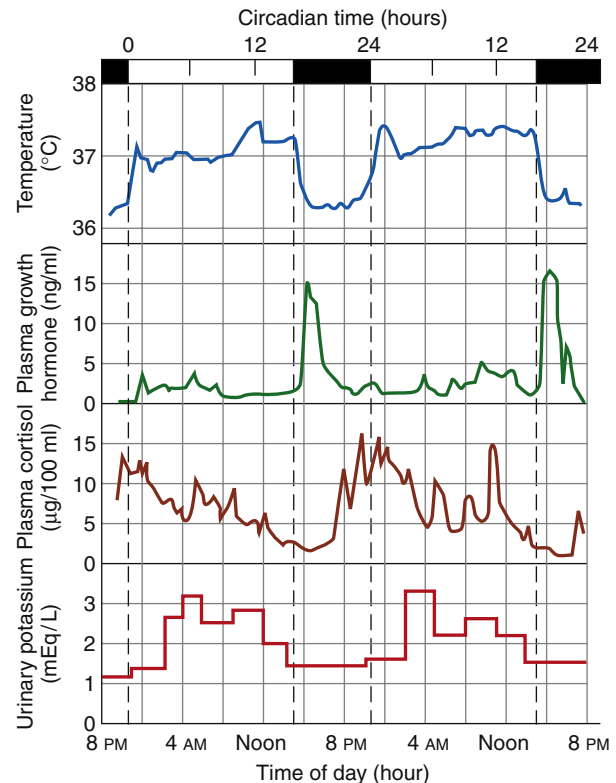

#### KEY POINTS

- Determining whether clinical findings are normal, abnormal, or normal variation is an essential but often difficult process in evaluating for the presence or absence of disease.
- Normal ranges for laboratory tests are typically defined as the mean  $\pm 2$  standard deviations; thus, 5% of the normal population may fall outside the normal range despite the absence of disease. Laboratory tests must be evaluated in concert with clinical information.
- The predictive value of a clinical test is the extent to which it can differentiate between the presence and absence of disease in an individual. Tests with high sensitivity and specificity generally have better predictive value.
- Variations in physiologic processes may be a result of factors other than disease or illness. Age, gender, genetic and ethnic background, geographic area, and time of day may influence various physiologic parameters.
- Trends and changes in a particular individual are more reliable than single observations.

## PATTERNS OF DISEASE IN POPULATIONS

### Concepts of Epidemiology

Differences among *individuals* are, of course, very important in determining the diseases to which they are susceptible and their reactions to

**FIGURE 1-2** Circadian rhythms of several physiologic variables in a human subject depict the effect of light and dark. In an experiment with lights on (*open bars* at top) for 16 hours and off (*black bars* at top) for 8 hours, temperature readings and plasma growth hormone, plasma cortisol, and urinary potassium levels exhibit diurnal variation. (Redrawn from Vander AJ et al: *Human physiology*, ed 7, New York, 1998, McGraw-Hill.)

the diseases once contracted. But epidemiology, or the study of *patterns of disease* involving aggregates of people (Figure 1-3), provides yet another important dimension. Information may be gained by examining the occurrence, incidence, prevalence, transmission, and distribution of diseases in large groups of people or populations.

### Endemic, Pandemic, and Epidemic Diseases

A disease that is native to a local region is called an *endemic disease*. If the disease is disseminated to many individuals at the same time, the situation is called an *epidemic*. *Pandemics* are epidemics that affect large geographic regions, perhaps spreading worldwide. Because of the speed and availability of human travel around the world, pandemics are more common than they once were. Almost every flu season, a new strain of influenza virus quickly spreads from one continent to another.

### Aggregate Factors

Principal factors affecting patterns of disease in human populations include the following: (1) age (i.e., time in the life cycle), (2) ethnic group, (3) gender, (4) socioeconomic factors and lifestyle considerations, and (5) geographic location.

**Age.** In one sense, life is entirely different during the 9 months of gestation. The structures and functions of tissues are different: they are primarily dedicated to differentiation, development, and growth. Certainly the environment is different; the individual is protected from the light of day, provided with predigested food (even preoxygenated blood), suspended in a fluid buffer, and maintained at incubator temperature. This is fortunate because the developing embryo or fetus has

**FIGURE 1-3** **A**, The aggregate focus in disease: influence of crowds upon disease transmission. Crowd gathered at a public market in Russia. **B**, Crowds gathered to purchase goods at a public market in Guangzhou, China. (Photographed by L-E Copstead.)

relatively few homeostatic mechanisms to protect it from environmental change. (The factors that produce disease in utero are discussed in Chapter 6.) Diseases that arise during the postuterine period of life and affect the neonate include immaturity, respiratory failure, birth injuries, congenital malformations, nutritional problems, metabolic errors, and infections. These conditions are discussed in separate chapters.

Accidents, including poisoning, take their toll in childhood. Infections in children reflect their increased susceptibility to agents of disease. Consideration of other childhood diseases is addressed in each chapter, as appropriate and given separate consideration throughout the text. The study of childhood processes and of changes that occur in this period of life is the domain of pediatrics; specific diseases that occur during maturity (ages 15 to 60) are emphasized in this text.

The changes in function that occur during the early years of life are termed *developmental processes*. Those that occur during maturity and postmaturity (age 60 and beyond) are called *aging processes*. The study of aging processes and other changes that occur during this period of life is called *gerontology*. The effects of aging on selected body systems are so important physiologically that they also receive separate consideration throughout the text. The immune, cardiac, respiratory, musculoskeletal, neurologic, special sensory, endocrine, gastrointestinal, and integumentary systems are among those affected by the process of aging.

**Ethnic group.** It is difficult to differentiate precisely between the effects of ethnicity on patterns of disease and the socioeconomic factors, religious practices, customs, and geographic considerations with

which ethnicity is inseparably bound. For example, carcinoma of the penis is virtually unknown among Jews and Muslims who practice circumcision at an early age (avoiding the carcinogenic stimulus that arises from accumulation of smegma about the glans penis).

However, comparisons reveal significant differences in the occurrence of certain disease states in ethnic groups that seem to be more closely related to genetic predisposition than to environmental factors. For example, sickle cell anemia has a much higher rate of occurrence in African populations, whereas pernicious anemia occurs more frequently among Scandinavians and is rare among black populations worldwide.

The study of racial and ethnic group variation in disease states is the domain of medical anthropology. Volumes have been written about disease-specific differences that relate to racial or ethnic group differences. In clinical practice, recognition of diversity in disease risk by racial or ethnic group is useful in disease diagnosis, prevention, and management. Ethnic group-specific differences, where important, are presented in individual chapters.

**Gender.** Particular diseases of the genital system obviously show important differences between the sexes; men do not have endometriosis nor do women have hyperplasia of the prostate, and carcinoma of the breast is more common in women than in men. Pyelonephritis is more common in young women than in men of comparable age (before they develop prostatic hyperplasia) because the external urethral orifice of women is more readily contaminated, and bacteria can more easily travel up a short urethra than a long one. Less obviously related to the reproductive system, the onset of severe atherosclerosis in women is delayed nearly 20 years or more over that in men, presumably because of the protective action of estrogenic hormone.

There are also gender-specific factors that defy explanation.<sup>17</sup> For example, systemic lupus erythematosus is much more common in women.<sup>18</sup> Toxic goiter and hypothyroidism are also more common in women.<sup>19</sup> Rheumatoid arthritis is more common in women, but osteoarthritis affects men and women with equal frequency.<sup>20</sup> Thromboangiitis obliterans (a chronic, recurring, inflammatory peripheral vascular disease) occurs more commonly in men.<sup>21</sup> Gender differences in predisposition to cancer and other diseases are presented throughout the text.

**Socioeconomic factors and lifestyle considerations.** The environment and the political climate of countries determine how people live and the health problems that are likely to ensue. The importance of poverty, malnutrition, overcrowding, and exposure to adverse environmental conditions, such as extremes of temperature, is obvious. Volumes have been written about the effects of socioeconomic status on disease. Sociologists study the influence of these factors. Social class influences education and occupational choices.

Disease is related to occupational exposure to such agents as coal dust, noise, or extreme stress.<sup>22</sup> Lifestyle considerations are closely related to socioeconomic factors. People living in the United States, for example, consume too much food, alcohol, and tobacco and do not exercise enough. Childhood obesity is a problem in the United States. Arteriosclerosis; cancer; diseases of the kidney, liver, and lungs; and accidents cause most deaths in the United States. By contrast, people living in developing nations suffer and frequently die from undernutrition and infectious diseases.

However, infectious disease is not limited to developing countries.<sup>23</sup> The Centers for Disease Control and Prevention (CDC) estimates that 2 million people annually acquire infections while hospitalized and 90,000 people die as a result of those infections. More than 70% of hospital-acquired infections have become resistant to at least one of the drugs commonly used to manage them, largely attributable to the overprescribing of antibiotics.<sup>24</sup> *Staphylococcus*, the leading cause of hospital infections, is now resistant to 95% of first-choice antibiotics and 30% of second-choice antibiotics. Poor hygiene is considered the leading

**FIGURE 1-4** Risk factors for schistosomiasis include the widespread use of irrigation ditches that harbor the intermediate snail host. (Photographed in China by L-E Copstead.)

source for infections acquired during hospitalizations. Unfortunately, efforts to convince health care personnel to reduce transmission of infection through practices as simple as more frequent and thorough hand washing have met with only modest success.

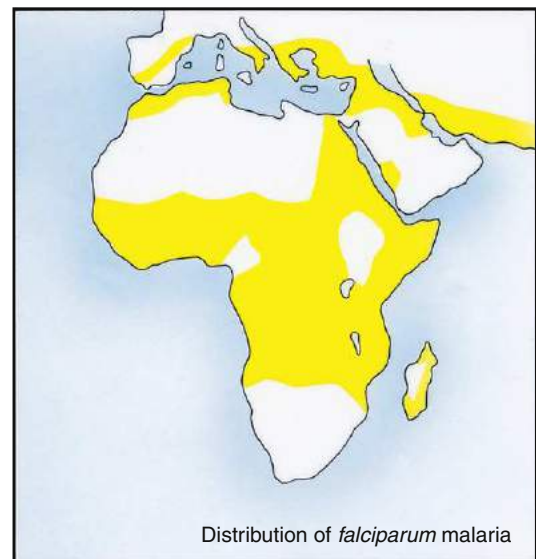

The incidence of many parasitic diseases is closely tied to socioeconomic factors and lifestyle considerations. Worm infections, for example, are related to the use of human feces as fertilizer. In some areas, such as parts of Asia, Africa, and tropical America, the frequency of schistosomiasis (a parasitic infestation by blood flukes) is directly related to the widespread use of irrigation ditches that harbor the intermediate snail host.<sup>25</sup> There is adequate opportunity for transmission of schistosomiasis because children often play in these ditches and families wash their clothes in ditch water (Figure 1-4).

Trichinosis, a disease caused by the ingestion of *Trichinella spiralis*, occurs almost entirely from eating inadequately cooked, infected pork. People who are fond of raw meat and inadequately cooked sausage are at highest risk.

Education is often very effective in changing lifestyle patterns that contribute to disease. In Tokyo, for example, mass public education about minimizing the use of sodium—a common ingredient in most traditional Japanese cooking—has been effective in changing dietary practices.

Examples of educational efforts directed at lifestyle modification in the United States are numerous.<sup>26-28</sup> Antidrug, antismoking, and pro-fitness messages fill the media and are prevalent on the Internet. Choosing healthy alternatives over unhealthy ones is made easier through positive peer pressure and support groups.

**Geographic location.** Patterns of disease vary greatly by geographic location. Certainly there is considerable overlap with ethnicity, socioeconomic factors, and lifestyle choices, but physical environment also is an important aspect. Obviously, frostbite in Antarctica and dehydration in the Sahara are examples of disorders that are more prevalent in specific geographic settings. However, important patterns of disease

**FIGURE 1-5** Geographic distribution of malaria. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 113.)

occur within individual countries. For example, the incidence and type of malnutrition vary tremendously by geographic region.

Many diseases have a geographic pattern for reasons that are clear. For example, malaria, an acute and sometimes chronic infectious disease resulting from the presence of protozoan parasites within red blood cells, is transmitted to humans by the bite of an infected female *Anopheles* mosquito. The *Anopheles* mosquito can live only in certain regions of the world<sup>29</sup> (Figure 1-5).

**FIGURE 1-6** Healthy aging: elders exercising in an aerobics class (A) and painting (B) illustrate the concept that aging and disease are not synonymous. The artist, a healthy woman in her mid-70s, is also a breast cancer survivor. (Photographed by Therese A. Capal, Rockville, Md.)

Fungal diseases are both more common and more serious in hot, humid regions. But some infectious diseases are highly limited geographically for reasons that are not well understood. For example, bartonellosis, which is also called Carrion disease, is found only in Peru, Ecuador, Chile, and Colombia.<sup>30</sup> This disease resembles malaria superficially in that the minute rickettsia-like organisms invade and destroy erythrocytes. Humans are infected by the bite of the sand fly. Although conditions in other parts of the world should be favorable for this disease, it remains limited geographically.

Taking a world view, there is widespread recognition of the importance of geographic factors in influencing human disease.<sup>31</sup> The World Health Organization (WHO) and the National Institutes of Health (NIH) have been deeply concerned with geographic problems in disease. Consult WHO and NIH home pages on the World Wide Web for additional information. (Web locations are provided on the Evolve website.)

### Levels of Prevention

The goal of health care should encompass much more than the prevention of illness. What is needed instead is some notion of positive health or physical “wholeness” that extends beyond the absence of ill health. WHO defines health as complete physical, mental, and social well-being and not merely the absence of disease or infirmity.<sup>31</sup> For some individuals, health implies the ability to do what they regard as worthwhile and to conduct their lives as they want. Aging and ill health are not synonymous, and many elders enjoy excellent health, even in the face of chronic disease (Figure 1-6).

Epidemiologists suggest that treatment implications fall into categories called *levels of prevention*. There are three levels of prevention: primary, secondary, and tertiary. Primary prevention is prevention of disease by altering susceptibility or reducing exposure for susceptible individuals. Secondary prevention (applicable in early disease, i.e., preclinical and clinical stages) is the early detection, screening, and management of the disease. Tertiary prevention (appropriate in the stage of advanced disease or disability) includes rehabilitative and supportive care and attempts to alleviate disability and restore effective functioning.<sup>32</sup>

**Primary prevention.** Prolongation of life has resulted largely from decreased mortality from infectious disease. Primary prevention in

terms of improved nutrition, economy, housing, and sanitation for those living in developed countries is also responsible for increased longevity. Certain childhood diseases—measles, poliomyelitis, pertussis (whooping cough), and neonatal tetanus—are decreasing in prevalence, owing to a rapid increase in coverage by immunization programs. More than 120 million children younger than age 5 in India were immunized against poliomyelitis in a single day in 1996.<sup>33</sup> Globally, coverage of children immunized against six major childhood diseases increased from 5% in 1974 to 80% in 1995.<sup>33</sup> In 1985 Rotary International launched the PolioPlus program to protect children worldwide from the cruel and fatal consequences of polio. In 1988 the World Health Assembly challenged the world to eradicate polio. Since that time, Rotary International’s efforts and those of partner agencies, including the WHO, the United Nations Children’s Fund, the CDC, and governments around the world, have achieved a 99% reduction in the number of polio cases worldwide.<sup>33</sup>

The prevalence of cardiovascular diseases in developed countries (except those in Eastern Europe) is diminishing, thanks to the spread of health education and promotion. Infant and child death rates and the overall death rate are continuing to decrease globally.

High school education programs about abstinence from sex and ways to “say no” to drugs, alcohol, and tobacco are other examples of primary prevention making a difference in the lives of people. Primary prevention also includes adherence to safety precautions, such as wearing seat belts, observing the posted speed limit on highways, and taking precautions in the use of chemicals and machinery. Violent crimes involving dangerous weapons must be stopped to achieve primary prevention of the traumatic or fatal injuries they cause.

Environmental pollutants poison the body’s organs. Some experts fear the emergence of an epidemic of cancer attributable to the carcinogenic chemicals afflicting the environment.<sup>34</sup> Public health measures to ensure clean food, air, and water prevent many diseases, including cancer. As air, water, and soil quality is improved, the risk of exposure to harmful carcinogens is minimized.

**Secondary prevention.** Yearly physical examinations and routine screening are examples of secondary prevention that lead to the early diagnosis of disease and, in some cases, cures. The routine use of

Papanicolaou (Pap) smears has led to a decline in the incidence of invasive cancer of the uterine cervix. Also, more women are examining their own breasts monthly for cancer; thus, earlier diagnoses are achieved.

Prenatal diagnosis of certain genetic diseases is possible. New diagnostic laboratory techniques provide definitive information for the genetic counseling of parents. This information can aid in predicting chances of involvement or noninvolvement of offspring for a given genetic disorder (e.g., Down syndrome). One technique, *amniocentesis*, consists of removing a small amount of fluid from the amniotic sac that surrounds the fetus and analyzing the cells and chemicals in the fluid. Blood samples can also be obtained from the fetus by amniocentesis; the amniotic fluid and fetal blood are then studied to determine defects in enzymes, to ascertain gender, and to measure substances associated with defects in the spinal cord and brain.

**Tertiary prevention.** Once a disease becomes established, treatment—within the context of traditional Western medicine—generally falls into one of the following two major categories: medical (including such measures as physical therapy, pharmacotherapy, psychotherapy, radiation therapy, chemotherapy, immunotherapy, and

experimental gene therapy) and surgical. Numerous other subspecialties of medicine and surgery also have evolved to focus on a given organ or technique. In a clinical setting, a large array of professional caregivers provides rehabilitative and supportive tertiary prevention to the diseased individual. Every professional brings the perspective of his or her discipline to the caregiving situation. Each makes clinical judgments about the patient's needs and problems and decides which goals and intervention strategies are most beneficial.

#### KEY POINTS

- Epidemiology is the study of patterns of disease in human populations.
- Diseases may be endemic, epidemic, or pandemic depending upon location and the number of people affected.
- Aggregate factors such as age, ethnicity, gender, lifestyle, socioeconomic status, and geographic location are epidemiologic variables that influence the occurrence and transmission of disease in populations.
- Understanding the epidemiologic aspects of a disease is essential for effective prevention and treatment.

## SUMMARY

Most people recognize what it is to be healthy and would define disease or illness as a change from or absence of that state. Under closer scrutiny, the concept of health is difficult to describe in simple, succinct terms. Correspondingly, the concepts of disease and illness also are complex. Environment, genetic constitution, socioeconomic status, lifestyle, and previous physical health all affect the timing and ultimate expression of disease in individuals.

Because humans exhibit considerable diversity, healthy structure and function are not precisely the same in any two individuals. By discovering common and expected patterns of responses to abnormalities, general prediction of etiology, pathogenesis, clinical manifestations, and targeted levels of prevention and intervention becomes possible.

Survival of the human species is dependent on its ability to respond to changes in the environment. Changes in the external environment, such as moving outside from a warm house on a cold winter day, demand physiologic adjustments in the body's internal environment beyond the simple addition of layers of clothing to the outside of the body. Variations in the internal environment, such as a fever caused by infection, also necessitate physiologic responses to return the body's temperature to the normal range. The human organism maintains a variety of highly complex interactions with both internal and external environments. These interactions facilitate ongoing compensatory changes designed to support the organism physically and psychologically. This process is necessary, allowing the perpetuation of both the

individual and the species. Researchers, however, have found that the body's efforts to adapt to prolonged and repeated or extraordinarily demanding environmental changes may be associated with many physical and psychological health problems. This chapter explores the historical and current perspectives of homeostasis, allostasis, and stress responses, and their relationship to illness.

### HOMEOSTASIS AND ALLOSTASIS

#### Homeostasis

The word *homeostasis* is derived from the Greek words *homeo*, or same, and *stasis*, or stable, and means remaining stable by remaining the

## CHAPTER 2 Homeostasis and Adaptive Responses to Stressors

same.<sup>1</sup> Homeostasis is conceptualized as a state of being in which all systems are in balance around a particular ideal “set-point.” From this perspective, bodily changes formerly seen as conflicting or detrimental are understood as adaptive or compensatory to the maintenance of homeostasis within the body as a whole. Homeostasis reflects a tendency to stabilize an organism’s functional systems, despite changes both internally and externally. Deviations from homeostasis resulting from these changes require elaborate systems to support its reestablishment. A great deal of discussion exists in the literature over the past several decades criticizing the inadequacy of the definition of homeostasis to encompass the entire process of maintaining a stable state in complex organisms. But the fact remains that homeostatic concepts are an essential starting point for an exploration of stress, adaptation, and disease.

Claude Bernard, a nineteenth century French physiologist, is credited with describing the basic premise of homeostasis. He believed that the various vital physiologic mechanisms of the body had as their goal the maintenance of a uniform and constant internal environment, or *milieu intérieur*, for the body. The stability of the internal environment was deemed necessary for the survival of the person, independent or free of the external environment.<sup>1,2</sup> Disease occurred when the body did not respond appropriately to maintain internal stability when threatened by perceived or actual events.<sup>1</sup> Building on Bernard’s work, Walter B. Cannon created a concept that he referred to as “homeostasis” in his 1932 book *The Wisdom of the Body*.<sup>1-4</sup> Homeostasis, according to Cannon, was a process in which each of the body’s biochemical or physiologic variables (e.g., body temperature; oxygen, sodium, calcium, and glucose levels; and pH) was maintained within a narrow set point range. Negative feedback loops were used to sense and correct any deviations from the set point ranges for the variables, thereby supporting the survival of the individual, despite threats from the external or internal environments. These environmental threats could range from temperature extremes and water loss or gain, to “savage animals,” to bacterial infection.<sup>1,3</sup> Box 2-1 provides examples of homeostatic systems designed to support the life of the person in the most basic sense.

### Allostasis

The original concept of homeostasis, with the principle that the body attempts to achieve balance around a single optimal level or set point for a given physiologic variable, has been challenged in recent decades. The innate complexity of biological organisms requires that set points be readjusted for different circumstances (i.e., diverse situations necessitate different homeostatic set points).<sup>5</sup> For example, respiratory rate needs to increase when vigorously exercising or when ill with pneumonia in order to obtain more oxygen. At the same time, when responding to an internal or external environmental challenge (i.e., a stressor), *multiple* physiologic parameters may have to raise or lower their levels or actions in order to meet the demands posed by the challenge and achieve some internal stability. Desired changes in one body system, though, may be detrimental to another; these changes, however, may ultimately be needed to support the survival of the organism as a whole

at that particular point in time.<sup>5</sup> For instance, in shock, when the life of the organism is at risk, blood flow to essential organs (brain and heart) is maintained by reducing perfusion to the kidneys, skin, and gastrointestinal tract. Simply stated, the body is not concerned about digesting dinner or making urine when it is trying to divert resources to a struggling brain and heart.

In 1988 Sterling and Eyer introduced the concept of **allostasis** in recognition of the complexity and variable levels of activity necessary to reestablish or maintain homeostasis.<sup>6</sup> They described allostasis as the ability to successfully adapt to challenges. In order to survive, “an organism must *vary* all the parameters of its internal milieu and match them appropriately to environmental demands.” Like homeostasis, allostasis is a derivation of the Greek words *allo*, meaning variable, and *stasis*, meaning stable. Therefore this term accentuates the role of allostatic systems in maintaining the organism’s stability by being variable.<sup>1</sup> Allostasis is a dynamic process that supports and helps the body achieve homeostasis; homeostasis, from this perspective, is seen as a steady-state. In essence, the organism’s overall stability is accomplished through change.<sup>1,7</sup>

Allostasis involves intricate regulatory processes orchestrated by the brain.<sup>8</sup> Through these processes, the body’s parameters are continuously reevaluated and readjusted in order to match resources to the needs dictated by the situation. These parameter readjustments (e.g., of heart rate, blood pressure, or glucose levels) entail altering multiple set points such that the person may be functioning at reduced or elevated levels or rates for numerous physiologic variables. Thus, an individual may have different set points for different circumstances (e.g., when resting versus running or when healthy versus sick). Allostasis comes into play in the complexity of social interactions, during changes in the weather, during reproduction, and even in the hibernation and migration patterns of bears and birds, as well as in critical illness.<sup>1,6,7,9</sup> Although the concept is occasionally challenged,<sup>7,10</sup> it has garnered broad support in both the physical and the behavioral sciences. It seems especially applicable to subsequent discussions of adaptation and disease.

#### KEY POINTS

- Contemporary concepts of homeostasis have a long history, reaching back to the ancient Greeks.
- Homeostasis is a state of equilibrium, of balance within the organism.
- Homeostatic responses refer to systems whose purpose is specifically to normalize selected physiologic variables.
- Allostasis is the overall process of adaptive change necessary to maintain survival and well-being.
- Allostasis may involve altering multiple physiologic variables in order to match the resources of the body to environmental demands. It helps the body achieve homeostasis.

### STRESS AS A CONCEPT

Referring to **stress** as something of an “ambiguous” term is an understatement. Its ubiquitous use in everyday parlance is matched by its frequent presence in the health and psychology literature. Stress often is interpreted as a physical, chemical, or emotional factor that produces tension in the body or the mind (“He’s experiencing a lot of stress”). But it also can mean the actual physical and mental state of tension (“I feel stressed”). Others use the term stress in relation to the response by the body to internal and external demands. Stress can be defined as a real or perceived threat to the balance of homeostasis. The neuroendocrinologist Robert Sapolsky more specifically distinguishes between the stress terminology and defines a stressor as anything that throws the body out of allostatic balance, whereas the stress response is

#### BOX 2-1 EXAMPLES OF HOMEOSTATIC SYSTEMS

Baroreceptor response to acute changes in blood pressure  
Vasopressin/antidiuretic hormone release from the posterior pituitary in response to changes in serum osmolality  
Hypothalamic-mediated responses to changes in body core temperature  
Central chemoreceptor responses to changes in  $\text{Paco}_2$   
Parathyroid gland response to changes in serum calcium level

the body's effort to try to restore the balance. To that end, stress is a natural outgrowth of the concept of homeostasis but is even more applicable to the dynamic concept of allostasis. Sapolsky's<sup>5</sup> definition also underscores an important point: The stress response by the body is meant to be helpful, at least in the short term; however, it becomes damaging when repeatedly activated or when it does not cease.

As early as the 1920s, Walter Cannon used the term stress in relation to humans and medicine. Hans Selye, however, often is erroneously credited with being the first person to borrow the term from the fields of engineering and physics and apply it to the human condition.<sup>5</sup> In the 1930s Selye was experimenting with assorted ovarian and placental hormonal preparations and other tissue extracts and toxic agents. He was injecting these into rats when he serendipitously uncovered a biological basis for stress.<sup>1,5,11</sup> Selye was expecting to find different physiologic responses in the rats, depending on which of the various substances was injected; however, to his surprise and disappointment, the same three changes occurred each time. In every animal tested, the cortex of the adrenal gland enlarged, lymphatic organs (thymus, spleen, and lymph nodes) shrank, and bleeding peptic ulcers developed in the stomach and duodenum. When Selye experimented with other noxious stimuli, such as exposing the rats to temperature extremes, surgery, or forced exercise, the same three changes occurred. Any kind of harmful physical stimuli he used produced the same observed physiologic changes. Selye termed the harmful stimuli or causative agents **stressors** and concluded that the changes observed represented a nonspecific response by the body to any noxious stimulus or demand, a general "stress" response.<sup>11</sup> Because so many different agents caused the same changes, Selye called this process a **general adaptation syndrome (GAS)** with three components: an *alarm reaction*, a *stage of resistance*, and a *stage of exhaustion*.<sup>1,5,11</sup> According to Selye, when confronted by stressors during daily life, individuals move through the first two stages repeatedly and eventually become adapted and "used to" the stressors.<sup>11</sup>

Selye's original conceptualization of the stress response and GAS has been criticized as being too simplistic for the complexities of humans. In particular, evidence suggests the body does not produce the same responses to all types of stressors. Depending on the type and severity of stressor, different patterns of hormone release occur, with more of some substances and less of others being produced and at different speeds and for varying lengths of time.<sup>5,12</sup> Moreover, Selye's early work in the 1930s concentrated on stimuli of a physical or biological nature.<sup>11</sup> Beginning in the 1970s, researchers began to realize that perception of these stimuli was important to individuals' responses to stress, and that responses could be physiologic, as Selye described, as well as behavioral in nature.

When stress is generated by extreme psychological or environmental demands, balance is disrupted, and allostatic reactions are initiated to restore balance.<sup>13</sup> The discussion that follows presents the GAS as a reflection of the responses to these diverse stimuli and incorporates much of the knowledge acquired since Selye's early pioneering work.

## The General Adaptation Syndrome and Allostasis

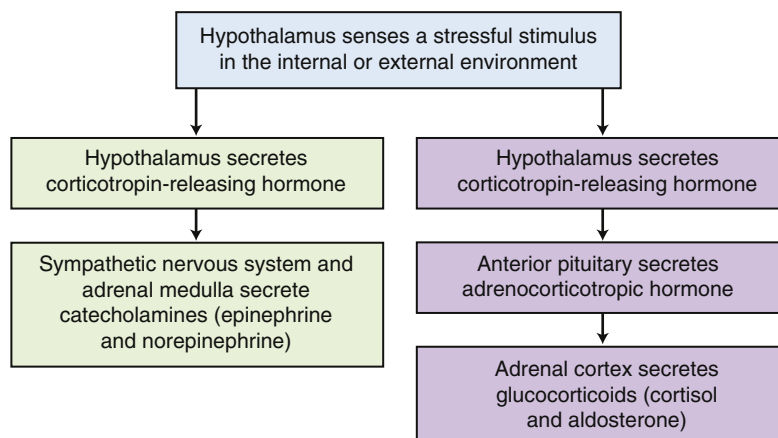

Components of the GAS can be subdivided into three unique, largely physiologic stages (Table 2-1). Examining the stages separately is the best way to understand the entire GAS. The specific chemicals involved are among those seen today as integral to the broader view of allostatic responses to stress in the maintenance of homeostasis. All will be discussed later in the chapter.

### Alarm Stage

The alarm stage has been called the **fight-or-flight response**, derived from Cannon's work, because it provides a surge of energy and physical alterations to either evade or confront danger<sup>12</sup> (Figure 2-1). This stage

**TABLE 2-1 STAGES OF THE GENERAL ADAPTATION SYNDROME**

ALARM	RESISTANCE	EXHAUSTION
Increased secretion of glucocorticoids and responses	Eventual normalization of glucocorticoid secretion	Increased glucocorticoid secretion followed by significant reduction
Increased sympathetic nervous system activity	Eventual normalization of sympathetic nervous system activity	Diseases of adaptation
Increased secretion of epinephrine (and some norepinephrine) from adrenal medulla	Eventual normalization of epinephrine and norepinephrine secretion from adrenal medulla	Loss of resistance to stressor; possible death of organism
Fight-or-flight manifestations	Resolution of fight-or-flight manifestations	
Reduced resistance to stressors	Increased resistance (adaptation) to stressor	

**FIGURE 2-1** Steps of Selye's alarm stage of the general adaptation syndrome. (Modified from McKenry L et al: *Mosby's pharmacology in nursing*, ed 22, St Louis, 2006, Mosby.)

## CHAPTER 2 Homeostasis and Adaptive Responses to Stressors

begins when the hypothalamus, as it monitors the internal and external environment, senses a need to activate the GAS in response to a stimulus, a stressor placing the balance of homeostasis at risk. The stressor might be physical or emotional, positive or negative—arguing with a friend, having an upper respiratory tract infection, running to catch a bus, or winning the lottery. The hypothalamus then secretes corticotropin-releasing hormone (CRH) to activate the sympathetic nervous system, which in turn also stimulates the adrenal medulla (the inner portion of the adrenal gland) to release the catecholamines—norepinephrine and epinephrine. The increased levels of catecholamines enable the body to rapidly take action to fight or flee the stressor. This series of events is part of the sympathetic-adrenal-medullary system, originally referred to as the fight-or-flight response by Walter Cannon. Additionally, the hypothalamus secretes CRH to also stimulate the anterior pituitary gland to release adrenocorticotropic hormone (ACTH). ACTH then causes the

adrenal cortex (the outer portion of the adrenal gland) to release substantial amounts of the glucocorticoids, specifically cortisol, eliciting its diverse responses, and also aldosterone. This cascade of effects is termed the **hypothalamic-pituitary-adrenal (HPA) axis**.<sup>4</sup> Once the pituitary gland is activated, the alarm stage progresses to the stage of resistance. This coordinated systemic response to stress is illustrated in Figure 2-2.

Allostasis is essentially the activation of these stress responses to evoke changes that return the organism to homeostasis. Mediators of allostasis include the aforementioned hormones, neurotransmitters of the HPA axis and the sympathetic-adrenal-medullary system (e.g., cortisol, epinephrine, and norepinephrine),<sup>1,8,9</sup> various other hormones presented later in this chapter, and also cytokines from the immune system. The alarm stage of the stress response with the release of its various hormones is meant to be helpful to the organism in overcoming the stressor, at least initially.

**FIGURE 2-2** Neuroendocrine interactions in response to a stressor. Receptors are excited by stressful stimuli and relay the information to the hypothalamus. The hypothalamus signals the adrenal cortex (by way of the anterior pituitary) and the sympathetic pathways (by way of the autonomic nervous system). The stress response is then mediated by the catecholamines (i.e., epinephrine and norepinephrine) and by the glucocorticoids (predominantly cortisol).

## Resistance or Adaptation Stage

If the alarm stage were to persist, the body would soon suffer undue wear and tear and become subject to permanent damage and even death.<sup>11</sup> To survive, the body must move beyond the alarm stage to a stage of resistance (also called adaptation) supportive of the allostatic return to a state of homeostasis. As the body moves into the stage of resistance, the sympathetic nervous system and adrenal medulla and cortex are functioning at full force to mobilize resources to manage the stressor. The resources include glucose, free fatty acids, and amino acids, and concentrations of all of these chemicals are elevated through the effects of cortisol and the catecholamines (i.e., epinephrine and norepinephrine). These resources are used for energy and as building blocks, especially the amino acids, for the later growth and repair of the organism after the stress abates. If the stressor is adequately addressed and resolved, the organism returns to its steady-state, having reattained allostatic balance.<sup>5</sup> This process described by Selye is clearly a part of the more recently described process of allostasis. However, with the current understanding of allostasis, it is possible that in order to adapt and reattain homeostasis, the organism may have to function at a new baseline steady-state for different physiologic variables, either higher or lower than the previous set points. For instance, the normal partial pressure of carbon dioxide (pCO<sub>2</sub>) in the blood is 35 to 45 mm Hg and the normal oxygen saturation is greater than 94% in a healthy individual. For someone with chronic obstructive pulmonary disease, a new normal pCO<sub>2</sub> value might be 50 to 60 mm Hg and the oxygen saturation may be 88% to 90%, while still maintaining a homeostatically normal serum pH.

## Exhaustion Stage

Exhaustion occurs when the body is no longer able to effect a return to homeostasis following prolonged exposure to noxious agents.<sup>11</sup> Selye postulated that when energy resources are completely depleted, death occurs because the organism is no longer able to adapt. He speculated that individuals are born with a given amount of adaptation energy. However, when these adaptive energy stores are depleted, no other resource exists to facilitate recovery. Diseases of adaptation such as hypertension and heart disease occur when the body is continuously taxed by stressors.<sup>11</sup> It is now understood that exhaustion and stress-related disease do not necessarily occur because resources are depleted; instead, they can occur because the actual stress response itself, with all of its various biological mediators, can be harmful when repeatedly activated.<sup>5</sup>

Concepts related to allostasis help with understanding the damaging effects of stress. The HPA axis, the sympathetic-adrenal-medullary system, and other systems (including the immune system) work to help the person adapt to and defend against stressors. Wear and tear on the body and on the brain occurs when these body systems are chronically over- or underactivated in their attempts to support an allostatic return to homeostasis. The accumulation of all of the various mediators produced by the systems is damaging to tissues over time. This wear and tear on the body and brain is called **allostatic load**.<sup>4,8,9</sup> Allostatic load is basically due to the typical demands that are part of daily life as well as unpredictable events. However, with chronic, unremitting, or excessive demands, allostatic load can become an overload. This allostatic overload reflects the “cost” to the body’s organs and tissues for an allostatic response that is excessive or ineffectively regulated and unable to deactivate.<sup>1,7,14</sup> It is essentially a re-envisioning of the effect of wear and tear on the body, both acutely and chronically, and is a more useful definition than homeostasis in discussions of pathophysiology.

## Stressors and Risk Factors

**Stressors** are agents or conditions that are capable of producing stress and endangering homeostasis. They initiate stress response systems in order to return to a state of allostatic balance. Every day the human

organism encounters stressors. These may be external to the individual (e.g., air pollution, radiation, a motor vehicle accident) or internal (e.g., low blood glucose level or a threat to self-esteem). Common general stressors are physical (e.g., extreme hot or cold air temperature), chemical (e.g., auto exhaust), biological (e.g., bacteria and viruses), social (e.g., overcrowding and relationships), cultural (e.g., behavioral norms), or psychological (e.g., feelings of hopelessness). Stressors of an emotional or mental origin may be actually present or anticipated, or may involve the recollection of prior traumatic events. Less commonly noted but extremely powerful stressors are psychosocial experiences over which a person may have little or no personal control. Racial<sup>15-18</sup> and socioeconomic stressors<sup>8,19-21</sup> as well as childhood abuse<sup>22</sup> can produce many of the manifestations of stress described in this chapter.

Stressors vary in their scope, intensity, and duration. A stressor of less intensity can still have a significant impact if it persists for some time. A glass of water held at arm’s length poses little stress initially, but as minutes turn into hours the stress on the body escalates. Even events associated with happiness may serve as stressors—holidays, childbirth, and vacations. Stressors of all types challenge human adaptation.

The identification of specific stressors in isolation provides little insight into today’s complex global society. As noted by Sapolsky,<sup>5</sup> a given stressor may have its own particular pattern of hormone release; however, researchers have explored innumerable factors that can indirectly increase or decrease the impact of stressors. It is now generally well accepted that inherent personal characteristics as well as the psychological context of the situation allow for a great deal of variation in the way humans perceive and respond to stressors, and thus the type of stress response produced.<sup>4,5</sup> The activation of both the sympathetic-adrenal-medullary system response and the HPA axis occurs with a wide variety of physical, mental, and psychosocial stressors. The HPA axis with its glucocorticoid response, however, seems to be notably prominent and dysregulated in cases of depression and posttraumatic stress disorder, and is also active when a person’s sense of self is negatively evaluated or the person lacks a sense of control.<sup>5,23</sup> On the other hand, the sympathetic system is particularly active with anxiety and vigilant states.<sup>5</sup> Furthermore, personality characteristics have been found to be associated with variations in cortisol release and sympathetic-adrenal-medullary system activation in the stress response.<sup>24</sup> Indeed, the effect of personality on the stress response differs with the situational context, including one’s past experiences and conditioning, cultural influences, and the availability of social support, and is influenced by one’s genetic profile<sup>4</sup> and gender.

Beginning in the early 1970s researchers started to examine gender differences related to stress and recent research has continued to expand what is known about these differences between men and women.<sup>14,25-29</sup> For example, one study in the 1980s examined the differences in performance and stress responses of men and women under controlled laboratory conditions.<sup>27</sup> When subjected to a stressful task, there was a 50% to 100% increase in epinephrine release in men, whereas there was little if any increase noted in women, who were also found to perform as well or better than their male counterparts. Women did have an elevation in epinephrine release in a more real-life stress situation (i.e., an academic examination), but these elevations remained well below those of men.<sup>27</sup> Although some researchers consider these differences, at least in part, to be related to gender-associated roles and psychological factors,<sup>26</sup> other researchers also attribute these variances to the effects of the sex hormones on the stress response.<sup>28,29</sup>

Developmental stage of life and age also appear to relate to the way the body responds to stressors. Variations in HPA axis function are noticeable during adolescence, when sex hormone secretion is

significantly elevated in both males and females.<sup>29</sup> A prolonged HPA activation in response to stress in childhood has been documented in both genders when compared with that of adults. This physiologic finding has been suggested to impact the vulnerability of brain development in adolescents exposed to high levels of stress during this period.<sup>29</sup> Adult women during the period between menarche and menopause have lower stress responses than men of the same age.<sup>28</sup> It has been hypothesized that this is a physiologic evolutionary effort to protect the fetus from the effects of exposure to elevated levels of cortisol, in particular. Postmenopause, the responses of both the sympathetic nervous system and the HPA axis appear to increase.<sup>28</sup> Clearly, stressors can affect the same person in different ways at different times over the course of a lifetime.

**Risk factors** alone are not inherently stressors, but rather conditions or situations that increase the likelihood of encountering or experiencing a stressor. Using a cellular phone while driving is a risk factor for having a motor vehicle accident; running in the dark is a risk factor for falling; inadequate immunization is a risk factor for certain infectious illnesses and even cancers. Risk factors include genetic predispositions and epigenetic factors, as well as early life experiences.<sup>4,30,31</sup> By being aware of risk factors, it is possible to decrease the probability of exposure to certain stressors and their inevitable threat to homeostasis.

### KEY POINTS

- Stress is a real or perceived threat to the balance of homeostasis. The stress response is meant to restore balance.
- Selye's theory of a GAS reflects the view of a nonspecific physiologic response to stress. It incorporates three stages reflecting the changes in the body's systemic response: alarm, resistance, and exhaustion.
- Stressors are agents or conditions capable of producing stress.
- The body's response to stressors is meant to be helpful, at least initially, in terms of mobilizing resources to help manage stressors.
- Response to a stressor depends on its magnitude and the meaning that the stressor has for an individual. Stressors may be perceived as more or less stressful. Perception depends on genetic constitution, gender, past experiences and conditioning, and cultural influences. Stressors may be external or internal. They may be physical, chemical, biological, sociocultural, or psychological.
- Individuals may be more vulnerable to the effects of stressors at certain times. The developmental stage of life and the effects of other previous or concurrent stressors all contribute to the stress response.
- Risk factors are conditions or situations that increase the likelihood of encountering or experiencing a stressor.

## NEUROHORMONAL MEDIATORS OF STRESS AND ADAPTATION

Numerous hormones and signaling molecules are involved in the daily maintenance of homeostasis through allostatic processes. These mediators are briefly described here, and their roles in allostasis, adaptation, and disease are discussed in later parts of this chapter. A key idea to the understanding of homeostasis is that once the challenges contributing to allostatic load have been resolved, levels of these chemicals should return to their baselines. However, in cases of allostatic overload, pathologies of a physiologic, psychological, or behavioral nature may result.

### Catecholamines: Norepinephrine and Epinephrine

Cannon identified that the body's response to threats resulted in the activation of the adrenal medulla and sympathetic nervous system. He deemed this the "sympathico-adrenal system" and believed it was

ultimately responsible for what he termed the "*fight-or-flight*" reaction. The purpose of the fight-or-flight reaction was the maintenance of the physical and psychological integrity of the organism.<sup>1,3,12</sup> The catecholamine neurotransmitters—epinephrine and norepinephrine—play integral roles in allostasis.

Release of catecholamines is initiated through the activation of the hypothalamus gland, a collection of nerve centers situated near the third ventricle close to the base of the brain (see Chapter 39). The cerebral cortex and limbic system (including the hippocampus and amygdala, important for memory and emotions) receive information regarding stressors and determine whether or not something is potentially harmful to the organism (i.e., whether it is stressful).<sup>8</sup> They relay the information to the hypothalamus. (It should be noted, though, that the stress response, depending on the type of stressor, may occur to some extent even in comatose and sedated individuals.<sup>32</sup>) In response to these stressors, the hypothalamus prompts the release of **norepinephrine** from the sympathetic branch of the autonomic nervous system and epinephrine and some norepinephrine from the adrenal medulla.<sup>33</sup> Norepinephrine is released by sympathetic neurons directly into the synaptic clefts near the effector organs and tissues. Preganglionic fibers from the sympathetic nervous system neurons synapse at the adrenal medulla, stimulating the release of **epinephrine** and, to a lesser extent, norepinephrine. The adrenal catecholamines are released into the bloodstream, and travel to effector organs and tissues (endocrine).<sup>33</sup> These circulating adrenal catecholamines have essentially the same effects as sympathetic nerve stimulation and are often seen as an extension of the sympathetic nervous system. The responses on the part of the sympathetic nervous system and the adrenal medulla may differ according to the stimulus.<sup>12</sup> During situations such as exposure to cold temperatures the sympathetic nervous system response with norepinephrine production dominates. Emotional distress or acute hypoglycemia, however, causes a greater response from the adrenal medulla, with increased production of epinephrine.<sup>12</sup>

The effects of catecholamines are profound. They affect cardiovascular function, control fluid volume by activating the renin-angiotensin-aldosterone mechanism, have a role in inflammation and immunity, and impact metabolism; and they are associated with attentiveness, arousal, and memory formation in the central nervous system.<sup>1,30,33,34</sup> Norepinephrine is the primary constrictor of smooth muscle in blood vessels. It therefore regulates blood flow through tissues and its distribution through the organs, as well as, importantly, maintenance of blood pressure. It also reduces gastric secretion and innervates the iris and ciliary muscles of the eyes, thereby dilating the pupils and increasing night vision and far vision.<sup>34</sup> Epinephrine enhances myocardial contractility and increases heart rate and venous return to the heart, thus increasing cardiac output. It additionally relaxes bronchial smooth muscle, thereby dilating the airways to enable better oxygenation. Epinephrine also has the metabolic effects of increasing glycogenolysis and the release of glucose from the liver and inhibiting insulin secretion, further elevating blood glucose levels. In the brain, the increased blood flow and availability of glucose lead to increases in mental attention and alertness. Epinephrine and norepinephrine also are able to exert immune system effects by affecting the production of cytokines by immune cells and adipose cells.<sup>33</sup> The effects of these catecholamines are summarized briefly in Table 2-2. For more detail, see Chapter 43.

### Adrenocortical Steroids: Cortisol and Aldosterone

Among the most versatile hormones in the human body, glucocorticoids have regulatory roles in the cardiovascular system and in maintaining fluid volume, and contribute to metabolism, immunity, and inflammatory responses, brain function, and even reproduction<sup>30</sup>

**TABLE 2-2 BRIEF SUMMARY OF EFFECTS OF CATECHOLAMINES ON TISSUES AND ORGANS OF THE BODY**

TISSUE/ORGAN	CATECHOLAMINE EFFECT
Heart	Increases rate Increases speed of impulse conduction Increases contractility
Respiratory tract	Relaxes bronchial smooth muscle to dilate airway
Vascular smooth muscle	
Skin, mesenteric bed, kidneys	Constricts to reduce perfusion
Skeletal muscle, lungs, heart	Dilates to increase perfusion
Peripheral vasculature	Constricts to increase blood pressure
Gastrointestinal tract	Decreases peristalsis Contracts sphincters Decreases gastric acid secretion
Eyes	Contracts radial muscle to dilate iris and pupil Relaxes ciliary muscle for far vision
Liver	Glycogenolysis and gluconeogenesis for increased glucose levels and thus energy
Central nervous system	Promotes arousal, attention, and vigilance

**TABLE 2-3 MAJOR EFFECTS OF GLUCOCORTICOIDS IN THE STRESS RESPONSE**

Metabolism	Catabolism of muscle, fat, lymphoid tissue, skin, and bone Liver gluconeogenesis Opposes insulin in transport of glucose into cells Increased appetite
Fluid balance	Sodium and water retention
Inflammation and infection	Suppressed inflammatory response Increased neutrophil release Decreased new antibody release Decreased T lymphocyte production and function Decreased production of eosinophils, basophils, and monocytes
Support catecholamines	Increased epinephrine synthesis Enhanced vasoconstriction

(Table 2-3). Glucocorticoids are lipid-soluble hormones, allowing them to pass through cell membranes to bind with receptors in the cytosol or nucleus and initiate changes in cellular activities. Practically every body tissue has intracellular glucocorticoid receptors.<sup>30</sup> As opposed to the catecholamines, the onset of their effects is slower, but the duration of action is longer.<sup>5</sup>

The **glucocorticoids** are so named because of their significant role in glucose metabolism. The primary glucocorticoid, **cortisol**, is secreted by the adrenal cortex in response to ACTH from the anterior pituitary. Release of ACTH is itself affected by another releasing hormone, CRH, from the hypothalamus. Negative feedback loops help to maintain cortisol level within a normal range. Cortisol is able to bind

to receptors on the hypothalamus and anterior pituitary gland to suppress CRH and ACTH release when it is excessive.<sup>23,35</sup>

The actions of the HPA axis may synergize or antagonize the effects of the catecholamines.<sup>30</sup> Catecholamines facilitate the release of ACTH, therefore helping to maintain the function of the HPA axis and release of cortisol. Glucocorticoids promote adrenal medulla synthesis of epinephrine through control of the major enzyme phenylethanolamine *N*-methyltransferase (PNMT). Glucocorticoids also support the actions of the catecholamines in the maintenance of normal blood pressure and, therefore, cardiac output. In skeletal muscle, catecholamines antagonize the catabolic glucocorticoid effects by impeding the breakdown of somatic protein.<sup>30</sup> Together, the catecholamines and glucocorticoids facilitate the brain's development of memory, which is especially important when hazardous circumstances have occurred.<sup>1,5</sup>

The metabolic effects of cortisol are significant. Cortisol affects protein metabolism. It has an *anabolic* effect leading to increased rates of protein synthesis in the liver. However, it has a *catabolic* effect in muscle, lymphoid, and adipose tissues, and on skin and bone. This protein breakdown produces increased levels of circulating amino acids. The resulting pool of amino acids from catabolized proteins ensures their availability for the liver. Cortisol then stimulates gluconeogenesis in the liver and a sixfold to tenfold increase in the rate of amino acid conversion to ketoacids and glucose. The catabolism of adipose tissue releases free fatty acids and glycerol that also can be used for gluconeogenesis and to create ketoacids for fuel. Gluconeogenesis ensures an adequate supply of glucose for body tissues in general, but nerve cells have priority. Cortisol may act to preserve available glucose for brain nerve cell use by limiting the uptake and oxidation of glucose by other cells in the body. Cortisol also promotes appetite and food-seeking behaviors.<sup>30</sup>

Glucocorticoids are known for their significant role in the control of the immune response. They suppress the acute-phase response to infection and inflammation, helping to curtail the possible effects of overactivity.<sup>30</sup> This is accomplished by inhibiting the production of select immune cytokines (signaling molecules), by increasing the production of other cytokines, and in some cases by directly inhibiting the proliferation and activation of specific immune system cells.<sup>30</sup> At the same time, when the acute stress of tissue injury or infection occurs, the resulting release of glucocorticoids and catecholamines assists the movement of the necessary immune cells to the affected location.<sup>5,30</sup> However, with prolonged stress and chronic elevation in the levels of glucocorticoids, desensitization and down-regulation (decrease) of glucocorticoid receptors may occur on some immune cells, eventually resulting in fewer antiinflammatory effects over time.<sup>36</sup> In fact, continued stress can even result in proinflammatory effects. Thus the relationship of the immune system to stress is quite multifaceted and our understanding of it is evolving.

**Aldosterone** is the primary **mineralocorticoid** steroid hormone secreted by the adrenal cortex. Stimulation of the sympathetic nervous system activates the renin-angiotensin system, and the release of aldosterone is the final chemical outcome. The specific stressor of fluid volume depletion also activates the release of renin, similarly initiating the renin-angiotensin system. The primary effect of aldosterone, once bound to receptors in the kidneys' distal tubules and collecting ducts, is reabsorption of sodium and an increase in the excretion of potassium. Because of osmotic force, water tends to follow sodium; therefore, enhanced reabsorption of sodium leads to increased extracellular fluid volume and increased blood pressure. Endogenous glucocorticoids have a small amount of mineralocorticoid effect, but the greatest effect on circulating volume is through aldosterone. Additionally, angiotensin II, whose formation stimulates aldosterone release, is a potent vasoconstrictor. This chemical mediator provides support for the catecholamine-induced increase in blood pressure.<sup>30</sup>

### Endorphins, Enkephalins, and Immune Cytokines

Stress naturally activates the inhibition of pain through the release of small peptides called endorphins and enkephalins.<sup>32,37</sup> First discovered in 1975, **endorphins** and **enkephalins** are endogenous opioids that are produced within the central nervous system and released in response to stressors, by certain foods (most notably chocolate), by laughter, and from massage or acupuncture.<sup>38</sup> The term *endorphin* comes from *endogenous* and *morphine*. Like the opiate drug morphine, endorphins raise the pain threshold (reduce pain) and produce sedation and euphoria. Some immune cells (T lymphocytes, granulocytes, and monocytes) also produce several types of endorphins that are released in response to stressors, CRH, antiinflammatory cytokines, and catecholamines.<sup>37</sup> Opioid receptors have been identified on immune cells, and when activated they modulate both immune cell proliferation and immune cell activity. In the presence of acute or chronic stress, activated immune cells (mast cells, neutrophils, macrophages, and T lymphocytes) can release proinflammatory cytokines that enhance pain.<sup>37,39</sup> Pain is a classic manifestation of the inflammatory response (Chapter 9). Thus the central and peripheral nervous systems and the immune system maintain an intricate “pain-related” communication that serves as part of the allostatic mechanism to return the system to homeostasis.<sup>37</sup>

Another example of the interaction between stress, the nervous system, and the immune system is interleukin-1, one of the cytokines secreted by macrophages and other immune cells. It is capable of impacting the production of CRH by the hypothalamus. Leukocytes are also capable of producing some of the other hormones, such as ACTH, that are involved in the signaling system.<sup>32</sup> Some researchers propose that stressors of relatively short duration (less than 2 hours) could augment facets of immune function, including the emigration of immune cells from the lymphoid tissues to the skin and peripheral components of the vascular system.<sup>40</sup> On the other hand, numerous studies over the years have shown that severe and persistent psychological stress can down-regulate, or suppress, immune functioning through innumerable and elaborate mechanisms.<sup>5,40</sup> Immune system suppression caused by severe or persistent stress represents a direct link between stress and illness. Expanded understanding of the interrelationships between the nervous, endocrine, and immune systems holds great promise in the identification of new therapeutic interventions.<sup>32,40</sup>

### Sex Hormones: Estrogen, Testosterone, and Dehydroepiandrosterone

As noted previously, women during the period between menarche and menopause have a different stress response than men of the same age, and this may be attributable to influences of sex hormones on allostasis. Cortisol exerts inhibiting effects on the female reproductive system by suppressing release of gonadotropin-releasing hormone, luteinizing hormone, estradiol, and progesterone. Excessive stress appears, in general, to inhibit female reproduction.<sup>14</sup> However, sexual stimulation may cause the gonadal axis to be resistant to suppression by the HPA axis. Estradiol down-regulates glucocorticoid receptor binding in the brain and alters regulatory feedback control. Androgens, such as testosterone and dehydroepiandrosterone (DHEA), may also inhibit the effects of glucocorticoids.<sup>30</sup> Androgens oppose the catabolic effects of glucocorticoids on bone and the impact of glucocorticoids on lymphoid tissues, inflammatory cytokines, and leukocytes. DHEA interacts with numerous neurotransmitters in the brain, counteracting the depressive tendencies often noted with glucocorticoids.<sup>30</sup> Numerous stressful stimuli, such as illness, surgery, strenuous physical exercise, heart failure, and stressful academic programs, result in a significant reduction in circulating testosterone levels. In combination with

another hormone, vasopressin, testosterone enhances blood pressure and heart rate reactivity and augments the “fight-or-flight” response. In contrast, the hormone oxytocin (whose impact is modulated by estrogen) and the endogenous opioids are thought to produce a calming effect during times of stress, resulting in the notion that women may have a “tend and befriend” response, rather than a “fight-or-flight” response in some situations.<sup>40-42</sup>

### Growth Hormone, Prolactin, and Oxytocin

**Growth hormone** (somatotropin) is released from the anterior pituitary gland and affects protein, lipid, and carbohydrate metabolism. It has anabolic effects, increasing protein synthesis and bone and muscle mass growth. It also increases fat mobilization (lipolysis) while decreasing the rate of carbohydrate utilization by peripheral tissues. Growth hormone is normally secreted in a cyclic basal pattern, primarily at night, and according to developmental stage. Growth hormone secretion is highest during adolescence and then gradually declines during middle age. Serum levels of growth hormone also increase, at least initially, following a variety of intensely stressful physical or psychological stimuli, such as strenuous exercise or extreme fear.<sup>43</sup> Growth hormone appears to enhance immune function. However, continued activation of the stress response eventually results in the decreased secretion of growth hormone, accounting for stunted growth in children experiencing prolonged chronic stress.<sup>5</sup>

**Prolactin** is similar in structure to growth hormone and is also secreted from the anterior pituitary gland in response to stress,<sup>32</sup> sexual activity, and suckling (even in men) and breast feeding. It interferes with ovulation.<sup>5,43</sup> Numerous tissues have receptors for prolactin in addition to the breast, including kidney, liver, and adrenal glands. Lymphocytes also have prolactin receptors, suggesting a role for prolactin in immune regulation. A significant increase in the level of growth hormone or prolactin tends to require more intense stimuli than the stress that increases the concentrations of catecholamines and glucocorticoids.

**Oxytocin** is produced during childbirth, lactation, and sexual behavior (in both genders) and has been associated with promoting bonding and social attachment. Oxytocin is thought to moderate the stress response and have a calming effect, with reductions in HPA and sympathetic activation and reduced perceived anxiety. Oxytocin also may have some analgesic effects. It is synthesized by the hypothalamus and secreted by the posterior pituitary gland and other brain regions. Oxytocin is believed to have stronger effects in females in comparison to males, because of the effects of estrogen on oxytocin.<sup>42</sup>

Through interactions of the primary stress hormones—catecholamines and glucocorticoids—as well as numerous other mediating influences, the allostatic process needed to sustain the human organism is achieved. In some cases, these stress-related hormones have similar and synergistic effects and in others they work in opposition. This state of counterbalancing helps to facilitate allostasis, ideally returning the human organism back toward homeostasis.

#### KEY POINTS

- Modern views of allostatic maintenance of homeostasis in the face of stress are primarily derived from an understanding of negative feedback, as well as the roles of the sympathetic nervous system and the glucocorticoid cortisol.
- The primary role of the sympathetic nervous system is appraisal of a stressful stimulus and release of norepinephrine. Norepinephrine released from sympathetic nerve endings increases heart rate and contractility, constricts blood vessels to decrease blood flow to less essential tissues and organs and raise blood pressure, reduces gastrointestinal motility and gastric acid secretion, dilates the pupils, and inhibits insulin secretion.

- Stress simultaneously stimulates sympathetic activation of the adrenal medulla to release epinephrine. Epinephrine's actions are similar to those of norepinephrine and are particularly important for increasing cardiac performance (increased heart rate, contractility, and cardiac output), promoting the release of glucose from the liver, and enhancing bronchodilation.
- Cortisol, from the adrenal cortex, has widespread effects on numerous tissues that are both synergistic and antagonistic with catecholamines, and has an antiinflammatory role.
- Aldosterone promotes fluid volume expansion and increases blood pressure.
- Endorphins and enkephalins are released by the central nervous system (CNS) in response to painful stressors, leading to decreased perception of pain and increased sedation and euphoria. Immune cells in the periphery also contribute to pain modulation.
- Understanding the role of the immune system in response to stressors is rapidly expanding. Immune cells respond to the hormones released by the HPA axis and sympathetic nervous system. They also release cytokines that in turn affect the functioning of these stress systems.
- Sex hormones and differential release of growth hormone, prolactin, and oxytocin produce mediating effects on the stress response that may differ between genders.

## ADAPTATION, COPING, AND ILLNESS

Although much has been learned about the dynamic biological systems and human/environmental interactions involved, stress is personal in that individual stress responses change with time and circumstances. Indeed, the effects of stress on each individual are impacted by genetics, socioeconomic status, environmental context, perception, developmental history, prior susceptibilities, preexisting health status, and individual coping abilities to manage stress.<sup>1,4,8,12</sup> Clearly, the maintenance of homeostasis requires the human organism to routinely initiate allostatic responses to the stressors of daily life, as well as the less frequent severe assaults on the integrity of the body and the mind, responsible for allostatic load. The roles of the sympathetic nervous system and the HPA axis have been defined and supportive chemical mediators described. Systemically, allostasis may be seen as beginning with some degree of the alarm stage (fight-or-flight activation), and ideally moving to an effective resolution through adaptation, ultimately culminating in a return to homeostasis. The effects of this process are seen in allostatic load and the occasional allostatic overload. The prolonged effects of allostatic overload—the long-term wear-and-tear costs of adaptation efforts—provide a conceptual foundation for examining the long-term consequences of stress to health.<sup>14</sup> What Selye called “diseases of adaptation” are the outcome of allostatic overload.<sup>44</sup>

### Adaptation and Coping

**Adaptation**, seen from the perspective of allostasis rather than simply as Selye's stage of the GAS, broadly refers to the biopsychosocial process of changing and adjusting physiology, morphology, and behavior in response to new or altered circumstances, internal and external in origin, in one's physical and social environments.<sup>7</sup> The term has been intertwined with allostasis, because allostasis is a process of attaining and maintaining stability through change, and leads to a state of adaptation.<sup>1,14</sup> Encountering favorable or unfavorable stressors requires multiple levels of biological, personal, and social change or adaptation. **Maladaptation**, a less frequently used term, refers to ineffective, inadequate, or inappropriate change in response to new or altered circumstances. **Coping** is another term used and is most often seen as a behavioral adaptive response to a stressor. Coping mechanisms are typically culturally based, and so vary with the individual within the

parameters of what is acceptable to the given culture. The coping behavior is usually dictated by the specific stressor; thus, it commonly varies with the circumstances, but individuals typically embrace a specific repertoire of coping behaviors. These behavioral adaptations allow an individual or a group to withstand successfully the stressful experience or the stress response generated by the experience. A coping strategy can be considered effective or functional if it helps resolve either the situation or the feelings. In some cases, such as exercise, the coping method can promote health.<sup>9</sup> A coping strategy is considered ineffective or dysfunctional if it does not achieve the desired goal. Coping that achieves unintended goals is considered dysfunctional. Being complex organisms, adaptation may result in the adoption of less than desirable coping behaviors, such as excessive eating or alcohol consumption, smoking, or other types of substance abuse.<sup>18</sup> Unfortunately, these dysfunctional coping behaviors can ultimately be damaging to overall health. Smoking and overeating contribute to atherosclerosis, the underlying pathophysiology of coronary artery disease and a risk factor for hypertension. Excess weight accumulated through overeating is a contributing factor for type 2 diabetes mellitus and metabolic syndrome. Although coping is customarily interpreted as behavioral adaptation only, the terms *coping* and *adapting* often are used interchangeably.

Perception and expectations of the stressor can affect its interpretation, and therefore the behavior evoked by it. Perceptions can be related to uncertainty about the meaning of the stressor. Consider the stressor of undue noise. The “bang” of a car backfiring could also be the sound of a gun being fired. Depending upon the environment and circumstances, one or the other etiology would be more expected, dictating different adaptive responses. The term *distress* describes the experience of perceiving an inability to cope with a stressor.<sup>12</sup> This distress further activates the HPA axis, escalating levels of circulating mediators, and may exacerbate existing allostatic load and preexisting pathophysiologic conditions.<sup>12</sup> For instance, the person with asthma who is experiencing an episode of acute shortness of breath is likely to become even more short of breath when discovering an inhaler is not readily available.

Adaptation to a particular stressor can occur in several ways. Loud noise is a known stressor. Yet people who live close to busy airports often reach a point at which they barely notice the noise of airplanes flying over their homes. They become *habituated* to the stressor (loud noise). One important way to habituate to a stressor is to manipulate or “train” the hypothalamus to react less forcefully to a perceived threat or stressor. Repeatedly ignoring a specific stressor prevents the inappropriate triggering of the GAS. The result is a more acceptable level of stress response. Techniques that accomplish this **desensitization** change the predominant brain waves of the individual from beta to alpha waves, which are slower and more normal. Biofeedback, visualization, and meditation are examples of therapies that use this principle. Practicing these techniques for 20 to 30 minutes daily can enhance the ability to alter how a stressor is perceived and modulate the stress response. These techniques have documented efficacy in modulating immune function.<sup>41</sup> Desensitization methods have been found to be beneficial for common stress-related conditions, such as migraine headache, chronic back pain, and hypertension.

### Allostatic Overload and Illness

When adaptation mechanisms are inadequate or the total amount of allostatic load is excessive, overwhelming allostasis capacities, the result is allostatic overload. There are several ways in which allostatic load can accumulate in an individual: (1) repeated exposures to multiple stressors, (2) inability to habituate or adapt to the stressor, (3) unnecessarily prolonged stress response or stress

**BOX 2-2 PHYSICAL AND BEHAVIORAL INDICATORS OF HIGH STRESS****Physical Indicators**

Elevated blood pressure  
 Increased muscle tension  
 Elevated pulse rate  
 Increased respiration  
 Sweaty palms  
 Cold extremities (hands and feet)  
 Fatigue  
 Tension headache  
 Upset stomach: nausea, vomiting, diarrhea  
 Change in appetite  
 Change in weight  
 Increased blood catecholamine level  
 Hyperglycemia  
 Restlessness  
 Insomnia

**Behavioral and Emotional Indicators**

Anxiety (nonspecific fears)  
 Depression  
 Increased use of mind-altering substances (e.g., alcohol, chemical substances)  
 Change in eating, sleeping, or activity pattern  
 Mental exhaustion  
 Feelings of inadequacy; loss of self-esteem  
 Increased irritability  
 Loss of motivation  
 Decreased productivity  
 Inability to make good judgments  
 Inability to concentrate  
 Increased absenteeism and illness  
 Increased proneness to accidents

response that continues after the stressor is removed, and (4) inadequate response to the stressor that causes other stress response mediators to attempt to compensate.<sup>8,9</sup> Homeostasis, the steady-state that previously existed, cannot be attained. Instead, allostatic overload occurs and the resulting maladaptation can be reflected in a range of pathophysiological states that span the traditional boundaries of health care, from psychiatric and endocrine disorders to inflammatory disease.

Hair loss, emotional tension, burnout, mouth sores, insomnia, asthma, heart palpitations, neuromuscular movement disorders (tics), tension headaches, muscle contraction backaches, digestive disorders, and irritable bladder are just a few of the common disorders that can be caused by or worsened by stress. Reproductive disorders such as menstrual irregularity in women<sup>14</sup> and male impotence also have been linked with the effects of allostatic overload. **Box 2-2** summarizes some of the physiologic and psychological effects of excessive stress. **Figure 2-3** depicts the multiple body organs and systems in which the effects of insufficient or overactive stress responses may be seen.

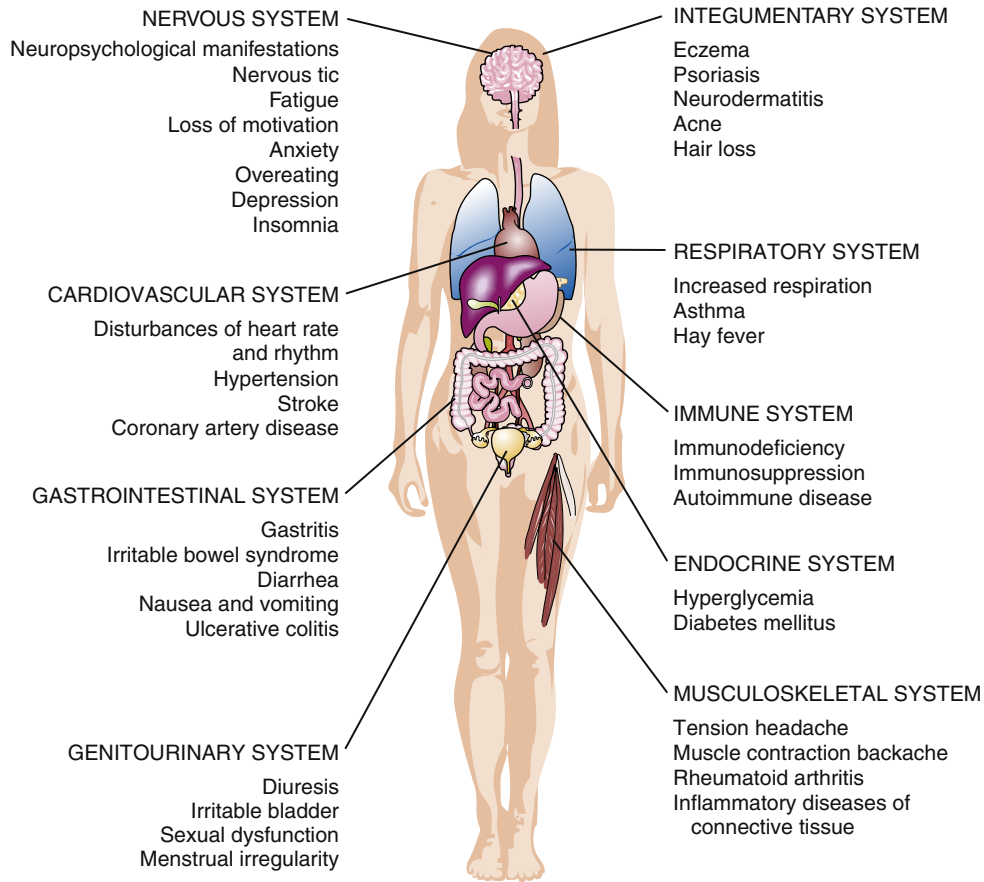

There is a strong physiologic basis for the role of the chemical mediators of stress in contributing to illness. Cortisol being released from the adrenal cortex supports Selye's stage of resistance or adaptation but may also be accountable for pathologic changes. The same can be said of the catecholamines and the other chemical mediators (e.g., immune cytokines).<sup>1,45</sup> Because these blood-borne chemicals have

such broad effects systemically, the impact of excessive or inadequate amounts is understandably wide-reaching. In some cases, the relationships have been well substantiated by research; in others, they are hypothesized based upon knowledge of the effects of these chemicals.

The relationship between excessive catecholamine levels and what have been called "stress-related" illnesses historically has often been associated with cardiovascular pathologies such as hypertension, stroke, and myocardial infarction. Abdominal fat cells are well supplied with cortisol receptors.<sup>45</sup> Excessive secretion of cortisol results in the collection of fat in this area. When this fat is released into the bloodstream, the resulting increase in the levels of circulating free fatty acids plays a role in cardiovascular risk.<sup>5,45</sup> Repeated or prolonged elevation of blood pressure, especially in combination with the metabolic effects of elevated cortisol levels, promotes the development of atherosclerosis and, ultimately, many cardiovascular pathologies.<sup>14</sup> Not only do catecholamines contribute to the development of atherosclerosis and hypertension, but also they increase the risk of developing cardiac dysrhythmias and sudden cardiac death, and even stress-induced cardiomyopathy.<sup>1</sup> They increase platelet activity, resulting in clot formation, and elevate serum lipid levels, significant factors in the pathogenesis of myocardial infarction. A growing body of evidence suggests that inflammation may mediate a link between stress and cardiovascular disease. Stress has been associated with the production of proinflammatory cytokines such as interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF). These cytokines can trigger the production of C-reactive protein (CRP), a cytokine associated with cardiovascular disease.<sup>39</sup>

The field of psychoneuroimmunology has provided substantive evidence of the roles of the stress hormones in the brain. In the central nervous system, specifically the brain, the mediators of adaptation facilitate learning, memory, and neuroendocrine and autonomic regulation.<sup>8,9,46</sup> This heightened memory, at least in the short term, allows the individual to be more aware of the potential stressor in the future.<sup>1,44</sup> Chronic over- or underactivity, however, may result in atrophy and death of some nerve cells (especially in the hippocampus), impairing memory,<sup>8,31</sup> whereas others have been found to hypertrophy (especially in the amygdala) and undergo remodeling, resulting in an increase in fear.<sup>1,8,44</sup> In essence, allostatic overload results in altered and impaired cognitive function. Some evidence suggests that inflammation associated with allostatic overload may play a role in learning and memory impairment. For instance, elevated levels of interleukin-6 (IL-6), a marker of inflammation associated with stress, were inversely related to memory in a study of middle-aged adults.<sup>8</sup>

Stress hormones have been found to be elevated and dysregulated in major depressive illness.<sup>31</sup> Abnormal patterns of cortisol secretion, elevated androgen levels in women, and increased levels of growth hormone and proinflammatory cytokines have been documented in major depressive illness.<sup>31,46</sup> In addition, other effects of long-term cortisol dysregulation, including demineralization of bone and increased abdominal fat deposits, have been noted.<sup>31</sup> Researchers also have found levels of cortisol and certain cytokines from immune cells to be elevated in depressed patients with fibromyalgia<sup>47</sup> and multiple sclerosis.<sup>48</sup> Depression is common with chronic disease, and the elevated cortisol levels associated with allostatic overload may be a significant finding in association with depression and the progression of some of the diseases. Another condition, posttraumatic stress disorder (PTSD), also appears to be associated with heightened sympathetic-adrenal-medullary responses as well as alterations in the HPA axis. Evidence suggests cortisol and norepinephrine help promote long-term memory consolidation and retention of traumatic and fearful events; however, administration of

**FIGURE 2-3** Effects of Allostatic Overload on Body Organs and Systems.

$\alpha$ - and  $\beta$ -blockers that interfere with the effects of norepinephrine has been shown to reduce the incidence of PTSD symptoms, although study results have been mixed.<sup>49,50</sup>

Allostatic mediators activate and maintain energy reserves, which is initially meant to be helpful in managing stressors. Nonetheless, obesity, diabetes, atherosclerosis, and other diseases are associated with their chronic activation.<sup>14,45</sup> The food-seeking behavior initiated by cortisol is beneficial in the short term, but when cortisol levels are increased by chronic stress of either a physiologic or a psychological origin, this adaptation gone awry results in obesity. Obesity is a risk factor for decreased effectiveness of glucose transport into the cells (insulin resistance), the pathophysiologic basis for type 2 diabetes.<sup>44</sup> Elevated cortisol levels also directly increase insulin resistance.<sup>45</sup> Additionally, obesity is associated with the production of proinflammatory cytokines, which also have been connected to diabetes.<sup>45</sup>

In acute stress, activation of the immune system allows for the coordinated defense of the body from damage.<sup>44</sup> At first, leukocytosis and immune function including phagocytosis and antibody production may be enhanced in order to protect the body from foreign invaders (e.g., bacteria and viruses), but then is followed quickly by immunosuppression.<sup>1</sup> Chronic activation of the stress mediators produces immunosuppression and increases the risk of infection<sup>5,33,40,44</sup> and has been implicated in the development of autoimmune diseases.<sup>5,14</sup> Such overactivation also prolongs existing infections and the development of secondary infections.<sup>1</sup> Research supports the hypothesis that physical and emotional stress and dysfunctional coping mechanisms impair both antibody and T cell-mediated responses to viruses and antiviral and antibacterial vaccines. Stressors of more than

1 month's duration have been found to be the greatest predictors of the development of colds. Cumulated evidence, in both human and animal models, supports the premise that stress-induced dysregulation of the cellular and humoral arms of the immune system increases risk of infectious disease. Stress has been found by numerous studies to accelerate the progression of human immunodeficiency virus (HIV) infection. Immune dysregulation can also include the excessive production of cytokines that have actions supporting the inflammatory response. Both physical and psychological stressors have been found to accomplish this, sensitizing the overall inflammatory response so that subsequent activations are markedly increased. This is important because many diseases are associated with inflammation: cancer, acute coronary syndrome resulting in myocardial infarction, chronic inflammatory bowel disease, and asthma, to name but a few. Wound healing also is impaired by multiple mediators of stress in excessive amounts.<sup>5,14,39</sup>

A new area of stress research attracting attention pertains to **telomeres** and **telomerase**. Telomeres are the tail ends of chromosomes that get shaved down with repeated cell division; and thus older cells tend to have shorter telomeres than younger ones. These cells with shortened telomeres are more susceptible to death. Telomeres are considered to be markers of "biological age" and may serve as a means of measuring a person's total accumulated exposure to stressors.<sup>31</sup> Chronic stress related to caregiving and lower socioeconomic status has been linked with shorter telomere length. Depression and several other diseases (e.g., cardiovascular disease) also have been associated with shortened telomeres.<sup>31,51</sup> This research suggests a mechanism by which stress may contribute to cell death and disease, because telomere shortening may be connected to some extent to

## CHAPTER 2 Homeostasis and Adaptive Responses to Stressors

elevated cortisol, catecholamine, and inflammatory cytokine levels produced as part of the stress response.<sup>31</sup> On the other hand, telomerase is an enzyme capable of lengthening telomeres and is inversely related to perceptions of stress. In one study, 30 men and women took part in a 3-month meditation retreat program aimed at reducing psychological distress. By the end of the study period, the participants had significantly higher telomerase activity levels in comparison to wait-list controls.<sup>52</sup> More research is needed to understand the relationships among telomeres, telomerase, stress, and stress-related diseases and coping methods, as well as aging and longevity.

### KEY POINTS

- Adaptation, or allostasis, is a network of biopsychosocial processes of responding to a stressor with the goal of re-establishing homeostasis. Coping mechanisms are usually seen as behavioral adaptations to stress but are often used interchangeably with adaptation.
- The wear-and-tear effect of adaptation on the body and mind is the allostatic load. It occurs as mediators produced by the stress response systems accumulate and contribute to tissue damage over time. Allostatic load reflects the cumulative costs of adaptation.
- A number of disorders are thought to be related to excessive stress or inappropriate stress responses—allostatic overload. These are a result of the dysregulation and excessive use of the mechanisms and mediators involved in the stress response.

### SUMMARY

Homeostasis is the state of balance of the body's biopsychosocial systems. Stressors evoke a stress response and initiate adaptive efforts, an allostatic process, designed to return to this steady-state. The response to stressors is affected by a wide variety of factors. Recently there has been an exponential increase in knowledge regarding the complex interactions of the HPA axis, the sympathetic nervous system, the immune system, and the chemical mediators of the stress response.

Excessive or prolonged stress and over- or underactivity of these chemical mediators produce disproportionate responses in the body, a condition of allostatic overload known as stress-induced illness. As humans strive to adapt to the constant changes of modern life, the study of stress and stress-related disease has become vital to public health and contributes to the development of increasingly sophisticated models of health and illness.

A basic principle of biology states that the cell is the fundamental unit of life. As more diseases are understood on the cellular and molecular levels, it appears that the cell is also the fundamental unit of disease. A knowledge explosion is currently occurring in the fields of cell and molecular biology, leading to a better understanding of human physiology and the cellular aspects of disease. Detailed knowledge of

cellular dysfunction has led to the development of more specific and appropriate prevention and treatment modalities for many disease processes. Thus, an understanding of cellular mechanisms is essential for health care providers and fundamental to the discussions of pathophysiologic processes presented throughout the remainder of this text.

**FIGURE 3-1** Structure of a typical eukaryotic cell showing intracellular organelles.

Cells are complex, membrane-bound units packed with a multitude of chemicals and macromolecules. They are able to replicate and thus form new cells and organisms. The very first cells on Earth probably arose from the spontaneous association of organic (carbon-containing) and inorganic molecules about 3.5 billion years ago.<sup>1</sup> Over billions of years, the self-replicating molecules now known as deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) are believed to have evolved by chance association and natural selection. Development of the cell membrane created a closed compartment that provided a selective advantage for the cell and accomplished the first separation of life (inside) from nonlife (outside). In this protected environment, the early cells continued to evolve and develop. Today, a large number of different cell types exist, but many of the basic biochemical mechanisms of these cells are remarkably similar. Scientists believe that all modern cells, from bacteria to human neurons, evolved from common primordial cells.<sup>2</sup> It is therefore possible to unlock many of the secrets of human cellular physiology by studying easily grown and rapidly proliferating cells, such as yeasts and bacteria.

Much of our knowledge of cell physiology has derived from study of the class of cells known as prokaryotic, which includes bacteria and archaea. Prokaryotic cells are smaller and simpler than eukaryotic cells, having no defined nucleus or cytoplasmic organelles. Fungi, plants, and animals belong to the eukaryotic class of cells, which possess a membrane-bound nucleus and a host of cytoplasmic organelles (Figure 3-1). In this chapter, the essentials of eukaryotic cell structure, physiology, metabolism, and communication are reviewed.

## PLASMA MEMBRANE

### Membrane Structure

All cells are enclosed by a barrier composed primarily of lipid and protein called the plasma membrane (plasmalemma). This cell membrane is a highly selective filter that shields internal cell contents from the external environment. The plasma membrane performs a variety of functions, including transport of nutrients and waste products, generation of membrane potentials, and recognition, communication, and growth regulation of cells. The cell membrane is a sensor of signals and enables the cell to respond and adapt to changes in its environment.

According to the fluid mosaic model first described in the 1960s by Singer and Nicolson,<sup>3</sup> the plasma membrane is a dynamic assembly of lipid and protein molecules. Most of the lipids and proteins move about rapidly in the fluid structure of the membrane. As shown in Figure 3-2, the lipid molecules are arranged in a double layer, or **lipid bilayer**, which is highly impermeable to most water-soluble molecules, including ions, glucose, and proteins. A variety of proteins embedded or “dissolved” in the lipid bilayer perform most of the membrane’s functions. Some membrane proteins are involved in the transport of specific molecules into and out of the cell; others function as enzymes or respond to external signals; and some serve as structural links that connect the plasma membrane to adjacent cells. The lipid structure of the plasma membrane is similar to the structure of the membrane that surrounds the cell’s organelles (e.g., nucleus, mitochondria, endoplasmic reticulum, Golgi apparatus, lysosomes).

**FIGURE 3-2** Section of the cell membrane showing the lipid bilayer structure and integral membrane proteins.

**FIGURE 3-3** Schematic drawing of a typical membrane phospholipid molecule showing the amphipathic nature of the structure.

### Lipid Bilayer

The bilayer structure of all biological membranes is related to the special properties of lipid molecules that cause them to spontaneously assemble into bilayers. The three major types of membrane lipids are cholesterol, phospholipids, and glycolipids. All three have a molecular structure that is **amphipathic**; that is, they have a hydrophilic (water-loving) charged or polar end and a hydrophobic (water-fearing) non-polar end.<sup>1</sup> This amphipathic nature causes the lipids to form bilayers in aqueous solution. A typical phospholipid molecule is shown in [Figure 3-3](#). The hydrophobic nonpolar tails tend to associate with other hydrophobic nonpolar tail groups to avoid association with polar water molecules. The hydrophilic polar head groups preferentially interact with the surrounding aqueous environment. A bilayer, with tails

**FIGURE 3-4** The amphipathic nature of membrane lipids results in bilayer structures that tend to form spheres.

sandwiched in the middle, allows both portions of the lipid molecules to be chemically “satisfied.” In addition, the lipid bilayers tend to close on themselves, forming sealed, spherical compartments ([Figure 3-4](#)). If the membrane is punctured or torn, it will spontaneously reseal itself to eliminate contact of the hydrophobic tails with water.

For the most part, individual lipid and protein molecules can diffuse freely and rapidly within the plane of the bilayer. The degree of membrane fluidity depends on the lipid composition. Saturated lipids have straight tails that can pack together and tend to stiffen the membrane, whereas lipids with bent, unsaturated hydrocarbon tails tend to increase fluidity. About 50% of the lipid in eukaryotic cell membranes is cholesterol, which serves to decrease membrane permeability and prevent leakage of small water-soluble molecules. In addition to affecting fluidity by the degree of saturation of tail groups, the phospholipids that inhabit the membrane also differ in the size, shape, and charge of the polar head groups. [Figure 3-5](#) shows the structures of the four most prevalent membrane phospholipids: phosphatidylethanolamine, phosphatidylserine, phosphatidylcholine, and sphingomyelin. Some membrane-bound proteins require specific phospholipid head groups to function properly. Some lipids—sphingolipids and cholesterol in

**FIGURE 3-5** Chemical structures of the four most common membrane phospholipids.

particular—may bind together transiently to form rafts in the sea of moving lipids. These rafts may surround and help organize membrane proteins into functional units. For example, a membrane receptor and its intracellular target proteins may associate together in a raft to facilitate transfer of information across the membrane.<sup>4</sup>

Glycolipids contain one or more sugar (i.e., carbohydrate) molecules at the polar head region. Glycolipids and glycoproteins are found only in the outer half of the lipid bilayer, with the sugar groups exposed at the cell surface (Figure 3-6). Membrane glycolipids are involved in cell recognition and cell-to-cell interactions.<sup>5</sup>

### Membrane Proteins

Approximately 50% of the mass of a typical cell membrane is composed of protein. The specific types of membrane proteins vary according to cell type and environmental conditions. Some membrane proteins, called *transmembrane proteins*, extend across the membrane bilayer and are in contact with both the extracellular and the intracellular fluids. Transmembrane proteins serve a variety of functions, including transport of charged and polar molecules into and out of cells and transduction of extracellular signals into intracellular messages. Other peripheral membrane proteins are less tightly anchored to the membrane. The common structural orientations of membrane proteins are shown in Figure 3-7. The amino acid structure of membrane proteins determines the way they are arranged in the membrane. Nonpolar amino acids tend to inhabit the hydrophobic middle of the membrane, whereas charged and polar amino acids protrude into the aqueous fluid or associate with polar lipid head groups. The three-dimensional structure of many membrane proteins is complex, with numerous twists and turns through the lipid bilayer.

The type of membrane proteins in a particular cell depends on the cell's primary functions. For example, a kidney tubule cell has a large proportion of transmembrane proteins, which are needed to perform the kidney's function of electrolyte and nutrient reabsorption. In

**FIGURE 3-6** Portion of the cell membrane showing orientation of membrane glycoproteins toward the outer surface of the cell.

contrast, the human red blood cell (RBC) contains mainly peripheral proteins attached to the inner surface of the membrane.<sup>6</sup> One of these proteins, spectrin, has a long, thin, flexible rodlike shape that forms a supportive meshwork or **cytoskeleton** for the cell. It is this cytoskeleton that enables the RBC to withstand the membrane stress of being forced through small capillaries.

Although proteins and lipids are generally free to move within the plane of the cell membrane, many cells are able to confine certain proteins to specific areas. Using the example of the kidney tubule cell again, it is important for the cell to keep transport proteins on its luminal side to reabsorb filtered molecules (Figure 3-8). This segregation of particular proteins is accomplished primarily by intercellular connections called **tight junctions**, which connect neighboring cells and function like a fence to confine proteins to an area of the membrane. Membrane proteins also can be immobilized by tethering them to cytoskeleton or extracellular matrix structures.

**FIGURE 3-7** Structural orientation of some proteins in the cell membrane. **A**, Membrane-associated protein with noncovalent attachment to plasma lipids. **B**, Membrane protein with noncovalent attachment to another membrane protein. **C**, Transmembrane protein extending through the lipid bilayer. **D**, Covalently attached peripheral membrane protein.

**FIGURE 3-8** Transport proteins may be confined to a particular portion of the cell membrane by tight junctions. Segregation of transport proteins is important for the absorptive functions of the kidney epithelial cells. *N*, Nucleus.

#### KEY POINTS

- The plasma membrane is composed of a lipid bilayer that is impermeable to most water-soluble molecules, including ions, glucose, and amino acids, but permeable to lipid-soluble substances, such as oxygen and steroid hormones.
- Proteins embedded in the lipid bilayer execute most of the membrane's functions, including transport and signal transduction.

## ORGANIZATION OF CELLULAR COMPARTMENTS

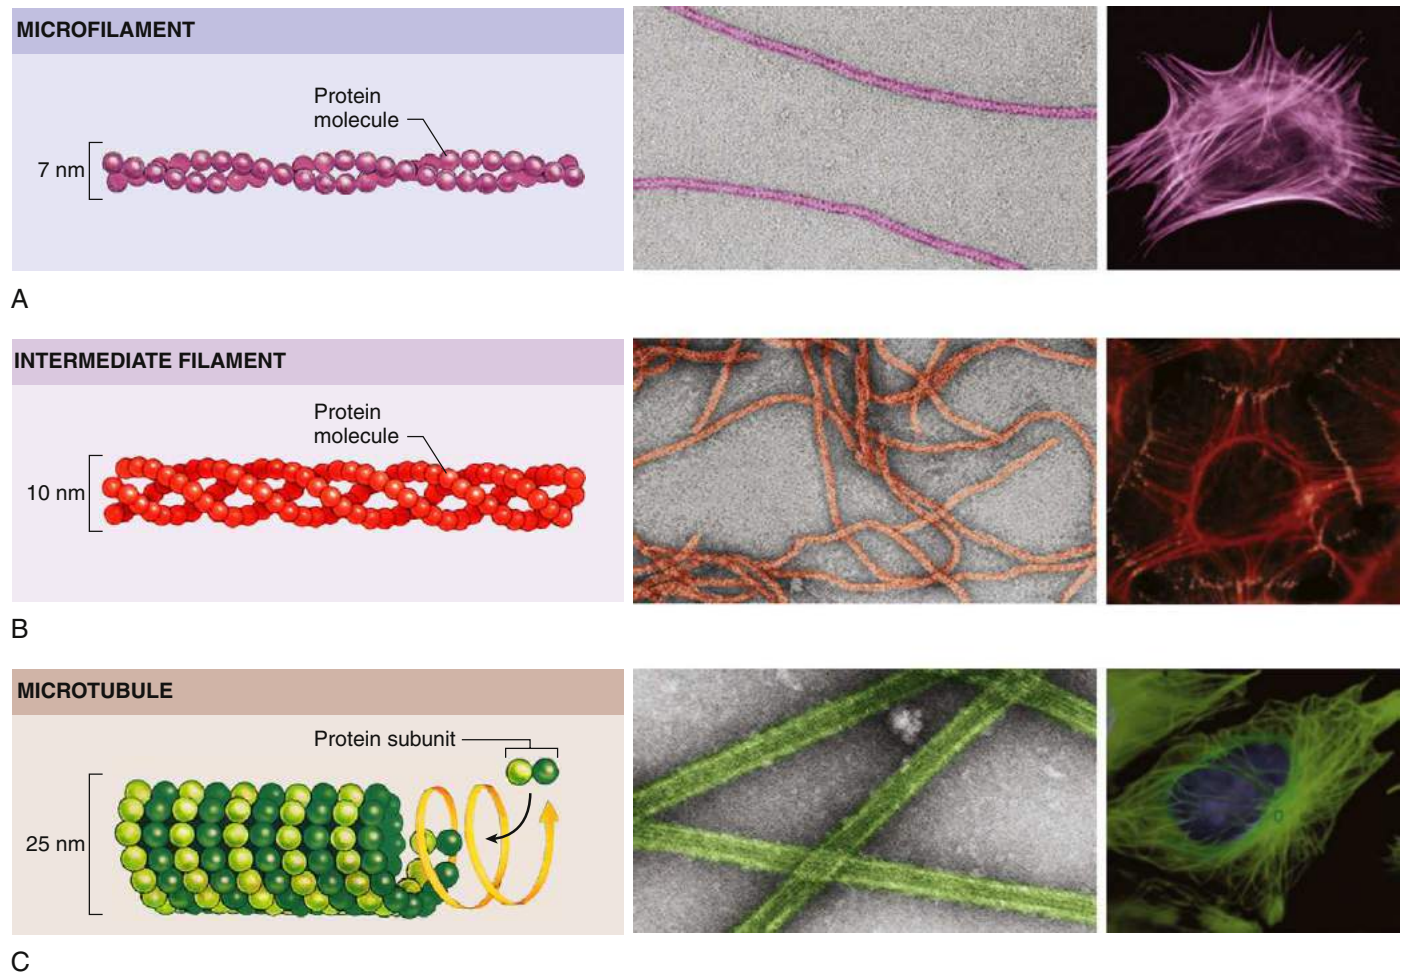

### Cytoskeleton

Eukaryotic cells have a variety of internal compartments, or **organelles**, that are membrane bound and carry out distinct cellular functions. The cell's organelles are not free to float around haphazardly in

the cytoplasmic soup; rather, they are elaborately organized by a protein network called the *cytoskeleton* (Figure 3-9).<sup>7</sup> The cytoskeleton maintains the cell's shape, allows cell movement, and directs the trafficking of substances within the cell. Three principal types of protein filaments make up the cytoskeleton: actin filaments, microtubules, and intermediate filaments.

All three types of filaments consist of small proteins that can assemble (polymerize) into filaments of varying length. The filament structures are dynamic and can be rapidly disassembled and reassembled according to the changing needs of the cell. Actin filaments play a pivotal role in cell movement. As one might expect, muscle cells are packed with actin filaments, which allows the cell to perform its primary function of contraction. However, nonmuscle cells also possess actin filaments that are important for complex movements of the cell membrane, such as cell crawling and phagocytosis. Such movements of the cell membrane are mediated by dense networks of actin filaments that cluster just beneath the plasma membrane and interact with specific proteins embedded in it. Actin and some of the other cytoskeletal proteins make specific contacts with and through the plasma membrane and are involved in information transfer from the extracellular environment to signaling cascades within the cell.

Organization of the cytoplasm and its organelles is achieved primarily by microtubules. In animal cells, microtubules originate at the cell center, or **centrosome**, near the nucleus and radiate out toward the cell perimeter in fine lacelike threads. Microtubules guide the orderly transport of organelles and vesicles in the cytoplasm as well as the equal distribution of chromosomes during cell division. Intermediate filaments, so named because their size is between that of microtubules and actin filaments, are strong, ropelike, fibrous proteins. A variety of intermediate filaments that differ from tissue to tissue have been identified. In addition to the three main groups of cytoskeletal filaments just described, a large number of accessory proteins are essential for cytoskeletal function. For example, the accessory protein myosin is needed to bind with actin to achieve motor functions. Different accessory proteins are present in different cell types.

**FIGURE 3-9** Schematic and micrographs of three major types of cytoskeletal proteins. **A**, Microfilaments shown are composed of actin proteins; **B**, intermediate filaments are a large group of various types of proteins; **C**, microtubules (see text). (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St. Louis, 2013, Mosby, p. 80. Micrographs from Pollard T, Earnshaw W: *Cell biology*, revised reprint, international edition, ed 1, Philadelphia, 2004, Saunders.)

## Nucleus

The largest cytoplasmic organelle is the nucleus, which contains the genetic information for the cell in the form of DNA. The human genome contains approximately 23,000 genes that code for proteins, representing less than 1.3% of the total DNA structure composed of more than 6 billion base pairs.<sup>8</sup> The nuclear contents are enclosed and protected by the nuclear envelope, which consists of two concentric membranes. The inner membrane forms an unbroken sphere around the DNA and contains protein-binding sites that help to organize the chromosomes inside. The outer nuclear membrane is continuous with the endoplasmic reticulum (ER) (see next section) and closely resembles it in structure and function (Figure 3-10). The nucleus contains many proteins that help mediate its functions of genetic control and inheritance. These proteins, including histones, polymerases, and regulatory proteins, are manufactured in the cytosol and transported to the nucleus through holes in the membrane called *nuclear pores*. The nuclear pores are selective as to which molecules are allowed access to the nuclear compartment, and in this way they protect the genetic material from enzymes and other molecules in the cytoplasm. The nuclear pores also mediate the export of products such as RNA and ribosomes that are synthesized in the nucleus but function in the cytosol. Ribosomes are manufactured in a specialized portion of the nucleus called the *nucleolus*. Nuclear pores are complexes of proteins that span

across both the inner and the outer nuclear membrane, creating a pathway between the cytoplasm and the nuclear lamina (see Figure 3-10).

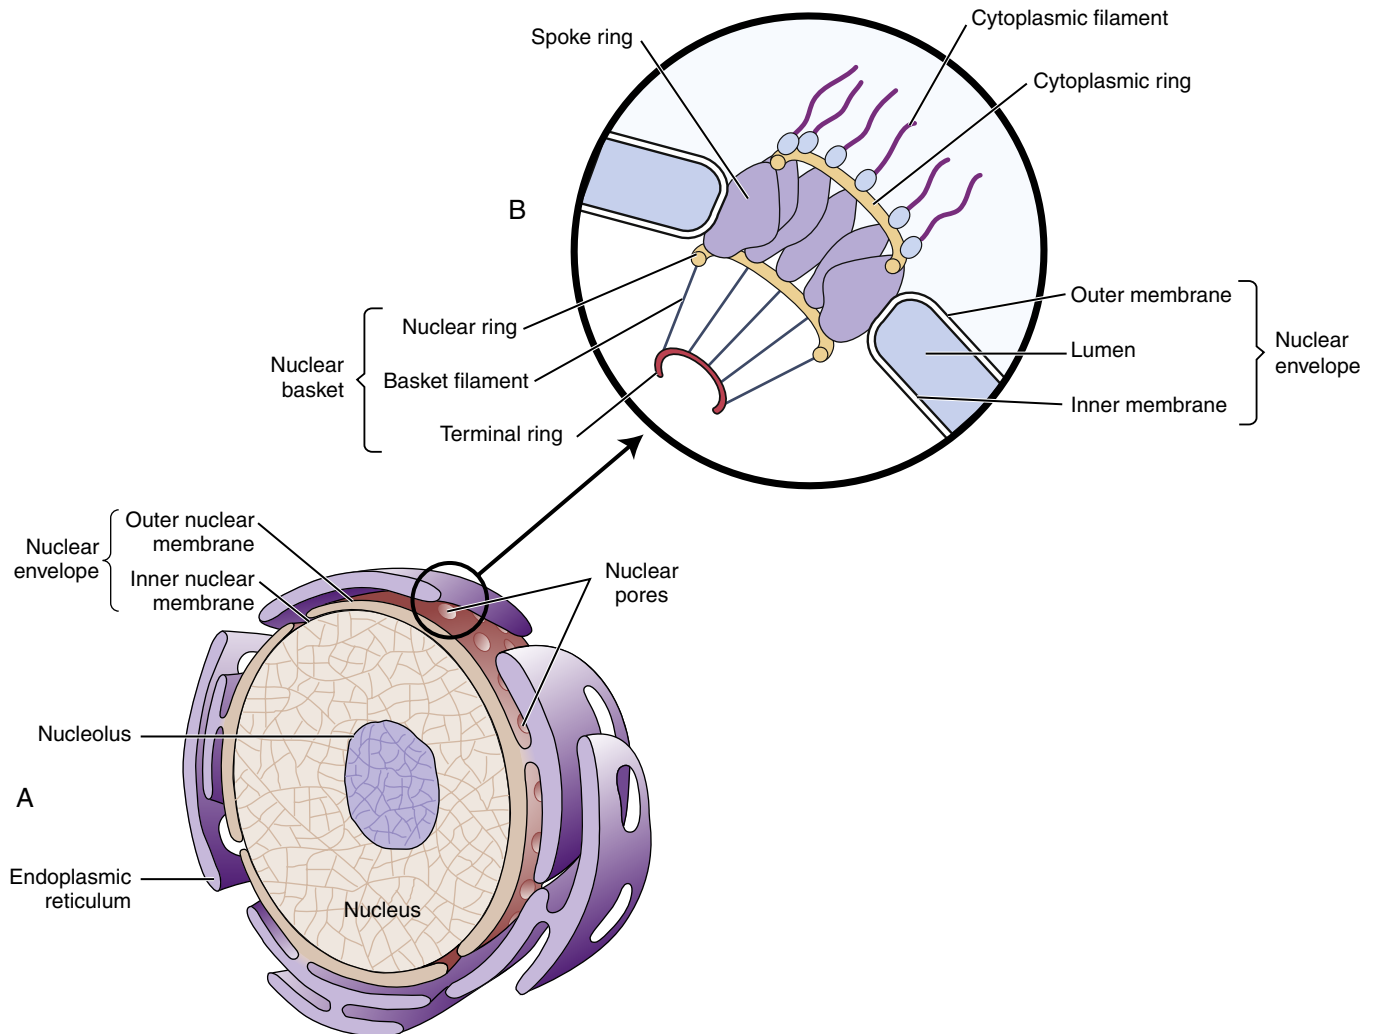

A major function of the nucleus is to protect and preserve genetic information so that it can be replicated exactly and passed on during cell division. However, the nucleus is continuously functioning even when the cell is not actively dividing. The nuclear DNA controls the production of cellular enzymes, membrane receptors, structural proteins, and other proteins that define the cell's type and behavior. (The structure and function of DNA are discussed in Chapter 5.)

During mitosis, the complex structure of the nuclear membrane and its pore-forming proteins breaks into small pieces that diffuse through the cell cytoplasm. After cell division is complete, pieces of nuclear membrane surround and gather the chromosomes and then fuse together to form a new nuclear membrane. Nuclear proteins and pore structures are then recruited back to their normal nuclear locations.<sup>9</sup>

## Endoplasmic Reticulum

The ER is a membrane network that extends throughout the cytoplasm and is present in all eukaryotic cells (Figure 3-11). The ER is thought to have a single continuous membrane that separates the lumen of the ER from the cytosol—it could be likened to a “gastrointestinal tract” in the cell. The ER plays a central role in the synthesis of membrane components, including proteins and lipids, for the plasma membrane and

**FIGURE 3-10** **A**, Structure of the double-membrane envelope that surrounds the cell nucleus. **B**, Detail of a nuclear pore.

cellular organelles, as well as in the synthesis of products to be secreted from the cell. The ER is divided into rough and smooth types based on its appearance under the electron microscope. The **rough ER** is coated with ribosomes along its outer surface. **Ribosomes** are complexes of protein and RNA that are formed in the nucleus and transported to the cytoplasm. Their primary function is the synthesis of proteins (see Chapter 5). Depending on the destination of the protein to be created, ribosomes may float free in the cytosol or may bind to the ER membrane. Proteins synthesized by free-floating ribosomes are released within the cytosol of the cell. Proteins to be transported into the ER have a special sequence of amino acids that directs the ribosome responsible for its synthesis to the ER membrane. Special proteins called signal recognition particles (SRPs) bind to the leading sequence of the protein and then bind to a receptor on the ER membrane. As the ribosome adds amino acids to the growing protein chain, it is pushed into the lumen of the ER through a pore in the ER membrane called a *translocon*.<sup>10</sup> After being processed in the ER and Golgi apparatus, the protein is eventually transported to the appropriate organelle or secreted at the cell surface. Free-floating and rough ER ribosomes are identical and interchangeable; their location depends on the amino acid structure of the protein they are producing at the time.<sup>11</sup>

Regions of ER that lack ribosomes are called **smooth ER**. The smooth ER is involved in lipid metabolism. Most cells have very little

smooth ER, but cells specializing in the production of steroid hormones or lipoproteins may have significant amounts of smooth ER. For example, the hepatocyte (liver cell) has abundant smooth ER—containing enzymes (P450) responsible for the manufacture of lipoproteins as well as the detoxification of harmful lipid-soluble compounds, such as alcohol. The cellular smooth ER can double in surface area within a few days if large quantities of drugs or toxins enter the circulation. Cells in the adrenal cortex and gonads that produce steroid hormones also have abundant smooth ER. In addition to synthetic functions, the ER also sequesters large amounts of calcium ions by pumping them from the cytoplasm. In response to specific signals, the ER releases calcium ions as part of important second-messenger cascades. Muscle cells have extensive smooth ER (sarcoplasmic reticulum) dedicated to the sequestration of calcium. When the cell is stimulated, the sarcoplasmic reticulum releases the calcium ions needed to accomplish muscle contraction.

### Golgi Apparatus

The **Golgi apparatus** or Golgi complex is composed of a stack of smooth membrane-bound compartments resembling a stack of hollow plates (see Figure 3-11). These compartments or *cisternae* are organized in a series of at least three processing compartments. The first compartment (*cis* face) lies next to the ER and receives newly

**FIGURE 3-11** Schematic drawing of the endoplasmic reticulum and its relationship to the Golgi apparatus and nuclear envelope.

synthesized proteins and lipids by way of ER transport vesicles. These transport vesicles are outgrowths that bud off from the ER membrane and diffuse to the Golgi, where they bind and become part of the Golgi apparatus membrane. The proteins and lipids then move through the middle compartment (medial) to the final compartment (*trans* face), where they depart for their final destination. As the lipid and protein molecules pass through the sequence of Golgi compartments, they are modified by enzymes that attach or rearrange carbohydrate molecules. After specific arrangement of these carbohydrates has occurred, the lipids and proteins are packaged into Golgi transport vesicles (secretory vesicles). The particular configuration of carbohydrate molecules on the lipid or protein is believed to serve as an “address label,” directing them to the correct destination within the cell. Golgi vesicles transport their contents primarily to the plasma membrane and to lysosomes.

### Lysosomes and Peroxisomes

Transport of Golgi vesicles to the membrane-bound bags of digestive enzymes known as **lysosomes** has been well described and provides a model for Golgi sorting and transport to other destinations. Lysosomes are filled with more than 40 different acid hydrolases, which are capable of digesting organic molecules, including proteins, nucleotides, fats, and carbohydrates.<sup>12</sup> Lysosomes obtain the materials they digest from three main pathways. The first is the pathway used to

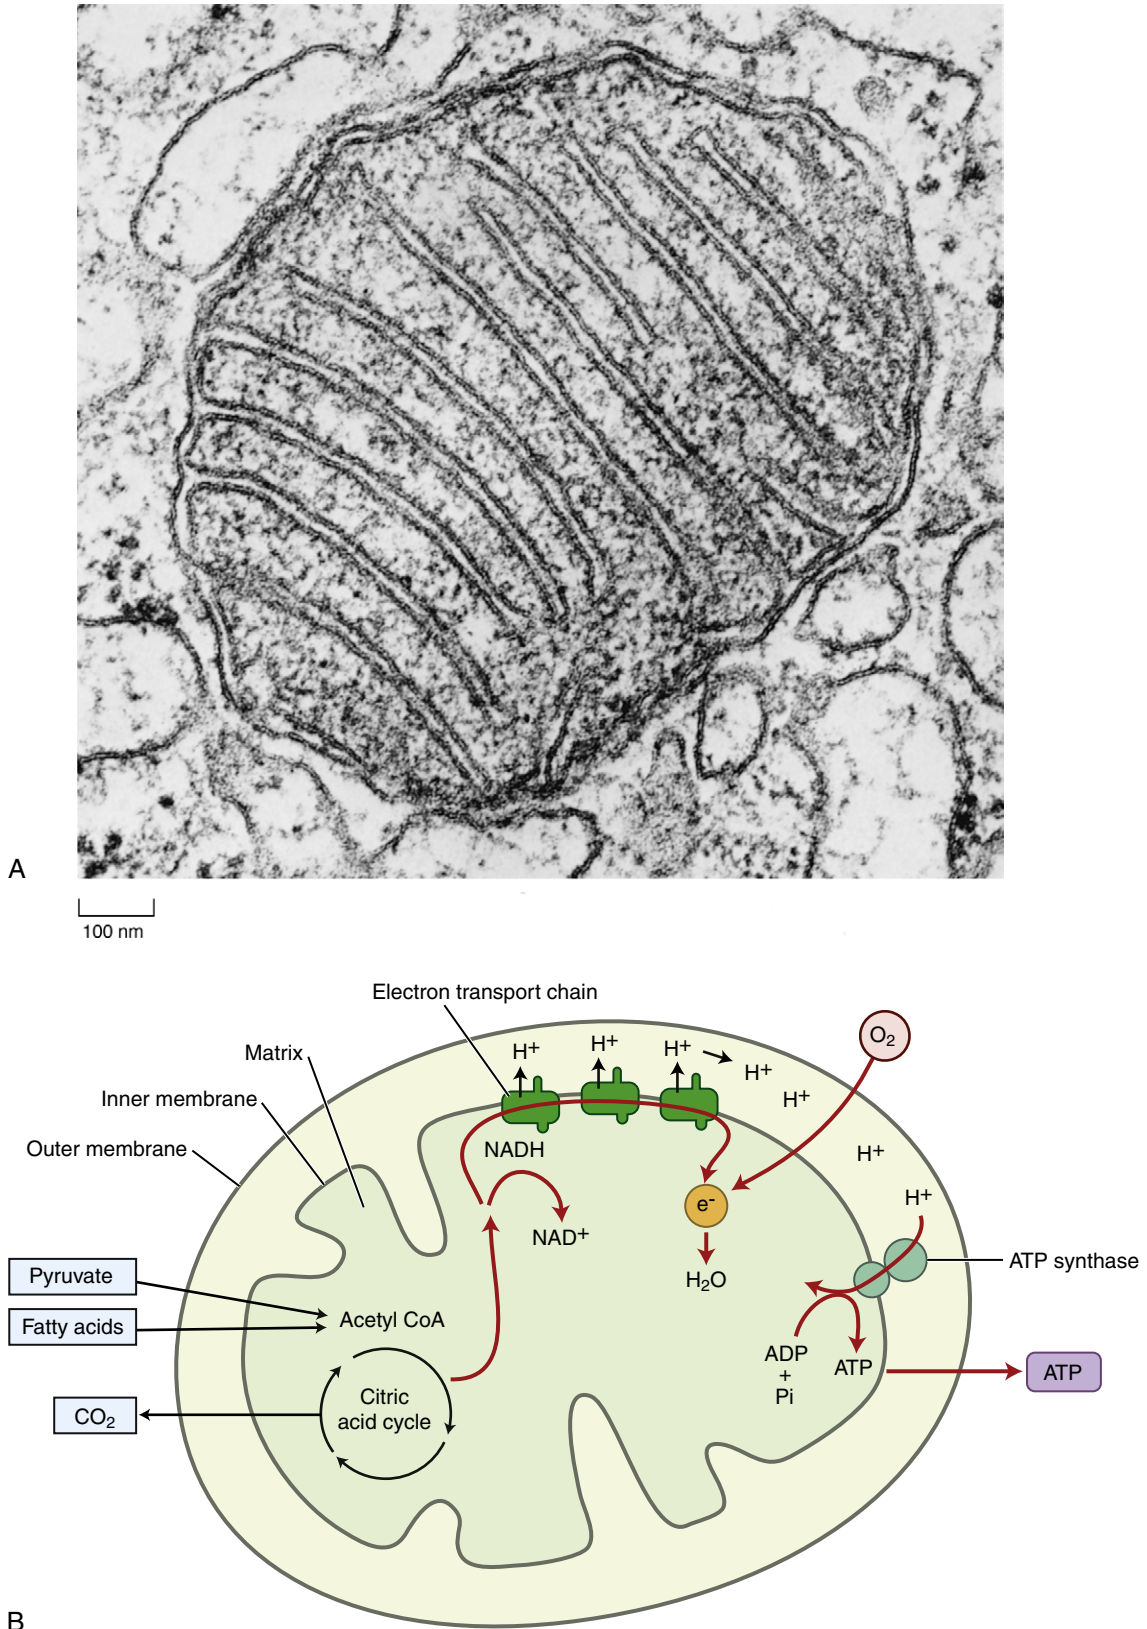

digest products absorbed by endocytosis. In this pathway, endocytotic vesicles bud off from the plasma membrane to fuse with endosomes. Endosomes mature into lysosomes as the Golgi delivers lysosomal enzymes to them; the pH inside the lysosome acidifies, and active digestion occurs. The second pathway is autophagy, whereby damaged and obsolete parts of the cell itself are destroyed. Unwanted cellular structures are enclosed by a membrane from the ER, which then fuses with the lysosome, leading to autodigestion of the cellular components. Autophagy also may occur during cell starvation or disuse, leading to a process called **atrophy**, in which the cell becomes smaller and more energy efficient. The third pathway providing materials to the lysosomes is present only in specialized phagocytic cells. White blood cells (WBCs), for example, are capable of ingesting large particles, which then form a **phagosome** capable of fusing with a lysosome. The final products of lysosomal digestion are simple molecules, such as amino acids, fatty acids, and carbohydrates, which can be used by the cell or secreted as cellular waste at the cell surface.

Discovery of the mechanism for sorting and transport of lysosomal enzymes was aided by studying patients suffering from the lysosomal storage diseases.<sup>13</sup> Patients with I-cell (inclusion cell) disease, for example, accumulate large amounts of debris in lysosomes, which appear as spots or “inclusions” in the cells. These lysosomes lack nearly all of the hydrolases normally present and thus are unable to perform lysosomal digestion. However, all the hydrolases missing from the lysosomes can be found in the patient’s bloodstream. The abnormality results from “mis-sorting” by the Golgi apparatus, which erroneously packages the enzymes for extracellular secretion rather than sending them to the lysosomes. Studies of this rare genetic disease resulted in the discovery that all lysosomal enzymes have a common marker, mannose-6-phosphate, which normally targets the enzymes to the lysosomes. Persons with I-cell disease lack the enzyme responsible for attaching this marker.

**Peroxisomes (microbodies)**, like lysosomes, are membrane-bound bags of enzymes that perform degradative functions. They are particularly important in liver and kidney cells, where they detoxify various substances, such as alcohol. In contrast to lysosomes, which contain hydrolase enzymes, peroxisomes contain oxidative enzymes. These enzymes use molecular oxygen to break down organic substances by an oxidative reaction that produces hydrogen peroxide. The hydrogen peroxide is then used by another enzyme (catalase) to degrade other organic molecules, including formaldehyde and alcohol. Catalase also prevents accumulation of excess hydrogen peroxide in the cell by converting it to water and oxygen. Peroxisomes also oxidize fatty acids ( $\beta$  oxidation) to produce acetyl coenzyme A (acetyl CoA) that is used in cellular metabolism. Unlike lysosomes, which acquire their enzymes from Golgi vesicles, peroxisomes import enzymes directly from the cytoplasm.

### Mitochondria

The **mitochondria** have been aptly called the “powerhouses of the cell” because they convert energy to forms that can be used to drive cellular reactions. A distinct feature of mitochondria is the large amount of membrane they contain. Each mitochondrion is bound by two specialized membranes. The inner membrane forms an enclosed space, called the *matrix*, which contains a concentrated mix of mitochondrial enzymes. The highly convoluted structure of the inner membrane with its numerous folds, called *cristae* (Figure 3-12), provides a large surface area for the important membrane-bound enzymes of the respiratory chain. These enzymes are essential to the process of oxidative phosphorylation, which generates most of the cell’s **adenosine triphosphate (ATP)**. The outer membrane contains numerous porin transport proteins forming large aqueous channels that make the membrane

**FIGURE 3-12** Electron micrograph (**A**) and schematic drawing (**B**) of the mitochondrial structure. The highly convoluted inner membrane provides a large surface area for membrane-bound metabolic enzymes. (**A**, From Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 28. Micrograph courtesy Daniel S. Friend. All rights reserved. Used under license from The American Society for Cell Biology.)

porous like a sieve. Fairly large molecules, including proteins up to 5000 daltons, can pass freely through the outer membrane such that the space between the outer and inner membranes is chemically similar to the cytosol. However, the inner membrane is quite impermeable, even to small molecules and ions. Specific protein transporters are required to shuttle the necessary molecules across the inner mitochondrial membrane.

Mitochondria are believed to have originated as bacteria that were engulfed by larger cells but that still retain some of their own DNA. Mitochondrial DNA codes for 22 transfer RNA molecules, 2 ribosomal RNAs that form mitochondrial ribosomes, and 13 proteins.<sup>14-16</sup> During evolution the majority of mitochondrial genes were transferred to locations within the nuclear genome. Thus only a few of the mitochondrial enzymes are produced from DNA located in the mitochondria; the majority are transcribed from nuclear DNA. Nuclear genes are translated into protein in the cytoplasm and then transported to the mitochondria, whereas mitochondrial gene-derived proteins are made within the mitochondria. There are several rare disorders associated with mitochondrial gene defects (see Chapter 6). The number and location of mitochondria differ according to cell type and function. Cells with high energy needs, such as cardiac or skeletal muscle, have many mitochondria. These mitochondria may pack between adjacent muscle fibrils, such that ATP is delivered directly to the areas of unusually high energy consumption. The details of mitochondrial energy conversion are discussed in the next section. Mitochondria also have an important role in programmed cell death, called *apoptosis*, which is discussed in Chapter 4.

#### KEY POINTS

- The cytoskeleton is made up of actin, microtubules, and intermediate filaments. These proteins regulate cell shape, movement, and the trafficking of intracellular molecules.
- The nucleus contains the genomic DNA. These nuclear genes code for the synthesis of proteins. There are about 23,000 protein-coding genes in the human genome.
- The endoplasmic reticulum and the Golgi apparatus function together to synthesize proteins and lipids for transport to lysosomes or to the plasma membrane.
- Lysosomes and peroxisomes are membrane-bound bags of digestive enzymes that degrade intracellular debris.
- Mitochondria contain enzymes necessary for oxidative phosphorylation to produce ATP. Mitochondria have their own small number of genes that code for some of the mitochondrial proteins.

## CELLULAR METABOLISM

All living cells must continually perform essential cellular functions such as movement, ion transport, and synthesis of macromolecules. Many of these cellular activities are energetically unfavorable (i.e., they are unlikely to occur spontaneously). Unfavorable reactions can be driven by linking them to an energy source such as ATP, which is a molecule that contains high-energy phosphate bonds. In normal cells where the ATP concentration is high, approximately 11 to 13 kcal of energy per mole of ATP is liberated when one of the phosphate bonds is hydrolyzed (broken with the aid of water) in a chemical reaction.<sup>15</sup> Enzymes throughout the cell are able to capture the energy released from ATP hydrolysis and use it to break or make other chemical bonds. In this way, ATP serves as the “energy currency” of the cell. A specific amount of ATP is “spent” to “buy” a specific amount of work. Most cells contain only a small amount of ATP, sufficient to maintain cellular activities for just a few minutes. Because ATP cannot cross the

plasma membrane, each cell must continuously synthesize its own ATP to meet its energy needs; ATP cannot be “borrowed” from other cells or “banked” in any significant quantity within a cell. ATP is synthesized primarily from the breakdown of glycogen and fat.

An average adult has enough glycogen stores (primarily in liver and muscle) to supply about 1 day’s needs, but enough fat to last for a month or more. After a meal, the excess glucose entering the cells is used to replenish glycogen stores or to synthesize fats for later use. Fat is stored primarily in adipose tissue and is released into the bloodstream for other cells to use when needed. When cellular glucose levels fall, glycogen and fats are broken down to provide glucose and fatty acyl molecules, respectively, which are ultimately metabolized to provide ATP. During starvation, body proteins can also be used for energy production by a process called *gluconeogenesis*.

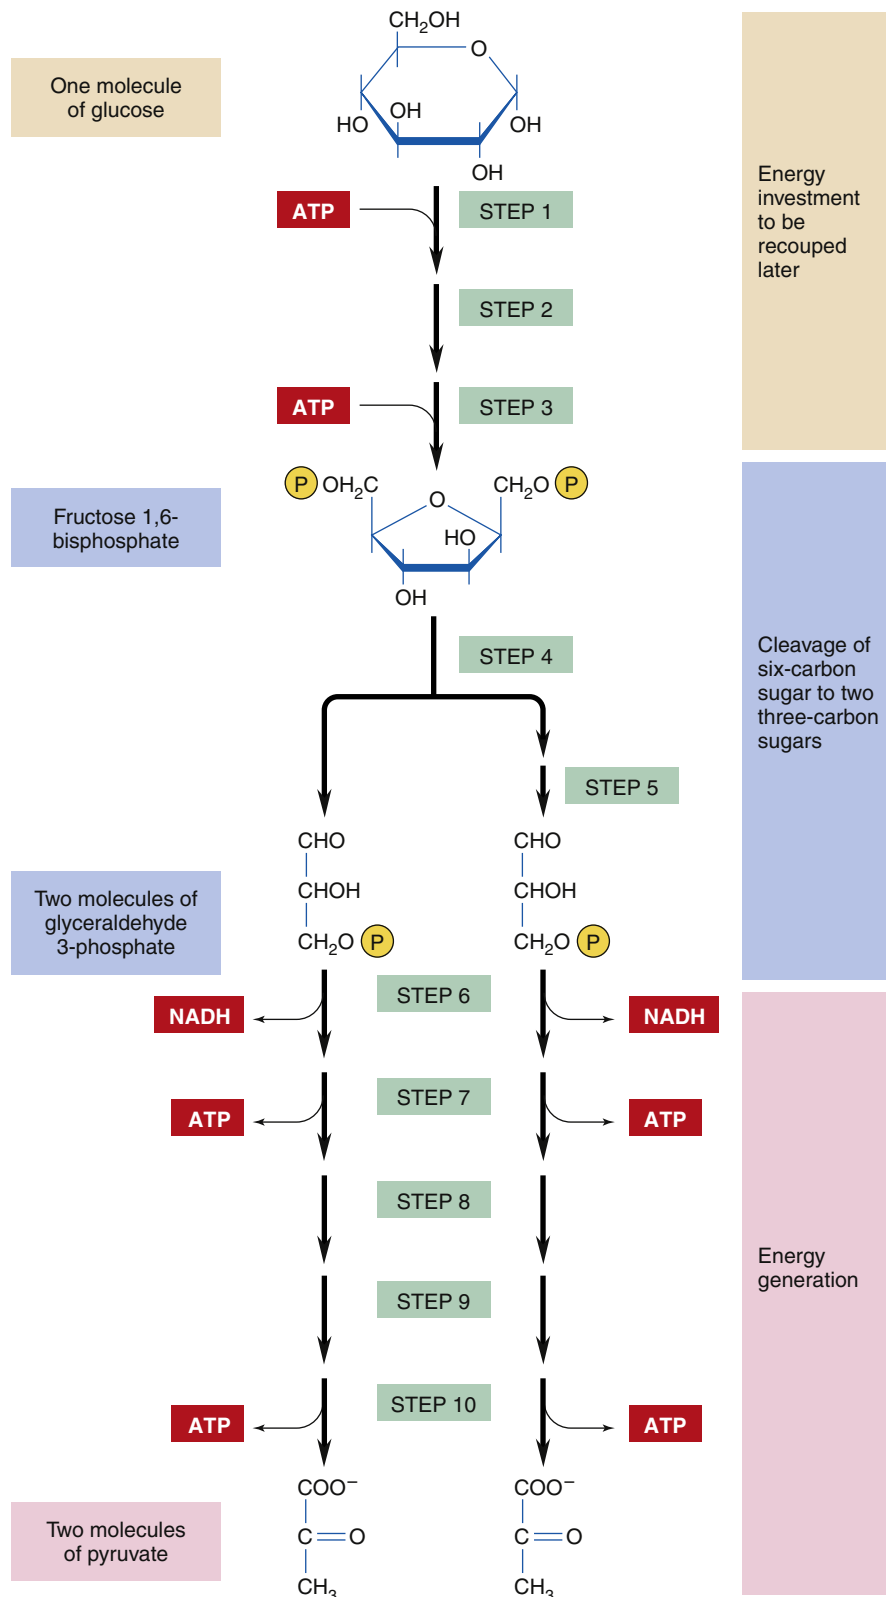

Cellular metabolism is the biochemical process whereby foodstuffs are used to provide cellular energy and biomolecules. Cellular metabolism includes two separate and opposite phases: anabolism and catabolism. **Anabolism** refers to *energy-using* metabolic processes or pathways that result in the synthesis of complex molecules such as fats. **Catabolism** refers to the *energy-releasing* breakdown of nutrient sources such as glucose to provide ATP to the cell. Both of these processes require a long, complex series of enzymatic steps. The catabolic processes of cellular energy production are briefly discussed in the following sections. (See Chapter 42 for a detailed discussion of metabolism.)

### Glycolysis

The catabolic process of energy production begins with the intestinal digestion of foodstuffs into small molecules: proteins into amino acids, polysaccharides into simple sugars (monosaccharides), and fats into fatty acids and glycerol. The second stage of catabolism occurs in the cytosol of the cell, where glucose molecules are further degraded by **glycolysis** into pyruvate (compounds with three carbon atoms). Glycolysis involves 10 enzymatic steps to break the 6-carbon glucose molecule into a pair of 3-carbon pyruvate molecules (Figure 3-13).<sup>15</sup> Glycolysis requires the use of two ATP molecules in the early stages but produces four ATP molecules in the later steps, for a net gain of two ATP molecules per glucose molecule. The production of ATP through glycolysis is relatively inefficient, and the pyruvate end products still contain substantial chemical energy that can be released by further catabolism in stage 3. However, glycolysis is an important provider of ATP under *anaerobic* conditions because oxygen is not required. Thus, ATP production by glycolysis becomes important during conditions of reduced cellular oxygenation, which may accompany respiratory and cardiovascular disorders. The pyruvate that accumulates during prolonged anaerobic conditions is converted to lactate and excreted from the cell into the bloodstream. Lactic acidosis is a dangerous condition that may result from excessive lactate production attributable to severe or prolonged lack of oxygen (see Chapter 20). In addition to the two molecules of ATP and pyruvate, each glucose molecule produces two reduced nicotinamide adenine dinucleotide (NADH) molecules, which contain high-energy electrons that are transferred to the electron transport chain in the mitochondria. Cells that do not contain mitochondria, such as RBCs, must rely totally on glycolysis for ATP production.

### Citric Acid Cycle

For most cells, glycolysis is only a prelude to the third stage of catabolism, which takes place in the mitochondria and results in the complete oxidation of glucose to its final end products, CO<sub>2</sub> and H<sub>2</sub>O. The third stage begins with the citric acid cycle (also called the Krebs cycle or the tricarboxylic acid cycle) and ends with the production of ATP by oxidative phosphorylation.<sup>15</sup> The purpose of the citric acid cycle is to break, by oxidation, the C-C and C-H bonds of the compounds produced in

**FIGURE 3-13** Ten enzymatic steps are required in glycolysis to break glucose into two three-carbon pyruvate molecules. A net gain of two ATP molecules is achieved. FIGURE 3-14 Space-filling model of acetyl CoA.

the second stage of catabolism. Pyruvate and fatty acids enter the mitochondrial matrix, where they are converted to acetyl CoA (Figure 3-14). The pyruvate dehydrogenase complex cleaves pyruvate to form one  $\text{CO}_2$ , one NADH, and one acetyl CoA molecule. Fatty acids are cleaved by a process called  $\beta$  oxidation to form one NADH and one reduced flavin adenine dinucleotide ( $\text{FADH}_2$ , another type of electron carrier). No  $\text{CO}_2$  is produced by  $\beta$  oxidation of fatty acids. Patients who have difficulty excreting  $\text{CO}_2$  because of respiratory disease are sometimes given a high-fat, low-carbohydrate diet to take advantage of the lower  $\text{CO}_2$  production that accompanies fat metabolism.

In the first reaction of the citric acid cycle, the two-carbon acetyl group is transferred from coenzyme A to a four-carbon oxaloacetate molecule. This results in the formation of the six-carbon molecule citrate, for which the cycle is named. In a series of enzymatic oxidations, carbon atoms are cleaved off in the form of  $\text{CO}_2$  (Figure 3-15); this  $\text{CO}_2$  is free to diffuse from the cell and be excreted by the lungs as a waste product. Two carbon atoms are removed to form two  $\text{CO}_2$  molecules for each complete turn of the cycle. The extra oxygen molecules needed to create  $\text{CO}_2$  are provided by the surrounding  $\text{H}_2\text{O}$ ; therefore, the citric acid cycle does not require molecular oxygen from respiration. However, the cycle will cease to function in the absence of

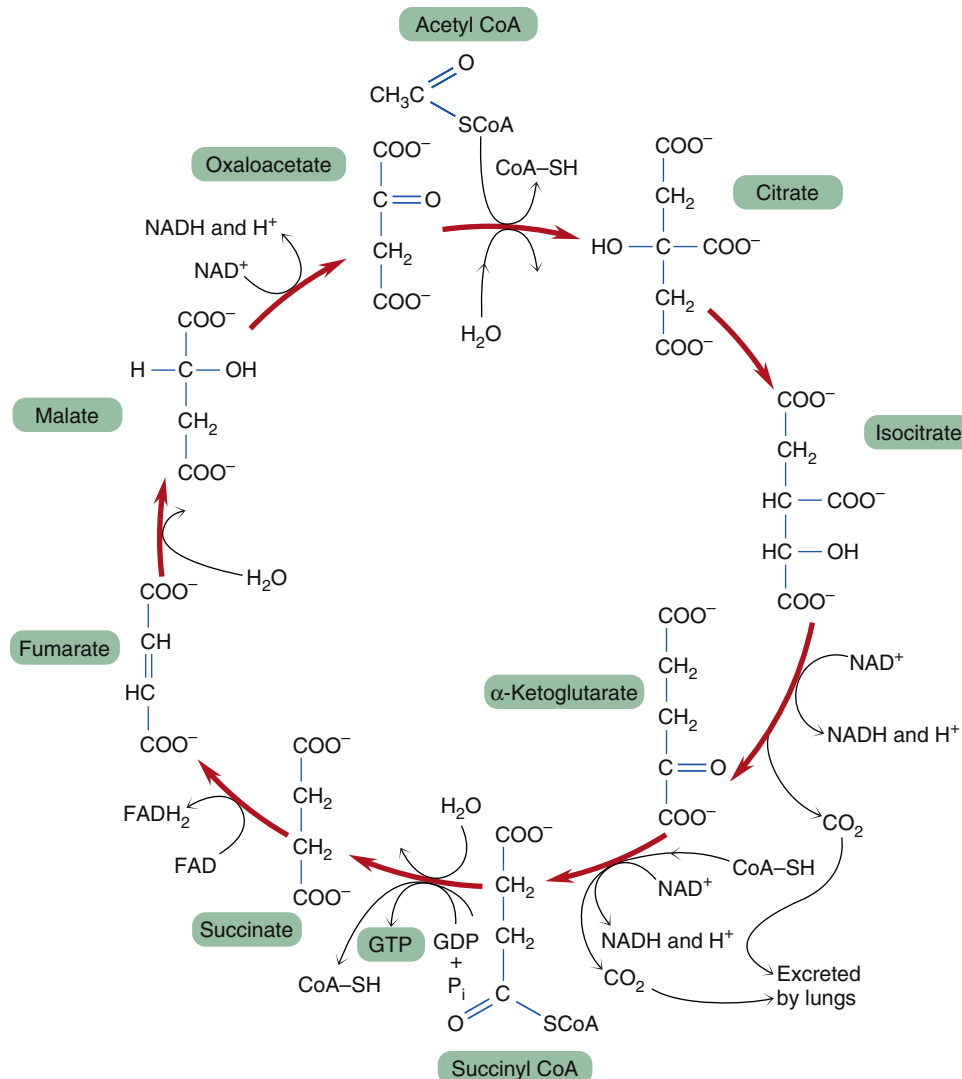

FIGURE 3-15 Chemical structures of the compounds of the citric acid cycle (Krebs cycle). In a series of enzymatic reactions, carbon atoms are cleaved to form  $\text{CO}_2$  and high-energy hydride ions, which are carried by FAD and NAD.

**FIGURE 3-16** Representation of the electron transport chain located in the inner mitochondrial membrane. High-energy electrons are passed along the chain until they combine with oxygen to form water. The energy released at each electron transfer is used to pump  $H^+$  across the membrane.

oxygen because the carrier molecules, NADH and  $FADH_2$ , cannot unload their electrons onto the electron transport chain (which does require oxygen) and thus are unavailable to accept electrons from the citric acid cycle.

Although the citric acid cycle directly produces only one ATP molecule (in the form of guanosine triphosphate [GTP]) per cycle, it captures a great deal of energy in the form of activated hydride ions ( $H^-$ ). These high-energy ions combine with larger carrier molecules, which transport them to the electron transport chain in the mitochondrial membrane. Two important carrier molecules are nicotinamide adenine dinucleotide ( $NAD^+$ ), which becomes NADH when reduced by  $H^-$ , and flavin adenine dinucleotide (FAD), which becomes  $FADH_2$  when reduced by  $H^-$ . The energy carried by these molecules is ultimately used to produce ATP through a process called *oxidative phosphorylation*. One glucose molecule provides for two turns of the cycle and produces a net of two GTP, four  $CO_2$ , two  $FADH_2$  and six NADH.<sup>14</sup>

### Oxidative Phosphorylation

Oxidative phosphorylation follows the processes of glycolysis and the citric acid cycle and results in the formation of ATP by the reaction adenosine diphosphate (ADP) and inorganic phosphate ( $P_i$ ):  $ADP + P_i \rightarrow ATP$ . The energy to drive this unfavorable reaction is provided by the high-energy hydride ions ( $H^-$ ) derived from the citric acid cycle. This energy is not used to form ATP directly; a series of energy transfers through reduction-oxidation (redox) reactions is required.<sup>14,15</sup> In eukaryotic cells, this series of energy transfers occurs along the **electron transport chain** on the inner mitochondrial membrane. The transport chain consists of three major enzyme complexes and two mobile electron carriers that shuttle electrons between the protein complexes (Figure 3-16). Respiratory chain proteins contain metal ions (iron, copper) that facilitate the transfer of electrons. The hydrogen molecules and their associated electrons are transported to the electron transport chain by the carrier molecules NADH or  $FADH_2$ . The path of electron flow is  $NADH \rightarrow NADH$  dehydrogenase complex  $\rightarrow$  ubiquinone  $\rightarrow b-c_1$  complex  $\rightarrow$  cytochrome  $c$   $\rightarrow$  cytochrome oxidase complex. With each redox reaction the electrons pass from one complex to the next and the free energy that is released is used to pump hydrogen ions ( $H^+$ ) out of the mitochondrial matrix. Each redox reaction provides enough energy to pump four protons ( $H^+$ ) across the membrane.<sup>14</sup> At the very

**FIGURE 3-17** Inner mitochondrial ATP synthetase captures the potential energy of the  $H^+$  gradient in a manner similar to a turbine. The proton gradient drives the synthesis of ATP from adenosine diphosphate (ADP) and inorganic phosphate ( $P_i$ ). A 360-degree rotation of the rotor requires 12  $H^+$  ions and produces 3 ATP molecules.

end of the transport chain, low-energy electrons are finally transferred to  $O_2$  to form  $H_2O$ . Oxidative phosphorylation is called *aerobic* because of this oxygen-requiring step. The last enzyme in the chain, cytochrome oxidase, collects four electrons and then transfers all four at once to a molecule of  $O_2$  to create two water molecules. If electrons are not transferred to oxygen in the correct ratio, then oxygen free radicals may be produced and damage the cell. Free radical generation is discussed in Chapter 4.

Thus far, little ATP synthesis has been accomplished. However, the enzymes of the transport chain have harnessed energy from the transported electrons in the form of a proton ( $H^+$ ) gradient. Finally, the proton gradient is used to power the synthesis of ATP. A special enzyme in the inner mitochondrial membrane (ATP synthase) allows protons to flow back into the mitochondria down their electrochemical gradient. The energy of the proton flow is used to drive ATP synthesis (Figure 3-17). Under normal cellular conditions a total of about 30

ATP molecules is formed from the complete oxidation of glucose into  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Two of these are from glycolysis, two from the citric acid cycle (in the form of GTP), and the remainder from oxidative phosphorylation.<sup>15</sup> The ATP formed within the mitochondria is transported to the cytosol by protein transporters in the mitochondrial membrane. The ATP is then available to drive a variety of energy-requiring reactions within the cell.

#### KEY POINTS

- Energy-requiring reactions within cells are driven by coupling to ATP hydrolysis.
- ATP is not stored and must be continuously synthesized by each cell to meet the cell's energy needs.
- Glycolysis is an anaerobic process that produces two ATP molecules, two NADH molecules, and two pyruvate molecules per glucose molecule. Pyruvate enters the mitochondria and is converted to acetyl CoA with release of a  $\text{CO}_2$  molecule. Pyruvate can also be converted to lactate when oxygen supply is insufficient for oxidative processes.
- The citric acid cycle in the mitochondrial matrix oxidizes the acetyl groups supplied by acetyl CoA to form large quantities of  $\text{H}^+$  (hydride ions), which are carried to the respiratory chain by NADH and  $\text{FADH}_2$ .
- The respiratory chain enzymes capture the energy from electron transfer and use it to produce an  $\text{H}^+$  (proton) gradient. Molecular oxygen is required at this stage (aerobic) to accept the electrons from the last enzyme in the transport chain.
- ATP is produced by ATP synthase, a protein in the mitochondrial membrane. ATP synthase produces ATP by capturing the energy of the proton gradient and using it to form a bond between ADP and inorganic phosphate ( $\text{P}_i$ ). In total, about 30 ATP molecules are produced per glucose molecule.

## FUNCTIONS OF THE PLASMA MEMBRANE

### Membrane Transport of Macromolecules

#### Endocytosis and Exocytosis

The transport of large molecules, such as proteins and polysaccharides, across the plasma membrane cannot be accomplished by the membrane transport proteins discussed earlier. Rather, macromolecules are ingested and secreted by the sequential formation and fusion of membrane-bound vesicles. Endocytosis refers to cellular ingestion of extracellular molecules. The process of cellular secretion is called exocytosis. There are two types of endocytosis, which are differentiated by the size of the particles ingested. Pinocytosis, or “cellular drinking,” is the method of ingesting fluids and small particles and is common to most cell types. Phagocytosis, or “cellular eating,” involves the ingestion of large particles, such as microorganisms, and is practiced mainly by specialized phagocytic WBCs. Endocytosis begins at the cell surface by the formation of an indentation or “pit” in the plasma membrane, which is coated with special proteins, including clathrin (*coated pit*). The indentation invaginates and then pinches off a portion of the membrane to become a vesicle (Figure 3-18). Each vesicle thus formed is internalized, sheds its coat, and fuses with an endosome. The contents of these endocytic vesicles usually accumulate in lysosomes, where they are degraded.

Endocytosis of certain macromolecules is regulated by specific receptors on the cell surface. These receptors bind the molecules (ligands) to be ingested and then cluster together in coated pits. The receptor-ligand complexes are internalized by the invagination process described previously. The vesicles generally fuse with endosomes where the ligand is removed from the receptor for processing by the cell. The receptor may be degraded in the lysosome or may be recycled to the cell surface to be used again. Receptor-mediated endocytosis

allows the cell to be selective about the molecules ingested and to regulate the amount taken into the cell. The cell can produce greater numbers of cell surface receptors to ingest more ligand.

An example of receptor-mediated endocytosis is cellular uptake of cholesterol. The process of cholesterol uptake by cells is shown in Figure 3-19. Most cholesterol in the blood is transported by protein carriers called low-density lipoproteins (LDLs). The cell can regulate the number of LDL receptors on its cell surface to increase or decrease the uptake of cholesterol. Once the LDL binds to its receptor, this complex is rapidly internalized in a coated pit. The coated vesicle thus formed sheds its coat and fuses with an endosome. In the endosome, the LDL receptor is retrieved and recycled to the cell surface to be reused. The LDL is transported to lysosomes and degraded to release free cholesterol, which the cell uses for synthesis of biomolecules such as steroid hormones.

Dangerously high blood cholesterol levels occur in some individuals who lack functional LDL receptors. These individuals inherit defective genes for making LDL receptor proteins (familial hyperlipidemia) and are incapable of taking up adequate amounts of LDL. Accumulation of LDL in the blood predisposes these individuals to development of atherosclerosis and heart disease (see Chapter 18).

Exocytosis is essentially the reverse of endocytosis. Substances to be secreted from the cell are packaged in membrane-bound vesicles and travel to the inner surface of the plasma membrane. There the vesicle membrane fuses with the plasma membrane and the contents of the vesicle arrive at the cell surface. Some secreted molecules may remain embedded in the cell membrane, others may be incorporated into the extracellular matrix, and still others may enter the extracellular fluids and travel to distant sites. Many substances synthesized by the cell, including new membrane components, are constantly being packaged and secreted. This continuously operative and unregulated pathway is termed *constitutive*. In some specialized cells, selected proteins or small molecules are packaged in secretory vesicles, which remain in the cell until the cell is triggered to release them. These special secretory vesicles are typically regulated by stimulation of cell surface receptors. For example, the mast cell, a special type of WBC, releases large amounts of histamine when its cell surface receptors are activated (Chapter 9).

### Membrane Transport of Small Molecules

All cells must internalize essential nutrients, excrete wastes, and regulate intracellular ion concentrations. However, the lipid bilayer is extremely impermeable to most polar and charged molecules. Transport of small water-soluble molecules is achieved by specialized transmembrane proteins called *transporter proteins*. Most membrane transporters are highly specific—a different transporter protein is required for each type of molecule to be transported. Only lipid-soluble molecules can permeate the lipid bilayer directly by simple diffusion.

Membrane transport proteins are of three basic kinds: ATP-driven pumps, carriers, and channel proteins. Channel proteins are the simplest of the three, forming a water-filled pore through the lipid bilayer. These pores are able to open and close to allow ions to pass through the membrane. The particular structure of the protein channel ensures that only ions of a certain size and charge can move through the membrane. Pumps and carrier proteins, however, bind to the solute to be transported and move it through the membrane by undergoing a structural, or conformational, change. Pumps and carriers have a transport maximum that is much lower than that of channels because they must bind to the molecules to be transported and then move them through the membrane. Pumps and carriers, which transport ions and nonelectrolyte molecules (e.g., glucose and amino acids), are also highly specific for the substances they transport.

**FIGURE 3-18** **A**, Representation of the steps of endocytosis. An invagination of the membrane occurs and pinches off to form a vesicle. Exocytosis progresses in essentially the reverse sequence. **B**, Electron micrograph showing the steps of endocytosis. (**B**, From Perry M, Gilbert A: Yolk transport in the ovarian follicle of the hen [*Gallus domesticus*]; lipoprotein-like particles at the periphery of the oocyte in the rapid growth phase, *J Cell Sci* 39:257-272, 1979.)

Lipid-soluble particles can cross the lipid bilayer directly by simple diffusion through the hydrophobic lipid portion of the membrane. Polar or charged molecules must cross the membrane via protein channels or carriers. Transport through membrane proteins may be a passive or an active process. Passive transport through membrane proteins is called *facilitated diffusion*. Diffusion of ions occurs passively because of an **electrochemical gradient**. The electrochemical gradient exists because of differences in intracellular and extracellular charge and/or concentration of chemicals and is governed by laws of physics. Channel proteins only allow particles to move down their electrochemical or concentration gradients. Some carriers are passive, but others use the movement of one ion flowing down its concentration gradient (usually  $\text{Na}^+$  moving into the cell) to move another substance uphill against its gradient.<sup>17</sup> This process is called *secondary active transport* because ATP is not used directly; however, ATP is necessary to run the pumps that maintain the sodium gradient. The lipid bilayer is quite impermeable to water because of its polar structure. Water moves across the plasma membrane through channels called *aquaporins*. Nearly all cells have aquaporins present in their cell membranes at all times, with the exception of a few specialized cells in the kidney tubules. Net movement of water across a membrane (osmosis) occurs in response to differences in osmotic pressure on either side of the membrane and is a passive process.

### Active Transport Pumps

Active transport is the process whereby protein transport pumps move solutes across the membrane against an electrochemical or concentration gradient. Primary active transport requires metabolic energy, which is supplied by ATP hydrolysis. There are three families of ATP-driven pumps: the F-type ATPases that move  $\text{H}^+$ ; the P-type adenosine triphosphatase (ATPase) that pump ions across membranes; and the ATP-binding cassette (ABC) transporters that transport a wide range of solutes. The ATP synthase located on the inner mitochondrial membrane is an example of an F-type pump; however, in that location it runs backward, allowing  $\text{H}^+$  to run down its electrochemical gradient and using the energy to form a bond between ADP and  $\text{P}_i$  (see Figure 3-17). As a general principle, pumps, carriers, and channels can transport either direction depending on the concentration of substrate on either side of the membrane.

**Sodium-potassium ion pump.** The sodium-potassium ( $\text{Na}^+\text{-K}^+$ ) pump is a P-type ATPase present in the plasma membranes of virtually all animal cells. It serves to maintain low sodium and high potassium concentrations in the cell. The  $\text{Na}^+\text{-K}^+$  transporter must pump ions against a steep electrochemical gradient. Almost one third of the energy of a typical cell is consumed by the  $\text{Na}^+\text{-K}^+$  pump. ATP hydrolysis provides the energy to drive the  $\text{Na}^+\text{-K}^+$  transporter. The  $\text{Na}^+\text{-K}^+$  pump behaves as an enzyme in its ability to split ATP to form ADP and  $\text{P}_i$ , leading to the protein being termed  *$\text{Na}^+\text{-K}^+$  ATPase*.

**FIGURE 3-19** Steps in the process of receptor-mediated endocytosis of cholesterol. Cholesterol is carried in the blood by LDL. The uptake of LDL with its associated cholesterol is mediated by a specific LDL-receptor protein on the cell surface. Once internalized, the cholesterol is removed from the LDL-receptor complex and used by the cell. The LDL receptors are sent back to the cell surface to bind more LDL.

Transport of sodium and potassium ions through the  $\text{Na}^+$ - $\text{K}^+$  carrier protein is *coupled*; that is, the transfer of one ion must be accompanied by the simultaneous transport of the other ion. The transporter moves three sodium ions *out* of the cell for every two potassium ions moved *into* the cell (Figure 3-20). The  $\text{Na}^+$ - $\text{K}^+$  pump is important in maintaining cell volume. It controls the solute concentration inside the cell, which in turn affects the osmotic forces across the membrane. If  $\text{Na}^+$  is allowed to accumulate within the cell, the cell will swell and could burst. The role of the  $\text{Na}^+$ - $\text{K}^+$  pump can be demonstrated by treating cells with digitalis, a drug that inhibits  $\text{Na}^+$ - $\text{K}^+$  ATPase. Cells thus treated will indeed swell and often rupture. The  $\text{Na}^+$ - $\text{K}^+$  pump is responsible for maintaining a steep concentration gradient for  $\text{Na}^+$  across the plasma membrane. This gradient can be harnessed to transport small molecules across the membrane in a process called secondary active transport. Carriers that use ATP directly are engaged in primary active transport.

**Membrane calcium transporters.** Numerous important cellular processes, such as cell contraction and growth initiation, are dependent on the intracellular calcium ion concentration. Intracellular  $\text{Ca}^{2+}$  is normally very low and tightly regulated. Two important calcium pumps, present in the plasma membrane and in the endoplasmic reticulum (sarcoplasmic reticulum of muscle cells), function to remove  $\text{Ca}^{2+}$  from the cell cytoplasm. Similar to the  $\text{Na}^+$ - $\text{K}^+$  transporter, these transporters use ATP as the energy source (Figure 3-21).

If calcium ion levels in the cytoplasm become dangerously elevated, calcium pumps in the mitochondrial membrane are activated. Calcium ions are actively pumped into the mitochondria using the energy of the proton ( $\text{H}^+$ ) gradient. This is the same proton gradient that the mitochondria use to synthesize ATP, and ATP production declines when the mitochondria are required to sequester  $\text{Ca}^{2+}$ . A high intracellular  $\text{Ca}^{2+}$  level is even more dangerous to the cell than a reduction in ATP production.

**FIGURE 3-20** Schematic drawing of the sodium-potassium transport protein, which uses ATP to pump  $\text{Na}^+$  out of the cell and  $\text{K}^+$  into the cell against steep electrochemical gradients. This transporter is responsible for maintaining a low intracellular concentration of  $\text{Na}^+$  and a large  $\text{Na}^+$  gradient across the membrane. The energy of this  $\text{Na}^+$  gradient can be harvested by other transporters to actively transport substances.

**ABC transporters.** Another important class of ATP-driven transporters is the ABC transporter family. These transporters all have a common ATP-binding domain, called the ATP binding cassette (ABC), which hydrolyzes ATP to provide energy for the transport process (Figure 3-22). This family of membrane transporters is the largest of

the transporter families. A clinically important member of this family is a chloride channel in the plasma membrane of epithelial cells. A defect in this transporter is responsible for cystic fibrosis, a common genetic disorder that affects the lungs and pancreas (see Chapter 22). Bacteria use ABC transporters to pump antibiotics out of the cell, resulting in drug resistance (see Chapter 8).

**Membrane Transport Carriers**

**Na<sup>+</sup>-driven carriers.** In animal cells, the Na<sup>+</sup> gradient created by the Na<sup>+</sup>-K<sup>+</sup> pump is used to power a variety of transporters by secondary active transport. An important Ca<sup>2+</sup> transporter located in the plasma membrane of cardiac muscle cells uses the electrochemical gradient of Na<sup>+</sup> to power the transport of Ca<sup>2+</sup> out of the cell (see Figure 3-21). The dependence of this calcium transporter on the sodium gradient helps

explain the inotropic effects of the commonly prescribed drug digitalis. Digitalis is a cardiac glycoside that inhibits the Na<sup>+</sup>-K<sup>+</sup> pump and allows the accumulation of intracellular Na<sup>+</sup>. The Na<sup>+</sup> concentration gradient across the membrane is thus decreased, leading to less efficient calcium removal by the Na<sup>+</sup>-dependent Ca<sup>2+</sup> pump. A more forceful cardiac muscle contraction results from the increased intracellular Ca<sup>2+</sup> concentration. Another example of a transporter that uses secondary active transport is the Na<sup>+</sup>-H<sup>+</sup> exchange carrier, which uses the Na<sup>+</sup> gradient to pump out excess hydrogen ions to help maintain intracellular pH balance. The Na<sup>+</sup> gradient also can be used to bring substances into the cell. For example, glucose and amino acid transport into epithelial cells is coupled to Na<sup>+</sup> entry. As Na<sup>+</sup> moves through the transporter, down its electrochemical gradient, the sugar or amino acid is “dragged” along. Entry of the nutrient will not occur unless Na<sup>+</sup> also enters the cell. The epithelial cells that line the gut and kidney tubules have large numbers of these nutrient transporters present in the luminal (apical) surfaces of their cell membranes. In this way, large amounts of glucose and amino acids can be effectively absorbed. The reuptake of numerous types of neurotransmitters from synapses also occurs via Na<sup>+</sup>-driven carrier proteins. The movement of Na<sup>+</sup> through carriers located in the presynaptic neuron drags the neurotransmitter from the synapse back into the nerve terminal, where it can be repackaged for reuse or metabolized by cellular enzymes.

**Passive transport carriers.** Some carriers are not linked to the Na<sup>+</sup> gradient and move substances across the membrane passively. The glucose transporters in many cell types belong to this class of transporters. In β cells of the pancreas, for example, the glucose transporters (Glut-1) are always present in the plasma membrane and let glucose into the cell according to its concentration in the extracellular fluid. In this way the pancreas detects blood glucose levels and releases an appropriate amount of insulin. In insulin-sensitive cells, such as muscle, liver, and adipose cells, the glucose carriers are sequestered inside the cell until insulin binds to its receptor at the cell surface. Receptor activation causes the glucose carriers (Glut-4) to move to the cell surface, where they allow passive influx of glucose (Figure 3-23).

**FIGURE 3-21** Two transporters of calcium ions are present in some cell membranes. One uses ATP as the energy source to pump calcium against a gradient (primary active transport). The other captures the potential energy of the sodium gradient to pump calcium out of the cell (secondary active transport).

**Membrane Channel Proteins**

In contrast to carrier proteins, which bind molecules and move them across the membrane by a conformational change, channel proteins

**FIGURE 3-22** The ABC transporters are the largest known family of membrane transport proteins. They are characterized by an ATP-binding domain that causes a substrate pocket to be exposed first on one side of the membrane and then on the other as ATP is bound and hydrolyzed to ADP and P<sub>i</sub>.

**FIGURE 3-23** In response to insulin binding to its receptor on the cell surface, carrier proteins that transport glucose (*Glut-4*) are moved to the cell surface where they passively transport glucose into the cell (facilitated diffusion).

form water-filled pores in the membrane. Nearly all channel proteins are involved in transport of ions and may be referred to as ion channels. Ions can flow through the appropriate channel at very high rates (100 million ions/sec); this is much faster than carrier-mediated transport.<sup>17</sup> However, channels are not linked to an energy source, so ions must flow passively down an electrochemical gradient. The channel proteins in the plasma membranes of animal cells are highly selective, permitting only a particular ion or class of ions to pass. Humans have about 400 genes that encode channel proteins.<sup>18</sup> Ion channels are particularly important in allowing the cell to respond rapidly to a variety of external stimuli. Most channels are not continuously open, but they open and close according to membrane signals. Ion channels may be stimulated to open or close in three principal ways: (1) *voltage-gated* channels respond to a change in membrane potential; (2) *mechanically gated* channels respond to mechanical deformation; and (3) *ligand-gated* channels respond to the binding of a signaling molecule (a hormone or neurotransmitter) to a receptor on the cell surface (Figure 3-24). In addition, some channels open without apparent stimulation and are referred to as *leak* channels. Ion channels are responsible for the development of membrane potentials and are of vital importance in nerve and muscle function, as discussed in the next section.

#### KEY POINTS

- Large, lipid-insoluble molecules are transported across the plasma membrane by endocytosis and exocytosis.
- Small, lipid-insoluble molecules are transported across the plasma membrane by three kinds of membrane proteins: ATP-driven pumps, carriers, and channels.

- Pumps use the energy of ATP to move solutes against a gradient. Examples of ATP-driven active transport include proton pumps,  $\text{Na}^+\text{-K}^+$  pumps,  $\text{Ca}^{2+}$  pumps, and ABC transporters.
- Carriers may be passive or use the  $\text{Na}^+$  gradient for secondary active transport. Neurotransmitter reuptake carriers and those that transport glucose and amino acids across the gut and renal tubules are examples of  $\text{Na}^+$ -driven carriers. Passive carriers include those that allow glucose entry into insulin-sensitive cells.
- Channels are always passive and allow ions to move down their electrochemical gradients when open. Channels open and close in response to specific signals, such as voltage changes, ligand binding, and mechanical pressure.

### Cellular Membrane Potentials

Animal cells typically have a difference in the electrical charge across the plasma membrane. There is a slight excess of negative ions along the inner aspect of the membrane and extra positive ions along the outer membrane. This separation of charges creates a membrane potential that can be measured as a voltage. Positive and negative ions separated by the plasma membrane have a strong attraction to one another that can be used by the cell to perform work, such as the transmission of nerve impulses. A relatively large membrane potential is created by the separation of a very small number of ions along the membrane (Figure 3-25).

#### Resting Membrane Potential

When there is no net ion movement across the plasma membrane, the electrical charge present inside the cell is called the *resting membrane*

**FIGURE 3-24** Gating of ion channels. **A**, Voltage-gated channel. **B**, Ligand-gated channel. **C**, Mechanically gated channel.

*potential* (RMP). The major determinant of the resting membrane potential is the difference in potassium ion concentration across the membrane.<sup>17,19</sup> The concentration of potassium inside the cell is much greater (about 30 times greater) than the extracellular potassium concentration. At rest, the membrane is permeable to  $K^+$ , but not to other positively charged cations, including  $Na^+$  and  $Ca^{2+}$ . Potassium ions remain inside the cell because of the attraction of fixed intracellular anions (negatively charged organic molecules such as proteins and phosphates that cannot diffuse out of the cell). Because the cell membrane is impermeable to  $Na^+$  and  $Ca^{2+}$ , only  $K^+$  is available to balance these negative intracellular ions. Thus, two opposing forces are acting on the potassium ion. The negative cell interior attracts  $K^+$  into the cell, whereas the huge  $K^+$  concentration gradient favors movement of  $K^+$  out of the cell. When the cell is at rest and not transmitting impulses these forces are balanced, and although the membrane is permeable to  $K^+$  there is no net movement. The voltage required to exactly balance a given potassium concentration gradient can be calculated mathematically.\*

\*The numeric value of the resting potential ( $M$ ) can be calculated from the ratio of extracellular to intracellular  $K^+$  concentration using the Nernst equation:  $M$  (in millivolts) =  $61 \log (K^+_{\text{outside}} \div K^+_{\text{inside}})$ .

The measured membrane potential is very close to that predicted mathematically and varies directly with changes in extracellular  $K^+$  ion concentration. For example, a typical nerve cell has a normal resting potential of about  $-85$  mV. If the extracellular  $K^+$  level is increased, more  $K^+$  ions will stay in the cell, owing to the reduced concentration gradient. These extra positive intracellular ions will neutralize more of the negative cellular anions, and the cell will *hypopolarize*, or become less negative. Conversely, if extracellular  $K^+$  levels fall, more  $K^+$  will exit the cell, owing to a greater concentration gradient. Fewer intracellular anions will be neutralized, and the cell interior will become more negative, or *hyperpolarized* (Figure 3-26). Changes in RMP can have profound effects on the ease of action potential generation in cardiac and nerve cells.

The RMP is described by the potassium equilibrium potential because the cell is relatively impermeable to other ions at rest. Under certain conditions, the membrane may become highly permeable to an ion other than potassium. The membrane potential will reflect the equilibrium potential of the most permeant ions.

Long-term maintenance of ion gradients across the cell membrane is accomplished primarily by the  $Na^+-K^+$  pump. The  $Na^+-K^+$  pump also contributes to the negative RMP in that it extrudes *three*  $Na^+$  for

every two  $K^+$  brought into the cell. However, this pump can be inhibited for minutes to hours in some tissues with little immediate effect on the resting membrane potential.

### Action Potential

Nearly all animal cells have negative resting membrane potentials, which may vary from  $-20$  to  $-200$  mV, depending on the cell type and organism. The cell membranes of some specialized cell types, mainly

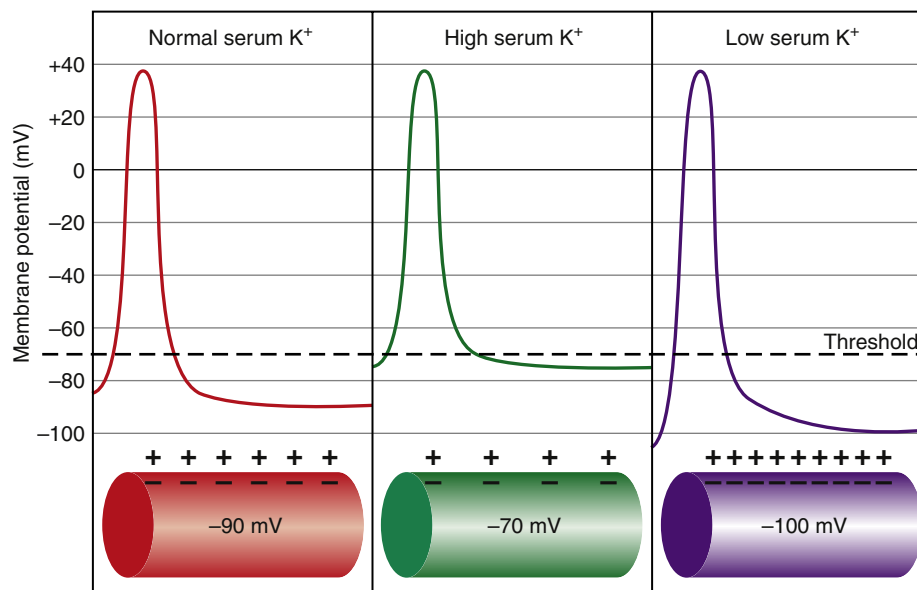

nerve and muscle, are capable of rapid changes in their membrane potentials. These cells are electrically “excitable” and can generate and propagate action potentials. In classic experiments, action potentials were determined to be rapid, self-propagating electrical excitations of the membrane that are mediated by ion channels that open and close in response to changes in voltage across the membrane (voltage-gated ion channels).<sup>20-24</sup> An action potential is triggered by membrane depolarization.

In nerve and muscle cells, the usual trigger for depolarization is binding of a neurotransmitter to cell surface receptors. Transmitter binding causes channels or pores in the membrane to open, allowing ions (primarily  $Na^+$ ) to enter the cell. This influx of positive ions causes a shift in the membrane potential to a less negative value, resulting in depolarization. *Threshold* is reached when a patch of the membrane becomes sufficiently depolarized (approximately  $-65$  mV in animal neurons) to activate voltage-gated sodium channels in the membrane. At threshold, these channels open rapidly and transiently to allow the influx of  $Na^+$  ions. A self-propagating process follows whereby  $Na^+$  influx in one patch of membrane causes membrane depolarization of the next patch and opens more voltage-gated  $Na^+$  channels, allowing more  $Na^+$  to enter the cell. This process is repeated many times while the action potential proceeds along the length of the cell (Figure 3-27). In this way, action potentials can transmit information rapidly over relatively long distances.

A typical neuronal action potential is shown in Figure 3-28. The various changes in membrane potential during the time course of the action potential are attributable to the flow of ions through membrane ion channels. The steep upstroke of the action potential corresponds to  $Na^+$  influx through “fast” sodium channels, as described previously. *Fast channels* are so termed because they open and close rapidly, with the entire process lasting less than 1 msec. This phase of rapid depolarization is terminated when the fast  $Na^+$  channels suddenly close and the repolarization phase begins. Fast  $Na^+$  channels are interesting in that they can assume at least three conformations (three-dimensional forms).<sup>25</sup> In addition to the open and closed conformations, the fast

**FIGURE 3-25** A relatively large membrane potential results from the separation of a very small number of ions across the plasma membrane.

**FIGURE 3-26** Effects of changes in extracellular  $K^+$  level on the resting membrane potential. A high level of serum  $K^+$  results in a hypopolarization of the membrane. A low serum  $K^+$  level results in membrane hyperpolarization. With high serum  $K^+$  levels, the resting membrane potential is closer to threshold, making it easier to achieve an action potential. A low serum  $K^+$  level moves the resting membrane potential away from threshold, making it more difficult to achieve an action potential.

**FIGURE 3-27** The action potential (AP) in excitable cells is propagated along the membrane by the sequential opening of voltage-gated sodium channels in adjacent sections of membrane. **A**, An action potential is initiated by the opening of sodium channels in a section of membrane. **B**, The action potential is regenerated in adjacent sections of membrane as more sodium channels open. The initial segment repolarizes as sodium channels close and potassium ions move out of the cell.

Na<sup>+</sup> channel has a refractory form during which the channel will not reopen in response to another depolarizing stimulus (Figure 3-29). This refractory period limits the rate at which action potentials can be generated.

Two major factors contribute to cellular repolarization: sodium conductance (inflow) is stopped by closing Na<sup>+</sup> channels, as described previously, and K<sup>+</sup> conductance (outflow) through K<sup>+</sup> channels increases. Although cells are always permeable to K<sup>+</sup>, during repolarization additional voltage-gated K<sup>+</sup> channels open allowing a higher rate of K<sup>+</sup> efflux. These K<sup>+</sup> channels respond to depolarization of the membrane in the same manner as fast Na<sup>+</sup> channels, but they take much longer to open and close. When K<sup>+</sup> channels open, K<sup>+</sup> flows out of the cell, owing to the concentration gradient and the loss of intracellular negativity that accompanies Na<sup>+</sup> influx. The outward flow of positive intracellular potassium ions helps to quickly return the membrane potential to its negative RMP value.

Action potentials in cardiac muscle cells are more complex than the neuronal ones just described. Recall that contraction depends on the presence of free intracellular calcium ions. Because Ca<sup>2+</sup> carries a charge, its entry into the cell cytoplasm is reflected in the membrane potential. In skeletal muscle, most of the free cytosolic calcium ions come from intracellular stores (sarcoplasmic reticulum) that are released when the cell is depolarized. In cardiac muscle cells, Ca<sup>2+</sup> entry through voltage-gated channels in the plasma membrane is also important. Calcium conductance into the cell tends to prolong the action potential, resulting in a plateau phase (Figure 3-30). This is of functional importance in cardiac tissue, because it allows time for muscular contraction before another impulse is conducted and

prevents the potentially disastrous condition of cardiac muscle tetany. (For a more thorough discussion of cardiac electrophysiology, see Chapter 17.)

**KEY POINTS**

- The negative value of the RMP is determined by the ratio of intracellular to extracellular K<sup>+</sup> ion concentration. Changes in serum K<sup>+</sup> concentration can have profound effects on the RMP.
- Cells with voltage-gated ion channels are excitable and can produce and conduct action potentials. An action potential results from the opening of “fast” Na<sup>+</sup> channels, which allows Na<sup>+</sup> to rush into the cell.
- Repolarization is caused by closure of Na<sup>+</sup> channels and efflux of K<sup>+</sup> from the cell. In cardiac muscle, repolarization is prolonged owing to Ca<sup>2+</sup> influx through “slow” Ca<sup>2+</sup> channels.

**INTERCELLULAR COMMUNICATION AND GROWTH**

**Cell Signaling Strategies**

Cells in multicellular organisms need to communicate with one another and respond to changes in the cellular environment. Coordination of growth, cell division, and the functions of various tissues and organ systems is accomplished by three principal means of communication: (1) through gap junctions that directly connect the cytoplasm of adjoining cells; (2) by direct cell-to-cell contact of plasma membranes or the extracellular molecules associated with the cell (extracellular matrix); and (3) by secretion of chemical mediators (ligands) that influence cells some distance away (Figure 3-31).<sup>26</sup>

**Gap junctions** are found in many tissues. They are connecting channels between adjacent cells that allow the passage of small molecules from one cell to the next. These junctions are formed by special transmembrane proteins called connexins that associate to form pores of about 1.5 nm in width. Small molecules, such as inorganic ions, glucose, amino acids, nucleotides, and vitamins, may pass through the pores, whereas macromolecules (e.g., proteins, polysaccharides, and nucleic acids) are too large to pass through pores. Gap junctions are particularly important in tissues in which synchronized functions are required, such as cardiac muscle contraction, vascular tone, and intestinal peristaltic movements. Gap junctions appear to be important in embryogenesis as well. Cellular differentiation may be mediated in part through chemical signaling through gap junctions. (See Chapter 5 for a discussion of the development and differentiation of tissue types.)

Direct contact of cell membrane receptors with signaling molecules present on the surface of other cells or extracellular matrix is an important means of local communication among cells in tissues. Contact-dependent signaling is particularly important for the development of the immune response. Such cell-to-cell contact during fetal development is thought to allow the cells of the immune system to discriminate between foreign and self tissues and to develop self-tolerance. If cell-to-cell contact does not occur during fetal life, the immune cells may later attack the body’s own cells, leading to the development of autoimmune diseases. (See Chapter 10 for a discussion of autoimmunity.) There are four major families of cell adhesion molecules (CAMs): immunoglobulin-cell adhesion molecules (Ig-CAMs); cadherins; integrins; and selectins. These cell adhesion proteins make contacts between cells and with the extracellular matrix and provide signals that maintain cell survival and differentiated cell types (Figure 3-32).

The best understood form of cell communication is signaling through secreted molecules or *ligands*. Three strategies of intercellular chemical signaling have been described, relating to the distances over which they operate (Figure 3-33). *Synaptic* signaling is confined to the

**FIGURE 3-28** A typical neuronal action potential showing changes in membrane potential and the associated ion conductances. NOTE: mmho is a measure of conductance (amperes per volt), also called millisiemens (mS). The steep upstroke of the action potential is attributed to the sudden influx of  $\text{Na}^+$  through voltage-gated "fast" sodium ion channels. Voltage-gated  $\text{K}^+$  channels open more slowly and stay open longer to allow  $\text{K}^+$  efflux from the cell, which aids in repolarization.

**FIGURE 3-29** Three possible states of the voltage-gated sodium channel. In the open state,  $\text{Na}^+$  is allowed to pass. In the refractory state, the channel is blocked by the inactivation gate and will not open in response to a depolarizing stimulus. In the closed state, the channel will open in response to a membrane depolarization.

cells of the nervous system and occurs at specialized junctions between the nerve cell and its target cell. The neuron secretes a chemical neurotransmitter into the space between the nerve and target cell; the neurotransmitter then diffuses across this synaptic cleft and binds receptors on the postsynaptic cell. Synaptic signaling occurs over very small

distances (50 nm) and involves only one or a few postsynaptic target cells. In *paracrine* signaling, chemicals are secreted into a localized area and are rapidly destroyed, so that only cells in the immediate area are affected. Growth factors (GFs), for example, act locally to promote wound healing without affecting the growth of the entire organism. *Endocrine* signaling is accomplished by specialized endocrine cells that secrete hormones that travel via the bloodstream to target cells widely distributed throughout the body. Endocrine signaling is slow in comparison to nervous signaling, because it relies on diffusion and blood flow to target tissues.

A fourth type of signaling, *autocrine* signaling, occurs when cells are able to respond to signaling molecules that they secrete. Autocrine communication provides a feedback signal to the secreting cell and is commonly linked to pathways that regulate ligand secretion rates. Abnormal autocrine stimulation is thought to be a mechanism in some forms of cancer (see Chapter 7).

Target cells respond to ligand signaling through specific protein *receptors*. Cells can respond to a particular ligand only if they possess the appropriate receptor. For example, all cells of the body are exposed to thyroid-stimulating hormone (TSH) as it circulates in the blood, but only thyroid cells respond because they alone possess TSH receptors. However, cells that possess the same receptor may respond very differently to a particular ligand. For example, binding of acetylcholine to its receptor on a glandular cell may induce secretion, whereas binding to the same receptor on a cardiac muscle cell causes a decrease in contractile force. The cellular response to signaling molecules is regulated both by the array of receptors the cell carries and by the internal machinery to which the receptors are linked.

**FIGURE 3-30** A typical cardiac muscle cell action potential showing the ion fluxes associated with each phase. Note that the repolarization phase is prolonged in comparison to the nerve action potential in Figure 3-28. This occurs because  $\text{Ca}^{2+}$  influx offsets the repolarizing effect of  $\text{K}^{+}$  efflux and a plateau in the membrane potential is seen. When the  $\text{Ca}^{2+}$  channels close, the membrane quickly repolarizes.

### Cell Surface Receptor–Mediated Responses

Most hormones, local chemical mediators, and neurotransmitters are water-soluble molecules that are unable to pass through the lipid bilayer of the cell. These ligands exert their effects through binding with a receptor on the surface of the target cell, which then changes or transduces the external signal into an intracellular message. There are

**FIGURE 3-31** Methods used for intercellular communication.

**FIGURE 3-32** Cell adhesion proteins interact with the extracellular matrix (integrins) and with neighboring cells to maintain cell survival and differentiation. (Redrawn from Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby.)

**FIGURE 3-33** Signaling by secreted ligands can occur over variable distances. **A**, Synaptic signaling over a very small distance between neuron and target cell. **B**, Paracrine signaling through the extracellular fluid between cells in a tissue. **C**, Long-range signaling from endocrine cells through the bloodstream to distant targets. **D**, Localized autocrine signaling in which the secreting cell is also the target cell.

**FIGURE 3-34** There are three major types of cell surface receptor proteins. **A**, Ion channel-linked receptors are also called ligand-gated channels. When the ligand binds, they open to allow specific ions through the membrane. **B**, Enzyme-linked receptors become activated kinases when a ligand binds to them. Kinases phosphorylate target proteins and change their activity. **C**, G-protein-linked (coupled) receptors have seven membrane-spanning segments with a ligand-binding pocket on the outside and a G-protein-activating portion on the inside. G-protein-linked receptors activate G-proteins, which in turn influence enzymes that produce second messengers.

three major classes of cell surface receptor proteins: ion channel-linked, enzyme-linked, and G-protein-coupled (Figure 3-34).<sup>26</sup>

*Ion channel-linked* receptors bind neurotransmitters, causing specific ion channels in the membrane to open or close. This type of signaling is prevalent in the nervous system, where rapid synaptic signaling between neurons is required. *Enzyme-linked* receptors catalyze enzyme reactions when they are activated by appropriate ligands. Nearly all enzyme-linked receptors function as *protein kinases*; that is, they mediate the transfer of phosphate groups from ATP (or GTP) to proteins (phosphorylate), and thus affect the activity of those proteins. The insulin receptor and most growth factor receptors are protein kinase receptors that phosphorylate and activate intracellular enzyme cascades. Enzyme-linked kinase receptors activate common kinase cascades including the PI3K-protein kinase B pathway, the RAS-MAP kinase pathway, and the JAK-STAT pathway (Figure 3-35).

A large number of signaling ligands bind to *G-protein-coupled receptors* (GPCRs). Most hormones and many drugs have their effects through G-protein-linked cascades. G-protein-coupled receptors act indirectly through a membrane-bound trimeric G-protein that binds GTP when activated by the receptor. The activated  $\alpha$  subunit of the trimeric G-protein influences the activity of specific target enzymes. The target enzymes of G-proteins produce second messengers that trigger specific intracellular cascades and alter cell function (Figure 3-36). The  $\alpha$  subunit of G-proteins has intrinsic enzyme activity that degrades GTP into GDP and  $P_i$  after a time. When GTP is bound, the G-protein is in the right conformation to activate its downstream targets, but when GTP is hydrolyzed to GDP and  $P_i$ , the G-protein resumes its inactive conformation and the activity of the signaling cascade is terminated.

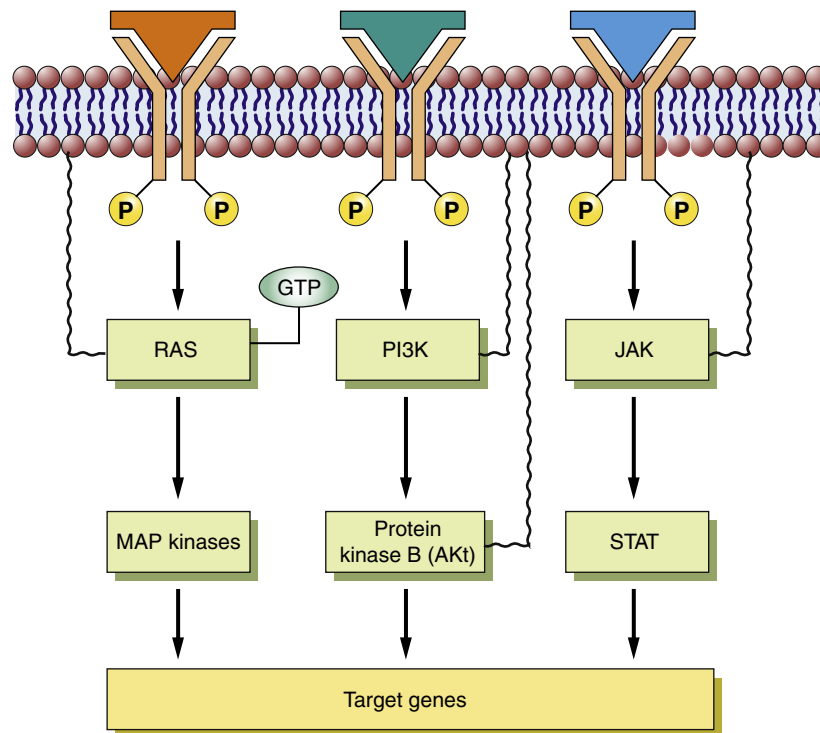

There are three principal G-protein-coupled signaling systems that, when activated, alter the intracellular concentration of one or more second messengers (see Figure 3-36). Numerous receptors

activate trimeric G-proteins whose  $\alpha$  subunit stimulates adenylyl cyclase to produce the second messenger cyclic adenosine monophosphate (cAMP). These G-proteins are called  $G_s$ . An increase in cAMP concentration is linked to different signaling cascades in different cell types. For example, cAMP causes glycogen breakdown in liver cells, increased force of contraction in cardiac cells, and increased secretion by glandular cells. Various cell types respond differently to the same second messenger because of differences in enzymes and other proteins in the cell.

Another important G-protein-coupled cascade is mediated by G-proteins called  $G_q$  whose  $\alpha$  subunit stimulates the enzyme phospholipase C. Phospholipase C cleaves a membrane phospholipid (PI[4,5]  $P_2$ ) to form two second messengers—inositol 1,4,5-trisphosphate ( $IP_3$ ) and diacylglycerol (DAG) (see Figure 3-36). The  $IP_3$  travels to the endoplasmic reticulum, where it stimulates the release of  $Ca^{2+}$  into the cytoplasm. The  $Ca^{2+}$  then triggers a change in cell function. DAG remains bound to the inner surface of the plasma membrane and can trigger several different intracellular cascades. Two important targets are the protein kinase C pathway and the eicosanoid pathway. Protein kinase C is a key enzyme in the growth response. The eicosanoid pathway results in the production of several arachidonic acid derivatives, including prostaglandins. These products are often secreted by the cell as signaling molecules to other nearby cells. Prostaglandins are important mediators of inflammation and platelet function.

The third trimeric G-protein type is called  $G_i$  because it is inhibitory to the production of cAMP. G-protein-coupled receptors such as the acetylcholine receptor in the heart activate  $G_i$ , whose  $\alpha$  subunit then inhibits adenylyl cyclase (see Figure 3-36). In this case, the  $\gamma\beta$  subunit of  $G_i$  is also activated and opens membrane potassium channels in the heart, which tend to slow the heart rate.

In addition to the four second messengers already mentioned (cAMP,  $IP_3$ , DAG, and  $Ca^{2+}$ ) there is a fifth called *cyclic guanosine*

**FIGURE 3-35** Many growth factor receptors activate protein kinase cascades within the cell. Three common pathways are shown. After binding of ligand, the receptor dimerizes and becomes phosphorylated. A cascade of kinase activations is initiated resulting in a change in target gene transcription. *GTP*, Guanosine triphosphate; *JAK*, janus kinase; *MAP*, mitogen-activated kinase; *PI3K*, phosphoinositide 3-kinase; *RAS*, rat sarcoma protein; *STAT*, signal transducer and activator of transcription.

*monophosphate* (cGMP), which is produced by the enzyme guanylyl cyclase (Figure 3-37). The primary activator of guanylyl cyclase is a small lipid-soluble gas molecule called *nitric oxide*. Nitric oxide is an important signaling molecule with widespread targets. It functions as a neurotransmitter in the brain and is an important smooth muscle relaxant in the vascular system. cGMP is also produced by a special class of enzyme-linked receptors (see Figure 3-37).

To be effective at communicating signals, all the receptor systems must be quickly turned off so that they can be responsive to the next incoming signal. A variety of strategies are used to quench the signaling cascades (Figure 3-38). For example, phosphodiesterases are enzymes that convert the cyclic nucleotides cAMP and cGMP to their inactive forms, AMP and GMP, respectively, and help to remove these second messengers soon after they are formed. Some drugs, such as caffeine and sildenafil citrate (Viagra), are phosphodiesterase inhibitors that slow the normal breakdown of cyclic nucleotides and prolong their activity. Many of the intracellular signaling cascades rely on kinases that phosphorylate their target proteins so as to change their activity. The action of kinases is countered by numerous phosphatase enzymes that quickly cleave the phosphates off the target proteins and inhibit their activity.

The cell also can regulate the activity and number of receptors on the cell surface.<sup>26</sup> Generally a cell decreases the number or activity of receptors when it is exposed to excessive concentrations of signaling molecules (see Figure 3-38). Receptors can be internalized in the cell where they are inactive but are available for later use, or they can be sent to lysosomes for degradation. Destruction of receptors in lysosomes is called *down-regulation*. (The production of extra receptors is called *up-regulation*.) Receptors that remain in the membrane also can be inhibited by phosphorylation, which blocks them from interacting

with their intracellular targets. Receptors that can bind ligand but do not produce a response are said to be uncoupled. The proteins that phosphorylate G-protein receptors are called G-protein-receptor kinases (GRKs). The mechanisms that “turn off” signaling cascades are vitally important to maintaining a responsive communication system.

### Intracellular Receptor–Mediated Responses

A small number of hormones are lipid soluble and can pass directly through the cell membrane to interact with receptors *inside* the cell. These receptors are located in the cell cytosol (e.g., cortisol) or may be associated with the cell nucleus. Intracellular receptors are specific for a particular ligand, just as surface receptors are. Binding of the ligand causes the receptor to become activated. Because lipid-soluble ligands enter the cell directly, no second messengers are needed. An activated cytosolic steroid receptor travels to the nucleus, where it binds with specific genes and regulates their activity (Figure 3-39). Thyroid receptors are also located within the cell. Thyroid hormone enters the cell through carriers in the membrane and travels to the nucleus. The thyroid receptor is already bound to DNA in the absence of thyroid hormone. When thyroid hormone finds its nuclear receptor, the complex dissociates and removes an inhibitory influence on gene transcription. Cellular responses to these gene regulatory receptor complexes are slow in comparison to the cell surface receptor responses and generally last longer.

### Regulation of Cellular Growth and Proliferation

In multicellular organisms such as humans, the growth and proliferation of cells and tissues must be strictly controlled to maintain a balance between cell birth rate and cell death rate. The system must be capable of rapidly increasing proliferation of a particular tissue to replace cells

**FIGURE 3-36** G-protein–coupled signaling. When the ligand binds to the receptor, an intracellular domain is changed into an active configuration that can interact with inactive trimeric G-proteins. The receptor induces the G-protein to release its bound GDP and P<sub>i</sub> in exchange for a GTP molecule. When GTP binds to the α subunit of the G-protein, it is activated and diffuses away from the γβ subunits to find its target enzyme (adenylyl cyclase [AC] or phospholipase C). The α GTP stimulates its target enzyme to produce a second messenger, which in turn activates a signaling cascade within the cell. After a time, the α subunit hydrolyzes its GTP to GDP and P<sub>i</sub> and becomes inactive. The α subunit is now in the correct conformation to reassociate with the γβ subunits and await another signal from the receptor. **A**, The G<sub>s</sub> pathway increases the production of cyclic adenosine monophosphate (cAMP). **B**, The G<sub>q</sub> pathway increases the production of inositol 1,4,5-trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). **C**, The G<sub>i</sub> pathway is inhibitory to the production of cAMP. In some cases the γβ subunit also has functional activity and may regulate ion channels. ER, Endoplasmic reticulum; PKC, protein kinase C.

**FIGURE 3-37** Cyclic GMP (*cGMP*) is an important second messenger. **A**, It can be synthesized by enzyme-linked receptors that are activated by water-soluble ligands such as atrial natriuretic peptide. **B**, Nitric oxide is an important signaling molecule that is lipid soluble and can diffuse across the cell membrane. Nitric oxide binds to and stimulates the enzyme guanylyl cyclase to produce *cGMP*.

**FIGURE 3-38** A variety of mechanisms exist to inhibit receptor-mediated signaling cascades. **A**, Phosphorylation of the receptor by receptor kinases such as G-protein receptor kinases (*GRKs*) uncouples the enzyme from its intracellular cascade. **B**, Receptor internalization temporarily reduces the number of receptors displayed at the cell surface. **C**, Receptor degradation results in a long-term reduction in receptors (down-regulation). **D**, The cyclic nucleotide second messengers can be degraded by phosphodiesterase enzymes to stop the intracellular cascade. **E**, Phosphatase enzymes counteract the phosphorylating activities of kinases and inhibit the intracellular cascade.

**FIGURE 3-39** Lipid-soluble ligands, such as steroid hormones and gases, can diffuse across the cell membrane and interact with receptors located within the cell cytoplasm or nucleus. Thyroid hormone is not lipid soluble and enters the cell through a carrier to interact with its intracellular receptor. When the ligand binds to its intracellular receptor, it forms a functional gene regulatory protein that affects the rate of transcription of its target genes. The response of the cell to intracellular ligands is generally slow and long lasting.

lost to injury and normal wear and tear while simultaneously inhibiting unwanted growth or proliferation of other cells. Special intercellular communication systems function to regulate the replication of individual cells in the body. Two important strategies of cell cycle control have been described. First, a variety of protein mitogens and growth factors are required in specific combinations for growth and proliferation of particular cell types. Second, cells respond to spatial signals from the extracellular matrix (from integrin receptors) and neighboring cells (from cell adhesion proteins) that indicate how much room is available. When conditions favor cell proliferation, the cell proceeds through the stages of the cell cycle (Figure 3-40). Dormant cells remain in  $G_1$  phase indefinitely. Cycling cells proceed through  $G_1$ , S phase (synthesis),  $G_2$ , M phase (mitosis), and cell division. S phase is characterized by duplication of DNA and synthesis of intracellular components in preparation for cell division. M phase, or mitosis, proceeds through six stages, beginning with prophase, in which the chromosomes condense and become visible, and ending with cytokinesis, when cell division is accomplished. The chromosomes of body cells are duplicated and distributed equally to the cell's progeny when it divides by mitosis, such that each daughter cell receives an identical full set of 46 chromosomes. The stages of mitotic cell division are explained in Figure 3-41. Mitosis is responsible for the proliferation of body cells in which little genetic variation is needed or desired. A more elaborate cell division process, meiosis, occurs in the germ cells (egg and sperm), where significant chromosomal rearrangements occur (see Chapter 6).

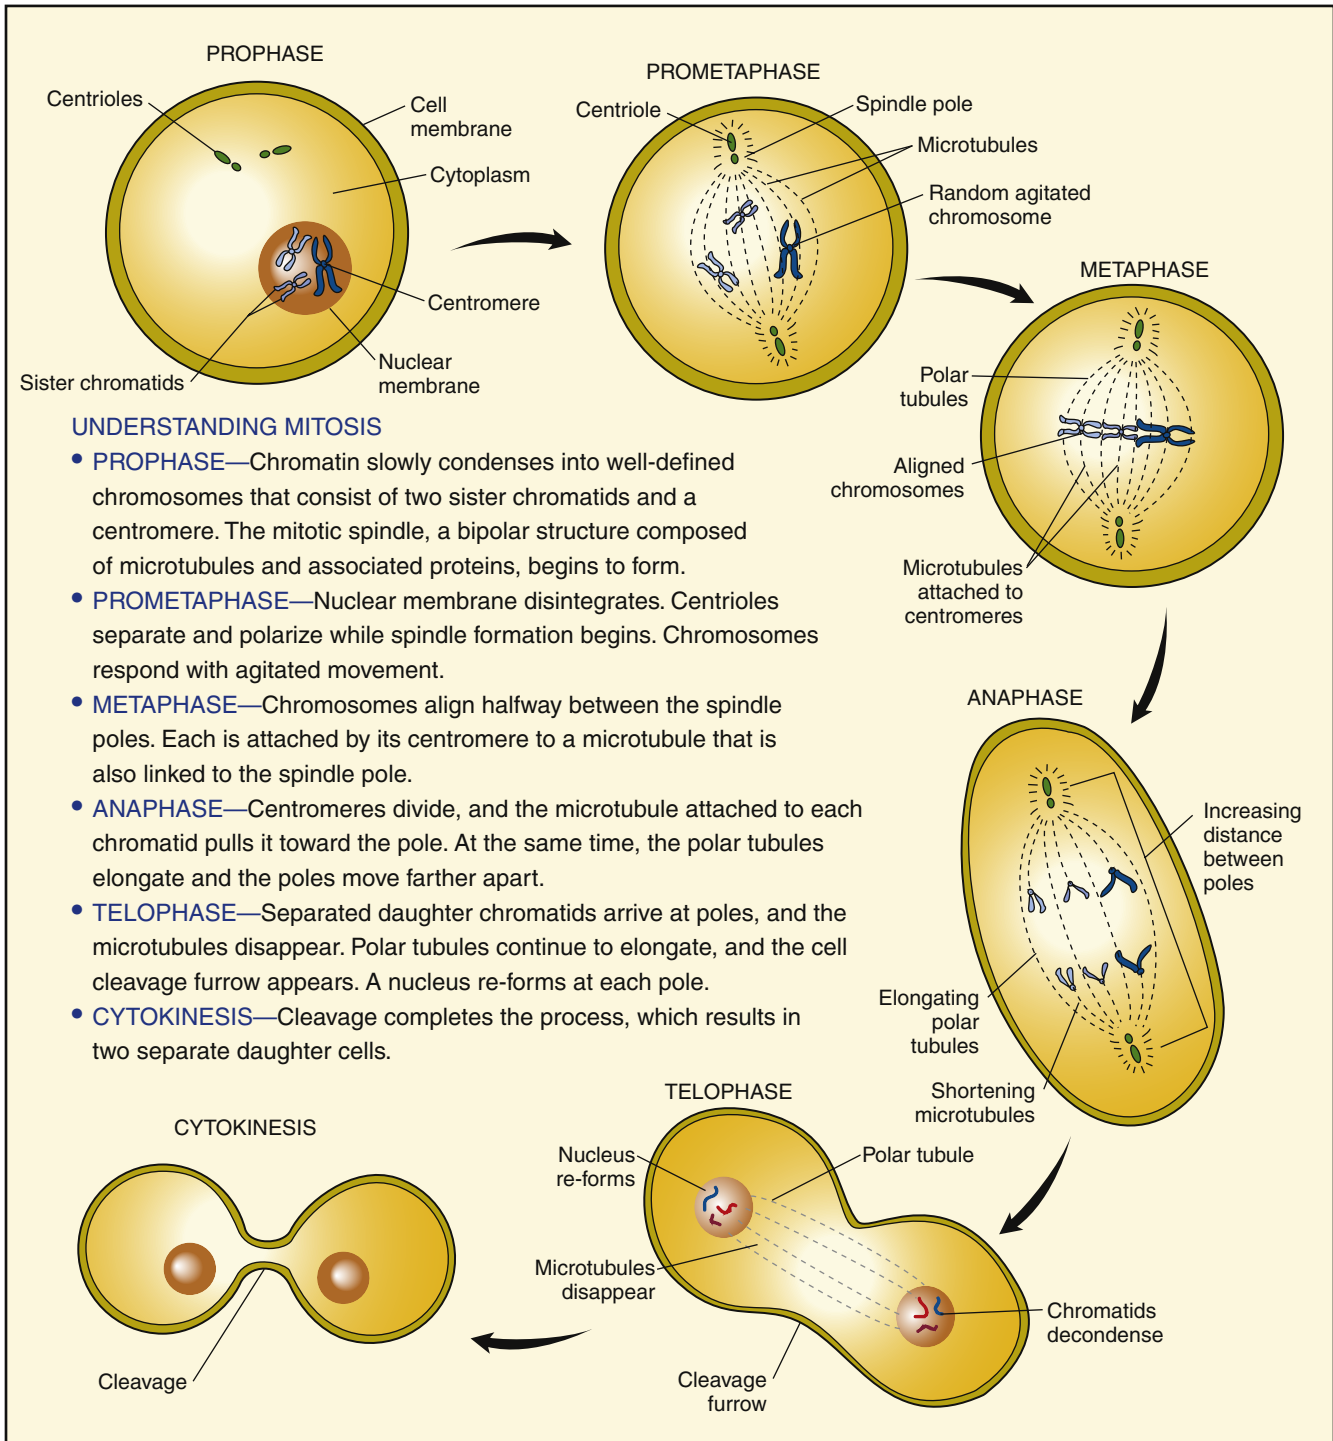

The **cell cycle** has been the subject of intense study in recent years because of its importance in cancer biology. Cancer cells continue to grow and divide unchecked, despite the lack of appropriate signals to stimulate them. Of particular interest are the events that prod the cell from its dormant state and cause it to begin the cycle. A simplified picture of a major component of this complex process is shown in Figure 3-42. The Rb protein (or pRb) is of central importance in preventing a cell from proceeding through the cell cycle.<sup>27</sup> The Rb protein functions to bind gene transcription factors called E2F so that they are unable to bind to DNA promoter regions and begin the processes of cell replication. The Rb protein can be induced to release the E2F transcription factors when appropriate mitogen signals arrive at the cell surface.

**FIGURE 3-40** Events of the cell cycle. The cycle begins late in  $G_1$  when the cell passes a restriction point. The cell then proceeds systematically through the S phase (synthesis),  $G_2$ , and M phase (mitosis).

These proliferation-promoting signals at the cell surface are transmitted to the Rb protein by way of cyclin-dependent signaling pathways within the cell. Proteins called *cyclins* accumulate in the cell and then bind to and activate cyclin-dependent kinases (cdk). The cdk then phosphorylates the Rb protein, changing its affinity for E2F so that it is released. The E2F then translocates to specific regions of DNA where it regulates more than 500 genes and promotes cell replication.<sup>28</sup>

To respond to a mitogen growth factor, a cell must have the corresponding receptor on its cell surface. Many cells in the body synthesize

**FIGURE 3-41** Six stages of mitotic cell division. (Redrawn from Nichols FH, Zwelling E, editors: *Maternal-newborn nursing: theory and practice*, Philadelphia, 1997, Saunders, p 307.)

**FIGURE 3-42** The mechanism of initiation of cellular replication requires appropriate stimulation by extracellular growth factors that bind their complementary receptors on the cell surface. Activation of the receptor stimulates signaling pathways within the cell that increase cyclin proteins. The cyclins bind to cyclin-dependent kinases (*Cdks*) to form active enzyme complexes. The active cyclin-Cdk enzymes phosphorylate Rb protein (*pRb*), inducing it to release E2F transcription factors that initiate replication. In the absence of appropriate growth factor signals, the Rb protein functions to inhibit unwanted cell proliferation.

and secrete mitogens, which then influence the proliferation of other cell types in a paracrine or endocrine fashion. Platelet-derived growth factor (PDGF) was one of the first mitogens to be discovered. It is secreted by platelets when they form blood clots in response to an injury. PDGF stimulates fibroblasts and smooth muscle cells in the damaged area to divide and replace cells lost to the injury. Numerous mitogens have been identified, and most cells require an appropriate combination of mitogen signals before they can enter the cell cycle. There are many signaling steps in the pathway from mitogen receptor to DNA activation. Somatic cells respond to growth factors by increasing cell size, whereas stem cell populations undergo cell division. Thus the same signaling ligands may have different effects depending on cell type and conditions. Similar signaling pathways may also trigger cell death (apoptosis) when cells have to be reduced or removed during tissue development and remodeling. The processes of abnormal cellular proliferation and cancer are further detailed in Chapter 7. The process of apoptosis is described in Chapter 4.

#### KEY POINTS

- Intercellular communication is accomplished by three principal means: (1) gap junctions, which directly connect the cytoplasm of adjoining cells; (2) direct cell-to-cell surface contact; and (3) secretion of chemical mediators (ligands). Most ligands are water-soluble molecules that interact with receptors on the cell surface. These receptors are of three general types: ion channel linked, enzyme linked, and G-protein coupled.
- Binding of a ligand to a G-protein receptor controls the production of second messengers (cAMP, IP<sub>3</sub>, DAG, Ca<sup>2+</sup>) within the target cell that initiate changes in cell function.
- Somatic cells divide by a process called *mitosis* in which daughter cells each receive an identical and complete set of 46 chromosomes.
- Cell replication normally requires specific extracellular mitogens that activate signaling systems within the cell. Cyclin proteins and cyclin-dependent kinases alter the function of Rb protein, causing it to release transcription factors that begin the process of cell replication.

## SUMMARY

Detailed knowledge of cell physiology is essential to understanding disease processes. Cells are complex, membrane-bound units that perform a variety of functions necessary to the maintenance of life. The major cell components and their functions are summarized in Table 3-1. The cell membrane is an important cellular structure that protects the cell interior and mediates information transfer to and from the extracellular environment. Proteins embedded in the membrane lipid bilayer perform most of the membrane functions, including transduction of extracellular messages, membrane transport, electrical excitation, and cell-to-cell communication.

Human cells have several important intracellular organelles. These include the cytoskeleton, which organizes the intracellular compartment;

the nucleus, which holds the cell's genetic material and directs the daily activities of the cell; the endoplasmic reticulum and the Golgi apparatus, which produce, package, and transport proteins and lipids to the plasma membrane and lysosomes; the lysosomes and peroxisomes, which perform the task of intracellular digestion of organic waste; and the mitochondria, which produce cellular energy in the form of ATP. The energy released by ATP hydrolysis is used by the cell to drive the many energetically unfavorable reactions needed to maintain cellular functions. Multicellular organisms have developed complex communication systems to control cell behavior, such as growth and differentiation into specialized cell types. Disruption of these cellular processes is at the root of pathophysiologic processes and disease.

**TABLE 3-1 STRUCTURE AND FUNCTION OF MAJOR CELLULAR COMPONENTS**

CELLULAR STRUCTURE	FUNCTIONS
Plasma membrane	Protective barrier separates life from nonlife Extracellular message transduction Transport of materials into and out of cell Maintenance and transmission of membrane potentials
Cytoskeleton	Cell-to-cell recognition, interaction Maintenance of cell shape Cell movement Trafficking within cell
Nucleus	Protection of genetic material Regulation of cell type and function through control of protein synthesis
Endoplasmic reticulum	Protein and lipid synthesis Lipid metabolism and detoxification
Golgi apparatus	Protein and lipid modification and sorting Transport of proteins and lipids to appropriate destinations
Lysosomes	Hydrolytic breakdown of organic waste
Peroxisomes	Oxidative breakdown of organic waste
Mitochondria	Cellular energy production (ATP)

ATP, Adenosine triphosphate.

## KEY QUESTIONS

- What are the usual cellular responses to reversible injury?
- How are reversible and irreversible cellular injuries differentiated?
- How do necrosis and apoptosis differ?
- To what kind of injuries are cells susceptible?
- What are the usual physiologic changes of aging and how are these differentiated from disease?

## CHAPTER OUTLINE

### Reversible Cell Injury, 58

- Hydropic Swelling, 58
- Intracellular Accumulations, 58

### Cellular Adaptation, 60

- Atrophy, 60
- Hypertrophy, 61
- Hyperplasia, 61
- Metaplasia, 61
- Dysplasia, 62

### Irreversible Cell Injury, 62

- Necrosis, 62
- Apoptosis, 64

### Etiology of Cellular Injury, 66

- Ischemia and Hypoxic Injury, 66
- Nutritional Injury, 67
- Infectious and Immunologic Injury, 67
- Chemical Injury, 69
- Physical and Mechanical Injury, 69

### Cellular Aging, 71

- Cellular Basis of Aging, 71
- Physiologic Changes of Aging, 72

### Somatic Death, 72

Disease and injury are increasingly being understood as cellular and genetic phenomena. Although pathophysiologic processes are often presented in terms of systemic effects and manifestations, ultimately it is the *cells* that make up the systems that are affected. Even complex multisystem disorders such as cancer ultimately are the result of alterations in cell function. As the mysterious mechanisms of diseases are understood on the cellular and molecular levels, more specific methods of diagnosis, treatment, and prevention can be developed. This chapter presents the general characteristics of cellular injury, adaptation, aging, and death that underlie the discussions of systemic pathophysiologic processes presented in later chapters of this text.

Cells are confronted by many challenges to their integrity and survival and have efficient mechanisms for coping with an altered cellular environment. Cells respond to environmental changes or injury in three general ways: (1) when the change is mild or short-lived, the cell may withstand the assault and completely return to normal. This is called a *reversible cell injury*. (2) The cell may adapt to a persistent but sublethal injury by changing its structure or function. Generally, adaptation also is reversible. (3) Cell death may occur if the injury is too severe or prolonged. Cell death is irreversible and may occur by two different processes termed *necrosis* and *apoptosis*. Necrosis is cell death caused by external injury, whereas apoptosis is triggered by intracellular

signaling cascades that result in cell suicide. Necrosis is considered to be a pathologic process associated with significant tissue damage, whereas apoptosis may be a normal physiologic process in some instances and pathologic in others.

## REVERSIBLE CELL INJURY

Regardless of the cause, reversible injuries and the early stages of irreversible injuries often result in cellular swelling and the accumulation of excess substances within the cell. These changes reflect the cell's inability to perform normal metabolic functions owing to insufficient cellular energy in the form of adenosine triphosphate (ATP) or dysfunction of associated metabolic enzymes. Once the acute stress or injury has been removed, by definition of a reversible injury, the cell returns to its preinjury state.

### Hydropic Swelling

Cellular swelling attributable to accumulation of water, or hydropic swelling, is the first manifestation of most forms of reversible cell injury.<sup>1</sup> Hydropic swelling results from malfunction of the sodium-potassium ( $\text{Na}^+\text{-K}^+$ ) pumps that normally maintain ionic equilibrium of the cell. Failure of the  $\text{Na}^+\text{-K}^+$  pump results in accumulation of sodium ions within the cell, creating an osmotic gradient for water entry. Because  $\text{Na}^+\text{-K}^+$  pump function is dependent on the presence of cellular ATP, any injury that results in insufficient energy production also will result in hydropic swelling (Figure 4-1). Hydropic swelling is characterized by a large, pale cytoplasm, dilated endoplasmic reticulum, and swollen mitochondria. With severe hydropic swelling, the endoplasmic reticulum may rupture and form large water-filled vacuoles. Generalized swelling in the cells of a particular organ will cause the organ to increase in size and weight. Organ enlargement is indicated by the suffix *-megaly* (e.g., *splenomegaly* denotes an enlarged spleen, *hepatomegaly* denotes an enlarged liver).

### Intracellular Accumulations

Excess accumulations of substances in cells may result in cellular injury because the substances are toxic or provoke an immune response, or merely because they occupy space needed for cellular functions. In some cases, accumulations do not in themselves appear to be injurious but rather are indicators of cell injury. Intracellular accumulations may be

categorized as (1) excessive amounts of normal intracellular substances such as fat, (2) accumulation of abnormal substances produced by the cell because of faulty metabolism or synthesis, and (3) accumulation of pigments and particles that the cell is unable to degrade (Figure 4-2).

Normal intracellular substances that tend to accumulate in injured cells include lipids, carbohydrates, glycogen, and proteins. Faulty metabolism of these substances within the cell results in excessive intracellular storage. In some cases, the enzymes required for breaking down a particular substance are absent or abnormal as a result of a genetic defect. In other cases, altered metabolism may be due to excessive intake, toxins, or other disease processes.

A common site of intracellular lipid accumulation is the liver, where many fats are normally stored, metabolized, and synthesized. Fatty liver is often associated with excessive intake of alcohol.<sup>2</sup> Mechanisms whereby alcohol causes fatty liver remain unclear, but it is thought to result from direct toxic effects as well as the preferential metabolism of alcohol instead of lipid (see Chapter 38 for a discussion of fatty liver). Lipids may also contribute to atherosclerotic diseases and accumulate in blood vessels, kidney, heart, and other organs. Fat-filled cells tend to compress cellular components to one side and cause the tissue to appear yellowish and greasy (Figure 4-3). In several genetic disorders, the enzymes needed to metabolize lipids are impaired; these include Tay-Sachs disease and Gaucher disease, in which lipids accumulate in neurologic tissue.

Glycosaminoglycans (mucopolysaccharides) are large carbohydrate complexes that normally compose the extracellular matrix of connective tissues. Connective tissue cells secrete most of the glycosaminoglycan into the extracellular space, but a small portion remains inside the cell and is normally degraded by lysosomal enzymes. The *mucopolysaccharidoses* are a group of genetic diseases in which the enzymatic degradation of these molecules is impaired and they collect within the cell. Mental disabilities and connective tissue disorders are common findings.

Like other disorders of accumulation, *excessive glycogen storage* can be the result of inborn errors of metabolism, but a common cause is diabetes mellitus.<sup>1</sup> Diabetes mellitus is associated with impaired cellular uptake of glucose, which results in high serum and urine glucose levels. Cells of the renal tubules reabsorb the excess filtered glucose and store it intracellularly as glycogen. The renal tubule cells also are a common site for abnormal accumulations of proteins. Normally, very little

**FIGURE 4-1** Cellular swelling in kidney tubule epithelial cells. **A**, Normal kidney tubule with cuboidal cells; **B**, early ischemic changes showing surface blebs and swelling of cells. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 14. Photograph courtesy Drs. Neal Pinckard and M. A. Venkatachalam, University of Texas Health Sciences Center, San Antonio, TX.)

protein escapes the bloodstream into the urine. However, with certain disorders, renal glomerular capillaries become leaky and allow proteins to pass through them. Renal tubule cells recapture some of the escaped proteins through endocytosis, resulting in abnormal accumulation.

Cellular stress may lead to accumulation and aggregation of denatured proteins. The abnormally folded intracellular proteins may cause

serious cell dysfunction and death if they are allowed to persist in the cell. A family of stress proteins (also called chaperone or heat-shock proteins) is responsible for binding and refolding aberrant proteins back into their correct three-dimensional forms (Figure 4-4). If the chaperones are unsuccessful in correcting the defect, the abnormal proteins form complexes with another protein called *ubiquitin*. Ubiquitin targets the abnormal proteins to enter a proteasome complex, where they are digested into fragments that are less injurious to cells (see Figure 4-4). In some cases, the accumulated substances are not metabolized by normal intracellular enzymes. In diabetes, for instance, high serum glucose levels result in excessive glucose uptake by neuronal cells because they do not require insulin for glucose uptake.<sup>3</sup> (Diabetes mellitus is discussed in Chapter 41.)

Finally, a variety of pigments and inorganic particles may be present in cells. Some pigment accumulations are normal, such as the accumulation of melanin in tanned skin, whereas others signify pathophysiologic processes. Pigments may be produced by the body (endogenous) or may be introduced from outside sources (exogenous). In addition to melanin, the iron-containing substances hemosiderin and bilirubin are endogenous pigments that, when present in excessive amounts, indicate disease processes. Hemosiderin and bilirubin are derived from hemoglobin. Excessive amounts may indicate abnormal breakdown of hemoglobin-containing red blood cells (RBCs), prolonged administration of iron, and the presence of hepatobiliary disorders. Inorganic particles that may accumulate include calcium, tar, and mineral dusts such as coal, silica, iron, lead, and silver. Mineral dusts generally are inhaled and accumulate in lung tissue (Figure 4-5). Inhaled dusts cause chronic inflammatory reactions in the lung, which generally result in destruction of pulmonary alveoli and capillaries and the formation of scar tissue. Over many years, the lung may become stiff and difficult to expand because of extensive scarring (see Chapter 23).

Deposits of calcium salts occur in conditions of altered calcium intake, excretion, or metabolism. Impaired renal excretion of phosphate may result in the formation of calcium phosphate salts that are deposited in the tissues of the eye, heart, and blood vessels. Calcification of the heart valves may cause obstruction to blood flow through the heart or interfere with valve closing. Calcification of blood vessels may result in narrowing of vessels and insufficient blood flow to distal tissues. Dead

**FIGURE 4-2** General mechanisms of intracellular accumulation: (1) abnormal metabolism as in fatty change in the liver, (2) mutations causing alterations in protein folding and transport so that defective proteins accumulate, (3) deficiency of critical enzyme responsible for lysosomal degradation, and (4) an inability to degrade phagocytosed particles such as coal dust. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 33.)

**FIGURE 4-3** Fatty liver showing large intracellular vacuoles of lipid. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 34. Photograph courtesy Dr. James Crawford, Department of Pathology, University of Florida School of Medicine, Gainesville, FL.)

**FIGURE 4-4** Roles of chaperone proteins in protein refolding and ubiquitin in protein degradation after stress-induced protein damage. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 31.)

**FIGURE 4-5** Accumulations of silicon dust in tissues of the lung. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 699. Photograph courtesy Dr. John Goldeski, Brigham and Women's Hospital, Boston, MA.)

and dying tissues often become calcified (filled with calcium salts) and appear as dense areas on x-ray films. For example, lung damage resulting from tuberculosis often is apparent as calcified areas, called *tubercles*.

With the exception of inorganic particles, the intracellular accumulations generally are reversible if the causative factors are removed.

#### KEY POINTS

- Hydropic swelling is an early indicator of cell injury. It results from  $\text{Na}^+\text{-K}^+$  pump dysfunction at the cell membrane.
- Intracellular accumulations of abnormal endogenous or exogenous particles indicate a disorder of cellular metabolism.
- Damage from accumulation of abnormal intracellular protein is limited by chaperone proteins that attempt to refold the protein into its correct shape and by the ubiquitin-proteasome system that digests targeted proteins into fragments.

**FIGURE 4-6** The adaptive cellular responses of atrophy, hypertrophy, hyperplasia, metaplasia, and dysplasia.

## CELLULAR ADAPTATION

The cellular response to persistent, sublethal stress reflects the cell's efforts to adapt. Cellular stress may be due to an increased functional demand or a reversible cellular injury. Although the term **adaptation** implies a change for the better, in some instances an adaptive change may not be beneficial. The common adaptive responses are atrophy (decreased cell size), hypertrophy (increased cell size), hyperplasia (increased cell number), metaplasia (conversion of one cell type to another), and dysplasia (disorderly growth) (Figure 4-6). Each of these changes is potentially reversible when the cellular stress is relieved.

### Atrophy

**Atrophy** occurs when cells shrink and reduce their differentiated functions in response to a variety of normal and injurious factors. The general causes of atrophy may be summarized as (1) disuse, (2) denervation, (3) ischemia, (4) nutrient starvation, (5) interruption of endocrine signals, (6) and persistent cell injury. Apparently, atrophy represents an effort by the cell to minimize its energy and nutrient consumption by decreasing the number of intracellular organelles and other structures.

A common form of atrophy is the result of a reduction in functional demand, sometimes called **disuse atrophy**. For example, immobilization by bed rest or casting of an extremity results in shrinkage of skeletal muscle cells. On resumption of activity, the tissue resumes its normal size. Denervation of skeletal muscle results in a similar decrease in muscle size caused by loss of nervous stimulation. Inadequate blood supply to a tissue is known as **ischemia**. If the blood supply is totally interrupted, the cells will die, but chronic sublethal ischemia usually results in cell atrophy. The heart, brain, kidneys, and lower leg are common sites of ischemia. Atrophic changes in the lower leg attributable to ischemia include thin skin, muscle wasting, and hair loss. Atrophy also is a consequence of chronic nutrient starvation, whether the result of poor intake, absorption, or distribution to the tissues. Many glandular tissues throughout the body depend on growth-stimulating (trophic) signals to maintain size and function. For example, the adrenal cortex, thyroid, and gonads are maintained by trophic hormones from the pituitary gland and will atrophy in their absence. Atrophy that results from persistent cell injury is most commonly related to chronic inflammation and infection.

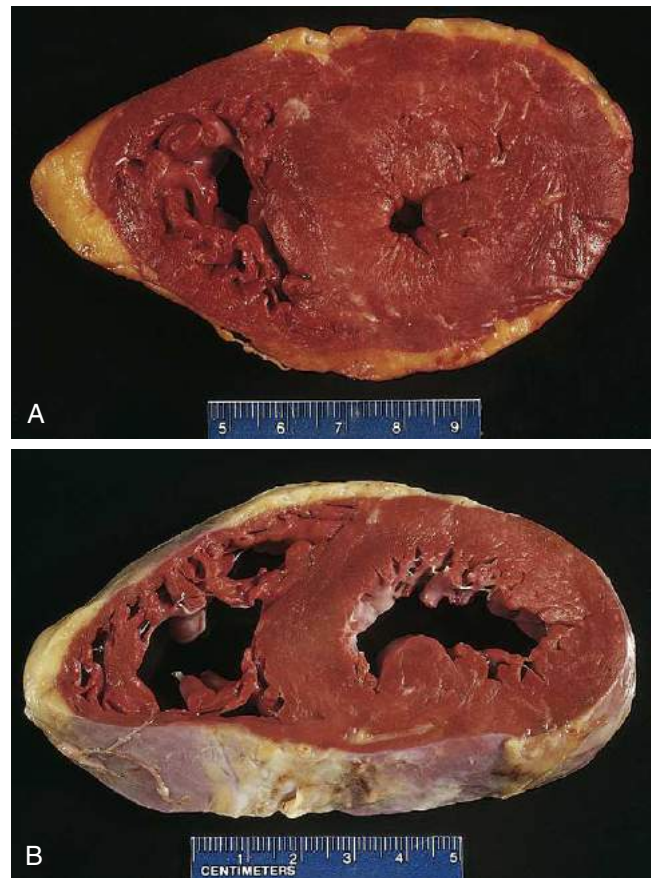

The biochemical pathways that result in cellular atrophy are imperfectly known; however, two pathways for protein degradation have been implicated. The first is the previously mentioned ubiquitin-proteasome system, which degrades targeted proteins into small fragments (see Figure 4-4). The second involves the lysosomes that may fuse with intracellular structures leading to hydrolytic degradation of the components. Certain substances apparently are resistant to degradation and remain in the lysosomal vesicles of atrophied cells. For example, lipofuscin is an age-related pigment that accumulates in residual vesicles in atrophied cells, giving them a yellow-brown appearance.

### Hypertrophy

**Hypertrophy** is an increase in cell mass accompanied by an augmented functional capacity. Cells hypertrophy in response to increased physiologic or pathophysiologic demands. Cellular enlargement results primarily from a net increase in cellular protein content.<sup>4</sup> Like the other adaptive responses, hypertrophy subsides when the increased demand is removed; however, the cell may not entirely return to normal because of persistent changes in connective tissue structures. Organ enlargement may be a result of both an increase in cell size (hypertrophy) and an increase in cell number (hyperplasia). For example, an increase in skeletal muscle mass and strength in response to repeated exercise is primarily the result of hypertrophy of individual muscle cells, although some increase in cell number is also possible because muscle stem cells (satellite cells) are able to divide. Physiologic hypertrophy occurs in response to a variety of trophic hormones in sex organs—the breast and uterus, for example. Certain pathophysiologic conditions may place undue stress on some tissues, causing them to hypertrophy. Liver enlargement in response to bodily toxins and cardiac muscle enlargement in response to high blood pressure (Figure 4-7) represent hyperplastic and hypertrophic adaptations to pathologic conditions. Hypertrophic adaptation is particularly important for cells, such as differentiated muscle cells, that are unable to undergo mitotic division.

### Hyperplasia

Cells that are capable of mitotic division generally increase their functional capacity by increasing the number of cells (**hyperplasia**) as well as by hypertrophy. Hyperplasia usually results from increased physiologic demands or hormonal stimulation. Persistent cell injury also may lead to hyperplasia. Examples of demand-induced hyperplasia include

**FIGURE 4-7** **A**, Hypertrophy of cardiac muscle in the left ventricular chamber. **B**, Compare with the thickness of the normal left ventricle. This is an example of cellular adaptation to an increased cardiac workload. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 6.)

an increase in RBC number in response to high altitude and liver enlargement in response to drug detoxification. Trophic hormones induce hyperplasia in their target tissues. Estrogen, for example, leads to an increase in the number of endometrial and uterine stromal cells. Dysregulation of hormones or growth factors can result in pathologic hyperplasia, such as that which occurs in thyroid or prostate enlargement.

Chronic irritation of epithelial cells often results in hyperplasia. Calluses and corns, for example, result from chronic frictional injury to the skin. The epithelium of the bladder commonly becomes hyperplastic in response to the chronic inflammation of cystitis.

### Metaplasia

**Metaplasia** is the replacement of one differentiated cell type with another. This most often occurs as an adaptation to persistent injury, with the replacement cell type better able to tolerate the injurious stimulation.<sup>1</sup> Metaplasia is fully reversible when the injurious stimulus is removed. Metaplasia often involves the replacement of glandular epithelium with squamous epithelium. Chronic irritation of the bronchial mucosa by cigarette smoke, for example, leads to the conversion of ciliated columnar epithelium to stratified squamous epithelium. Metaplastic cells generally remain well differentiated and of the same tissue type, although cancerous transformations can occur. Some cancers of the lung, cervix, stomach, and bladder appear to derive from areas of metaplastic epithelium.

## Dysplasia

**Dysplasia** refers to the disorganized appearance of cells because of abnormal variations in size, shape, and arrangement. Dysplasia occurs most frequently in hyperplastic squamous epithelium, but it may also be seen in the mucosa of the intestine. Dysplasia probably represents an adaptive effort gone astray. Dysplastic cells have significant potential to transform into cancerous cells and are usually regarded as *preneoplastic* lesions. (See Chapter 7 for a discussion of cancer.) Dysplasia that is severe and involves the entire thickness of the epithelium is called *carcinoma in situ*. Mild forms of dysplasia may be reversible if the inciting cause is removed.

### KEY POINTS

- Adaptive cellular responses indicate cellular stress caused by altered functional demand or chronic sublethal injury.
- Hypertrophy and hyperplasia generally result from increased functional demand. Atrophy results from decreased functional demand or chronic ischemia. Metaplasia and dysplasia result from persistent injury.

## IRREVERSIBLE CELL INJURY

Pathologic cellular death occurs when an injury is too severe or prolonged to allow cellular adaptation or repair. Two different processes may contribute to cell death in response to injury: necrosis and

apoptosis. Necrosis usually occurs as a consequence of ischemia or toxic injury and is characterized by cell rupture, spilling of contents into the extracellular fluid, and inflammation. Apoptosis (from a Greek word meaning *falling off*, as in leaves from a tree) occurs in response to injury that does not directly kill the cell but triggers intracellular cascades that activate a cellular suicide response. Apoptotic cells generally do not rupture and are ingested by neighboring cells with minimal disruption of the tissue and without inflammation. Apoptosis is not always a pathologic process and occurs as a necessity of development and tissue remodeling.

## Necrosis

Necrotic cells demonstrate typical morphologic changes, including a shrunken (pyknotic) nucleus that is subsequently degraded (karyolysis), a swollen cell volume, dispersed ribosomes, and disrupted plasma and organelle membranes (Figure 4-8). The disruption of the permeability barrier of the plasma membrane appears to be a critical event in the death of the cell.<sup>5</sup>

Localized injury or death of tissue is generally reflected in the entire system as the body attempts to remove dead cells and works to compensate for loss of tissue function. Several manifestations indicate that the system is responding to cellular injury and death. A general inflammatory response is often present, with general malaise, fever, increased heart rate, increased white blood cell (WBC) count, and loss of

**FIGURE 4-8** Comparison of cellular changes in necrosis and apoptosis. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 13.)

## CHAPTER 4 Cell Injury, Aging, and Death

appetite. With the death of necrotic cells, intracellular contents are released and often find their way into the bloodstream. The presence of specific cellular enzymes in the blood is used as an indicator of the location and extent of cellular death. For example, an elevated serum amylase level indicates pancreatic damage, and an elevated creatine kinase (MB isoenzyme) or cardiac troponin level indicates myocardial damage. The location of pain caused by tissue destruction may also aid in the diagnosis of cellular death.

Four different types of tissue necrosis have been described: coagulative, liquefactive, fat, and caseous (Figure 4-9). They differ primarily in the type of tissue affected. *Coagulative* necrosis is the most common. Manifestations of coagulative necrosis are the same, regardless of the cause of cell death. In general, the steps leading to coagulative necrosis may be summarized as follows: (1) ischemic cellular injury, leading to (2) loss of the plasma membrane's ability to maintain electrochemical gradients, which results in (3) an influx of calcium ions and mitochondrial

**FIGURE 4-9** The four primary types of tissue necrosis. **A**, Coagulative; **B**, liquefactive; **C**, fat; **D**, caseous. (**A**, From Crowley L: *Introduction to human disease*, ed 4, Sudbury, MA, 1996, Jones and Bartlett, [www.jbpub.com](http://www.jbpub.com). Reprinted with permission. **B-D**, From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, pp 16-17.)

**FIGURE 4-10** Cellular injury as a consequence of intracellular calcium overload. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 19.)

dysfunction, and (4) degradation of plasma membranes and nuclear structures (Figure 4-10). The area of coagulative necrosis is composed of denatured proteins and is relatively solid. The coagulated area is then slowly dissolved by proteolytic enzymes and the general tissue architecture is preserved for a relatively long time (weeks). This is in contrast to liquefactive necrosis.

When the dissolution of dead cells occurs very quickly, a liquefied area of lysosomal enzymes and dissolved tissue may result and form an abscess or cyst. This type of necrosis, called *liquefactive necrosis*, may be seen in the brain, which is rich in degradative enzymes and contains little supportive connective tissue. Liquefaction may also result from a bacterial infection that triggers a localized collection of WBCs. The phagocytic WBCs contain potent degradative enzymes that may completely digest dead cells, resulting in liquid debris.

*Fat necrosis* refers to death of adipose tissue and usually results from trauma or pancreatitis. The process begins with the release of activated digestive enzymes from the pancreas or injured tissue. The enzymes attack the cell membranes of fat cells, causing release of their stores of triglycerides. Pancreatic lipase can then hydrolyze the triglycerides to free fatty acids and glycerol, which precipitate as calcium soaps (saponification). Fat necrosis appears as a chalky white area of tissue.

*Caseous necrosis* is characteristic of lung tissue damaged by tuberculosis. The areas of dead lung tissue are white, soft, and fragile, resembling clumpy cheese. Dead cells are walled off from the rest of the lung tissue by inflammatory WBCs. In the center, the dead cells lose their

cellular structure but are not totally degraded. Necrotic debris may persist indefinitely.

**Gangrene** is a term used to describe cellular death involving a large area of tissue. Gangrene usually results from interruption of the major blood supply to a particular body part, such as the toes, leg, or bowel. Depending on the appearance and subsequent infection of the necrotic tissue, it is described as dry gangrene, wet gangrene, or gas gangrene. *Dry gangrene* is a form of coagulative necrosis characterized by blackened, dry, wrinkled tissue that is separated from adjacent healthy tissue by an obvious line of demarcation (see Figure 4-9, A). It generally occurs only on the extremities. Liquefactive necrosis may result in *wet gangrene*, which is typically found in internal organs, appears cold and black, and may be foul smelling because of the invasion of bacteria. Rapid spread of tissue damage and the release of toxins into the bloodstream make wet gangrene a life-threatening problem. *Gas gangrene* is characterized by the formation of bubbles of gas in damaged tissue. Gas gangrene is the result of infection of necrotic tissue by anaerobic bacteria of the genus *Clostridium*. These bacteria produce toxins and degradative enzymes that allow the infection to spread rapidly through the necrotic tissue. Gas gangrene may be fatal if not managed rapidly and aggressively.

## Apoptosis

The number of cells in tissues is tightly regulated by controlling the rate of cell division and the rate of cell death. If cells are no longer needed, they activate a cellular death pathway resulting in cell suicide. In contrast to necrosis, which is messy and results in inflammation and collateral tissue damage, apoptosis is tidy and does not elicit inflammation. Apoptosis is not a rare event; large numbers of cells are continually undergoing programmed cell death as tissues remodel. During fetal development, for example, more than half of the nerve cells that form undergo apoptosis. It is estimated that more than 95% of the T lymphocytes that are generated in the bone marrow are induced to undergo apoptosis after reaching the thymus. These are normal physiologic processes that regulate normal system function. Apoptosis also has been implicated in pathologic cell death and disease. For example, it has been estimated that the area of tissue death following a myocardial infarction (heart attack) is about 20% necrotic and 80% apoptotic.<sup>6</sup> It is difficult to measure the degree of apoptotic cell death because neighboring cells rapidly ingest their apoptotic neighbors and few are ever present in the tissue.<sup>7</sup> Death of cancer cells in response to radiation or chemotherapy is believed to be primarily caused by apoptotic mechanisms. When the rate of apoptosis is greater than the rate of cell replacement, tissue or organ function may be impaired. Apoptosis is now recognized as a primary factor in diseases such as heart failure (Chapter 19) and dementia (Chapter 45). The mechanisms regulating apoptosis are complex, and only major concepts are included here.

There are two types of environmental or extrinsic signals that may induce apoptosis. First, apoptosis may be triggered by withdrawal of “survival” signals that normally suppress the apoptotic pathways.<sup>7</sup> Normal cells require a variety of signals from neighboring cells and from the extracellular matrix in order to stay alive (Figure 4-11). If these contacts or signals are removed, the cell death cascade is activated. Cancer cells are notorious for their ability to survive despite the lack of appropriate survival signals from their environment (see Chapter 7). A second mechanism of triggering apoptosis involves extracellular signals, such as the *Fas* ligand, that bind to the cell and trigger the death cascade through activation of “death receptors” (Figure 4-12).

Apoptosis can also be triggered by intrinsic pathways. Cells have ways to monitor their condition and usefulness internally. When excessive, irreparable damage occurs to the cell’s DNA or other vital structures, growth and division stalls for a while to permit repair. If the

**FIGURE 4-11** Each cell displays a set of receptors that enable it to respond to extracellular signals that control growth, differentiation, and survival. **A**, Extracellular signals are provided by the neighboring cells, secreted signaling molecules, and the extracellular matrix. **B**, Withdrawal of these survival signals induces the cell to initiate apoptosis.

**FIGURE 4-12** Induction of apoptosis by *Fas* ligand. **A**, Target cell binds to *Fas* ligand on a signaling cell. **B**, Active *Fas* receptors organize and activate caspases. **C**, The caspases degrade the nucleus and trigger cell death.

damage is too great, the cell will trigger its own death. Mitochondrial damage with leakage of cytochrome *c* into the cytoplasm is a critical activator of the intrinsic apoptotic pathway. This pathway is governed in part by a protein called p53. The amount of p53 in a cell is normally quite low but increases in response to cellular DNA damage. If high levels of p53 are sustained, apoptosis will occur.<sup>8</sup> Thus p53 is important in preventing the proliferation of cells with damaged DNA. A large number of cancers (50%) are associated with a mutation in the *P53* gene, which allows cancer cells to escape this monitoring system.<sup>8</sup>

Regardless of the initiating event, apoptosis involves numerous intracellular signals and enzymes (Figure 4-13). A family of enzymes called caspases is the main component of the proteolytic cascade that degrades key intracellular structures leading to cell death. The caspases are proenzymes that are activated in a cascade. Activation of a few *initiator* caspases at the beginning of the cascade results in a rapid domino effect of caspase activation. Some caspases cleave key proteins, such as the nuclear lamina, to destroy the nuclear envelope, whereas others activate still more enzymes that chop up the DNA. All of this

destruction is contained within an intact plasma membrane, and the cell remnants are then assimilated by its neighbors. Neighboring cells are prompted to ingest apoptotic cells because a phospholipid that is normally located only on the cytoplasmic side of a healthy cell (phosphatidylserine) flips to the outside of the lipid bilayer. This membrane lipid signals neighbors and tissue macrophages to bind and assimilate the cell components and suppresses the inflammatory response that normally accompanies phagocytosis.<sup>7</sup>

#### KEY POINTS

- Necrosis occurs when the injury is too severe or prolonged to allow adaptation and is usually a consequence of disrupted blood supply.
- Local and systemic indicators of cell death include pain, elevated serum enzyme levels, inflammation (fever, elevated WBC count, malaise), and loss of function.
- Different tissues exhibit necrosis of different types: heart (coagulative), brain (liquefactive), lung (caseous), and pancreas (fat).

**FIGURE 4-13** Schematic of the events of apoptosis. Numerous triggers can initiate apoptosis through intrinsic cell injury pathways (mitochondrial), such as withdrawal of survival factors, various cell injuries, and protein overload or misfolding; or through extrinsic cell injury pathways (death receptors), such as binding to *Fas* or tumor necrosis factor receptors. A number of intracellular regulatory proteins may inhibit or promote the activation of caspases, which, when activated begin the process of cellular degradation and apoptotic cell fragmentation. Fragments are internalized by phagocytic cells. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 28.)

- Gangrene refers to a large area of necrosis that may be described as dry, wet, or gas gangrene. Gas gangrene and wet gangrene may be rapidly fatal.
- Apoptosis is cell death resulting from activation of intracellular signaling cascades that cause cell suicide. Apoptosis is tidy and not usually associated with systemic manifestations of inflammation.

## ETIOLOGY OF CELLULAR INJURY

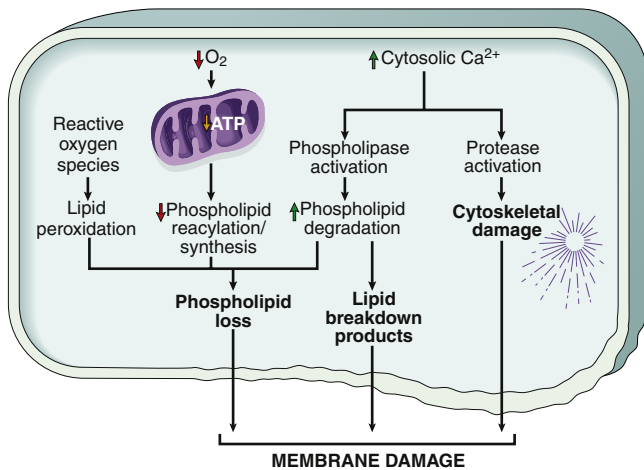

Cellular injury and death result from a variety of cellular assaults, including lack of oxygen and nutrients, infection and immune responses, chemicals, and physical and mechanical factors. The extent of cell injury and death depends in part on the duration and severity of the assault and in part on the prior condition of the cells. Well-nourished and somewhat adapted cells may withstand the injury better than cells that are poorly nourished or unadapted. Common causes of cellular injury include hypoxic injury, nutritional injury, infectious and immunologic injury, chemical injury, and physical and mechanical injury.

### Ischemia and Hypoxic Injury

Living cells must receive a continuous supply of oxygen to produce ATP to power energy-requiring functions. Lack of oxygen (**hypoxia**) results in power failure within the cell. Tissue hypoxia is most often caused by *ischemia*, or the interruption of blood flow to an area, but it

may also result from heart failure, lung disease, and RBC disorders. Ischemia is the most common cause of cell injury in clinical medicine and injures cells faster than hypoxia alone. Faster injury occurs because ischemia not only disrupts the oxygen supply but also allows metabolic wastes to accumulate and deprives the cell of nutrients for glycolysis. The cellular events that follow oxygen deprivation are shown in **Figure 4-14**. Decreased oxygen delivery to the mitochondria causes ATP production in the cell to stall and ATP-dependent pumps, including the  $\text{Na}^+\text{-K}^+$  and  $\text{Ca}^{2+}$  pumps, to fail. Sodium accumulation within the cell creates an osmotic gradient favoring water entry, resulting in hydropic swelling. Excess intracellular calcium collects in the mitochondria, further interfering with mitochondrial function. A small amount of ATP is produced by anaerobic glycolytic pathways, which metabolize cellular stores of glycogen. The pyruvate end products of glycolysis accumulate and are converted to lactate, causing cellular acidification. Lactate can escape into the bloodstream, resulting in **lactic acidosis**, which can be detected by laboratory tests. Cellular proteins and enzymes become progressively more dysfunctional as the pH falls. Up to a point, ischemic injury is reversible, but when the plasma, mitochondrial, and lysosomal membranes are critically damaged, cell death ensues.<sup>1</sup>

Cell death resulting from ischemia may be slow to develop, generally taking many minutes to hours. In fact, most cellular damage occurs after the blood supply to the tissues has been restored—a so-called *reperfusion injury*. Ischemia-reperfusion is a complex phenomenon, but three critical components have been identified: (1) calcium

**FIGURE 4-14** Mechanisms of ischemia-induced cell injury. Cellular damage often occurs through the formation of reactive oxygen radicals. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 22.)

overload, (2) formation of reactive oxygen molecules (free radicals), and (3) subsequent inflammation.

Restoration of blood flow to ischemic cells bathes them in a fluid high in calcium ions at a time when their ATP stores are depleted and they are unable to control ion flux across the cell membrane. Accumulation of calcium ions in the cytoplasm can trigger apoptosis or activate enzymes that degrade lipids in the membrane (lipid peroxidation).

The ischemic episode also primes cells for abnormal generation of reactive oxygen molecules, such as superoxide ( $O_2^-$ ), peroxide ( $H_2O_2$ ), and hydroxyl radicals ( $OH^-$ ).<sup>9</sup> These reactive oxygen molecules are free radicals that have an unpaired electron in an outer orbital. They steal hydrogen atoms and form abnormal molecular bonds. Molecules that react with free radicals are in turn converted to free radicals, continuing the destructive cascade. Reactive oxygen species damage cell membranes, denature proteins, and disrupt cell chromosomes. Oxygen free radicals also have been linked to initiation of the inflammatory cascade.

Ischemia primes cells for the generation of oxygen radicals by allowing the buildup of ATP precursors, such as adenosine diphosphate (ADP) and pyruvate, during the period of hypoxia. When oxygen supply is reestablished, there is a disorganized burst of high-energy electrons that partially reduce oxygen and form oxygen radicals. The ischemia-reperfusion event frequently is followed by a generalized inflammatory state,<sup>10</sup> which may lead to ongoing cellular and organ damage for days and weeks following the initial event. WBCs recruited to the area release enzymes and other chemicals that further damage the cells in the area. (Mechanisms and causes of ischemic tissue injury are described further in Chapter 20.)

### Nutritional Injury

Adequate amounts of fats, carbohydrates, proteins, vitamins, and minerals are essential for normal cellular function. Most of these essential nutrients must be obtained from external sources because the cell is unable to manufacture them. The cell is unable to synthesize many of the 20 amino acids needed to form the proteins of the body. Likewise, most vitamins and minerals must be obtained from exogenous sources. Cell injury results from deficiencies as well as excesses of essential nutrients.

Certain cell types are more susceptible to injury from particular nutritional imbalances. Iron deficiency, for example, primarily affects

RBCs, whereas vitamin D deficiency affects bones. All cell types must receive glucose for energy as well as fatty acid and amino acid building blocks to synthesize and repair cellular components. Nutritional deficiencies result from poor intake, altered absorption, impaired distribution by the circulatory system, or inefficient cellular uptake. Common causes of malnutrition include (1) poverty, (2) chronic alcoholism, (3) acute and chronic illness, (4) self-imposed dietary restrictions, and (5) malabsorption syndromes.<sup>11</sup> Vitamin deficiencies are common even in industrialized countries because of pervasive use of processed foods. Some examples of vitamin deficiency disorders are shown in Table 4-1. Deficiencies of minerals, especially iron, also are common (Table 4-2).

Nutritional excesses primarily result from excessive intake, although deficient cellular uptake by one cell type may contribute to excess nutrient delivery to other cell types. For example, in the condition of diabetes mellitus, some cell types have deficient receptors for insulin-dependent glucose uptake, which causes excessive amounts of glucose to remain in the bloodstream. As a result, cells that do not require insulin to take in glucose, such as neurons, may have abnormally high intracellular glucose levels. An excess of caloric intake above metabolic use produces overweight and obesity syndromes. Excess body fat can be estimated by measuring the ratio of body weight (in kilograms) to height (in meters squared) to derive the body mass index (BMI). A BMI greater than 27 kg/m<sup>2</sup> imparts a health risk and a BMI greater than 30 kg/m<sup>2</sup> is considered to be obesity.<sup>12</sup> Numerous health problems are associated with excess body fat, including heart and blood vessel disease, musculoskeletal strain, diabetes, hypertension, and gallbladder disease. Metabolism is explored in Chapter 42.

### Infectious and Immunologic Injury

Bacteria and viruses are common infectious agents that may injure cells in a variety of ways. The virulence of a particular biological agent depends on its ability to gain access to the cell and its success in altering cellular functions. (See Chapter 8 for a detailed discussion of infectious processes.) Some of the injurious effects are directly due to the biological agent, but added injury may be done indirectly by triggering the body's immune response.

Most bacteria do not gain entry into the cell and so accomplish their injurious effects from the outside. (Notable exceptions include *Mycobacterium tuberculosis*, *Shigella*, *Legionella*, *Salmonella*, and *Chlamydia*.) Some bacteria produce and secrete powerful destructive enzymes that digest cellular membranes and connective tissues. For example, collagenase and lecithinase are produced by *Clostridium perfringens*. Other bacteria produce **exotoxins**, which interfere with specific cellular functions when released from the bacterium. *Clostridium botulinum* and *Clostridium tetani*, for example, produce life-threatening toxins that disrupt normal neuromuscular transmission. Cholera and diphtheria are well-known examples of exotoxin-related diseases. Exotoxins are primarily proteins and are generally susceptible to destruction by extremes of heat. Certain gram-negative bacteria (e.g., *Escherichia coli*, *Klebsiella pneumoniae*) contain another type of toxin, **endotoxin**, in their cell wall. On lysis of the bacteria, the endotoxin is released, causing fever, malaise, and even circulatory shock.<sup>13</sup>

The indirect cellular injury attributable to the bacteria-evoked immune response may be more damaging than the direct effects of the infectious agent. White blood cells secrete many enzymes and chemicals meant to destroy the invading organism, including histamines, kinins, complement, proteases, lymphokines, and prostaglandins. Normal body cells may be exposed to these injurious chemicals because they are too close to the site of immunologic battle. Immune cells are particularly adept at producing free radicals, which can attack host cell membranes and induce significant cell injury.

TABLE 4-1 VITAMINS: MAJOR FUNCTIONS AND DEFICIENCY SYNDROMES

VITAMIN	FUNCTIONS	DEFICIENCY SYNDROMES
<b>Fat Soluble</b>		
Vitamin A	A component of visual pigment Maintenance of specialized epithelia Maintenance of resistance to infection	Night blindness, xerophthalmia, blindness Squamous metaplasia Vulnerability to infection, particularly measles
Vitamin D	Facilitates intestinal absorption of calcium and phosphorus and mineralization of bone	Rickets in children Osteomalacia in adults
Vitamin E	Major antioxidant; scavenges free radicals	Spinocerebellar degeneration
Vitamin K	Cofactor in hepatic carboxylation of procoagulants—factors II (prothrombin), VII, IX, and X; and protein C and protein S	Bleeding diathesis
<b>Water-Soluble</b>		
Vitamin B <sub>1</sub> (thiamine)	As pyrophosphate, is coenzyme in decarboxylation reactions	Dry and wet beriberi, Wernicke syndrome, Korsakoff syndrome
Vitamin B <sub>2</sub> (riboflavin)	Converted to coenzymes flavin mononucleotide and flavin adenine dinucleotide, cofactors for many enzymes in intermediary metabolism	Ariboflavinosis, cheilosis, stomatitis, glossitis, dermatitis, corneal vascularization
Niacin	Incorporated into NAD and NAD phosphate; involved in a variety of redox reactions	Pellagra—"three D's": dementia, dermatitis, diarrhea
Vitamin B <sub>6</sub> (pyridoxine)	Derivatives serve as coenzymes in many intermediary reactions	Cheilosis, glossitis, dermatitis, peripheral neuropathy
Vitamin B <sub>12</sub>	Required for normal folate metabolism and DNA synthesis Maintenance of myelination of spinal cord tracts	Megaloblastic pernicious anemia and degeneration of posterolateral spinal cord tracts
Vitamin C	Serves in many oxidation-reduction (redox) reactions and hydroxylation of collagen	Scurvy
Folate	Essential for transfer and use of 1-carbon units in DNA synthesis	Megaloblastic anemia, neural tube defects
Pantothenic acid	Incorporated in coenzyme A	No nonexperimental syndrome recognized
Biotin	Cofactor in carboxylation reactions	No clearly defined clinical syndrome

From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 438.

NAD, Nicotinamide adenine dinucleotide.

TABLE 4-2 SELECTED TRACE ELEMENTS AND DEFICIENCY SYNDROMES

ELEMENT	FUNCTION	BASIS OF DEFICIENCY	CLINICAL FEATURES
Zinc	Component of enzymes, principally oxidases	Inadequate supplementation in artificial diets Interference with absorption by other dietary constituents Inborn error of metabolism	Rash around eyes, mouth, nose, and anus called acrodermatitis enteropathica Anorexia and diarrhea Growth retardation in children Depressed mental function Depressed wound healing and immune response Impaired night vision Infertility
Iron	Essential component of hemoglobin as well as a number of iron-containing metalloenzymes	Inadequate diet Chronic blood loss	Hypochromic microcytic anemia
Iodine	Component of thyroid hormone	Inadequate supply in food and water	Goiter and hypothyroidism
Copper	Component of cytochrome <i>c</i> oxidase, dopamine β-hydroxylase, tyrosinase, lysyl oxidase, and unknown enzyme involved in cross-linking collagen	Inadequate supplementation in artificial diet	Muscle weakness Neurologic defects
Fluoride	Mechanism unknown	Interference with absorption Inadequate supply in soil and water Inadequate supplementation	Abnormal collagen cross-linking Dental caries
Selenium	Component of glutathione peroxidase Antioxidant with vitamin E	Inadequate amounts in soil and water	Myopathy Cardiomyopathy (Keshan disease)

From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 439.

Viruses are small pieces of genetic material that are able to gain entry into the cell.<sup>14</sup> They may be regarded as intracellular parasites that use the host cell's metabolic and synthetic machinery to survive and replicate. In some cases the virus remains in the cell for a considerable time without inflicting lethal injury. In other cases the virus causes rapid lysis and destruction of the host cell.

Virally infected cells may trigger their own destruction when they express viral proteins on the cell surface that are foreign to the host's immune system. The hepatitis B virus is an example of such an indirectly cytopathic virus that causes immune-mediated cell death. The hepatitis B virus consists of double-stranded DNA that becomes incorporated into the host cell's nucleus, where it can be transcribed by the

**TABLE 4-3 HEALTH EFFECTS OF OUTDOOR AIR POLLUTANTS**

POLLUTANT	POPULATIONS AT RISK	EFFECTS*
Ozone	Healthy adults and children	Decreased lung function
	Athletes, outdoor workers	Increased airway reactivity
	Asthmatics	Lung inflammation
		Decreased exercise capacity
Nitrogen dioxide	Healthy adults	Increased hospitalizations
	Asthmatics	Increased airway reactivity
	Children	Decreased lung function
Sulfur dioxide	Healthy adults	Increased respiratory tract infections
	Patients with chronic lung disease	Increased respiratory symptoms
	Asthmatics	Increased mortality
		Increased hospitalization
Acid aerosols	Healthy adults	Decreased lung function
	Children	Increased hospitalizations
	Asthmatics	Altered mucociliary clearance
		Increased respiratory tract infections
Particulates	Children	Decreased lung function
	Individuals with chronic lung or heart disease	Increased hospitalizations
	Asthmatics	Increased respiratory tract infections
		Decreased lung function
		Excess mortality
		Increased attacks

From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 404.

\*See Chapters 22 and 23 for a discussion of respiratory disorders.

normal DNA polymerases. The mRNA transcripts of the viral genes are transported to the cytoplasm and translated into structural proteins and enzymes, which are used to make more copies of the virus. Such virally infected cells may remain functional virus factories until they are destroyed by the host's immune system.

### Chemical Injury

Toxic chemicals or poisons are plentiful in the environment (Tables 4-3 and 4-4). Some toxic chemicals cause cellular injury directly, whereas others become injurious only when metabolized into reactive chemicals by the body. Carbon tetrachloride (CCl<sub>4</sub>) is an example of the latter.<sup>15</sup> Carbon tetrachloride, a formerly used dry-cleaning agent, is converted to a highly toxic **free radical**, CCl<sub>3</sub><sup>•</sup>, by liver cells. The free radical is very reactive, forming abnormal chemical bonds in the cell and ultimately destroying the cellular membranes of liver cells, causing liver failure. In high doses, acetaminophen, a commonly used analgesic, may have similar toxic effects on the liver.

Many toxins are inherently reactive and do not require metabolic activation to exert their effects. Common examples are heavy metals (e.g., lead and mercury), toxic gases, corrosives, and antimetabolites. Some toxins have an affinity for a particular cell type or tissue, whereas others exert widespread systemic effects. For example, carbon monoxide binds tightly and selectively to hemoglobin, preventing the red blood cell from carrying sufficient oxygen. Lead poisoning, however, has widespread effects, including effects on nervous tissue, blood cells, and the kidney. Extremely acidic or basic chemicals are directly corrosive to cellular structures. Certain chemicals interfere with normal

**TABLE 4-4 SELECTED INDOOR AIR POLLUTANTS WITH SIGNIFICANT HEALTH RISKS**

POLLUTANT	SOURCE
Carbon monoxide	Fuel combustion, fire, furnace
Wood smoke	Fireplaces, woodstoves
Formaldehyde	Manufacture of construction materials
Radon	Natural ground radiation
Asbestos fibers	Old insulation, shingles
Manufactured mineral fibers	Insulation, building materials
Aerosols	Spray bottle propellants

metabolic processes of the cell. Some of these antimetabolites have been utilized in the form of cytotoxic agents for the management of cancer.

### Physical and Mechanical Injury

Injurious physical and mechanical factors include extremes of temperature, abrupt changes of atmospheric pressure, mechanical deformation, electricity, and ionizing radiation.<sup>11</sup>

Extremes of cold result in the hypothermic injury known as frostbite. Before actual cellular freezing, severe vasoconstriction and increased blood viscosity may result in ischemic injury. With continued exposure to cold, a rebound vasodilatory response may occur, leading to intense swelling and peripheral nerve damage. The cytoplasmic solution may freeze, resulting in the formation of intracellular ice crystals and rupture of cellular components. Frostbite generally affects the extremities, ears, and nose, and is often complicated by gangrenous necrosis.

Extremes of heat result in hyperthermic injury or burns. High temperatures cause microvascular coagulation and may accelerate metabolic processes in the cell. Burns result from direct tissue destruction by high temperatures and are classified according to the degree of tissue destruction. Burns are discussed in Chapter 54.

Abrupt changes in atmospheric pressure may result from high-altitude flying, deep-sea diving, and explosions. Pressure changes may interfere with gas exchange in the lungs, cause the formation of gas emboli in the bloodstream, collapse the thorax, and rupture internal organs. A well-known example of pressure injury is the condition of “the bends,” which afflicts deep-sea divers who surface too quickly. The rapid decrease in water pressure results in the formation of bubbles of nitrogen gas in the blood, which may obstruct the circulation and cause ischemic injury.

Destruction of cells and tissues resulting from mechanical deformation ranges from mild abrasion to severe lacerating trauma. Cell death may result from direct trauma to cell membranes and resulting blood loss or from obstruction of blood flow and hypoxia. Nonpenetrating trauma generally results from physical impact with a blunt object such as a fist, a car steering wheel, or the pavement. Surgery is a common cause of tissue trauma. Other causes of penetrating trauma are bite, knife, and gun wounds. Trauma-induced inflammatory swelling may further compromise injured tissues.

Electrical injury may occur when the cells of the body act as conductors of electricity. The electrical current damages tissues in two ways: (1) by disruption of neural and cardiac impulses, and (2) by hyperthermic destruction of tissues. Resistance to the flow of electrons results in heat production, which damages the tissues. The current tends to follow the path of least resistance—through neurons and body fluids—causing violent muscle contractions, thermal injury, and coagulation in

FIGURE 4-15 Types of electromagnetic radiation.

blood vessels. In general, greater injury is suffered with high-voltage alternating current applied to a low-resistance area (e.g., wet skin).

There are many forms of electromagnetic radiation, ranging from low-energy radio waves to high-energy  $\gamma$ -rays or photons (Figure 4-15). Radiation is capable of injuring cells directly by breaking chemical bonds and indirectly by generating free radicals. Cellular DNA is particularly susceptible to damage from radiation exposure.<sup>16</sup> A direct hit of the radiant energy on the DNA molecule may result in breakage of the chemical bonds holding the linear DNA together. This type of direct bond breakage generally results from the high-energy forms of radiation, such as x-rays and  $\gamma$ -rays. The molecular bonds of DNA also may be indirectly disrupted by ionizing radiation. *Ionization* refers to the ability of the radiant energy to split water molecules by knocking off orbital electrons (**radiolysis**). Radiolysis creates activated free radicals that steal electrons from other molecules and disrupt chemical bonds. Many forms of radiation are capable of ionization, but the medium-energy  $\alpha$  and  $\beta$  particles that result from decay of atomic nuclei are especially destructive. Low-energy electromagnetic radiation, such as that created by microwaves, ultrasound, computers, and infrared light, cannot break chemical bonds, but it can cause rotation and vibration of atoms and molecules.<sup>17</sup> The rotational and vibrational energy is then converted to heat. It is probable that the resulting localized hyperthermia may result in cellular injury. Early studies reported a higher incidence of certain cancers in persons occupationally exposed to radiofrequency microwave electromagnetic radiation, but further analysis failed to confirm these findings.<sup>11</sup>

At the cellular level, radiation has two primary effects: (1) genetic damage and (2) acute cell destruction (Figure 4-16). The vulnerability of a tissue to radiation-induced genetic damage depends on its rate of proliferation. Genetic damage to the DNA of a long-lived, nonproliferating cell may be of little consequence, whereas tissues with rapid cellular division have less opportunity to repair damaged DNA before passing it on to the next generation of cells. (Genetic mutation is discussed in Chapter 6.) Hematopoietic, mucosal, gonadal, and fetal cells are particularly susceptible to genetic radiation damage.

Radiation-induced cell death is attributed primarily to the radiolysis of water, with resulting free radical damage to the plasma membrane. Whole-body exposure to sufficiently high levels of radiation (300 rad) results in acute radiation sickness with hematopoietic failure, destruction of the epithelial layer of the gastrointestinal tract, and neurologic dysfunction. The high levels of irradiation that cause acute radiation sickness are associated with events such as nuclear accidents and bombings. Radiation exposure from diagnostic x-rays, cosmic

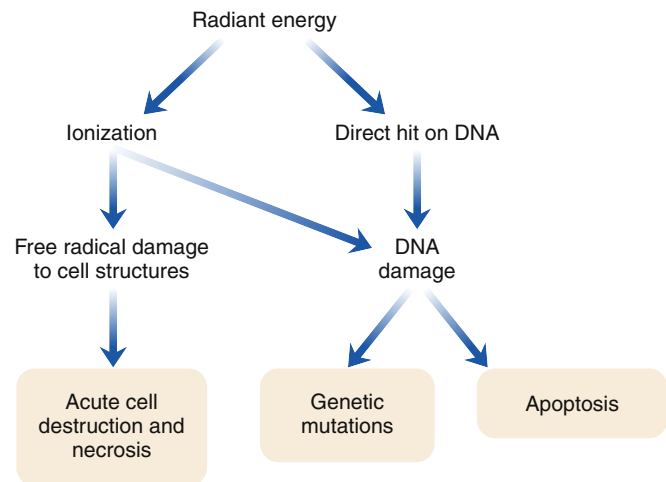

FIGURE 4-16 The mechanism of radiation-induced genetic and cell injury.

rays, and natural radiant chemicals in the earth is far below the level that would result in acute radiation sickness. The signs and symptoms of acute radiation sickness are shown in Figure 4-17. The fact that radiation induces cell death in proliferating cells is used to advantage in the management of some forms of cancer. Radiation therapy may be used when a cancerous growth is confined to a particular area. Injury associated with radiation therapy is generally localized to the irradiated area. Small arteries and arterioles in the area may be damaged, leading to blood clotting and fibrous deposits that compromise tissue perfusion. Most irradiated cells are thought to die through the process of apoptosis rather than from direct killing effects of radiation.<sup>18</sup> Radiation induces cell damage that triggers the apoptotic pathway in cells that cannot efficiently repair the damage. Cells most susceptible to apoptotic death are those that tend to have high rates of division.

#### KEY POINTS

- Hypoxia is an important cause of cell injury that usually results from poor oxygenation of the blood (hypoxemia) or inadequate delivery of blood to the cells (ischemia).
- Reperfusion injury to cells may occur when circulation is restored, as a result of the production of partially reduced oxygen molecules that damage cell membranes and trigger immune-mediated injury.

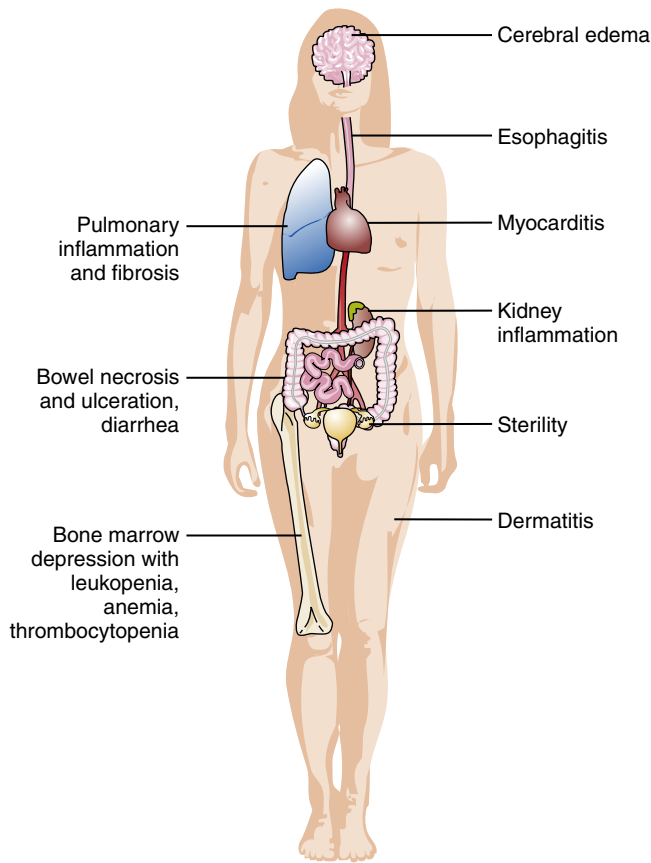

FIGURE 4-17 Signs and symptoms of acute radiation sickness.

- Nutritional injury is a common cause of dysfunction and disease. Malnutrition is rampant in many poor countries, whereas industrialized nations are facing an epidemic of obesity-related disorders, including heart disease and diabetes.
- Cellular damage attributable to infection and immunologic responses is common. Some bacteria and viruses damage cells directly, whereas others stimulate the host's immune system to destroy the host's cells.
- Chemical, physical, and mechanical factors cause cell injury in various ways. Chemicals may interfere with normal metabolic processes in the cell. Injury resulting from physical factors, such as burns and frostbite, causes direct destruction of tissues. Radiation-induced cell death is primarily a result of radiolysis of water, with resulting free radical damage to the cell membrane.

## CELLULAR AGING

The inevitable process of aging and death has been the subject of interest and investigation for centuries. Despite scientific study and the search for the “fountain of youth,” a satisfactory explanation for the process of cellular aging and methods for halting the aging process have not been revealed. The maximal human life span has remained constant at about 90 to 110 years, despite significant progress in the management of diseases.<sup>19</sup> It seems apparent that aging is distinct from disease, and that the life span is limited by the aging process itself rather than by the ravages of disease. Although the elderly are certainly more vulnerable to diseases, the aging process and disease processes are generally viewed as different phenomena. In practice, the distinction between aging and disease may be difficult to make. For example, the aging skeleton normally loses some bone mass, but too much bone

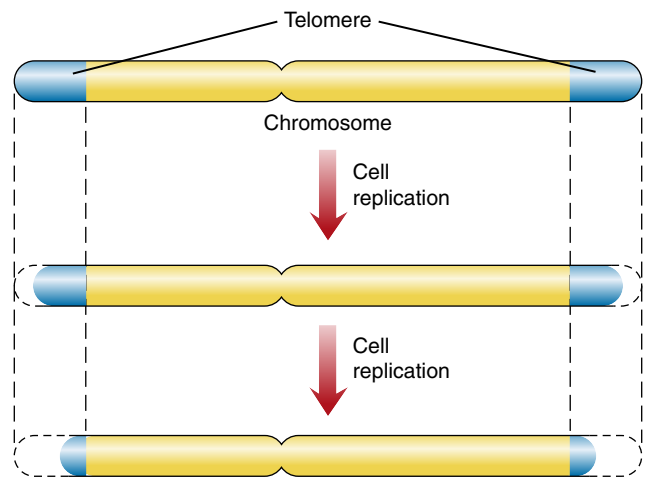

FIGURE 4-18 The end caps of the chromosomes are called *telomeres*. In most body cells, the telomeres progressively shorten with each cell replication until a critical point is reached, at which time the cell becomes dormant or dies.

loss results in osteoporosis—a disease process. Likewise, a loss of blood vessel elasticity is generally viewed as a normal aging change, but at what point does too much arterial stiffness become abnormal? This confusion results from the continued inability to identify the irreversible and universal processes of cellular aging as separate from the potentially reversible effects of disease.

## Cellular Basis of Aging

Cellular aging is the cumulative result of a progressive decline in the proliferative and reparative capacity of cells coupled with exposure to environmental factors that cause accumulation of cellular and molecular damage. Several mechanisms are believed to be responsible for cellular aging. These include DNA damage, reduced proliferative capacity of stem cells, and accumulation of metabolic damage.

Damage to cellular DNA is a common phenomenon resulting from various factors, including ultraviolet radiation, oxidative stress from normal metabolism, and errors in DNA replication. A host of DNA repair mechanisms is present in normal cells to prevent accumulation of DNA damage. With aging these repair systems appear to become less able to keep pace with DNA damage, and cell replication may be inhibited or apoptosis initiated. Support for this idea comes from the premature aging syndromes that are associated with defective DNA repair mechanisms.

The *programmed senescence theory* states that aging is the result of an intrinsic genetic program. Support for the theory of a genetically programmed life span comes primarily from studies of cells in culture. In classic experiments by Hayflick, fibroblastic cells in culture were shown to undergo a finite number of cell divisions.<sup>20</sup> Fibroblasts taken from older individuals underwent fewer cell divisions than those from younger individuals. Given an adequate environment, the information encoded in the cellular genome is thought to dictate the number of possible cell replications, after which damaged or lost cells are no longer replaced. It has been postulated that cells undergo a finite number of replications because the chromosomes shorten slightly with each cell division until some critical point is reached (Figure 4-18), at which time the cell becomes dormant or dies. The end caps of the chromosomes, called **telomeres**, are the sections that shorten with each cell division.<sup>21</sup> Certain cells (germ cells, such as egg and sperm) are able to replenish their telomeres, which gives them potential immortality. The enzyme that rebuilds the telomeres has been named *telomerase*. Stem

cells, which are capable of mitosis, also express telomerase, but at low levels. Progressive loss of telomerase gene expression with aging may contribute to reduced proliferative capacity. Interestingly, a number of cancer cell types have been found to produce telomerase, whereas most normal somatic cells do not (Chapter 7).

Aging may also be a result of accumulated metabolic cell damage over time. The *free radical theory* was prompted in part by the observation that larger animals, which have slower metabolic rates, generally have longer life spans.<sup>1</sup> Metabolic rate, in turn, determines the production of activated oxygen free radicals. Aging is thought to result from the cumulative and progressive damage to cell structures, particularly the cell membrane, by these oxygen radicals. Protection from metabolic damage is provided by a number of antioxidant mechanisms. Over time these protective mechanisms may become less efficient, allowing metabolic damage to accumulate in cells. Accumulated damage may eventually trigger apoptotic mechanisms leading to tissue degeneration.

### Physiologic Changes of Aging

All the body systems show age-related changes that can be generally described as a decrease in functional reserve or inability to adapt to environmental demands. An overview of the tissue and systemic changes of aging is presented in Table 4-5. The details of age-related changes in the various body systems are described in later chapters of this book.

#### KEY POINTS

- Aging is theoretically distinct from disease. The maximal life span is limited by the aging process itself rather than by the ravages of disease.
- Aging is thought to be the result of accumulated DNA damage, decreased proliferative capacity of stem cells, and accumulated metabolic damage. Cells may age more quickly when DNA repair mechanisms are faulty and when metabolic damage is excessive because of reduced antioxidant activity.
- Age-related changes in body systems can generally be described as a decrease in functional reserve and a reduced ability to adapt to environmental demands.

### SOMATIC DEATH

Death of the entire organism is called *somatic death*. In contrast to localized cell death, no immunologic or inflammatory response occurs in somatic death. The general features of somatic death include the absence of respiration and heartbeat. However, this definition of death is insufficient because, in some cases, breathing and cardiac activity may be restored by resuscitative efforts. Within several minutes of cardiopulmonary arrest, the characteristics of irreversible somatic death become apparent. Body temperature falls, the skin becomes pale, and blood and body fluids collect in dependent areas. Within 6 hours, the accumulation of calcium and the depletion of ATP result in perpetual actin-myosin cross-bridge formation in muscle cells. The presence of stiffened muscles throughout the body after death is called *rigor mortis*. Rigor mortis progresses to limpness or flaccidity as the tissues of the body begin to deteriorate. Tissue deterioration or putrefaction becomes apparent 24 to 48 hours after death.<sup>22</sup> Putrefaction is associated with the widespread release of lytic enzymes in tissues throughout the body, a process called *postmortem autolysis*.

The determination of “brain death” has become necessary because of the technological ability to keep the heart and lungs working through artificial means, even though the brain is no longer functional. Criteria

**TABLE 4-5 OVERVIEW OF THE PHYSIOLOGIC CHANGES OF AGING**

SYSTEM	PHYSIOLOGIC CHANGES
Cardiovascular	<ul style="list-style-type: none"> <li>↓ Vessel elasticity caused by calcification of connective tissue (↑ pulmonary vascular resistance)</li> <li>↓ Number of heart muscle fibers with ↑ size of individual fibers (hypertrophy)</li> <li>↓ Filling capacity</li> <li>↓ Stroke volume</li> <li>↓ Sensitivity of baroreceptors</li> <li>Degeneration of vein valves</li> </ul>

Immune	<ul style="list-style-type: none"> <li>↓ Inflammatory response</li> <li>↓ In T cell function owing to involution of thymus gland</li> </ul>
Integumentary	<ul style="list-style-type: none"> <li>↓ Subcutaneous fat</li> <li>↓ Elastin</li> <li>Atrophy of sweat glands</li> <li>Atrophy of epidermal arterioles causing altered temperature regulation</li> </ul>

for determining brain death as proof of somatic death may vary by geographic area but generally include unresponsiveness, flaccidity, absence of brainstem reflexes (e.g., swallowing, gagging, pupil and eye movements), absence of respiratory effort when the subject is removed from the mechanical ventilator, absence of electrical brain waves, and lack of cerebral blood flow.

#### KEY POINTS

- Somatic death is characterized by the absence of respirations and heartbeat. Definitions of brain death have been established to describe death in instances in which heartbeat and respiration are maintained mechanically.
- After death, body temperature falls, blood and body fluids collect in dependent areas, and rigor mortis ensues. Within 24 to 48 hours the tissues begin to deteriorate and rigor mortis gives way to flaccidity.

## SUMMARY

Cells and tissues face many challenges to survival, including injury from lack of oxygen and nutrients, infection and immune responses, chemicals, and physical and mechanical factors. Cells respond to environmental changes or injury in three general ways: (1) If the change is mild or short lived, the cell may withstand the assault and return to its preinjury status. (2) The cell may adapt to a persistent but sublethal injury by changing its structure or function. (3) Cell death by apoptosis or necrosis may occur if the injury is too severe or prolonged. Characteristics of reversible cell injury include hydropic swelling and the accumulation of abnormal substances. Cell necrosis is characterized by irreversible loss of function, release of cellular enzymes into the

bloodstream, and an inflammatory response. The disruption of the permeability barrier of the plasma membrane appears to be a critical event in necrotic cellular death. Apoptosis is characterized by a tidy, noninflammatory autodigestion of the cell.

Aging is a normal physiologic process characterized by a progressive decline in functional capacity and adaptive ability. The biological basis of aging remains largely a mystery, but several theories have been proposed to explain certain aspects of the process. At present, most sources differentiate between the biological alterations of aging and the alterations consequent to disease processes. In practice, however, the distinction may be difficult to make.

The ability of scientists to study and manipulate genes has evolved at an incredible pace, including the complete sequencing of all 6.4 billion nucleotides in an entire human genome. A better understanding of the role that genetics plays in cellular function and disease has spurred efforts to develop therapies to correct genetic abnormalities. The science of genetics developed from the premise that invisible, information-containing elements called **genes** exist in cells and are passed on to daughter cells when a cell divides. The nature of these elements was at first difficult to imagine: what kind of molecule could direct the daily activities of the organism and be capable of nearly limitless replication? The answer to this question was discovered in the late 1940s and was

almost unbelievable in its simplicity. It is now common knowledge that genetic information is stored in long chains of stable molecules called **deoxyribonucleic acid (DNA)**. The human genome contains approximately 23,000 genes encoded by only four different molecules. These molecules are the deoxyribonucleotides containing the bases *adenine (A)*, *cytosine (C)*, *guanine (G)*, and *thymine (T)*. Genes are composed of varying sequences of these four bases, which are linked together by sugar-phosphate bonds. By serving as the templates for the production of body proteins, genes ultimately affect all aspects of an organism's structure and function. When the sequencing of an entire human genome was completed in 2004 it became clear that the genome

**FIGURE 5-1** A nucleotide consists of a sugar (deoxyribose), a phosphate group, and one of the four nucleotide bases. Nucleotides are joined by repeating sugar-phosphate bonds to form long chains, called *polymers*. A, Adenine; C, cytosine; G, guanine; T, thymine.

is much more complex than the sum of its genes. Only 1.3% of chromosomal DNA codes for proteins and many DNA sequences code for ribonucleic acid (RNA) molecules that function in the nucleus to regulate gene function. Methods to rapidly survey the DNA sequences of a particular person are available and genetics is an increasingly important consideration in the etiology, pathogenesis, and pharmacologic treatment of a variety of diseases. However, genetic inheritance involves more than the transfer of genes from parent to offspring. For example, the nutritional exposures of grandparents may influence the metabolic physiology of grandchildren through a process known as **epigenetics**. Epigenetics is further explored in Chapter 6. Knowledge of the basic principles of genetics and gene regulation is a prerequisite to understanding not only conventional genetic diseases but also nearly every pathophysiologic process. This chapter examines the biochemistry of genes (molecular genetics), the regulation of gene expression, and the processes of tissue differentiation. Principles of genetic inheritance precede the discussion of genetic diseases in Chapter 6.

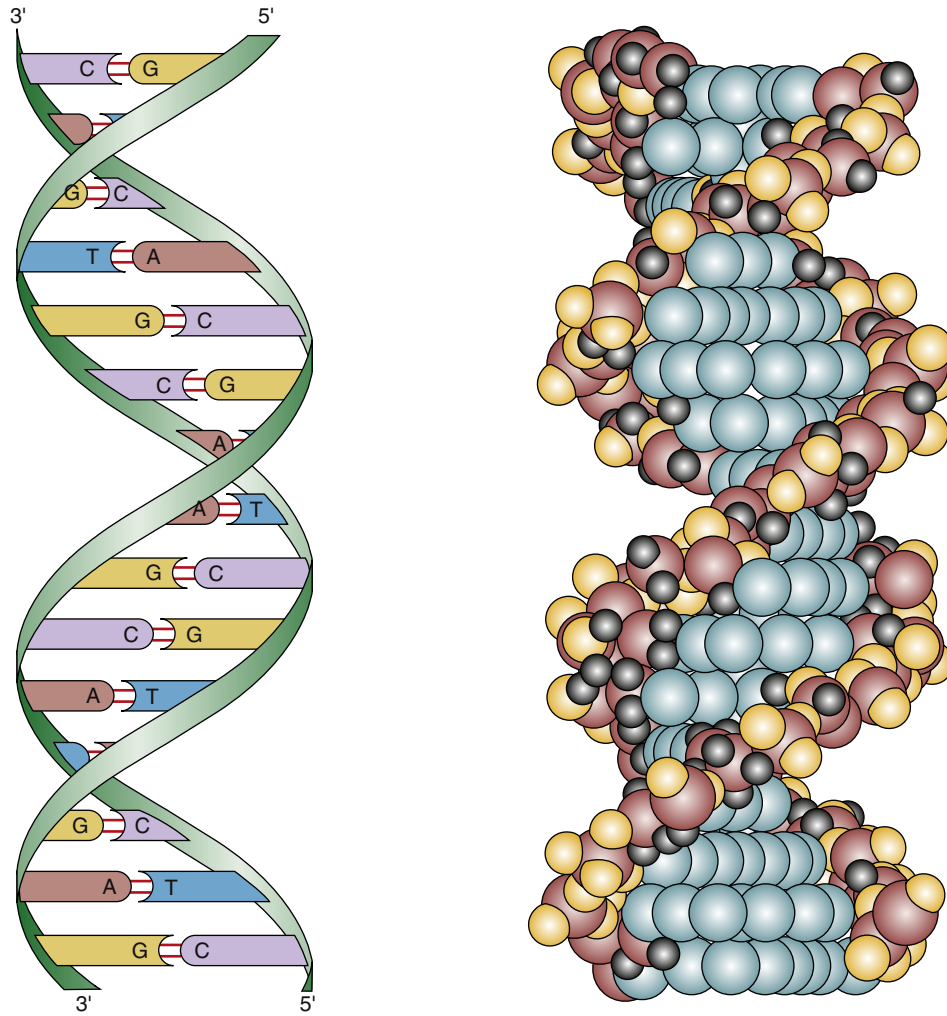

## MOLECULAR GENETICS

### Structure of DNA

In humans, DNA encodes genetic information in 46 long double-stranded chains of nucleotides called chromosomes.<sup>1</sup> The **nucleotides** consist of a 5-carbon sugar (deoxyribose), a phosphate group, and one of the four nucleotide bases (Figure 5-1). The nucleotide bases are divided into two types based on their chemical structure. The pyrimidines, cytosine and thymine, have single-ring structures. The purines, guanine and adenine, have double-ring structures (Figure 5-2). DNA polymers are formed by the chemical linkage of these nucleotides. The sugar-phosphate linkages, also called *phosphodiester bonds*, join the

**FIGURE 5-2** The two types of DNA bases are the single-ring pyrimidines and the double-ring purines. Thymine (T) and cytosine (C) are pyrimidines, and adenine (A) and guanine (G) are purines. Base pairing occurs between A and T and between C and G because of hydrogen bonds (*dots*).

**FIGURE 5-3** A schematic and space-filling model of the DNA double helix as proposed by Watson and Crick. The pairing of bases is specific and complementary: Cytosine (*C*) always pairs with guanine (*G*), and adenine (*A*) always pairs with thymine (*T*).

phosphate group on one sugar (attached to the 5-carbon) to the 3-carbon of the next sugar (see Figure 5-1). The four kinds of bases (A, C, G, T) are attached to the repeating sugar-phosphate chain. The bases of one strand of DNA form weak bonds with the bases of another strand of DNA. These noncovalent hydrogen bonds are specific and complementary (Figure 5-3). The bases G and C always bond together and the bases A and T always bond together. Nucleotides that are able to bond together in this complementary way are called *base pairs*.

In the early 1950s, Watson and Crick proposed that the structure of DNA was a double helix.<sup>2</sup> In this model, DNA can be envisioned as a twisted ladder, with the sugar-phosphate bonds as the sides of the ladder and the bases forming the rungs (see Figure 5-3). There is one complete turn of the helix every 10 base pairs. The two strands of DNA must be complementary to form the double helix; that is, the bases of one strand must pair exactly with their complementary bases on the other strand. The helix is wound around proteins called histones to form *nucleosomes* (Figure 5-4). DNA coupled to histones and other nuclear proteins is termed *chromatin*. When a cell is not dividing, the chromatin is loosely packed within the nucleus and not visible under the light microscope. During cell division, the chromatin becomes tightly condensed into the 46 chromosomes that become visible during mitosis.

The discovery of the double-helix model was profound because it immediately suggested how information transfer could be accomplished by such simple molecules. Because each DNA strand carries a nucleotide sequence that is exactly complementary to the sequence of its partner, both strands can be used as templates to create an exact copy of the original DNA double helix. When a cell divides to form two daughter cells, each daughter cell must receive a complete copy of the parent cell's DNA. The process of DNA replication requires separation of the DNA double helix by breaking the hydrogen bonds between the base pairs. Specific replication enzymes then direct the attachment of the correct (complementary) nucleotides to each of the single-stranded DNA templates. In this way, two identical copies of the original DNA double helix are formed and passed on to the two daughter cells during cell division.

### DNA Replication

Although the underlying principle of gene replication is simple, the cellular machinery required to carry out the replication process is complex, involving a host of enzymes and proteins.<sup>3</sup> These “replication machines” can duplicate DNA at a rate of 1000 nucleotides per second and complete the duplication of the entire genome in about 8 hours.<sup>4</sup> The DNA double helix must first separate so that new nucleotides can

**FIGURE 5-4** DNA is packaged by wrapping around protein complexes called histones to form beadlike structures called *nucleosomes*. During cell division, the coiled DNA becomes very condensed into chromosomes that are visible under the light microscope. During interphase and when genes are being transcribed, the DNA is more loosely packaged and not visible.

be paired with the old DNA template strands. The DNA double helix is normally very stable: the base pairs are locked in place so tightly that they can withstand temperatures approaching the boiling point. In addition, DNA is wrapped around histones and bound by a host of DNA-binding proteins through which the replication machinery must navigate. DNA replication is started by special proteins (initiator proteins) that pry the DNA strands apart at specific places along the chromatin, called *replication origins*. Then special enzymes (DNA helicases) are needed to rapidly unwind and separate the DNA strands, whereas helix-destabilizing proteins (also called single-stranded DNA-binding proteins) bind to the exposed DNA strands to keep them apart until replication can be accomplished (Figure 5-5). As the DNA is unwound in the replication fork, it becomes overly twisted downstream, so another set of enzymes, topoisomerases, cuts nicks in the DNA and allows it to unwind to prevent tangling. Ligases repair the nicks.

Once a portion of the DNA double helix has been separated, an enzyme complex, DNA polymerase, binds the single strands of DNA and begins the process of forming a new complementary strand of DNA. The polymerases match the appropriate base to the template base and catalyze the formation of the sugar-phosphate bonds that form the backbone of the DNA strand. Replication proceeds along the DNA strand in one direction only: from the 3' end toward the 5' end.<sup>4</sup> The ends of the DNA strands are labeled 3' and 5' according to the

exposed carbon atom at that end. Because two complementary DNA strands are antiparallel, DNA replication is asymmetrical; one strand, the leading strand, is replicated as a continuous polymer, but the lagging strand must be synthesized in short sections in a “backstitching” process (see Figure 5-5). The backstitched fragments of DNA, called Okazaki fragments, are then sealed together by DNA ligase to form the unbroken DNA strand. DNA polymerase is unable to replicate DNA located at the very ends of the chromosomes (the telomeres), so another special enzyme complex, telomerase, is needed for this. The telomeres are fairly short, being composed of approximately 1000 repeats of a GGGTTA sequence. When the telomeres are replicated, one side of the double helix (3' end) is always longer and loops around and tucks back into the strand. This prevents nuclear enzymes from mistaking the ends of the chromosomes as broken DNA ends and trying to attach them to each other. In many somatic cell types, telomerase activity is low and the cell’s chromosomes become slightly shorter with each cell division. Chromosomal shortening has been proposed as a mechanism of “counting” the number of replications and may be important in cellular aging and prevention of cancer (see Chapter 7). DNA replication is said to be semiconservative because each of the two resulting DNA double helices contains one newly synthesized strand and one original (conserved) strand (Figure 5-6).

The DNA polymerase also has the ability to proofread the newly synthesized strands for errors in base pairing. If an error is detected, the enzyme will reverse, remove the incorrect nucleotide, and replace it with the correct one. The fidelity of copying during DNA replication is such that only about one error is made for every  $10^9$  base pair replications.<sup>5</sup> The self-correcting function of the DNA polymerases is extremely important because errors in replication will be transmitted to the next generation of cells.

### Genetic Code

How do an organism’s genes influence its structural and functional characteristics? A central theory in biology maintains that a gene directs the synthesis of a protein. It is the presence (or absence) and relative activity of various structural proteins and enzymes that produce the characteristics of the cell. This definition of genes as protein-coding elements is not entirely correct because many “genes” code for ribonucleic acid (RNA) molecules as their final functional products and some genes may code for more than one protein product through alternate splicing of the RNA messages. Protein synthesis still holds a predominant place in understanding how genes direct cell structure and function. One of the surprising outcomes of the Human Genome Project was how little of the DNA in chromosomes contains coding segments (less than 2%) and the low number of genes that exist (23,000). Before the completion of the Human Genome Project, it was estimated that the human genome contained 100,000 genes.

Proteins are composed of one or more chains of amino acids (polypeptides) that fold into complex three-dimensional structures. Cells contain 20 different types of amino acids that connect in a specific sequence to form a particular protein (Table 5-1). Each type of protein has a unique sequence of amino acids that dictates its structure and activity.

If genes are to direct the synthesis of proteins, the information contained in just four kinds of DNA nucleotide bases must code for 20 different amino acids. This so-called genetic code was deciphered in the early 1960s.<sup>6,7</sup> It was determined that a series of three nucleotides (triplet) was needed to code for each of the 20 amino acids. Because there are four different bases, there are  $4^3$ , or 64, different possible triplet combinations. This is far more than needed to code for the 20 known amino acids. Three of the nucleotide triplets or **codons** do not code for amino acids and are called *stop codons* because they signal the

**FIGURE 5-5** Summary of the major proteins of the DNA replication fork. Helicase unwinds the DNA double helix, whereas helix-destabilizing proteins keep the strands from reuniting. The leading strand (top) can be replicated in a continuous manner, whereas the lagging strand (bottom) must be synthesized in pieces. Okazaki fragments are formed in a “backstitching” direction and then sealed together with DNA ligase.

end of a protein code. The remaining 61 codons code for 1 of the 20 amino acids (see Table 5-1). Obviously, some of the amino acids are specified by more than one codon. For example, the amino acid arginine is determined by six different codons. The code has been highly conserved during evolution and is essentially the same in organisms as diverse as humans and bacteria.

Several intermediate molecules are involved in the process of DNA-directed protein synthesis, including the complex protein-synthesizing machinery of the ribosomes and several types of RNA. RNA is structurally similar to DNA, except that the sugar molecule is ribose rather than deoxyribose, and one of the four bases is different in that uracil replaces thymine. Because of the biochemical similarity of uracil and thymine, both can form base pairs with adenine. In addition, RNA can form stable single-stranded molecules, whereas DNA strands anneal together, forming a double-stranded molecule.

Several functionally different types of RNA are involved in protein synthesis and cell function. The number and variety of RNA molecules existing within the nucleus is large (Box 5-1) and the exact function of most has yet to be determined. Some perform messenger RNA (mRNA) splicing, ribosome assembly, and quality control of RNA messages before they are transferred to the cytoplasm. The roles of three types of RNA that participate in protein production are well understood. Ribosomal RNA (rRNA) is found associated with the ribosome (see Chapter 3) in the cell cytoplasm. Messenger RNA is synthesized from the DNA template in a process termed **transcription** and carries the protein code to the cytoplasm, where the proteins are manufactured. The amino acids that will be united to form proteins are carried in the cytoplasm by a

third type of RNA, transfer RNA (tRNA), which interacts with mRNA and the ribosome in a process termed **translation**.

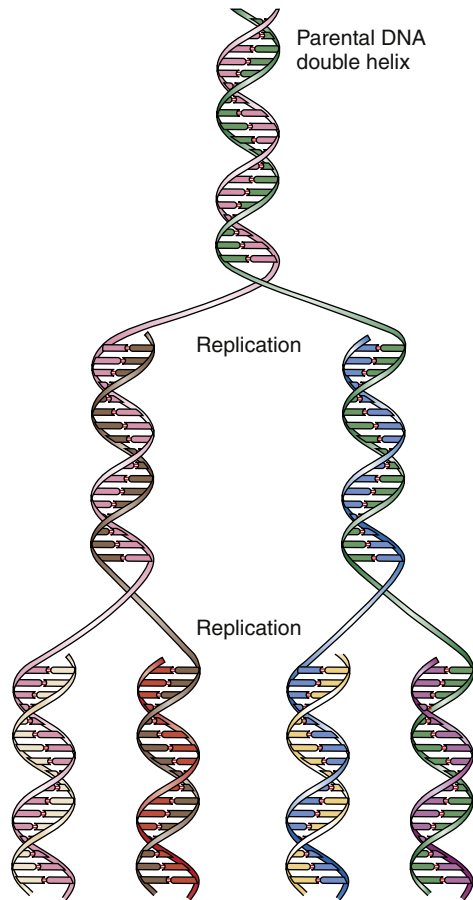

### Transcription

Transcription is the process whereby mRNA is synthesized from a single-stranded DNA template. The process is similar in some respects to DNA replication. Double-stranded DNA must be separated in the region of the gene to be copied, and specific enzyme complexes (DNA-dependent RNA polymerases) orchestrate the production of the mRNA polymer. Only one of the DNA strands contains the desired gene sequence and serves as the template for the synthesis of mRNA. This strand is called the *sense strand*. The other strand is termed the *nonsense* or *antisense strand* and is not transcribed into an RNA message.

Some genes are continuously active in certain cells, whereas others are carefully regulated in response to cellular needs and environmental signals. Special sequences of DNA near a desired gene may enhance or inhibit its rate of transcription. In general, a gene is transcribed when the RNA polymerase–enzyme complex binds to a promoter region just upstream of the gene’s start point. This binding event requires the cooperative function of numerous DNA-binding proteins. Once bound at the promoter, the RNA polymerase directs the separation of the DNA double helix and catalyzes the synthesis of the RNA message by matching the appropriate RNA bases to the DNA template (Figure 5-7). The RNA message is directly complementary to the DNA sequence, except that uracil replaces thymine.

In higher organisms, the DNA template for a particular protein is littered with stretches of bases that must be removed from the original

**FIGURE 5-6** DNA replication is semiconservative. Each of the new DNA double helices contains one newly synthesized strand and one original strand.

RNA transcript (pre-mRNA) before it can be translated into a protein. These intervening segments, called **introns**, are removed in the nucleus by a complex splicing process, resulting in an mRNA sequence that contains only the wanted segments, called **exons**. Introns range from 10 to 100,000 nucleotides in length.<sup>8</sup> On average, 90% of a gene is composed of introns and only 10% remains in the final mRNA transcript; thus, a single gene may contain dozens of introns that must be precisely removed. The function of introns remains largely a mystery, although they are believed to be important in the evolution of new genetic information and in gene regulation. Many of these intron sequences are conserved across species, which implies an important function. The removal of introns and splicing of the RNA transcript is mediated by a group of small RNA molecules located in specialized areas of the nucleus called the *spliceosomes*. The *snRNAs*, or small nuclear RNAs, cause the introns to loop out like a lariat, bringing the adjacent exons close together, followed by cutting and splicing. Another group of RNA-protein complex molecules called *small nuclear ribonucleoproteins* (snRNPs) attach to the pre-mRNA and prevent its escape through the nuclear envelope until all the necessary splicing has been accomplished.<sup>9</sup> Most pre-mRNA transcripts can be spliced in different ways to increase the number of different protein forms produced by a single gene.<sup>8</sup>

The processed mRNA is finally transported to the cell cytoplasm through pores in the nuclear membrane that contain complexes that inspect the mRNA for certain structural characteristics that distinguish it from RNA debris. The mRNA then directs the synthesis of a protein in cooperation with tRNA and the ribosomes. Each mRNA may serve as a template for thousands of copies of protein before it is degraded.

**Translation**

Translation is the process whereby messenger RNA is used to direct the synthesis of a protein. The mRNA is read in linear fashion from one end to the other, with each set of three nucleotides serving as a codon

**TABLE 5-1 RNA CODONS FOR THE DIFFERENT AMINO ACIDS AND FOR START AND STOP**

for a particular amino acid. The codons in the mRNA do not directly recognize the amino acids. Intermediary molecules or “translators” are required. These intermediaries are the tRNA molecules. A schematic drawing of a tRNA molecule is shown in Figure 5-8, illustrating its L-shaped, three-dimensional structure. A codon reading area (anticodon) is located at one end and an amino acid attachment at the other. A group of specialized enzymes that have a binding pocket for a particular amino acid and a reading pocket for the anticodon are needed to attach the correct amino acid to its appropriate tRNA. The anticodon is formed by a sequence of three nucleotides. Recognition between the mRNA codon and the tRNA anticodon is accomplished by the same kind of complementary base pairing as was described for DNA. The complex machinery of the ribosome is needed to align the tRNA on the mRNA and to catalyze the peptide bonds that hold the amino acids together. **Ribosomes** are large complexes of protein and RNA. Each ribosome is composed of two subunits that are first assembled in a special part of the nucleus called the *nucleolus* and then transported through the nuclear pores to the cytoplasm. The smaller subunit binds the mRNA and the tRNA, whereas the larger subunit catalyzes the formation of peptide bonds between the incoming amino acids. The

ribosome must first find the appropriate starting place on the mRNA to set the correct reading frame for the codon triplets. Then the ribosome moves along the mRNA, translating the nucleotide sequence into an amino acid sequence, one codon at a time<sup>10</sup> (Figure 5-9). The newly synthesized protein chain is released from the ribosome when a “stop codon” signaling the end of the message is reached. The new protein is typically bound by “chaperone” proteins that help it fold into its final three-dimensional shape. Amino acids belong to one of three groups—polar, nonpolar, or charged—which affects how the protein is processed and folded into its final structure (Figure 5-10).

### BOX 5-1 TYPES OF RNA PRODUCED IN CELLS

mRNA—messenger RNA; codes for proteins  
 rRNA—ribosomal RNA; within ribosomes, catalyzes protein synthesis  
 tRNA—transfer RNA; adaptors between mRNA and amino acids in protein synthesis  
 snRNA—small nuclear RNA; splicing of pre-mRNA in the nucleus  
 snoRNA—small nucleolar RNA; processing of rRNA in the nucleolus  
 scaRNA—small cajal RNA; modifies snoRNA and snRNA  
 miRNA—micro RNA; regulates gene expression by blocking mRNA translation  
 siRNA—small interfering RNA; turns off gene expression through alteration in chromatin

### KEY POINTS

- Genes are the basic units of inheritance and are composed of DNA located on chromosomes. Genes direct the daily activities of the cell by controlling the production of proteins. Less than 2% of DNA forms genes that code for proteins. Some DNA codes for RNA transcripts that perform a variety of functions, but no function is known for the majority of the genomic DNA.
- The structure of DNA can be envisioned as a twisted ladder, with the sugar-phosphate bonds as the sides of the ladder and the four nucleotide bases (adenosine [A], cytosine [C], guanine [G], and thymine [T]) forming the rungs. The nucleotides form complementary base pairs, C with G and A with T.
- The DNA double helix must separate into single strands to provide a template for synthesizing new, identical DNA strands that can be passed on to daughter cells during cell division. DNA replication is accomplished by the enzyme complex DNA polymerase. DNA synthesis has extremely high fidelity.
- A linear sequence of DNA that codes for a particular protein is called a gene. During transcription, genes provide a template for the synthesis of mRNA by the enzyme complex RNA polymerase.
- After appropriate cutting and splicing of the pre-mRNA transcript, the mRNA is transported to the cytoplasm and translated into a protein. Each nucleotide triplet (codon) in the mRNA codes for a particular amino acid. Protein synthesis is accomplished by ribosomes, which match the mRNA codon with the correct tRNA anticodon and then catalyze the peptide bond to link amino acids together into a linear protein.

**FIGURE 5-7** A moving RNA polymerase complex unwinds the DNA helix ahead of it while rewinding the DNA behind. One strand of the DNA serves as the template for the formation of mRNA.

## REGULATION OF THE GENOME

The genome contains the genetic information of the cell and ultimately determines its form and function. All the various cells in a multicellular organism contain the same genes, and differences in cell type are thought to be the result of differences in DNA *expression*. To maintain the cell's phenotype, some genes must be actively transcribed, whereas others remain quiescent. In addition, the cell must be able to change the expression of certain genes to respond and adapt to changes in the cellular environment. At any one time, a cell expresses 30% to 60% of its approximately 23,000 genes.<sup>11</sup> There is evidence that gene expression can be regulated at each of the steps in the pathway from DNA to RNA to protein synthesis. The proteins made by a cell can be controlled

**FIGURE 5-8** Schematic drawing of a transfer RNA (tRNA) molecule. Each tRNA binds a specific amino acid, which corresponds with the three-base sequence at the anticodon end.

in the following ways: (1) regulating the rate and timing of gene transcription; (2) controlling the way the mRNA is spliced; (3) selecting the mRNAs that are transported to the cytoplasm; (4) selecting the mRNAs that are translated by ribosomes; (5) selectively destroying certain mRNAs in the cytoplasm; or (6) selectively controlling the activity of the proteins after they have been produced.<sup>11</sup>

For a majority of genes, the most important regulators of expression are the transcriptional controls. Cells contain DNA-binding proteins that are able to enhance or inhibit gene expression. These gene regulatory proteins recognize and bind only particular DNA sequences and thus are specific to the genes they regulate.<sup>12</sup> The genome contains about 2000 different genes that code for gene regulatory proteins, each of which works in combination with others to control numerous genes. The ability to regulate gene expression allows the cell to alter its structure and function in response to signals from its environment.

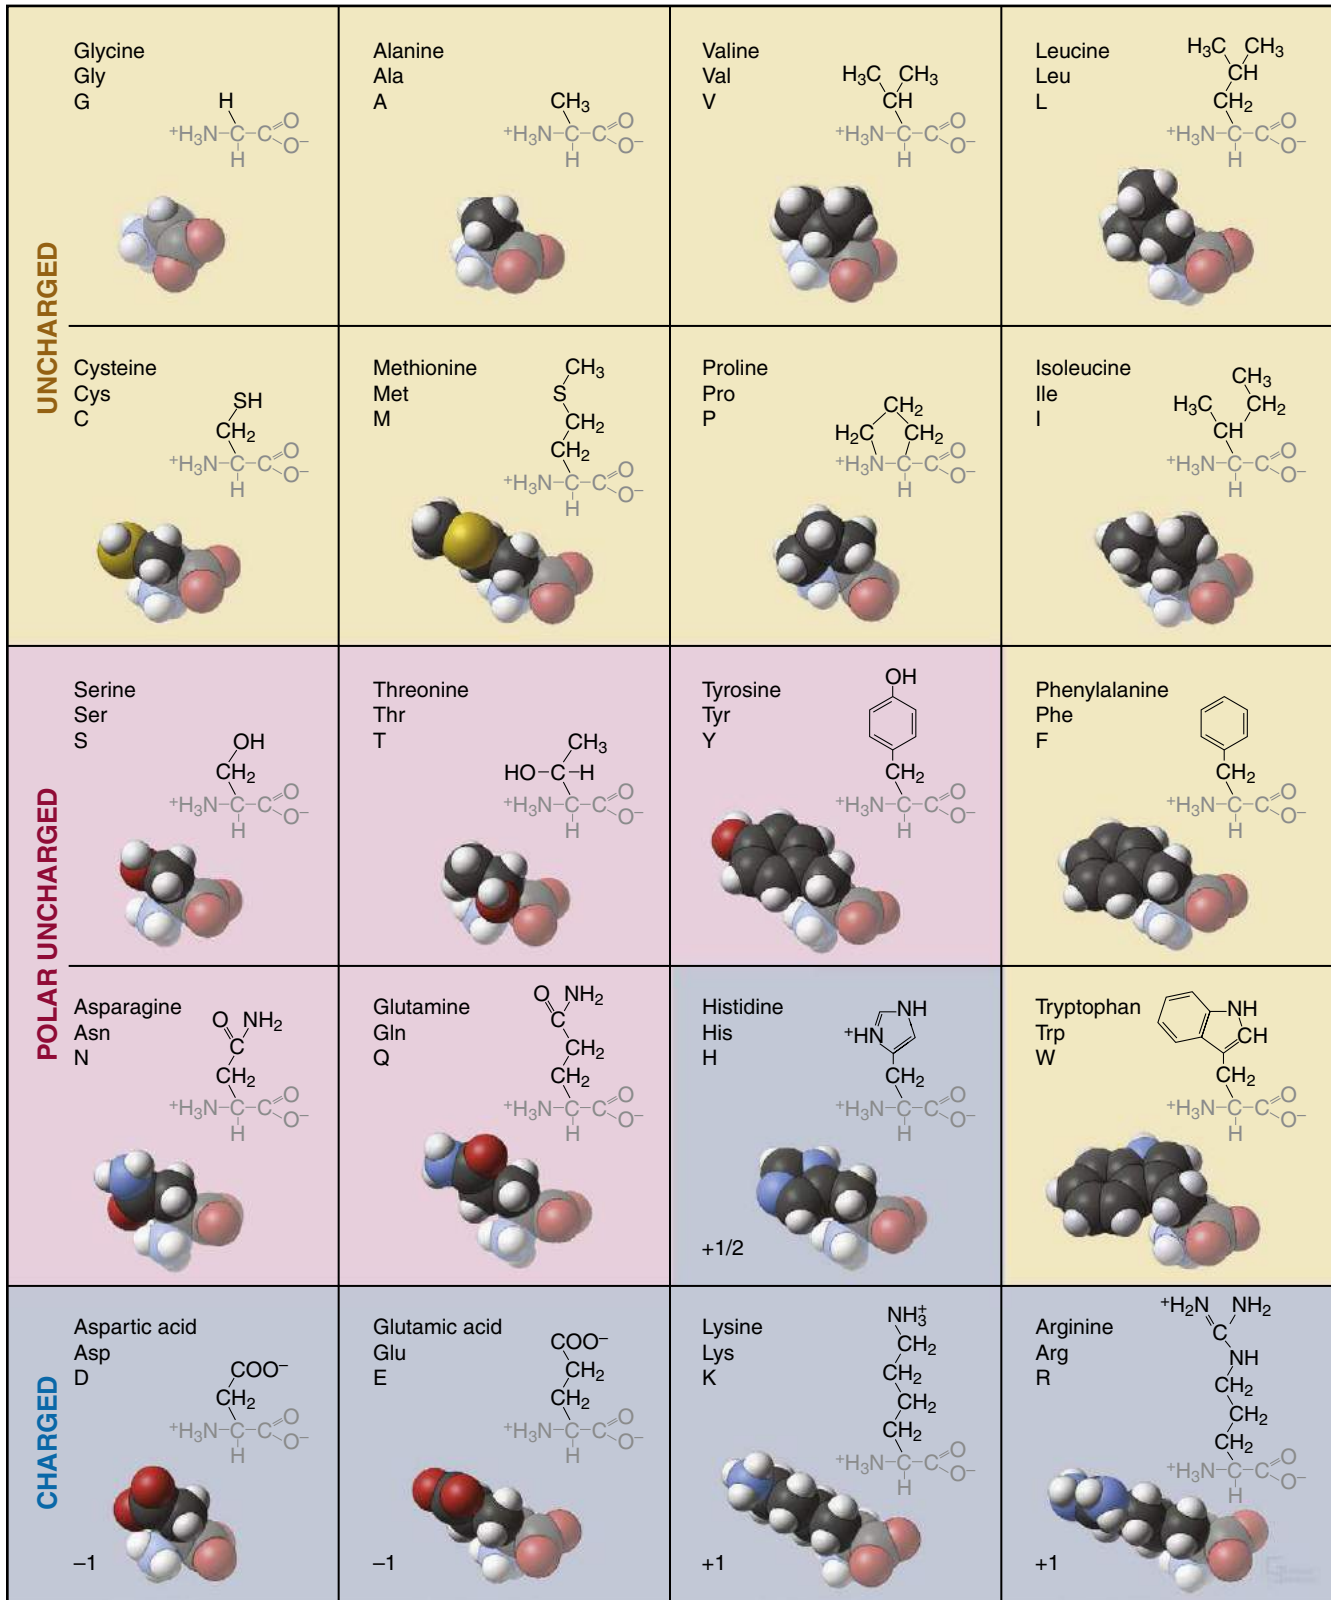

### Transcriptional Controls

The gene regulatory proteins described in the preceding paragraphs are thought to control gene transcription by binding near the promoter sequence of DNA, where the RNA polymerase must attach to initiate transcription of the gene.<sup>13</sup> Binding of the regulatory proteins may either enhance or inhibit RNA polymerase binding and subsequent transcription of the gene. This is sometimes referred to as “turning on” or “turning off” a gene. The DNA-binding proteins are able to recognize their specific binding sites because of small variations in structure of the external surface of the DNA double helix and do not require separation of the strands to bind. These regulatory DNA-binding proteins can be categorized either as positive controls that activate transcription (*activators*) or as negative controls that inhibit transcription (*repressors*).

In humans, the strategies for gene regulation are complex. Gene regulatory proteins often bind DNA segments far from the gene being regulated, and binding of several gene regulatory proteins in combination is often necessary. A critical step in initiating gene transcription in human cells is the assembly of general transcription factors at the promoter region.<sup>14</sup> General transcription factors are a group of DNA-binding proteins necessary for RNA polymerase activity, and initiation of transcription does not occur without them. Regulatory gene activator proteins help to collect the transcription factors at the promoter of the correct gene by first recognizing and binding to a specific DNA

**FIGURE 5-9** Synthesis of a protein by the ribosomes attached to a mRNA molecule. Ribosomes attach near the start codon and catalyze the formation of the peptide chain. The mRNA strand is read in groups of three nucleotides (codons) until the stop codon is reached and the peptide is released. Several ribosomes may translate a single mRNA into multiple copies of the protein.

**FIGURE 5-10** The 20 amino acids that form proteins have different chemical structures that affect their solubility in lipids and water. Nonpolar amino acids tend to locate in the lipid bilayer or in the interior of globular proteins whereas polar and charged amino acids interact well with water. (From Pollard T, Earnshaw W: *Cell biology*, 2007, Philadelphia, Saunders.)

**FIGURE 5-11** Gene activator proteins coordinate the assembly of general transcription factors at the promoter region of the gene to be transcribed. RNA polymerase is unable to bind and begin transcription until the requisite transcription factors are in place.

sequence and then coordinating the assembly of the transcription factors (Figure 5-11).

Inhibition of transcription is achieved by gene repressor proteins, which also recognize and bind specific DNA sequences but inhibit the assembly of transcription factors at the site. Some repressor proteins may function simply by binding to and physically blocking the promoter region, but most appear to exert their effects through more complex mechanisms, such as compacting the DNA to make it difficult to pry open, interfering with activator proteins, and binding up or inhibiting transcription factors. Inappropriate transcription of genes in a particular cell may have dire consequences for the cell or for the organism as a whole and is therefore a carefully regulated process. The presence, position, and activity of gene regulatory proteins may be regulated by various signaling cascades within the cell. Many of these signaling cascades are triggered by changes in the cell's environment, which then alter gene transcription (see Chapter 3). This process is very complex, with numerous signaling pathways often converging on a particular gene regulatory system. Even after the mRNA transcript is produced it may not be allowed to reach the ribosome for translation. Small RNA molecules called micro RNA (miRNA) and small interfering RNA (siRNA) can anneal to complementary segments of the mRNA within the nucleus. In some cases, these small RNAs regulate gene splicing, but in other cases they “silence” the gene by preventing the mRNA from being translated into a protein.

#### KEY POINTS

- All the cells in an individual have essentially the same DNA; however, cells differ greatly in structure and function. This occurs because genes are selectively expressed in particular cells.
- Gene expression can be regulated at any step in the pathway from DNA to RNA to protein synthesis. The most important regulators are transcriptional controls.
- A critical step for initiation of gene transcription is the assembly of general transcription factors at the promoter region of the gene.
- The actions of general transcription factors and RNA polymerase are controlled by a large number of regulatory proteins that specifically bind to DNA. The presence of certain DNA-binding proteins at specific sites can activate or repress the transcription of a particular gene in response to signals in the cell's environment.
- A number of small RNA molecules function to regulate mRNA transcription and translation.

## DIFFERENTIATION OF TISSUES

### Cell Diversification and Cell Memory

The cells of a multicellular organism tend to specialize to perform particular functions in coordination with other cells and tissues of the body. Cells not only must become different during development but also must remain different in the adult, after the original cues for cell diversification have disappeared. The differences among cell types are ultimately the result of the differentiating influences experienced in the embryo. Differences are maintained because the cells retain the effects of those past influences and pass the memory on to their descendants. When a skin cell divides to replace lost skin cells, the daughter cells are also skin cells; when a liver cell divides, its daughter cells are liver cells; and so on. The behavior of cells of higher organisms is governed by their genome and their present environment, as well as by their developmental history.

There is substantial evidence that the differences in tissue structure and function in a particular organism are not due to deletions or additions to the genes.<sup>15</sup> All the cells of an organism contain essentially the same genes. It is the expression of a relatively few tissue-specific genes that results in differences among cell types.<sup>11</sup> The exact mechanisms leading to the stable expression of tissue-specific genes in particular cell types are partly unknown; however, differences in DNA packaging and the combination of gene regulatory proteins passed on during cell division are thought to be important. The DNA in human cells is extensively packaged, so that 40 inches of linear DNA can be compacted to fit into the cell nucleus. However, different regions of chromosomes can be more or less condensed<sup>1</sup> (see Figure 5-4).

Some regions of DNA, called **heterochromatin**, are so condensed that they are not open to transcription. It is thought that the pattern of packaging as well as the DNA-binding proteins that regulate it are transmitted to progeny when a cell divides such that the pattern of gene expression is maintained as the cell's developmental memory. An example of this mechanism is the inactivation of one of the X chromosomes in females.<sup>16</sup> In mammals, all female cells contain two X chromosomes (XX), whereas male cells contain an X and a Y chromosome (XY). One of the X chromosomes in females is permanently inactivated early in development by condensed packaging. This apparently occurs to prevent a double dose of the X gene products. Which of the two X chromosomes is inactivated in a particular cell is a random event. However, the same X chromosome will be inactive in all of the

cell's progeny. Segments of other chromosomes are also highly condensed into heterochromatin, which varies in different cell types. The processes that initiate variations in DNA packaging are not well understood; however, the pattern of inactivated genes in a particular cell type is “remembered” in subsequent generations of cells and may explain, in part, how differentiated tissues remain differentiated in the adult.

## Mechanisms of Development

Embryonic development is associated with selective gene expression that controls four essential processes to enable a single cell to develop into a complex organism: (1) cell proliferation, (2) cell specialization, (3) cell-to-cell interactions, and (4) cell movement and migration.<sup>17</sup> Each time a cell divides it must retain memory of the developmental events that have preceded the division so that it can progress along a developmental pathway toward becoming a differentiated tissue. Cells have a genetic memory: the genes a cell expresses and the way it behaves depend on the cell's past as well as its present environment. There is no overall controlling center; each cell must make its own developmental decisions.

There are two major classes of proteins that are particularly important for multicellular development: (1) transmembrane proteins in the cell surface that participate in cell adhesion and communication; and (2) DNA-binding proteins that regulate gene transcription. Differences between cells in an embryo are a necessary prelude to development of a multicellular organism and arise in various ways. Very early in embryonic development, cells begin to divide asymmetrically so that daughter cells are not identical—those on the outside of the group of cells receive different environmental cues than those on the inside, which are surrounded by other cells. These simple differences in cell-to-cell adhesion may alter the transcription of a set of genes. The altered genetic expression will then be passed on to daughter cells in the next cell division, making them diverge further from the original cell. Subsequently, the cell will respond differently to environmental influences, which further alter the cell's structure and function. Thus cells become committed to a developmental pathway over the course of many cell divisions that transmit the history of previous exposures through sequential changes in gene expression.

Continued interactions with nearby cells, chemical gradients, and extracellular matrix components provide clues to guide the cell to its appropriate form and location in the developing organism. Chemicals that control the patterning of fields of nearby tissue are termed **morphogens**. For example, cells in the head region may specialize to secrete a “position signal” for other cells. The morphogen is progressively degraded as it diffuses through the neighboring tissue, such that it has higher concentration close to the source. A particular cell will have information regarding its proximity to the head region based on the surrounding concentration of the chemical. Morphogens are thought to be effective only over small distances. Thus the gross distinctions between head and tail, for example, must be made very early in the embryo, and morphogens can provide only a general pattern for future development. Successive levels of detail can be provided later by other positional signals.

The organization of molecules surrounding the cell surface also provides positional information. The extracellular matrix is composed of a large meshwork of molecules that is produced locally by cells in the area. Some common components include the proteins collagen and elastin, long polysaccharide chains called *glycosaminoglycans*, and a variety of peptides, growth factors, and hormones. The extracellular matrix is highly organized, with components binding to each other and to the cell membrane in specific ways. The extracellular matrix is thought to be important in cell development through its ability to screen or modulate the transport of molecules, such as growth factors,

to the cell membrane and through direct contacts with the cell membrane that effect changes in cell structure and function.<sup>18</sup>

The extracellular matrix surrounding the cells in different locations provides positional information to cells that must migrate to their final destination.<sup>18</sup> In vertebrates, connective tissue cells appear to provide much of this positional information. While the migratory cell travels through the connective tissue, it continually samples the surroundings, searching for cues to guide it. Migratory cells with specific cell surface receptors may interact differentially with the extracellular matrix in different areas. In this way the migratory cell can be guided along particular paths and induced to settle in particular areas. Once the migratory cell has settled, local extracellular matrix molecules may further affect the cell's growth rate, differentiation, and likelihood of survival.

Interactions between the extracellular matrix and nearby cells are mediated primarily by binding proteins called **integrins**.<sup>19</sup> Integrins are transmembrane proteins that tie the cell's cytoskeleton to particular matrix structures (see Chapter 3). They enable the cytoskeleton and extracellular matrix to communicate across the plasma membrane in specific ways. In addition to inducing cells to bind in a particular location, integrins have been shown to activate intracellular signaling pathways, which may influence cell behavior in numerous ways (e.g., cell shape, polarity, metabolism, development, and differentiation).

The steps leading to the development of differentiated tissues in a multicellular organism are such that, once differentiated, a cell type generally does not revert to earlier forms. Some cells in a tissue are terminally differentiated and have limited capacity to change form or replicate. Tissues also maintain less-differentiated stem cells that are able to proliferate depending on environmental cues. Some stem cells, located mainly in the bone marrow, are quite similar to embryonic stem cells and can be recruited into tissues where they proliferate and differentiate into tissue cells. The ability of these multipotent or pluripotent stem cells to survive and differentiate correctly in their adopted home depends on making complex cell-to-cell and cell-to-matrix connections. In the absence of an appropriate environment, the cells will undergo apoptosis and die (see Chapter 4).

## Differentiated Tissues

The more than 200 different cell types in the adult human are generally classified into 4 major tissue categories: epithelium, connective tissue, muscle, and nerve.<sup>20</sup> Tissue types and some of their subtypes are summarized in Table 5-2. Most of the organ systems of the body are combinations of these four tissue types mixed in a highly organized and cooperative manner.

### Epithelial Tissue

Epithelial cells cover the majority of the external surfaces of the body and line the glands, blood vessels, and internal surfaces. Epithelial cells adopt a variety of shapes and functions, depending on their locations. For example, the *stratified* epithelium that composes the epidermis of the skin is several layers thick and is primarily protective in function. New epithelial skin cells are formed from stem cells in the deepest part of the epidermis, where it contacts the basal lamina. As cells mature, they move outward toward the surface until they become keratinized and finally flake away (Figure 5-12). Keratin is a tough protective protein that is present in large quantities in the outer skin layers of flattened, dead epithelial cells. The epidermis in humans is completely replaced about once per month, but turnover can occur more rapidly after injury to the skin.<sup>20</sup>

In addition to stratified epithelium, the epithelium may be characterized as simple or pseudostratified according to the number and arrangement of cell layers (Figure 5-13). *Simple* epithelium consists of a single layer of cells, all of which contact the basement membrane.

**TABLE 5-2 MAJOR CATEGORIES AND LOCATION OF BODY TISSUES**

TISSUE TYPE	LOCATIONS
<b>Epithelial Tissue</b>	
Simple squamous	Lining of blood vessels, pulmonary alveoli, Bowman capsule
Simple cuboidal	Thyroid, sweat, and salivary glands; kidney tubules
Simple columnar	Lining of intestine, glandular ducts
Pseudostratified (mixed cell shapes)	Male urethra, respiratory tract passages
Stratified squamous	Skin, mucous membranes
Stratified columnar	Epiglottis, anus, parts of pharynx
Stratified transitional (layers of different cell shapes)	Bladder
<b>Connective Tissue</b>	
Loose	Widespread locations, dermis of skin, adipose tissue, organs
Dense/supportive	Cartilage, bone, tendons, joints, fascia surrounding muscles
Hematopoietic	Bone marrow, lymph tissue, plasma
<b>Muscle Tissue</b>	
Skeletal	Voluntary muscles of body
Cardiac	Heart (myocardium)
Smooth	Intestine, blood vessels, bladder, uterus, airways
Myoepithelial	Mammary, sweat, and salivary glands
<b>Nervous Tissue</b>	
Neurons	Central and peripheral nerves
Neuroglia	Primarily central nervous system

**FIGURE 5-12** Organization of epidermal skin layers, showing the flattened keratinized outer layer. Epithelial cells are continually produced by stem cells at the basal lamina and then migrate to the surface.

**FIGURE 5-13** Various epithelial tissue shapes and layering.

Simple epithelium is found in the lining of blood vessels and body cavities, in many glands, and in the alveoli of the lungs. The simple epithelium that lines the blood vessels is called *endothelium*. Simple epithelium also forms the kidney tubules and lines the intestine, where absorption is its primary function. *Stratified* epithelium consists of two or more layers of epithelial cells and is found in mucous membranes, such as the mouth, and in the skin, as mentioned previously. Epithelium that appears to be more than one layer thick because of a mixture of cell shapes but is actually a single layer is called *pseudostratified* epithelium. The linings of the respiratory tract and some glands contain pseudostratified epithelium.

Epithelial cells may also be classified according to cell shape. The three basic cell shapes are squamous, cuboidal, and columnar. Squamous cells are thin in comparison to their surface area and have a flattened appearance. Cuboidal cells are approximately equal in width and height, similar to a cube. Columnar cells are a bit taller than they are wide, resembling a rectangular column. Several classifications of epithelial tissue are given in [Table 5-2](#), using both shape and layering as criteria.

**FIGURE 5-14** Schematic drawing of loose connective tissue. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 144.)

### Connective Tissue

Connective tissue is the most abundant and diverse tissue in the body, including cell types as different as bone cells, fat cells, and blood cells.<sup>20</sup> Connective tissue commonly functions as a scaffold on which other cells cluster to form organs, but it does much more than hold tissues together. Connective tissue cells often form an elaborate extracellular matrix, which is thought to be important in the maintenance of cell differentiation (Figure 5-14). Connective tissue cells play an important part in the support and repair of nearly every tissue and organ in the body. Three major classifications of connective tissue are commonly identified: loose connective tissue, dense or supportive tissue, and hematopoietic tissue.

Loose connective tissue appears unstructured, with a fair amount of space between fibers of the extracellular matrix. The matrix contains a number of cell types and an elaborate meshwork of protein and other molecules (Figure 5-15). The primary protein constituents are collagen, elastin, and reticular fibers. Collagen is composed of tough, non-elastic bundles of protein fibers that are secreted by fibroblasts. It gives structural strength to skin, tendons, ligaments, and other tissues. The ability of a structure to withstand deforming and stretching forces is due, in large part, to elastin, which can return to its original length after being stretched, like a rubber band. Elastin is important to the function of structures such as the aorta, which must expand to accept the blood ejected from the heart during systole and bounce back to its original shape during diastole. Reticular fibers are short branching fibers that provide networks for the attachment of connective tissue to other cell types, such as epithelial cell attachments in glands, hematopoietic cells in bone marrow, and the parenchymal cells (functional cells) in organs. Cell types associated with loose connective tissue include the fibroblasts, mast cells, and adipocytes (fat cells).

Dense or supportive connective tissue is rich in collagen, which gives strength to structures such as cartilage, tendon, bone, and ligaments. The collagen fibers are more organized and densely packed than fibers found in loose connective tissue. Cartilage cells, or

### Loose connective tissue

**FIGURE 5-15** Scanning electron micrograph of fibroblasts in loose connective tissue of a rat cornea. The matrix is composed primarily of collagen fibers (magnification  $\times 440$ ). (From Solomon EP: *Introduction to human anatomy and physiology*, ed 3, Philadelphia, 2009, Saunders, p 36.)

### Bone

**FIGURE 5-16** Photomicrograph of a section of compact bone showing circular networks formed by the action of osteoclasts and osteoblasts as they remodel the bone. The osteocytes occupy the lacunae and canals. (From Solomon EP: *Introduction to human anatomy and physiology*, ed 3, Philadelphia, 2009, Saunders, p 36.)

chondrocytes, may be found in the trachea, joints, nose, ears, vertebral disks, organs, and the young skeleton. Once formed, the collagenous extracellular matrix structures require little maintenance and do not receive a blood supply. Bone is a very dense form of connective tissue composed of a mixture of tough collagen fibers and solid calcium phosphate crystals in approximately equal proportions. Throughout the bone's hard extracellular matrix are channels and cavities occupied by living cells (osteocytes) (Figure 5-16). These cells incessantly model and remodel their bony environment, responding to environmental signals. These osteocytes are of two kinds: the cells that erode old bone

**FIGURE 5-17** Scanning electron micrograph of red and white blood cells in the lumen of a blood vessel. Red blood cells are smooth and concave, whereas white blood cells are rough and rounded. (From Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 1451. Courtesy Ray Moss.)

are called *osteoclasts*, whereas the cells that form new bone are called *osteoblasts*. Osteoblasts detect when a bone is subjected to a greater load stress and adapt by strengthening the bone mass. Conversely, when the load is removed, as during bed rest, the osteoclasts busily digest the bone, often resulting in some of the common complications of immobility. Osteoclasts, like macrophages, are derived from monocytes that are produced in the bone marrow. The monocytes travel via the bloodstream and collect at sites of bone resorption, where they fuse together to become osteoclasts.<sup>21</sup> Osteocyte activity is essential for bone growth and the repair of bone injuries. (See Chapter 50 for a detailed description of the musculoskeletal system.)

The blood-forming organs of the body are formed by a specialized type of connective tissue called *hematopoietic* tissue. The blood cells include the red cell, or **erythrocyte**, which is specialized for the transport of oxygen; the platelet, or **thrombocyte**, which is important in blood coagulation; and a host of white cells, or **leukocytes**, which mediate immune function. Blood-forming tissue is located in the bone marrow, spleen, and lymphatic tissue. Hematopoietic cells are necessarily nomadic, traveling to distant areas of the body and sometimes settling in a particular organ, sometimes moving continuously (Figure 5-17). Blood cells have a short life span in comparison to other cells and must continually be replenished. This is accomplished by the hematopoietic stem cells. Stem cells reside primarily in the bone marrow and are multipotent; they may differentiate into any of the blood cell types. This results in a system that can respond quickly to the changing needs of the body.

### Muscle Tissue

The term *muscle* refers to tissues that are specialized for contraction. Muscle cells, or myocytes, are usually long and thin and packed with the proteins actin and myosin, which constitute the contractile apparatus. In mammals, there are four main categories of muscle cells: skeletal, cardiac, smooth, and myoepithelial (Figure 5-18).<sup>20</sup> Contraction in all four types depends on the presence of intracellular free calcium and

occurs because of interactions between actin and myosin filaments. Actin and myosin filaments differ among cell types with regard to amino acid sequence, arrangement within the cell, and the mechanisms that control contraction. The mechanism of muscle contraction has been called *the sliding filament hypothesis* or *cross-bridge theory*. These terms describe the interactions of the actin and myosin filaments while they form bonds and pull past each other, causing the muscle cell to shorten. Contraction is initiated by an increase in intracellular free calcium concentration and requires energy in the form of adenosine triphosphate (ATP). A detailed description of actin-myosin cross-bridging and the role of calcium, troponin, and tropomyosin can be found in Chapter 17.

*Skeletal muscle* is responsible for nearly all voluntary movements. Skeletal muscle cells fuse together to form long multinucleated fibers that can be huge, up to 0.5 meter (m) in length. Once fused and differentiated into mature skeletal muscle cells, they cannot enter the cell cycle and divide to produce new cells. Skeletal muscle stem cells (satellite cells) are retained in the muscle tissue and can proliferate in response to muscle damage. The actin and myosin proteins in skeletal muscle are aligned in orderly arrays, giving the tissue a striped appearance under the microscope, which in turn has led to the term *striated muscle*. Skeletal muscle contracts in response to stimulation from the motor neurons of the nervous system (see Chapter 50). As in other types of muscle, stimulation results in an increase in free calcium concentration within the cell. In skeletal muscle, the calcium originates from internal storage sites in the sarcoplasmic reticulum. Contraction is initiated when the calcium binds troponin, a regulatory protein attached to the actin filament. Because of the high energy requirements of contracting skeletal muscle, the cells are packed with energy-producing mitochondria.

Like skeletal muscle, *cardiac muscle* also has a striated appearance attributable to the systematic organization of its actin and myosin filaments. Cardiac muscle cells are linked by special structures, called *intercalated disks* and *gap junctions*, that cause the tissue to behave as

**FIGURE 5-18** The four classes of muscle cells. **A**, Skeletal muscle. **B**, Heart (cardiac) muscle. **C**, Smooth muscle (bladder). **D**, Myoepithelial cells in a mammary gland. a **syncytium**: all the cells contract synchronously. Cardiac muscle contracts in response to activation of pacemaker cells in the heart that have the special property of automaticity. *Automaticity* refers to the inherent ability of the cell to initiate an action potential without outside stimulation. The contractile mechanisms of cardiac muscle are similar to those of skeletal muscle, requiring free calcium to interact with troponin, resulting in the formation of actin-myosin cross-bridges. In cardiac muscle, some of the free calcium originates from the sarcoplasmic reticulum, but diffusion into the cell through channels in the cell membrane is also necessary. These membrane calcium channels represent an important difference from skeletal muscle, because they can be manipulated by drugs (calcium channel blockers) without disrupting skeletal muscle control. (Cardiac muscle is discussed in Chapter 17.)

*Smooth muscle* comprises a diverse group of tissues located in organs throughout the body. Smooth muscle generally is not under voluntary control and therefore is called *involuntary muscle*. Some types of smooth muscle are able to contract intrinsically, and most are influenced by the autonomic nervous system. Smooth muscle is found in blood vessels and in the walls of hollow organs, such as those of the gastrointestinal tract, uterus, and large airways.

The structure of smooth muscle differs considerably from that of skeletal and cardiac muscle, and therefore some classification schemes consider it to be a member of the connective tissue family.<sup>20</sup> The actin and myosin filaments are less organized in smooth muscle, and the muscle does not have striations. Smooth muscle contraction tends to

be slower and can be maintained indefinitely. This is critical to the function of blood vessels, which must maintain a degree of contraction or vascular tone to maintain the blood pressure. Smooth muscle has no troponin and uses the protein calmodulin as the calcium-binding regulatory protein. When calmodulin binds calcium ions in the cytoplasm, it activates the enzyme myosin light chain kinase (MLCK), which phosphorylates myosin and stimulates the rate of cross-bridge formation. Actin filaments are attached to structural proteins called dense bodies that pull in the sides of the muscle cell when actin-myosin cross-bridging causes the filaments to increasingly overlap (Figure 5-19). Smooth muscle contraction is highly dependent on the diffusion of extracellular calcium into the cell through calcium channels in the plasma membrane (sarcolemma). Thus, like cardiac muscle, smooth muscle can also be affected by drugs that alter the calcium channel's ability to conduct calcium. For example, calcium channel-blocking drugs are used to cause the smooth muscle in arterial blood vessels to relax as a treatment for high blood pressure.

*Myoepithelial cells* represent the fourth class of muscle cells. They are located in the ducts of some glands (e.g., mammary, sweat, and salivary). Unlike all other types of muscle, myoepithelial cells lie in the epithelium and are derived from embryonic ectoderm, whereas skeletal, cardiac, and smooth muscle are derived from embryonic mesoderm. Myoepithelial cells contract in response to specific stimuli (e.g., oxytocin in the mammary gland) and serve to expel the contents from the gland.

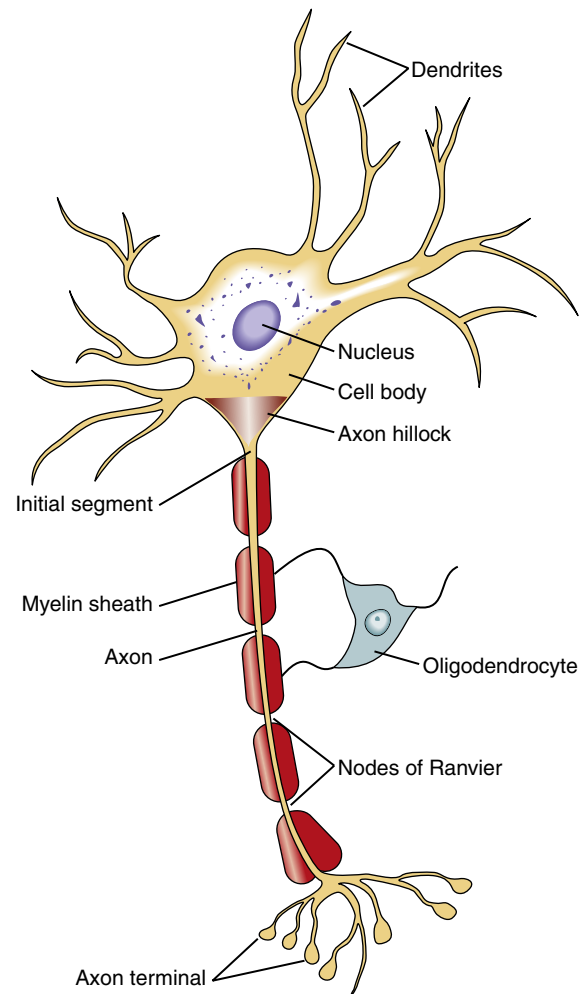

**FIGURE 5-19** Schematic drawing of a smooth muscle cell when relaxed (**A**) and contracted (**B**). Contraction begins with the entry of  $\text{Ca}^{2+}$  into the cell through L-type voltage-gated calcium channels.  $\text{Ca}^{2+}$  is also released from the sarcoplasmic reticulum. The calcium ions bind to cytoplasmic calmodulin to form a complex that activates myosin light chain kinase (MLCK). The kinase attaches a phosphate to the myosin head area, which stimulates its cycling activity. The myosin binds to actin filaments and tugs on them with each cross-bridge cycle. While the myosin and actin filaments pull closer together and overlap more, the muscle cell shortens. The actin filaments are attached to dense bodies that are analogous in function to the Z-disk protein in cardiac and skeletal muscle. Smooth muscle can maintain long-term actin-myosin cross-bridges that maintain a level of tone.

### Nervous Tissue

Nervous tissue is widely distributed throughout the body, providing a rapid communication network between the central nervous system and various body parts. Nerve cells are specialized to generate and transmit electrical impulses very rapidly. Like muscle, nerves are excitable; they respond to stimulation by altering their electrical potentials. This excitability is caused by the presence of voltage-sensitive ion channels located in the plasma membrane of the nerve cell. Movement of ions through these channels results in the production and propagation of action potentials along the length of the neuron. Neurons communicate their action potentials to other nerve and muscle cells through synapses. At the synapse, the presynaptic neuron releases a chemical neurotransmitter into the space between itself and the next neuron (synaptic cleft), where it diffuses across and interacts with receptors on the postsynaptic neuron.

A typical neuron is composed of three parts: a cell body, an axon, and one or more dendrites (Figure 5-20). The cell body contains the nucleus and other cytoplasmic organelles. The axon is generally long (as long as 1 m) and may be encased in a myelin sheath. The axons usually conduct impulses away from the cell body, whereas the dendritic processes usually receive information and conduct impulses toward the cell body. Neurons are classified on the basis of the number of projections extending from the cell body. Neurons are terminally differentiated and incapable of replicating. However, neural stem cells are located in certain areas of the brain and may replicate to form either neurons or glial cells in response to specific signals (see Chapter 43).

In addition to neurons, nervous tissue contains a variety of supportive cells, termed **neuroglia** (“nerve glue”), that nourish, protect,

**FIGURE 5-20** Diagram of a typical neuron showing the cell body, axon, and dendrites. Neurons have many shapes and sizes.

insulate, and clean up debris in the central nervous system. These include the astrocytes, oligodendroglia, ependymal cells, and microglia. (See Chapter 43 for a detailed description of nervous system anatomy and physiology.)

#### KEY POINTS

- The structure and function of cells are influenced by the genome and environment as well as by developmental history.
- Embryonic development is associated with selective gene expression that controls four essential processes to enable a single cell to develop into a complex organism: (1) cell proliferation; (2) cell specialization; (3) cell-to-cell interactions; and (4) cell movement and migration.
- Terminally differentiated cell types have limited capacities to divide. Some tissues, such as skin and bone marrow, maintain large numbers of stem cells, which have great capacity to proliferate. Tissues are able to recruit multipotent stem cells from the bone marrow that have the capacity to become differentiated tissue cells if given appropriate survival and developmental conditions.
- Different cell types in the adult human are classified into four major categories: epithelium (e.g., skin, glands, endothelium); connective tissue (e.g., bone, cartilage, fat, blood); muscle (e.g., skeletal, cardiac, smooth); and nervous tissue (e.g., neuronal, glial).

## SUMMARY

The development, differentiation, and daily activities of a cell are directed by its genes. Genes are sequences of nucleotides that provide the template for the production of RNA or cellular proteins. In large part, the kinds and amounts of cellular proteins determine cell structure and function. All the cells of the body possess essentially the same

DNA, but through complex processes of differentiation they become specialized to perform particular functions. Different sets of genes are active in different cell types. The four major classes of differentiated tissues are epithelial, connective, muscle, and nerve. These four tissues interdependently form the functioning systems of the body.

Geneticists and parents alike have marveled at the development of a recognizable human baby, with eyes and ears, toes and fingers, from its simple beginning as a single cell containing one set of genes. Considering the enormous list of potentially disastrous genetic and environmental influences, the birth of a healthy normal child does indeed seem like a miracle. Although the risk of bearing a child with mental or physical defects is small for most parents, it is real and is often a source of worry during the prenatal period. It has been estimated that most people harbor five to eight defective genes that are recessive and therefore of little consequence until they are transmitted to offspring.<sup>1</sup> In addition, there are many known and unknown environmental hazards to which the parent and fetus may be exposed. Disorders that are present at birth are called *congenital*, whether the cause is genetic, environmental, or both. Some congenital disorders are associated with structural defects attributable to errors in fetal development and are called **congenital malformations**. It is estimated that about 3% of newborns have a major malformation of cosmetic or functional significance.<sup>2,3</sup> Malformations are frequently associated with genetic causes; however, environmental influences (teratogens) also may adversely affect the developing fetus, and in half of cases a clear explanation for a malformation cannot be found. Approximately 30% to 40% of all birth malformations are associated with genetic factors—6% are associated with chromosomal abnormalities, 8% are associated with single-gene disorders, and 20% to 30% are most likely multifactorial.<sup>3</sup> Some inherited genetic disorders do not become apparent until later in

**FIGURE 6-1** Scanning electron micrograph of a chromosome showing the two sister chromatids attached at the centromere. Sister chromatids separate during meiosis with one chromatid being distributed to each daughter cell. (From Pollard T et al: *Cell biology*, ed 2, Philadelphia, 2007, Saunders, p 224.)

**FIGURE 6-2** A standard map of the banding pattern of each of the 23 chromosomes of the human. Somatic cells contain two copies of each chromosome. The centromere region is marked by the line. (From Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 203.)

**FIGURE 6-3** Comparison of meiosis and normal mitotic cell division, showing only one homologous chromosome pair. In meiosis, the homologous chromosomes form a pair and exchange sections of DNA in a process called *crossing over*. Two nuclear divisions are required in meiosis to form the haploid germ cells.

childhood or adulthood and therefore are not considered to be congenital. In this chapter, the general principles of inheritance; genetic and environmental causes of congenital disorders; and the principles of diagnosis, counseling, and gene therapy are described.

### PRINCIPLES OF INHERITANCE

“Whom does the baby look like?” is frequently asked of new parents. It is common knowledge that traits tend to run in families, but Gregor Mendel, a nineteenth-century monk turned geneticist, was the first to notice that traits were transmitted in a predictable way from parent to offspring.<sup>4</sup> Height, weight, skin color, eye color, and hair color are some of the physical traits that characterize an individual; other inherited traits contribute to risk for disease. **Phenotype** refers to the physical and biochemical attributes of an individual that are outwardly apparent. These traits are a result of the expression of the individual’s

unique genetic makeup, or **genotype**. In humans, genes are organized into 46 different chromosomes that become visible under the microscope only during cell division (see Chapter 5).

Before cell division, chromosomes look like X’s of varying sizes and shapes. The X-shaped chromosome is really made up of two identical linear chromosome units, called **chromatids**, which separate during meiosis. The point at the middle of the X at which the two sister chromatids are united is the **centromere** (Figure 6-1). Human chromosomes are **diploid**; they occur as pairs. One member of the pair comes from the mother, and one member comes from the father. Under the microscope the members of a pair appear to be identical (**homologous**), although they are different in DNA sequence. Chromosomes are characterized on the basis of total size, length of the arms of the X, and characteristic banding patterns when exposed to certain stains (karyotype) (Figure 6-2).

Of the 23 pairs of chromosomes, 22 are homologous and are called **autosomes**. The remaining pair, the **sex chromosomes**, differs in males

and females. Females receive an X chromosome from each parent, whereas males receive an X chromosome from their mother and a Y chromosome from their father. Thus, the genotype is a result of the union of 23 maternal and 23 paternal chromosomes at conception. Sexual reproduction allows the mixing of genomes from two different individuals to produce offspring that differ genetically from one another and from their parents. This source of genetic variability is advantageous to the species because it allows for adaptation and evolution in a changing environment.

For the 2 germ cells (i.e., egg and sperm) to combine to form a cell with the normal complement of 46 chromosomes (23 pairs), each germ cell must contribute half of the total. **Meiosis** refers to a special form of cell division that results in germ cells that are **haploid**; they have half of the normal number of chromosomes. In contrast to mitosis (see Chapter 3), meiosis involves two divisions of chromosomal DNA. A comparison of meiotic and mitotic cell division is shown in **Figure 6-3**.

During the first phase of meiosis, pairs of homologous chromosomes with duplicated sister chromatids come in close contact. Portions of the homologous chromosomes are exchanged in a process called **crossing over** (**Figure 6-4**). This results in a mixing of the maternal and paternal genes of the cell to form a new combination of genes within the chromosomes. Genetic recombination is very precise, such that genes are exchanged intact and not interrupted in the middle. On average, each homologous pair of chromosomes has one to three crossover events occurring during the first meiotic division.<sup>5</sup> The first cellular division of meiosis results in two cells, each with 46 chromosomes. These two cells undergo a second division in which the sister chromatids are pulled apart (similar to normal mitosis), resulting in four cells, each having only 23 chromosomes. Each of the germ cells has a different combination of genes that, when passed on through sexual reproduction, will form a new, genetically unique individual.

The genes that code for a particular gene product, such as an enzyme, are located at a particular position (locus) on the chromosome. Genes come in several forms, called alleles. A person has two alleles for each gene, one received from each parent. If both alleles are identical, the individual is said to be homozygous for that gene. If two different alleles are present, the individual is heterozygous.

Some traits involve only one gene locus and are called single-gene (or monogenic) traits. The transmission of single-gene traits from parent to offspring follows predictable patterns that can be demonstrated using the Punnett square (**Figure 6-5**). In a Punnett square, alleles for a gene are represented by capital and lowercase letters. A capital letter is used for a **dominant** allele, and a lowercase letter represents a **recessive** allele. As the term implies, a dominant allele will mask a recessive allele, making the associated trait apparent. A recessive trait is apparent only if *both* alleles for the trait are recessive (homozygous). Dominant genes often code for functional enzymes or structural proteins, and recessive genes code for non-functional ones. The Punnett square is based on the mendelian principle that all genes are inherited independently from each other in a random manner. Thus, if both parents are heterozygous for a dominant trait (Aa), the offspring will have a 25% probability of being AA, a 50% probability of being Aa, and a 25% probability of being aa. Persons having the AA and Aa genotypes will *express* the trait in a similar manner. The trait will be absent in the aa genotype. Many genetic diseases are carried on the recessive allele and are manifested only by the homozygous (aa) genotype (e.g., cystic fibrosis, phenylketonuria). Persons who are heterozygous for the disease (Aa) are said to be **carriers** because they are able to pass the defective recessive gene to their offspring even though they do not exhibit the trait.

Some alleles are not clearly dominant or recessive and result in a blending or **codominant** expression of the trait. Blood type, for example, has three distinct alleles: A, B, and O. The A and B alleles may both be expressed together, resulting in the AB blood type. Most traits result from the interaction of several gene loci and are called **polygenic**.

Polygenic traits are heritable, but predicting their occurrence is more difficult than with single-gene traits. Polygenic traits are often affected by environmental factors, in which case they are called **multifactorial**. Examples of multifactorial traits are height, weight, and blood pressure. These traits are influenced by multiple genes as well as environmental factors (such as dietary intake, which influences the ultimate expression of those genes). Most common diseases, such as heart disease, asthma, diabetes, and cancer, are multifactorial as well.

### DNA Mutation and Repair

The term **mutation** refers to a permanent change in DNA structure. Genetic mutation is a rare event despite the daily exposure of cells to numerous mutagenic influences. Radiation, chemicals, viruses, and even some products of normal cellular metabolism are all potential **mutagens**. Most mutations, however, occur spontaneously as a result of copying errors during DNA replication.<sup>3</sup> Regardless of the cause, only a few of these changes in DNA result in permanent alterations (mutations). The stability of the genes, and thus the low mutation rate, depends on efficient DNA repair mechanisms.

There are a variety of cellular DNA repair mechanisms. Most require the presence of a normal complementary DNA template to correctly repair the damaged strand of DNA. Single-stranded breaks or loss of bases from only one DNA strand are readily repaired. Double-stranded

**FIGURE 6-4** Crossing over during meiotic prophase I results in a reassortment of genes between homologous chromosomes.

breaks, involving both strands of complementary DNA, may result in permanent loss of genetic information at the break point when the broken strands are reunited. Different types of DNA damage are detected and repaired by different enzyme systems. The steps in one type of DNA repair are shown in Figure 6-6.

Genetic mutations are generally of two types: a point mutation, which involves a single base pair substitution, or a frameshift mutation, which often changes the genetic code dramatically. A sequence of three DNA bases (codon) is required to code for each amino acid. A point mutation in the gene may cause the affected codon to signify an abnormal amino acid. The inclusion of the abnormal amino acid in the sequence of the protein may or may not be of clinical significance. Sickle cell anemia and  $\alpha_1$ -antitrypsin deficiency are examples of point mutation disorders in which a single amino acid substitution causes significant dysfunction.

A frameshift mutation is due to the addition or deletion of one or more bases, which changes the “reading frame” of the DNA sequence. The DNA sequence is normally “read” in groups of three bases, with no spaces between codons. All of the codon triplets will be changed in the DNA downstream from a frameshift mutation, resulting in a protein with a greatly altered amino acid sequence (Figure 6-7). Numerous genetic disorders are due to mutations in a gene that codes for a particular protein. These are termed *single-gene* or *Mendelian* disorders. Mutations may also alter chromosome structure through loss, gain, or translocation of chromosome segments. These processes are discussed later in the chapter.

**FIGURE 6-5** Punnett square shows the distribution of parental genes to their offspring. This example shows the mating of two heterozygous individuals. A, Dominant gene; a, recessive gene.

**KEY POINTS**

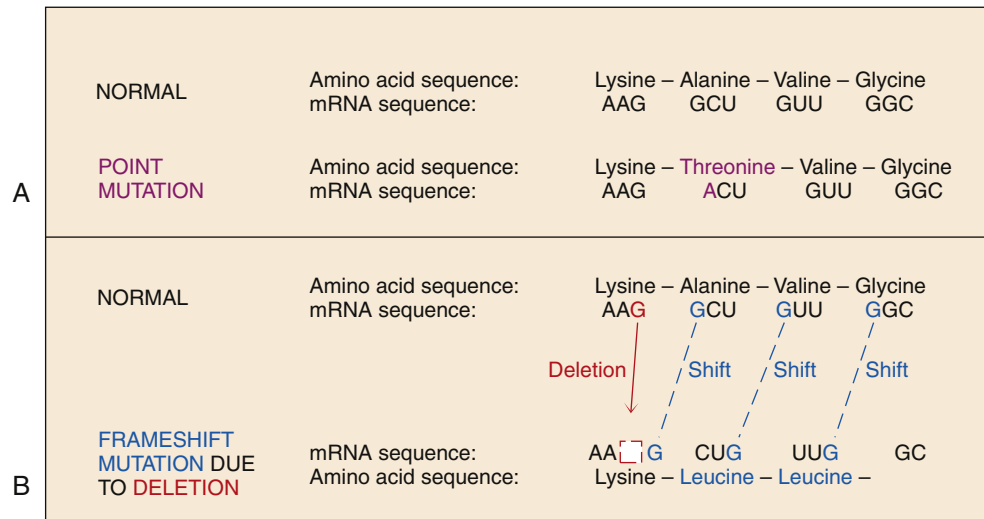

- Human DNA is organized into 46 chromosomes (23 pairs). Paired chromosomes look similar under the microscope but differ in DNA sequence. One member of each pair is inherited from the mother, and the other from the father.
- Twenty-two pairs of chromosomes are autosomes. The remaining pair, the sex chromosomes, confers maleness (XY) or femaleness (XX).
- During meiotic cell division, the chromosomes are distributed to daughter cells. Meiosis results in four daughter cells, each having half the normal number of chromosomes (23 chromosomes).
- Genes that code for a particular trait may come in several forms or alleles. Genotype refers to the particular set of alleles an individual receives. Phenotype refers to an individual’s observable attributes. People with different genotypes may have similar phenotypes.
- Some traits involve only one gene locus and are called *single-gene traits*. The transmission of these traits from parent to offspring follows predictable patterns. The expression of single-gene traits is determined by whether the gene is dominant or recessive. Dominant genes usually code for functional enzymes; recessive genes do not. Most traits result from the interaction of several genes. These polygenic traits do not follow predictable patterns of inheritance.

**GENETIC DISORDERS**

Genetic disorders may be apparent at birth or may not be clinically evident until much later in life. The majority of genetic disorders are inherited from the affected individual’s parents; however, new (de novo) mutations sometimes occur during gamete formation or arise

**FIGURE 6-6** Steps of DNA repair. In step 1 the damaged section is removed; in steps 2 and 3 the original DNA sequence is restored.

**FIGURE 6-7** Schematic illustration of mutations that alter the messenger RNA sequence and the resulting protein amino acid sequence. **A**, Point mutation alters one amino acid. **B**, Frameshift mutation alters all downstream amino acids.

during fetal development. Genetic disorders encountered clinically are only a small percentage of those that occur and represent the less extreme aberrations that permit live birth.

Disorders that are genetic in origin traditionally have been divided into three groups: (1) chromosomal aberrations, (2) mendelian single-gene disorders, and (3) polygenic or multifactorial disorders. A fourth group encompasses a number of single-gene defects that do not follow classic mendelian patterns of inheritance. This group includes triplet repeat (trinucleotide) mutations, mitochondrial gene mutations, and mutations influenced by genomic imprinting. General principles of transmission and selected examples are included for each of the four groups.

## CHROMOSOMAL ABNORMALITIES

Chromosomal defects are generally due to an abnormal number of chromosomes or alterations in the structure of one or more chromosomes. Errors in the separation of chromosomes during meiosis may result in abnormal numbers of chromosomes. These defects, as well as large structural defects (involving more than 5 to 10 million base pairs), can be detected using traditional genetic testing methods such as karyotyping.<sup>6</sup> Chromosomal abnormalities occur commonly but are most often lethal; as many as 50% of spontaneous pregnancy losses (miscarriages) involve a chromosomal abnormality.<sup>1</sup> Based on traditional chromosome analysis, 0.5% to 1% of newborn infants have been found to have some form of chromosomal abnormality.<sup>1,3</sup> In recent years, the development of molecular testing methods has allowed detection of much smaller structural defects, increasing the detection rate of chromosomal abnormalities.<sup>6</sup>

### Aberrant Number of Chromosomes

The union of sperm and egg results in a fertilized egg (zygote) with the full complement of 46 chromosomes: 22 pairs of autosomes and 2 sex chromosomes (euploid). **Aneuploidy** refers to an abnormal number of chromosomes—in humans, either more or less than 46. Aneuploidy is most commonly caused by nondisjunction.<sup>3</sup> **Nondisjunction** means that paired homologous chromosomes fail to separate normally during either the first or the second meiotic division (Figure 6-8). The

resulting germ cells then have an abnormal number of chromosomes: one germ cell will have 22 chromosomes and the other will have 24 chromosomes. When the abnormal germ cell combines with a normal germ cell containing 23 chromosomes, the resulting zygote will either be deficient by one chromosome (45) or have an extra chromosome (47). In anaphase lag, one chromosome lags behind and is therefore left out of the newly formed cell nucleus. This results in one daughter cell with the normal number of chromosomes and one with a deficiency of one chromosome, a condition called **monosomy**. **Polysomy** refers to the condition of having too many chromosomes.

The causes of aneuploidy are poorly understood; however, advanced maternal age, abnormalities in parental chromosome structure, and abnormalities in crossing over are known to increase the risk of abnormalities in chromosome number in humans.<sup>7</sup> Aneuploidy occurs rather frequently during human gametogenesis; however, zygotes with abnormal chromosome numbers are usually nonviable. Approximately one third of human miscarriages involve an aneuploid fetus.<sup>8</sup> Although monosomy involving the autosomes is not usually compatible with life, autosomal polysomy may result in a viable fetus when a single extra copy of a chromosome carrying relatively few genes is present. Severe disability, however, nearly always results (e.g., trisomy 21—Down syndrome). Disorders involving extra or missing sex chromosomes are more common and less debilitating.

### Abnormal Chromosome Structure

Alterations in chromosome structure are usually due to breakage and loss or rearrangement of pieces of the chromosomes during meiosis or mitosis. During meiosis, the homologous chromosomes normally pair up and exchange genetic alleles in a process called *crossing over*. Normal crossing over involves precise gene exchange between homologues only, with no net gain or loss of DNA. When the normal process of crossing over goes awry, portions of chromosomes may be lost, attached upside down, or attached to the wrong chromosome. Mitosis also presents opportunities for chromosomal breakage and rearrangement. The severity of the chromosomal rearrangement ranges from insignificant to lethal, depending on the number and importance of the gene loci involved. Gene locations can be described by their position on the long arm (q arm) or the short arm (p arm) of the chromatid. For

**FIGURE 6-8** Mechanism of nondisjunction leading to aneuploidy. For simplicity, only one pair of chromosomes is shown.

example, the gene locus 2p13 is located on the short arm of chromosome 2 at region 1, band 3 (Figure 6-9). The common types of chromosomal rearrangements are translocations, inversions, deletions, and duplications (Figure 6-10).

Chromosomal *translocations* result from the exchange of pieces of DNA between nonhomologous chromosomes. If no genetic material is lost, as in a reciprocal translocation, the individual may have no symptoms or disorder. However, an individual with a reciprocal translocation is at increased risk of producing abnormal gametes. The exchange of a long chromatid arm for a short one results in the formation of one very large chromosome and one very small chromosome (see Figure 6-10). This is called a robertsonian translocation and is responsible for a rare hereditary form of Down syndrome, discussed later in the chapter. Isochromosomes occur when the sister chromatids separate incorrectly at the centromere such that the two identical short arms remain together, as do the two long arms.

*Inversion* refers to the removal and upside-down reinsertion of a section of chromosome (see Figure 6-10). Like balanced translocations, inversions involve no net loss or gain of genetic material and are often without consequence to the individual. Difficulties result, however, when homologous chromosomes attempt to pair up during meiosis. The chromosome with an inverted section may not pair up properly, resulting in duplications or loss of genes at the time of crossing over. Thus, the offspring of an individual harboring an inversion may be affected.

Loss of chromosomal material is called *deletion*. Deletions result from a break in the arm of a single chromosome, resulting in a fragment of DNA with no centromere. The piece is then lost at the next cell division. Chromosomal deletions have been associated with some forms of cancer, including retinoblastoma (see Chapter 7). Deletions at both ends of a chromatid may cause the free ends to attach to one another, forming a ring chromosome.

In contrast to a deletion, where genes are lost, *duplication* results in extra copies of a portion of DNA. The consequences of duplications are generally less severe than those from loss of genetic material.

**FIGURE 6-9** Metaphase chromosome showing location of centromere and long and short arms of the chromatids. Gene loci are described by the chromosome number, location on short (*p*) or long (*q*) arm, region, and band.

### Examples of Autosomal Chromosome Disorders

#### Trisomy 21 (Down Syndrome)

Trisomy 21 is a chromosomal disorder in which individuals have an extra copy of chromosome 21. It is the most common of the chromosomal disorders and a leading cause of mental disability, occurring in about 1 in 700 live births.<sup>3</sup> The incidence varies among populations

**FIGURE 6-10** Types of chromosomal rearrangement. (Adapted from Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 160.)

and over time, however, and reflects trends in maternal age, prenatal diagnosis, and termination of affected pregnancies.<sup>9</sup> The syndrome, first described by Langdon Down in 1866,<sup>10</sup> includes intellectual disability, protruding tongue, low-set ears, epicanthal folds, poor muscle tone, and short stature (Figure 6-11). Children with Down syndrome often are afflicted with congenital heart deformities and an increased susceptibility to respiratory tract infections and leukemia. Precise causes of these signs and symptoms are unknown, although the gene-dosage hypothesis relates them to overexpression of certain genes contained on chromosome 21.<sup>11</sup>

In 95% of cases, the extra chromosome 21 is thought to be of maternal origin, and the incidence of trisomy 21 is clearly associated with advanced maternal age.<sup>3</sup> Table 6-1 demonstrates a rise in the incidence of Down syndrome from maternal age 20 to 50 years. The reason for increased susceptibility of the ovum to nondisjunction with age remains unknown.

A rare form of Down syndrome (occurring in about 4% of cases) is due to a chromosomal translocation of the long arm of chromosome 21 to another chromosome. This form of Down syndrome is not associated with increased maternal age but is passed from parent to offspring. Therefore, testing for translocations in newborns with Down syndrome is recommended to determine recurrence risk for families.

### Trisomy 18 (Edwards Syndrome) and Trisomy 13 (Patau Syndrome)

Trisomy of chromosomes 18 or 13 is much less common than trisomy 21 and more severe. Most affected pregnancies are lost before term, and liveborn infants usually do not survive more than a few days or

weeks.<sup>3</sup> It is not insignificant that the few trisomy conditions compatible with life involve chromosomes containing the smallest numbers of genes. Trisomies involving chromosomes 8, 9, and 22 also have been described but are extremely rare.

### Cri du Chat Syndrome

Deletion of part of the short arm of chromosome 5 results in a syndrome characterized by severe mental retardation, round face, and congenital heart anomalies. The syndrome was so named because of the characteristic cry of the affected infant, which is caused by laryngeal malformation and resembles a cat crying. Some children afflicted with this syndrome survive to adulthood, and they generally thrive better than those with the trisomies.

### Examples of Sex Chromosome Disorders

#### Klinefelter Syndrome

The incidence of Klinefelter syndrome is about 1 in 600 liveborn males, making it the most common sex chromosome abnormality.<sup>12</sup> Individuals with Klinefelter syndrome usually have an extra X chromosome (an XXY genotype). However, individuals with more than one extra X (XXXY and XXXXY) have also been described. The presence of the Y chromosome determines the sex of these individuals to be male; however, the extra X chromosomes result in abnormal sexual development and feminization. The condition is rarely diagnosed before puberty, when lack of secondary sex characteristics may become apparent. Associated symptoms reflect a lack of testosterone and include testicular atrophy and infertility, tall stature with long arms and legs, feminine hair distribution, gynecomastia (breast enlargement), high-pitched voice, and marginally impaired intelligence (Figure 6-12).<sup>5</sup> Testosterone

therapy can achieve a dramatic reduction in the feminine characteristics associated with Klinefelter syndrome.

### Turner Syndrome

Also known as monosomy X, Turner syndrome is associated with the presence of only one normal X chromosome and no Y chromosome. The absence of the Y chromosome results in a female phenotype; however, the ovaries fail to develop or fail prematurely. In some cases of Turner syndrome, the second X chromosome is not entirely missing but is structurally abnormal. In the majority of cases, the missing or

FIGURE 6-12 Typical clinical manifestations of Klinefelter syndrome. (From Moore KL, Persaud TVN: *The developing human: clinically oriented embryology*, ed 8, Philadelphia, 2007, Saunders, p 466.)

**FIGURE 6-13** Typical clinical manifestations of Turner syndrome. (From Connor JM, Ferguson-Smith MA: *Essential medical genetics*, ed 5, London, 1997, Blackwell Scientific, p 123.)

damaged X chromosome is of paternal origin. Most fetuses with monosomy X are lost during pregnancy, and the incidence is about 1 in 3000 live female births.<sup>3,5</sup> Principal characteristics of Turner syndrome include short stature, webbing of the neck, a wide chest, lymphedema of the hands and feet at birth, congenital heart defects, and failure to develop secondary sexual characteristics<sup>13</sup> (Figure 6-13).

### Multiple X Females and Double Y Males

A relatively common disorder of the sex chromosomes is the presence of an extra copy of the X chromosome in females (XXX) or of the Y chromosome in males (YYY). Most individuals appear normal; however, females may experience menstrual abnormalities, and males will generally be taller than average. A tendency toward mental retardation has been noted in females with more than four X chromosomes.

## MENDelian SINGLE-GENE DISORDERS

In contrast to the chromosomal disorders described above, mendelian disorders result from mutations in single genes. The affected genes may

code for abnormal enzymes, structural proteins, regulatory proteins, or regulatory RNA molecules. An individual has two copies or alleles of each gene (one allele from each parent). A recessive gene is expressed only when the individual is homozygous for the gene; that is, the individual has two identical copies. Dominant genes require only one allele in order to be expressed. Mendelian disorders are generally classified according to the *location* of the defective gene (autosomal or sex chromosome) and the *mode of transmission* (dominant or recessive). The great majority of mendelian disorders are familial (attributable to mutant genes inherited from the parents), but 15% to 20% represent new mutations.<sup>1</sup> The occurrence of new mutations ranges widely. For example, new mutations for Huntington disease are rare, whereas 80% of individuals with achondroplasia represent new mutations.<sup>1</sup> A detailed **pedigree** may be used to trace the transmission of the disease through a family. The pedigree (Figure 6-14), showing family relationships and the members who have been affected by the disease, is a useful tool in determining the pattern of inheritance as recessive, dominant, or sex-linked. Mendelian genetics is based on the principle that single genes are randomly and independently transmitted to offspring such that there is a 50:50 chance of receiving one or the other of a parent's alleles for a particular gene. It is important to note that there are many exceptions to these rules, but they generally are useful in predicting transmission patterns for a number of single-gene disorders. More than 10,000 single-gene traits and disorders have been identified.<sup>3</sup> A comprehensive database of the chromosomal location and sequence of these single-gene traits and disorders, called *Online Mendelian Inheritance in Man*, can be accessed at [www.ncbi.nlm.nih.gov/omim](http://www.ncbi.nlm.nih.gov/omim).

### Autosomal Dominant Disorders

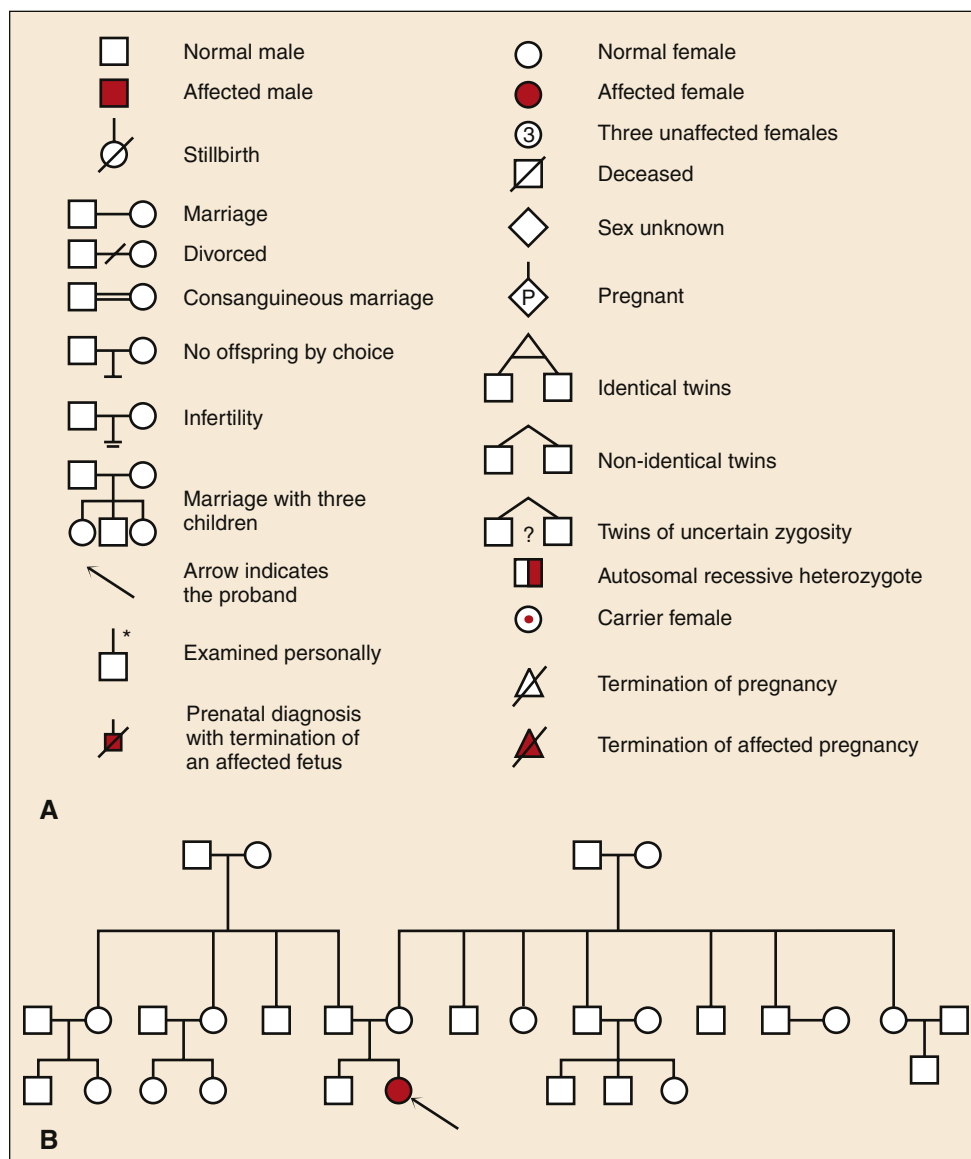

Autosomal dominant disorders are due to a mutation of a dominant gene located on one of the autosomes. Autosomal dominant disorders follow predictable patterns of inheritance (Figure 6-15), which may be summarized as follows:

- Males and females are equally affected.
- Affected individuals usually have an affected parent.
- Unaffected individuals do not transmit the disease.
- Offspring of an affected individual (with normal mate) have a 1 in 2 chance of inheriting the disease.
- The rare mating of two individuals, each carrying one copy of the defective gene (heterozygous), results in a 3 in 4 chance of producing an affected offspring.

The list of known autosomal dominant disorders is long. Many are described in later chapters as they relate to system pathophysiology. A partial list is presented in Table 6-2. In general, autosomal dominant disorders involve key structural proteins or regulatory proteins, such as membrane receptors. Marfan syndrome and Huntington disease are commonly cited examples of autosomal dominant disorders and are briefly described here.

### Marfan Syndrome

Marfan syndrome is a disorder of the connective tissues of the body. Individuals with Marfan syndrome are typically tall and slender with long, thin arms and legs (Figure 6-16). Because of the long, thin fingers, this syndrome has also been called *arachnodactyly* ("spider fingers"). It is commonly suggested that President Abraham Lincoln may have had this disorder. Although skeletal and joint deformities are problematic, the cardiovascular lesions are the most life threatening. The medial layer of blood vessels, particularly the aorta, tends to be weak and susceptible to dilation and rupture. Dysfunction of the heart valves may occur from poor connective tissue support. Marfan syndrome has been traced to hundreds of different mutations in the fibrillin 1 gene on chromosome 15.<sup>3,5</sup> Fibrillin 1 is a glycoprotein secreted

**FIGURE 6-14** A, Common symbols for pedigree analysis. B, Typical family pedigree chart.

by fibroblasts into the extracellular matrix. It provides important scaffolding for deposition of other matrix proteins such as elastin. Marfan-type fibrillin 1 appears to be more susceptible to proteolytic degradation than normal fibrillin, leading to the weakened connective tissues typical of the disease.

### Huntington Disease

Huntington disease is an autosomal dominant disease that primarily affects neurologic function. The symptoms of mental deterioration and involuntary movements of the arms and legs do not appear until approximately age 40 years. The disease was formerly called Huntington chorea (from the Greek *khoreia*, meaning “dance”) because of the uncontrolled movements of the limbs. The delayed onset of symptoms means that the disease may be transmitted to offspring before the parent is aware that he or she harbors the defective gene. The prevalence rate is about 1 in 20,000 persons.<sup>5</sup>

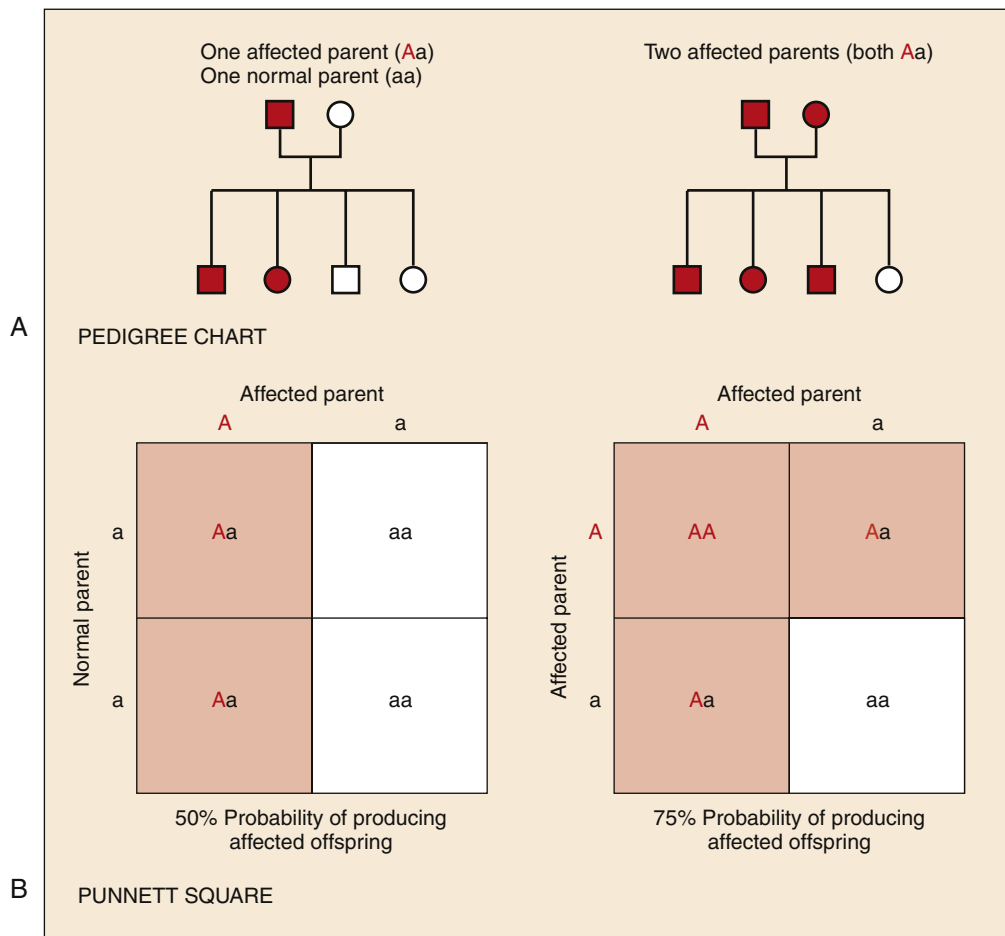

The gene abnormality in Huntington disease has been localized to chromosome 4, where an abnormally large number of triplet repeats (CAG) has been noted. Triplet repeats of more than 40 are reliably associated with development of the disease, and the greater the number

of triplet repeats, the earlier the onset of symptoms.<sup>5</sup> The Huntington disease protein (huntingtin) has a long segment of glutamine amino acids that are coded by the CAG triplet repeat. The protein forms aggregates in brain tissue, which are thought to contribute to the pathogenesis of neurodegeneration.<sup>5</sup> Clinical manifestations and pathophysiology of Huntington disease are discussed in Chapter 45.

### Autosomal Recessive Disorders

Autosomal recessive disorders are due to a mutation of a recessive gene located on one of the autosomes. Autosomal recessive disorders follow predictable patterns of inheritance (Figure 6-17), which may be summarized as follows:

- Males and females are equally affected.
- In most cases, the disease is not apparent in the parents or relatives of the affected individual, but both parents are carriers of the mutant recessive gene.
- Unaffected individuals may transmit the disease to offspring.
- The mating of two carriers (heterozygous) results in a 1 in 4 chance of producing an affected offspring and a 2 in 4 chance of producing an offspring who carries the disease.

**FIGURE 6-15** Typical pattern of inheritance of an autosomal dominant trait (e.g., Marfan syndrome). **A**, Pedigree chart. **B**, Punnett square.

	Achondroplasia
Metabolic	Familial hypercholesterolemia
	Acute intermittent porphyria

From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 141.

It is estimated that nearly everyone carries several mutated recessive genes, and related individuals are more likely to carry the *same* recessive genes.<sup>1</sup> Because recessive diseases are only expressed when both alleles for a particular gene are mutant (homozygous), they are often associated with **consanguinity**—the mating of related

individuals.<sup>5</sup> The closer the biological relationship, the greater the proportion of shared genes and the greater the risk of producing affected offspring.

Recessive disorders often involve abnormal enzymatic functions. The gene for a particular enzyme may be absent or present in a mutated, and therefore nonfunctional, form. The enzyme deficiency usually is not apparent in heterozygotes carrying one normal gene and one mutated gene because the normal gene produces enough of the necessary enzyme. In the homozygous state, neither gene for the enzyme is functional, resulting in an enzyme deficiency. A partial list of the large number of autosomal recessive disorders that have been identified is given in Table 6-3. Many of these diseases involve the inability to metabolize nutrients (inborn errors of metabolism) or to synthesize cellular components because of enzyme deficiencies. Albinism, phenylketonuria, and cystic fibrosis are described here as representative examples. Other disorders are described in the discussions of system pathophysiology in later chapters.

### Albinism

Albinism refers to a lack of pigmentation of the hair, skin, and/or eyes. There are several types of albinism; all types involve disruption of melanin synthesis. Albinism is currently classified according to the affected gene. In oculocutaneous albinism, which is inherited in an autosomal recessive fashion, pigmentation of the skin, hair, and eyes is decreased.<sup>14</sup> Affected individuals are at risk for sunburn and skin cancer, and generally exhibit impaired vision, nystagmus (involuntary eye movements), and photosensitivity.

**FIGURE 6-16** Clinical manifestations of Marfan syndrome. Skeletal deformities such as pectus excavatum and abnormal curvature of the thoracic spine are common findings. (From Turnpenny P: *Emory's elements of medical genetics*, ed 14, Philadelphia, 2012, Churchill Livingstone, p 301.)

### Phenylketonuria

Phenylketonuria (PKU) results from an inability to metabolize the amino acid phenylalanine because of lack of the enzyme phenylalanine hydroxylase. It is one of several enzyme deficiencies that are often referred to as *inborn errors of metabolism*. The symptoms of the disorder are due to the accumulation of dietary phenylalanine in the body, which primarily affects the nervous system. Children with PKU tend to be overly irritable and tremorous and have slowly developing mental retardation. Excess phenylalanine is excreted in the urine in the form of phenylketones, hence the name phenylketonuria. Infants typically have a musty odor because of excess phenylalanine by-products in the sweat and urine. The enzyme deficiency can be detected soon after birth and managed with a low-phenylalanine diet. Because treatment must be instituted very early to prevent mental retardation, routine screening for PKU is performed at birth.

### Cystic Fibrosis

Cystic fibrosis is one of the most common single-gene disorders. About 4% of Caucasian Americans harbor the defective gene, and the incidence of cystic fibrosis is approximately 1 in 3200 live births.<sup>15</sup> The clinical abnormalities associated with cystic fibrosis have been traced to a defect in a membrane transporter for chloride ions in epithelial cells. The alteration in chloride transport is associated with production of abnormally thick secretions in glandular tissues. The lung bronchioles and pancreatic ducts are primarily affected, often resulting in progressive destruction of these organs (see Chapter 22).

The cystic fibrosis gene was isolated in 1989 and mapped to chromosome 7. More than 1300 different mutations of this gene have been identified, all of which cause a defect in chloride transport across the cell membrane; however, the severity of chloride channel dysfunction varies widely with different mutations.<sup>1</sup> The most common mutation, accounting for about 70% of cystic fibrosis cases, is due to a deletion of three nucleotides that normally code for a phenylalanine at position 508.<sup>3</sup> The absence of this single amino acid apparently causes the protein to fold abnormally, preventing its release from the endoplasmic reticulum, where it is eventually degraded. A schematic of the normal chloride transporter (called *cystic fibrosis transmembrane conductance regulator* [CFTR] protein is shown in Figure 6-18. This transporter belongs to the family of ABC transporters that bind and hydrolyze ATP (see Chapter 3).

The discovery and characterization of the cystic fibrosis gene and CFTR protein have made it possible to envision effective gene therapy for this disorder. Clinical trials have been published; however, efficiency for delivering genes to target cells has been low.<sup>16</sup> Reliable genetic screening for the common forms of cystic fibrosis is readily available, making prevention and early management possible.

### Sex-Linked (X-Linked) Disorders

Sex-linked disorders occur because of a mutation of the sex chromosomes. Disorders linked to the Y chromosome are extremely rare, and for that reason the terms *sex-linked* and *X-linked* are often used interchangeably. Nearly all X-linked disorders are recessive. Females express the X-linked disease only in the rare instance in which both X chromosomes carry the defective gene. Males, however, do not have the safety margin of two X chromosomes and express the disease if their one and only X chromosome is abnormal. X-linked disorders follow predictable patterns of inheritance (Figure 6-19), which are dependent on the sex of the offspring, and may be summarized as follows:

- Affected individuals are almost always male.
- Affected fathers transmit the defective gene to none of their sons but to all of their daughters.
- Unaffected males do not carry the defective gene.
- A carrier female has a 1 in 2 chance of producing an affected son and a 1 in 2 chance of producing a carrier daughter.
- Females are affected only in the rare homozygous state that may occur from the mating of an affected or carrier mother and an affected father.

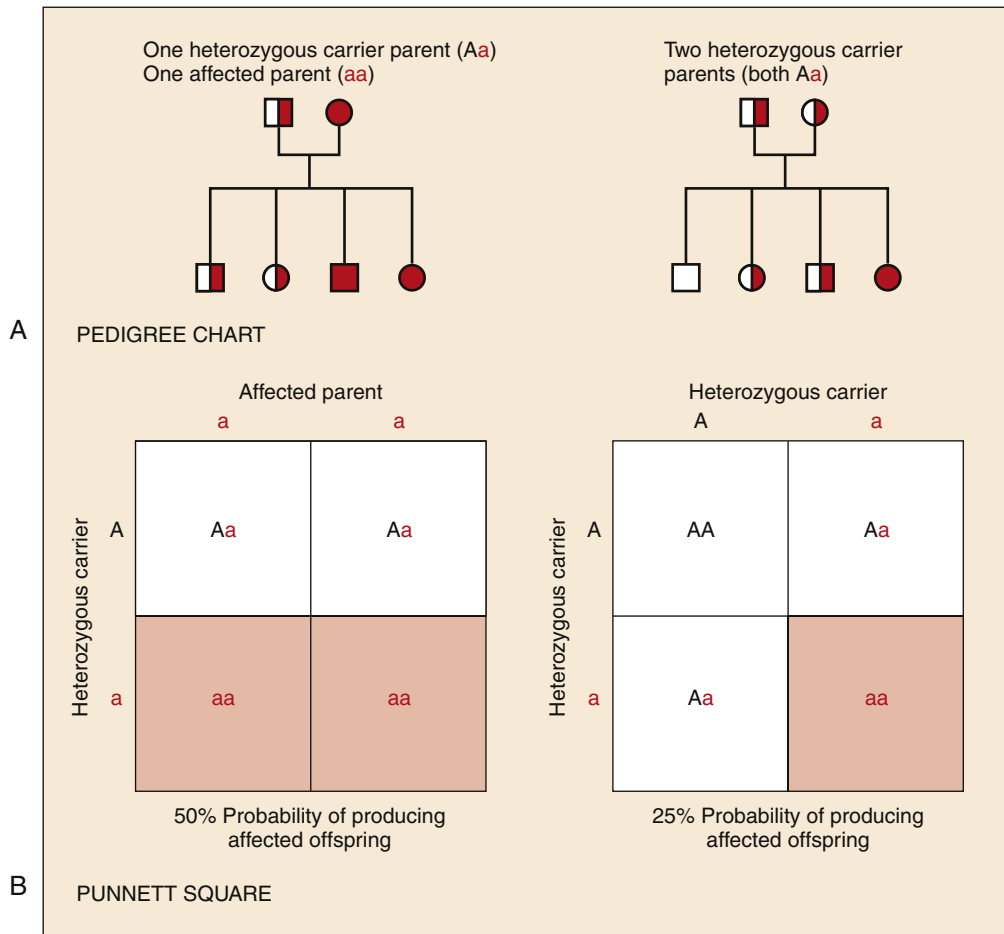

Several X-linked recessive disorders have been identified, as presented in Table 6-4. A well-known example of an X-linked disease is hemophilia A.

### Hemophilia A

Hemophilia A is a bleeding disorder associated with a deficiency of factor VIII, a protein necessary for blood clotting. Individuals afflicted with hemophilia A bleed easily and profusely from seemingly minor injuries (see Chapter 14). The transmission of hemophilia A in the European royal families constitutes one of the best-known pedigrees available (Figure 6-20). Queen Victoria of England was the first known carrier of the disease. A number of her male descendants were affected by it.

## NONMENDELIAN SINGLE-GENE DISORDERS

Transmission of certain single-gene disorders does not follow the classic mendelian principles of random and independent assortment. Three such categories have been described: (1) disorders caused by long triplet repeat mutations, such as fragile X syndrome; (2) disorders

**FIGURE 6-17** Typical pattern of inheritance of an autosomal recessive trait (e.g., cystic fibrosis, sickle cell anemia). **A**, Pedigree chart. **B**, Punnett square.

attributable to mitochondrial DNA mutations; and (3) disorders associated with genomic imprinting.

### Triplet Repeat Mutations

Fragile X syndrome is a prototypical example of disorders characterized by long repeating sequences of three nucleotides, called *triplet (or trinucleotide) repeat mutations*. Fragile X syndrome is the most common cause of familial mental retardation, exhibiting a prevalence rate of about 1 in 4000 males (1 in 8000 females).<sup>5</sup> A typical constriction on the long arm of the X chromosome can be detected on cytogenic studies. This narrowed area is composed of long repeating triplets of the sequence CGG. Normal individuals have an average of 29 CGG repeats at this gene locus. Persons with fragile X syndrome have significantly more: 200 to 1000 or more triplet repeats. Persons who have an intermediate number of repeats (60 to 200) are said to have a *premutation* and are at significant risk for producing affected offspring, although they themselves are unaffected.<sup>1,3</sup> The premutation is unstable and predisposed to amplification during oogenesis, but much less so during spermatogenesis.<sup>1</sup> As the premutation is passed on through the female lineage, the number of triplet repeats tends to increase as does the risk of mental retardation in the offspring. As might be guessed, the transmission patterns of this disorder are quite unusual. Males with fragile X syndrome tend to be more severely affected, apparently because the presence of a second X chromosome in females moderates the clinical symptoms. The protein normally produced by the fragile X gene (*FMR1*) is crucial to the development and function of cerebral neurons.<sup>3</sup>

**FIGURE 6-18** Schematic illustration of the cystic fibrosis transmembrane conductance regulator (*CFTR*) located in an epithelial cell. *CFTR* is a transmembrane protein that transports chloride from the cytoplasm into the lumen of the bronchiole. Mutations in the *CFTR* transporter gene are believed to cause the thick secretions typical of cystic fibrosis. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 467.)

**FIGURE 6-19** Typical inheritance pattern for X-linked disorders. The risk of disease varies according to the gender of the offspring.

## Mitochondrial Gene Mutations

Nearly all cellular genes are located in the cell nucleus; however, several mitochondrial genes are transmitted to daughter cells within the mitochondria when a cell divides. Essentially all mitochondria are contributed to a zygote by the egg, and therefore mitochondrial genes are of maternal origin because sperm contain few, if any, mitochondria.<sup>5</sup>

**TABLE 6-4 X-LINKED RECESSIVE DISORDERS**

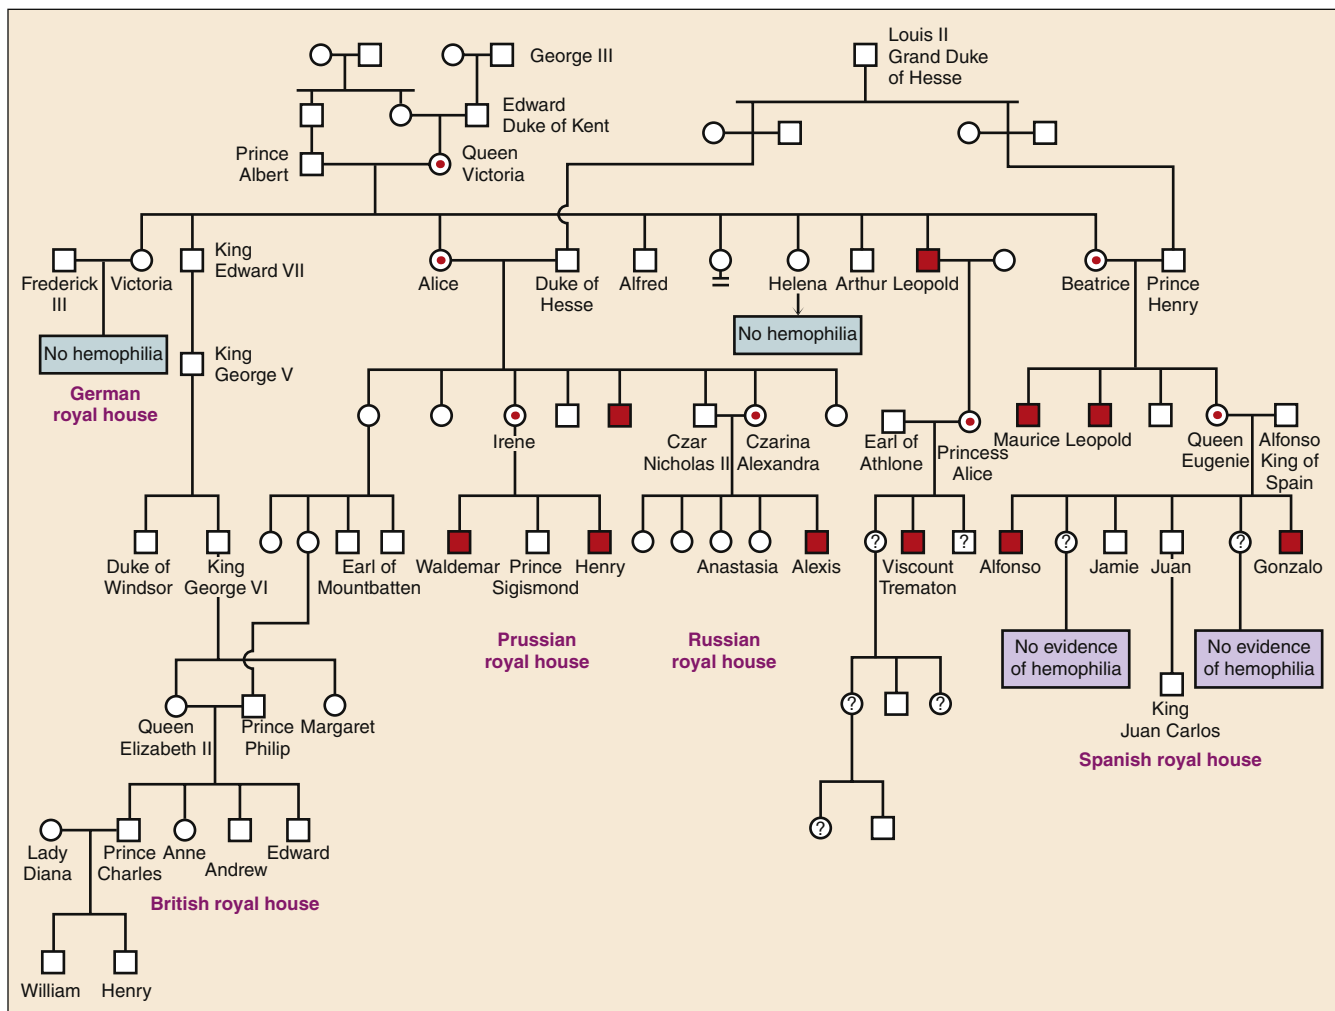

SYSTEM	DISORDER
Musculoskeletal	Duchenne muscular dystrophy

	Lesch-Nyhan syndrome
Nervous	Fragile X syndrome

From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 142.

Mothers transmit mitochondrial DNA to both sons and daughters, but only daughters transmit the mitochondrial genes to their offspring. Mitochondrial DNA is much more prone to mutation than nuclear DNA.<sup>5</sup> Mitochondrial DNA codes for enzymes involved in oxidative phosphorylation reactions, and mutations tend to cause dysfunction in tissues with high utilization of ATP such as nerve, muscle, kidney, and liver cells.

## Genomic Imprinting

The concept of genomic imprinting challenges the long-held belief that the parental origin of a gene does not make any difference to the cells that inherit the gene. Genomic imprinting is a process whereby maternal and paternal chromosomes are marked differentially within the cell (by methylation of DNA for example). Genomic imprinting can be illustrated by considering two very different syndromes, which at first glance appeared to be a result of the same chromosomal defect. Prader-Willi syndrome and Angelman syndrome both result from a deletion at the same location on chromosome 15.<sup>5</sup> Prader-Willi syndrome is characterized by mental retardation, short stature, obesity, poor muscle tone, and hypogonadism. Patients with Angelman syndrome are also mentally retarded, but they have ataxia and seizures and tend to laugh inappropriately. The fact that two different syndromes result from the same mutation was puzzling until it was discovered that the Prader-Willi mutation is always on the paternally derived chromosome 15,

**FIGURE 6-20** Pedigree chart for the transmission of the X-linked disease hemophilia A in the royal families of Europe.

**FIGURE 6-21** Angelman and Prader-Willi syndromes are examples of genetic imprinting, where the location of a mutation on the maternal or paternal homologous chromosome produces a different outcome. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 172.)

whereas the Angelman syndrome mutation is always on the maternally derived chromosome 15. Two genes are normally present in the region; the “Angelman gene” is normally active on a maternal chromosome and silent (imprinted) on the paternal chromosome, whereas the “Prader-Willi” gene is normally active on only the paternal chromosome and silent on the maternal chromosome. Thus normal cells have only one functional copy of each gene. The disorders arise when there is a deletion mutation of chromosome 15. A different syndrome arises if the area on a maternal chromosome is deleted compared to the paternal one (Figure 6-21). These findings imply that the cell is not blind to the parental origin of chromosomes and that homologous chromosomes may be marked and function differently within the cell.

## POLYGENIC AND MULTIFACTORIAL DISORDERS

Most human traits develop in response to more than one gene; such traits are called *polygenic*. Environmental influence also has a role in gene expression; traits and disorders influenced by multiple genes as well as environmental factors are called *multifactorial*. Multifactorial traits do not follow clear-cut modes of inheritance but do tend to “run in families.” Characteristics governed by multifactorial inheritance tend to have a range of expression in the population and demonstrate a “bell curve” distribution. They are thought to be produced by the interaction of several genes, each contributing a small additive effect and modulated by environmental influences, such as diet. Height, weight, and intelligence are multifactorial, as are most common health conditions and diseases. Most multifactorial disorders also present a range of severity, although a few disorders are either present or absent. In the latter case, it may be that a certain threshold number of defective genes must be inherited before the disease is expressed.<sup>5</sup>

It is extremely difficult to predict the risk of occurrence of multifactorial disorders based on family history, and empirical estimates have been derived, based on observing inheritance in the population. Recurrence risk is specific for each disorder and varies among different populations, but in general the risk is much less than that found in mendelian disorders. As an example, neural tube defects, which are multifactorial, occur in 2% to 3% of siblings of probands. Based on such a recurrence risk, parents of one affected child have a 2% to 3% chance of bearing a second affected child.<sup>5</sup>

In contrast to single-gene and chromosomal abnormalities, which are rare, multifactorial disorders are very common. High blood pressure, atherosclerosis, cancer, diabetes mellitus, cleft lip, and several forms of congenital heart defects are governed by multifactorial inheritance. This list is destined to grow as knowledge of the role of genetic mechanisms in cellular function and disease expands.

### KEY POINTS

- Genetic disorders are of three general types: chromosomal aberrations, single-gene disorders, and polygenic/multifactorial disorders.
- Chromosome disorders result from an abnormality in number or structure. The presence of only one chromosome of a homologous pair is termed *monosomy* (e.g., Turner syndrome), and the presence of an excessive number of chromosomes is called *polysomy* (e.g., Down syndrome). Abnormal rearrangement of portions of the chromosomes (translocation, inversion, deletion, duplication) can result in loss or unusual expression of genes.
- Single-gene disorders result from mutations that alter the nucleotide sequence of one particular gene. Mendelian disorders are transmitted predictably and include autosomal dominant (e.g., Huntington disease), autosomal recessive (e.g., cystic fibrosis), and sex-linked (e.g., hemophilia) disorders.

- Some single-gene disorders have unusual transmission patterns, which violate Mendel's laws. These include triplet repeat mutations, mitochondrial DNA mutations, and genomic imprinting disorders.
- Multifactorial disorders are very common and result from the interaction of multiple genes and environmental influences. Disorders such as high blood pressure, cancer, and diabetes are multifactorial.

## ENVIRONMENTALLY INDUCED CONGENITAL DISORDERS

Adverse influences during intrauterine life are a significant cause of errors in fetal development that result in congenital malformations. The study of developmental anomalies is called *teratology* (from the Greek *teras*, or “monster”). Most malformations are associated with genetic causes; however, numerous environmental influences that may adversely affect the developing fetus, such as chemicals, radiation, and viral infections, have been identified (Table 6-5). Factors that cause congenital malformation are called **teratogens**. Many substances are thought to have teratogenic potential, based on experiments in animals, but few are proved in humans. Exposure to a known teratogen may, but need not, result in a congenital malformation. Susceptibility to a teratogen depends on the amount of exposure, the developmental stage of the fetus when exposed, the prior condition of the mother, and the genetic predisposition of the fetus.<sup>3</sup>

### Periods of Fetal Vulnerability

The timing of the exposure to a teratogen greatly influences fetal susceptibility and the resulting type of malformation. The intrauterine development of humans can be divided into two stages: (1) the embryonic period, which extends from conception to 9 weeks of development, is followed by (2) the fetal period, which continues until birth. Before the third week of gestation, exposure to a teratogen generally either damages so few cells that the embryo develops normally, or damages so many cells that the embryo cannot survive and spontaneous abortion occurs. Between the third and ninth weeks of gestation the embryo is very vulnerable to teratogenesis, with the fourth and fifth weeks being the time of peak susceptibility.<sup>1,3</sup> Organ development (organogenesis) occurs during this period; the process is very sensitive to injury, regardless of the cause. Each organ has a critical period during which it is most vulnerable to malformation (Figure 6-22). Unfortunately, an embryo may be exposed to teratogens during the vulnerable period because the mother does not yet realize she is pregnant. The fetal period, from 3 to 9 months, is primarily concerned with further growth and maturation of the organs, and susceptibility to errors of morphogenesis is significantly less. Fetal insults occurring after the third month are more likely to result in growth retardation or injury to normally formed organs.

### Teratogenic Agents

The teratogenic potential of many agents is unknown. Several chemicals, some infections, and large doses of radiation are definitely associated with a higher risk of congenital disorders. In general, teratogens cause errors in morphogenesis by interfering with cell proliferation, migration, or differentiation. The specific mechanisms of action of most teratogens are unknown.

### Chemicals and Drugs

The list of proven teratogenic chemicals and drugs includes thalidomide, alcohol, anticonvulsants, warfarin, folate antagonists, androgenic

**TABLE 6-5 CAUSES OF CONGENITAL MALFORMATIONS IN HUMANS**

CAUSE	MALFORMED LIVE BIRTHS (%)
<b>Genetic</b>	
Chromosomal aberrations	10-15
Mendelian inheritance	2-10
<b>Environmental</b>	
Maternal/placental infections (e.g., rubella, toxoplasmosis, syphilis, cytomegalovirus, human immunodeficiency virus)	2-3
Maternal disease states (e.g., diabetes, phenylketonuria, endocrinopathies)	6-8
Drugs and chemicals (e.g., alcohol, folic acid antagonists, phenytoin, thalidomide, warfarin, 13- <i>cis</i> -retinoic acid)	≈1
<b>Irradiation</b>	≈1
<b>Multifactorial</b>	20-25
<b>Unknown</b>	40-60

Adapted from Stevenson RE et al, editors: *Human malformations and related anomalies*, New York, 1993, Oxford University Press, p 115; Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 450.

hormones, angiotensin-converting enzyme inhibitors, and organic mercury. Almost no drugs or chemicals are considered to be totally safe, and the current trend is to discourage pregnant women from using *any* drugs or chemicals. A classification system for determining relative risk of medications in pregnancy has been developed (Table 6-6). Two agents, thalidomide and alcohol, illustrate the teratogenic potential of chemicals.

In the 1960s, an increase in the incidence of congenital limb deformities was traced to maternal use of thalidomide, a tranquilizer, during early pregnancy.<sup>3</sup> Exposure during the vulnerable period (20 to 35 days following conception) was associated with a very high risk of fetal malformation. Typically, the arms were short and flipperlike, although deformities ranged from mild abnormalities of the digits to complete absence of the limbs. Damage to other structures, particularly the ears and heart, also occurred. Thalidomide is one of the most potent teratogens known.

The chronic ingestion of large amounts of alcohol is known to cause a group of congenital anomalies referred to as *fetal alcohol syndrome* (FAS). Fetal alcohol syndrome represents the severe end of a wide spectrum of conditions called fetal alcohol spectrum disorders (FASDs) that are associated with maternal alcohol use.<sup>17</sup> It is estimated that between 0.5 and 2.0 of every 1000 newborns suffer from FAS. The prevalence of FASD is estimated to be much higher, reaching 1% and much higher in populations with high alcohol use among women of childbearing age.<sup>18</sup> Affected infants suffer from growth retardation, developmental delay, learning and behavioral problems, malformations of the head and face, and cardiac defects, although alterations to the developing brain result in the most devastating deficits.<sup>18,19</sup> Multiple mechanisms for alcohol teratogenesis have been suggested.<sup>20</sup> Data are insufficient to determine what, if any, level of alcohol intake during pregnancy is safe. It is clear that factors other than the absolute amount of alcohol intake during pregnancy are important in determining risk of FAS. Complete abstinence from alcohol during pregnancy is recommended.

## CHAPTER 6 Genetic and Developmental Disorders

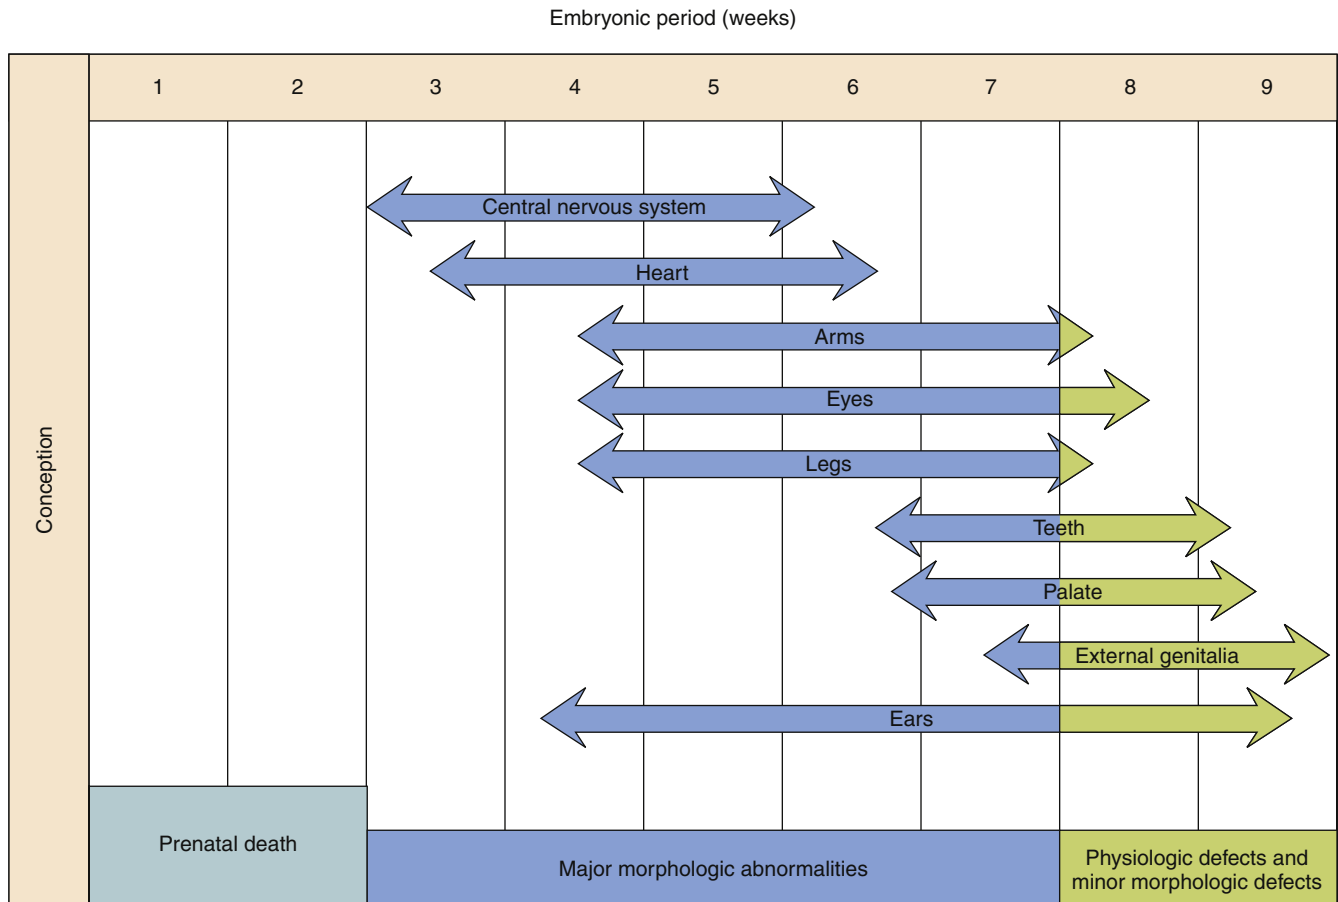

FIGURE 6-22 Vulnerable periods of fetal organ development.

TABLE 6-6 PREGNANCY CATEGORIES FOR MEDICATION ADMINISTRATION

CATEGORY	INTERPRETATION
<b>A</b>	Adequate and well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities to fetus in any trimester of pregnancy.
<b>B</b>	Animal studies have revealed no evidence of harm to fetus; however, there are no adequate and well-controlled studies in pregnant women. <b>OR</b> Animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate risk to fetus in any trimester.
<b>C</b>	Animal studies have shown an adverse effect, and there are no adequate and well-controlled studies in pregnant women. <b>OR</b> No animal studies have been conducted, and there are no adequate and well-controlled studies in pregnant women.
<b>D</b>	Adequate and well-controlled or observational studies in pregnant women have demonstrated risk to fetus. However, benefits of therapy may outweigh potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
<b>X</b>	Adequate and well-controlled or observational studies in animals or pregnant women have demonstrated positive evidence of fetal abnormalities or risks. Use of the product is contraindicated in women who are or may become pregnant.

### Infectious Agents

A number of perinatal infections have been implicated in the development of congenital malformations.<sup>3</sup> Certain viral infections appear to carry the greatest threat, although protozoa and bacteria have also been implicated. As with other teratogens, the gestational age of the fetus at the time of infection is critically important. Perhaps the best known viral teratogen is rubella. The risk period for rubella infection begins

just before conception and extends to 20 weeks' gestation, after which the virus rarely crosses the placenta. Rubella-induced defects vary but typically include cataracts, deafness, and heart defects. Several other organisms cause a similar constellation of congenital defects; therefore the acronym **TORCH** was developed to alert clinicians to the potential teratogenicity of these infections. TORCH stands for **t**oxoplasmosis, **o**thers, **r**ubella, **c**ytomegalovirus, **h**erpes. The major features of the

**FIGURE 6-23** Major clinical findings in the TORCH (toxoplasmosis, others, rubella, cytomegalovirus, herpes) complex of infective congenital disorders.

TORCH complex are shown in [Figure 6-23](#). The category of “others” includes several less frequently seen causes: hepatitis B, coxsackievirus B, mumps, poliovirus, and others. All microorganisms of the TORCH complex are able to cross the placenta and infect the fetus.

Toxoplasmosis is a protozoal infection that can be contracted from ingestion of raw or undercooked meat and from contact with cat feces. Cytomegalovirus and herpes simplex virus are generally transmitted to the fetus by chronic carrier mothers. Cytomegalovirus and herpes simplex virus often colonize in the genital area of the mother. Infants who escape infection in utero may still acquire the virus as they pass through the birth canal (see [Chapter 34](#)).

### Radiation

In addition to being mutagenic, radiation is also teratogenic. The teratogenic potential of radiation became apparent from the increased incidence of congenital malformations in children born to women who underwent irradiation of the cervix for cancer and in the children of atomic bomb victims in World War II. It is not known if lower levels of radiation, such as those used in diagnostic x-rays, are teratogenic. It is generally recommended that pregnant women avoid diagnostic x-rays or use appropriate lead shielding.

### Other Disorders of Infancy

An infant may be afflicted with a variety of problems at birth that do not fall into the category of genetic or developmental malformations. These problems generally arise later in uterine life and often involve mechanical factors or problems with the health of the mother and placenta. For example, babies with low birth weight or immaturity at birth may have difficulty breathing and taking in adequate nutrition. Interruption of the placental oxygen supply because of maternal hemorrhage, sedation, or blood incompatibility may result in fetal brain

injury. A difficult labor and delivery may result in a variety of injuries during the birth process. The details of these disorders of infancy and childhood may be found in specialized texts.

### KEY POINTS

- Environmental factors that adversely affect the developing fetus are called teratogens. Exposure to teratogens is particularly dangerous during the third to ninth weeks of gestation.
- Known teratogens include chemicals and drugs, infections, and radiation. The teratogenic potential of many chemicals and drugs is unknown, so pregnant women are usually advised to avoid all drugs if possible.
- Of the infectious agents, viruses are the most teratogenic, particularly organisms of the TORCH variety (toxoplasmosis, others, rubella, cytomegalovirus, herpesvirus).

## DIAGNOSIS, COUNSELING, AND GENE THERAPY

In recent years, the ability to diagnose and manage genetic and developmental disorders has improved dramatically. Although pedigree analysis continues to be an important method for identifying at-risk individuals, for a number of disorders it is now possible to determine if parents carry defective genes or if a particular fetus is afflicted. Currently, the ability to detect genetic mutations far exceeds the ability to offer definitive genetic treatment, triggering many ethical concerns. Unfortunately, many individuals at risk for transmitting recessive genetic diseases are not identified until the birth of an afflicted child. Genetic counseling and prenatal assessment then become extremely important in assisting the family in regard to future pregnancies.

### Prenatal Diagnosis and Counseling

A number of conditions are associated with a higher risk of congenital anomalies and are indications for instituting counseling and prenatal diagnostic examination. These conditions include (1) a maternal age of 35 years or greater; (2) a history of previously bearing a child with a chromosomal disorder (such as trisomy 21); (3) a known family history of X-linked disorders; (4) a family history of inborn errors of metabolism; (5) the occurrence of neural tube anomalies in a previous pregnancy; and (6) awareness that the mother is a known carrier of a recessive genetic disorder. As diagnostic methods become more cost-effective, general screening for other risk factors may be undertaken. Samples for prenatal testing of the fetus are usually obtained by amniocentesis, chorionic villus biopsy, or umbilical cord blood. Postnatal genetic analysis is usually done on peripheral blood samples of lymphocytes.

Ultrasound and amniocentesis are mainstays of prenatal diagnostic examination. **Ultrasound** is a noninvasive procedure that uses sound waves to produce a reflected image of the fetus. It is commonly used to determine gestational age, fetal position, and placental location. Ultrasound is also useful in detecting visible congenital anomalies such as spina bifida (neural tube defect); heart defects; and malformations of the face, head, body, and limbs.

**Amniocentesis** may be performed to determine genetic and developmental disorders not detectable by ultrasound. During amniocentesis, a needle is inserted through the abdomen or vagina and into the uterus. A sample of amniotic fluid containing skin cells shed by the fetus is removed for analysis. The amniotic fluid can be analyzed for abnormal levels of certain substances secreted by the fetus, such as  $\alpha$ -fetoprotein, which may indicate neural tube defects. The live skin cells can be cultured and subjected to biochemical, chromosomal, and genetic analysis. Only certain genetic and developmental disorders can be reliably detected by these procedures, and they may not provide the needed information until relatively late in the pregnancy. Amniocentesis cannot generally be

performed before 16 weeks' gestation. **Chorionic villus sampling (CVS)** involves the removal of a piece of tissue directly from the chorion (the outer membrane of the fetal sac). It can be performed at 8 weeks' gestation. Whether obtained via amniocentesis or CVS, fetal cells provide small amounts of DNA that can then be amplified into a larger quantity by a process called polymerase chain reaction (PCR). This DNA can then be analyzed by a variety of methods to determine the genetic sequence, the presence or absence of particular genes, or the presence of mutations. The fetal genome can be scanned for particular genes by exposing the processed DNA to microchips that are coated with thousands of genetic sequence probes in specific locations. Complementary base pairing between the probes fixed on the microchip and the DNA being tested is used to detect the presence of particular gene sequences.

**Embryoscopy** allows direct visualization of the embryo as early as the first trimester of pregnancy. The scope is inserted through the cervix and into the uterus. Embryoscopy can be used to identify developmental progress and to diagnose structural anomalies. An exciting application of this technique is the potential to directly manage genetic disorders with targeted gene or stem cell therapy. The early diagnosis of congenital disorders allows a greater number of treatment options. Some disorders can be managed in utero; others may require early delivery, immediate surgery, or cesarean section to minimize fetal trauma. Early warning of fetal difficulties allows parents time to prepare emotionally for the birth of the child. In some instances, termination of the pregnancy may be the treatment of choice.

### Genetic Analysis and Therapy

An exciting outcome of the Human Genome Project is the potential for gene therapy—the treatment of genetic disease by replacing the defective gene with a normal, healthy gene. This idea once sounded like science fiction, but clinical trials are under way to manage a number of genetic disorders.<sup>21</sup> The first federally approved gene therapy procedure was performed in 1990 to treat a child who suffered from a rare condition called *severe combined immunodeficiency (SCID)* by introducing a functional gene for the enzyme adenosine deaminase. In the past, children who suffered from SCID had severely compromised immune systems and generally died from overwhelming infections unless their environment was strictly controlled. Use of gene therapy has shown some success in improving immune function and allowing these children to live in the outside world, although the safety of gene therapy is a continuing challenge.<sup>22</sup>

Gene therapy has the potential for alleviating human suffering by curing genetic diseases, but it is accompanied by a number of moral and ethical dilemmas. Tampering with the human gene pool could have serious implications for human evolution. There is also the potential for using the technology to create “new and improved” human beings or human clones.

### Recombinant DNA Technology

Over the past 30 years, DNA has gone from being the most difficult cellular molecule to study to being the easiest. The great advances in molecular genetics during this time are due to plummeting costs of DNA sequencing and the development of recombinant DNA technologies. It is now possible to select a specific region of DNA, produce unlimited copies of it, determine its nucleotide sequence, use it to make unlimited quantities of a desired protein, or alter its DNA sequence at will (genetic engineering) and reinsert it into a living cell. These tools provide the means to decipher the nucleotide sequence of an individual human genome, to create DNA probes to explore an individual's genetic makeup for specific mutations, to mass-produce therapeutic proteins and vaccines, and to cure genetic disorders by replacing mutated genes with normally functioning ones.

**FIGURE 6-24** Fluorescence in situ hybridization assay showing an interphase nucleus. The red probe hybridized to chromosome 21 and the green probe hybridized to chromosome 13. Three copies of chromosome 21 are identified, confirming the diagnosis of trisomy 21. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 161. Photograph courtesy Dr. Stuart Schwartz, Department of Pathology, University of Chicago, Chicago, IL.)

Recombinant DNA technology comprises a number of techniques, the most important of which are briefly described here.

- The long, difficult-to-handle DNA strands are more easily studied if cut into smaller pieces. This is accomplished by using restriction enzymes that cleave DNA at specific sites. The resulting pieces can then be separated by electrophoresis according to their size. A section of DNA can be collected and efficiently sequenced by automated means.
- Nucleic acid hybridization techniques take advantage of the natural tendency for DNA and RNA to find and bind to a complementary nucleotide sequence. A labeled piece of DNA or RNA can therefore be used to search for or “probe” for its complementary sequence among the many millions of sequences in a cell or cell extract. For example, in a fluorescence in situ hybridization assay, a probe for a specific site on a chromosome is attached to a fluorescent label and incubated with a cell. The fluorescence is then examined to identify the location and number of copies of the particular chromosome sequence (Figure 6-24). Without the hybridization technique, finding a desired gene among the 3 billion base pairs in the human genome could take many years of intense effort, like finding the proverbial needle in a haystack. Hybridization is also the method behind the “gene chip assay” technology. As an outcome of the Human Genome Project, the DNA sequences for the thousands of human genes and common mutations have been identified. Specific DNA sequence probes for these genes can be synthesized and attached to a fixed position on a plate (microchip). The DNA of interest can then be exposed to the chip, and the probes will preferentially bind to DNA segments having complementary bases. The position of the probe and the degree of DNA binding can then be analyzed by computer to produce a specific genetic analysis of gene mutations.
- DNA cloning is the technique used to produce many identical copies of a DNA sequence containing a gene of interest. The availability

of large quantities of a purified gene sequence makes study and gene manipulation possible. A number of different techniques can be used to clone DNA. The polymerase chain reaction (PCR) technique is very efficient if the DNA sequence is already partially known. Basically, the DNA sequence of interest is mixed with special DNA polymerases that use the DNA sequence as a template to produce double-stranded DNA. Each DNA thus produced can in turn act as a template for production of another DNA. Large quantities can be produced very rapidly by PCR. The DNA can also be cloned by inserting it into bacteria by use of a viral or plasmid vector. Bacteria that incorporate the desired gene are identified by hybridization with a labeled probe. The desired bacteria then are allowed to proliferate, making a copy of the DNA sequence along with their own genome with each cell division.

- Genetic engineering refers to a process whereby a gene of interest is altered from its original form. The altered (mutated) gene can be reintroduced into a cell to disclose its effect on cell function and thus elucidate the normal function of the original gene and its protein product. Genetic engineering has been applied to plants to increase their value as food crops. Genetically engineered cells can be turned into protein factories to produce hormones, such as insulin, in large quantity.

Gene therapy relies heavily on these techniques to facilitate identification of genetic mutations, study of gene function, and development of methods to repair or replace mutated genes. Many more applications of recombinant DNA technology will become apparent as research on the genetic basis of human function and disease proceeds.

#### KEY POINTS

- Risk factors that indicate the need for prenatal diagnostic examination and counseling include advanced maternal age (older than 35 years), a family history of genetic disorders, and the previous birth of a child with chromosomal or neural tube defects.
- Ultrasound, amniocentesis, and chorionic villus sampling are the mainstays of prenatal assessment for genetic disorders.
- DNA sequences that are complementary to a gene of interest can be synthesized and used to probe a genome to determine if and where the gene is present. These hybridization techniques make screening for genetic disorders relatively fast and simple.
- Gene therapy is the treatment of genetic disease by replacing defective genes with normal genes. Gene therapy is possible because of the advances attained in recombinant DNA technology over the past 30 years.

## SUMMARY

Genetic and developmental disorders are responsible for a number of congenital malformations. Congenital disorders are caused by genetic and environmental factors that disrupt normal fetal development. Genetic disorders are classified as (1) chromosomal alterations, including structural and numeric abnormalities; (2) mendelian disorders, including autosomal dominant, autosomal recessive, and X-linked disorders; (3) nonmendelian single-gene disorders, including triplet repeats, mitochondrial gene defects, and genetic imprinting disorders; and (4) polygenic or multifactorial disorders. Known environmental

teratogens include radiation, infectious organisms, and various chemicals and drugs. The embryo is particularly susceptible to teratogens during the period of organogenesis, which extends from the third to the ninth week of gestation. Pedigree analysis, ultrasound, amniocentesis, and chorionic villus biopsy may provide helpful information regarding genetic risk and the prenatal condition of at-risk infants. DNA sequencing of normal and mutated genes has made it possible to efficiently screen for genetic disorders and develop gene therapies for a variety of genetic diseases.

**Neoplasia** means “new growth.” In common use, the term implies an *abnormality* of cellular growth and may be used interchangeably with the term *tumor*. It is no surprise that the discovery of a tumor in an individual can evoke feelings of disbelief, anger, and dread. Characterization of the tumor cells is of critical importance to determine whether the tumor is benign or malignant. The term *cancer* is applied only to malignant neoplasms. The diagnosis of a **benign** growth is received with great relief inasmuch as the tumor is generally easily cured. The diagnosis of a **malignant** cancer, on the other hand, may herald months of intensive and often uncomfortable treatment with uncertain outcomes. Cancer remains the second leading cause of death in the United States for both men and women.

It is increasingly clear that cancer is associated with *altered expression of cellular genes* that normally regulate cell proliferation and differentiation. A unified theory of cancer causation has emerged, and new methods for cancer therapy continue to be developed. Cancer is a complex, multifaceted disorder with each individual cancer having some unique properties. A better understanding of the molecular characteristics of individual cancers is encouraging the development of specific therapies that target each cancer’s weaknesses.

## BENIGN VERSUS MALIGNANT GROWTH

### Characteristics of Benign and Malignant Tumors

The terms *benign* and *malignant* refer to the overall consequences of a tumor to the host. Generally, malignant tumors have the potential to kill the host if left untreated, whereas benign tumors do not. This difference is not strict because some benign tumors may be located in critical areas. For example, a benign tumor may be life threatening if it causes pressure on the brain or blocks an airway or blood vessel. Histologic examination of a tumor is the primary mode for determining its benign or malignant nature. Certain tumor characteristics have historically been shown to indicate malignant potential. Important considerations include localization of the tumor and determination of the degree of tumor cell differentiation.

Benign tumors do not invade adjacent tissue or spread to distant sites. Many benign tumors are encapsulated by connective tissue, which is an indication of strictly local growth. Any evidence that tumor cells have penetrated local tissues (invasiveness), lymphatics, or blood vessels suggests a malignant nature with potential to spread to distant sites (metastasize).

As a general rule, benign cells more closely resemble their tissue type of origin (e.g., skin, liver) than do malignant cells. The degree of tissue-specific differentiation has traditionally been used to predict malignant potential. A lack of differentiated features in a cancer cell is called **anaplasia**, and a greater degree of anaplasia is correlated with a more aggressively malignant tumor.<sup>1</sup> Anaplasia is indicated by variation in cell size and shape within the tumor, enlarged nuclei, abnormal mitoses, and bizarre-looking giant cells (Figure 7-1). Regardless of histologic appearance, invasion of local tissue or evidence of **metastasis** to distant sites confirms the diagnosis of malignancy.

Other differences between benign and malignant tumors have been noted (Table 7-1). Benign tumors generally grow more slowly, have little vascularity, rarely have necrotic areas, and often retain functions similar to those of the tissue of origin. Conversely, malignant tumors often grow rapidly and may initiate vessel growth in the tumor. They frequently have necrotic areas and are dysfunctional.

### Tumor Terminology

General rules for the naming of tumors have been developed to indicate the tissue of origin and the benign or malignant nature of the tumor. The suffix *-oma* is used to indicate a benign tumor, whereas *carcinoma* and *sarcoma* are used to indicate malignant tumors.

TABLE 7-1 GENERAL CHARACTERISTICS OF BENIGN AND MALIGNANT TUMORS

CHARACTERISTIC	BENIGN	MALIGNANT
Histology	Typical of tissue of origin	Anaplastic, with abnormal cell size and shape
Growth rate	Few mitoses	Many mitoses
Localization/metastasis	Slow	Rapid
	Strictly local, often encapsulated/no metastasis	Infiltrative/frequent metastases
Tumor necrosis	Rare	Common
Recurrence after treatment	Rare	Common
Prognosis	Good, unless in critical area	Poor if untreated

**FIGURE 7-1** **A**, Normal Papanicolaou smear from the uterine cervix showing large, flat epithelial cells with small nuclei. **B**, Typical histologic appearance of anaplastic tumor cells showing variation in cell size and shape, with large, hyperchromatic nuclei. (From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 220. Courtesy Dr. Richard M. DeMay, Department of Pathology, University of Chicago.)

Carcinoma refers to malignant tumors of epithelial origin and sarcoma to malignant tumors of mesenchymal (nerve, bone, muscle) origin. Thus a benign tumor of glandular tissue would be called an adenoma, but a malignant tumor of the same tissue would be called an adenocarcinoma (Table 7-2). Some notable exceptions to the rules are lymphomas, hepatomas, and melanomas, which are all highly malignant despite their *-oma* suffix. Leukemia refers to a malignant growth of white blood cells. The great majority of human cancers (90%) are carcinomas from malignant transformation of epithelial cells.<sup>2</sup>

### The Malignant Phenotype

Cells growing in normal tissue have predictable relationships with neighboring cells. In a particular tissue, the rate of cell proliferation is precisely matched to the rate of cell death. Normal cells require constant reassurance in the form of survival signals from their environment that their continued existence is desirable, and they proliferate only when space is available and appropriate mitogen-stimulating signals are present. Normal cells also respond to signals instructing them to actively destroy themselves

in a process called *apoptosis* (see Chapter 4). Cancer cells, however, do not obey the rules; they have escaped the normal mechanisms of growth control. A number of antisocial properties develop in malignant cells that allow them to proliferate at the expense of other cells and tissues of the body. These abnormal behaviors can be summarized as follows:

- Cancer cells proliferate despite lack of growth-initiating signals from the environment.
- Cancer cells escape apoptotic signals and achieve a kind of immortality in that they are capable of unlimited replication.
- Cancer cells lose their differentiated features and contribute poorly or not at all to the function of their tissue.
- Cancer cells are genetically unstable and evolve by accumulating new mutations at a much faster rate than normal cells.
- Cancer cells invade their local tissue and overrun their neighbors.
- Perhaps worst of all, cancer cells gain the ability to migrate from their site of origin to colonize distant sites where they do not belong.

TABLE 7-2 NOMENCLATURE FOR NEOPLASTIC DISEASES

CELL OR TISSUE OF ORIGIN	BENIGN	MALIGNANT
<b>Tumors of Epithelial Origin</b>		
Squamous cells	Squamous cell papilloma	Squamous cell carcinoma
Basal cells	—	Basal cell carcinoma
Glandular or ductal epithelium	Adenoma Cystadenoma	Adenocarcinoma Cystadenocarcinoma
Transitional cells	Transitional cell papilloma	Transitional cell carcinoma
Bile duct	Bile duct adenoma	Bile duct carcinoma (cholangiocarcinoma)
Liver cells	Hepatocellular adenoma	Hepatocellular carcinoma
Melanocytes	Nevus	Malignant melanoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Skin adnexal glands		
Sweat glands	Sweat gland adenoma	Sweat gland carcinoma
Sebaceous glands	Sebaceous gland adenoma	Sebaceous gland carcinoma
Germ cells (testis and ovary)	—	Seminoma (dysgerminoma), embryonal carcinoma, yolk sac carcinoma
<b>Tumors of Mesenchymal Origin</b>		
Hematopoietic/lymphoid tissue	—	Leukemia, lymphoma, Hodgkin disease, multiple myeloma
Neural and retinal tissue		
Nerve sheath	Neurilemmoma, neurofibroma	Malignant peripheral nerve sheath tumor
Nerve cells	Ganglioneuroma	Neuroblastoma
Retinal cells (cones)	—	Retinoblastoma
Connective tissue		
Fibrous tissue	Fibromatosis (desmoid)	Fibrosarcoma
Fat	Lipoma	Liposarcoma
Bone	Osteoma	Osteogenic sarcoma
Cartilage	Chondroma	Chondrosarcoma
Muscle		
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Endothelial and related tissues		
Blood vessels	Hemangioma	Angiosarcoma Kaposi sarcoma
Lymph vessels	Lymphangioma	Lymphangiosarcoma
Synovium	—	Synovial sarcoma
Mesotheilium	—	Malignant mesothelioma
Meninges	Meningioma	Malignant meningioma

From Murphy GP, Lawrence W, Lenhard RE, editors: *American Cancer Society textbook of clinical oncology*, Atlanta, 1995, Author, p 77. Reproduced by permission of the American Cancer Society.

Most cancers are thought to arise from stem cells that are present in tissues. Tissue stem cells are capable of unlimited proliferation, entering the cell cycle to produce two daughter cells—with one cell retaining the original stem cell properties and the other becoming a more differentiated cell, but still capable of proliferation. Normally, the partially differentiated cells can undergo only a limited number of cell divisions before they permanently leave the cell cycle and become senescent.<sup>2</sup> Either a stem cell or a partially differentiated cell has the potential to acquire the genetic mutations necessary to become malignant.

### KEY POINTS

- Malignant tumors have the potential to kill the host, whereas benign tumors generally do not. The primary difference between malignant and benign tumors is the propensity of malignant tumors to invade adjacent tissue and spread to distant sites (metastasize).
- The suffix *-oma* is used to indicate a benign tumor (e.g., fibroma). *Carcinoma* and *sarcoma* are used to indicate malignancy (e.g., fibrosarcoma). Exceptions include melanomas, lymphomas, hepatomas, and leukemia, all of which are malignant.
- Malignant cells exhibit antisocial properties that allow them to ignore growth-controlling signals from the environment. Cancer cells proliferate excessively, become immortal, invade locally, and may travel to distant sites where they establish new colonies.

## EPIDEMIOLOGY AND CANCER RISK FACTORS

Cancer accounts for approximately 25% of all deaths, which makes it the second leading cause of death in the United States. Most cancer deaths (77%) occur in persons older than 55 years. The American Cancer Society (ACS) estimates that men have almost a 1 in 2 lifetime risk of developing cancer and women have slightly higher than a 1 in 3 risk. The 5-year relative survival rate for all cancers combined is about 68%.<sup>3</sup> The 5-year survival rate does not distinguish between those who were cured and those who have relapsed or are still in treatment. Fortunately, the current view of cancer causation predicts that many cancers are preventable. Indeed, one third of cancer-related deaths may be attributed to lifestyle factors. Lifestyle factors of particular importance are tobacco use, nutrition, and obesity.<sup>4</sup> Sun exposure is a significant risk factor for skin cancer (Chapter 53), and sexual exposure to certain strains of human papillomavirus predisposes to cervical cancer (Chapter 34). The high incidence and relative ease of screening for breast, cervical, colorectal, and prostate cancers has prompted the development of guidelines for early detection of these cancers. The current recommendations for early detection of cancer in average-risk, asymptomatic persons are shown in Table 7-3. Statistics regarding some of the major forms of cancer are shown in Figure 7-2. Further discussions of particular cancers can be found in chapters relating to corresponding body systems.

### Tobacco Use

The impact of tobacco use on cancer-related death can be most vividly seen by looking at cancer death rates in the United States from 1930 to 2007 (Figure 7-3). Whereas all other cancer-related death rates declined or remained relatively stable, the death rate from lung cancer increased dramatically. The increase is attributable almost entirely to smoking. Lung cancer remains the leading cause of cancer death in both men and women, accounting for 30% of all cancer deaths. Lung cancer has one of the worst survival rates of all cancers—only 15%. In addition to

lung cancer, tobacco use has been linked with cancer of the pancreas, bladder, kidney, mouth, esophagus, and cervix (Figure 7-4). Smoking prevalence among adults in the United States declined from 42% in 1965 to 21% in 2004 and has remained stable at 21%, with rates being approximately 5% lower in women than in men. An estimated 45 million U.S. adults currently smoke cigarettes. Approximately 20% of high school students reported being cigarette smokers in 2009. In 2006, only 8% of college graduates were current smokers, compared to 21% in 1983.<sup>3</sup>

Carcinogens can be grouped into two major types: those that cause genetic damage (initiators) and those that promote growth of the tumor (promoters). Tobacco smoke contains hundreds of compounds, many of which have known genotoxicity (e.g., polycyclic aromatic hydrocarbons, nicotine derivatives) and probably serve as initiators. Tobacco smoke also contains promoters, which spur the mutant cells to proliferate. Second-hand smoke contains more than 7000 chemicals, of which 69 are known to cause cancer.<sup>3</sup> The American Cancer Society estimates that about 3400 nonsmoking adults die from lung cancer each year as a result of exposure to second-hand smoke.<sup>3</sup>

### Nutrition

The scientific study of nutrition and cancer is complex, and it is not clear how single nutrients, combinations of nutrients, overnutrition and energy imbalance, or the amount and distribution of body fat affect a person's risk for specific cancers.<sup>3</sup> The ACS suggests a mostly plant-based diet emphasizing a variety of vegetables, fruits, and whole grains. The ACS endorses limiting the intake of red and processed meats, while controlling total caloric intake to maintain a healthy weight. Individual nutritional supplements are not recommended for cancer prevention.<sup>3</sup> The results of randomized clinical trials of antioxidant supplements and selenium have shown no reduction in risk for cancer, at least in generally well-nourished populations.<sup>3</sup>

### Fat

Several epidemiologic studies performed in the 1970s and early 1980s suggested a relationship between high-fat diets and the development of breast, colon, and prostate cancer. In some studies, however, higher fat intake was found to be protective against some cancers. A pooled analysis of seven large studies found no link between fat intake and the risk of breast cancer.<sup>5</sup> The results of one large, randomized clinical trial investigating the effect of a low-fat diet on the occurrence of invasive breast cancer found no difference between the control and low-fat groups after 8 years of follow-up in postmenopausal women.<sup>6</sup> Fat or calorie intake and high production of insulin may affect breast cancer outcomes depending on tumor cell type and hormone responsiveness. Further research on the specific type of fat intake and other cofactors is needed to clarify the fat-cancer relationship. Several studies in animals have shown that regardless of fat intake, tumor growth may be inhibited by caloric restriction. Some investigators have proposed a link between high insulin production and breast cancer.

### Fiber

Fiber is a general term for nondigestible dietary substances that remain in the intestinal lumen, increase fecal bulk, and improve bowel regularity. Fiber includes a diversity of compounds such as cellulose, bran, and pectin. An association between fiber intake and colorectal cancer proposed in the early 1970s was based on a study comparing the incidence of certain ailments in Americans and Africans.<sup>7</sup> A number of correlational and comparison studies done since that time have yielded conflicting results, and large randomized trials failed to show a benefit.<sup>8</sup> Part of the difficulty may be linked to the way that different studies

**TABLE 7-3 SCREENING GUIDELINES FOR THE EARLY DETECTION OF CANCER IN AVERAGE-RISK ASYMPTOMATIC PEOPLE**

CANCER SITE	POPULATION	TEST OR PROCEDURE	FREQUENCY
Breast	Women, age 20+	Breast self-examination	Beginning in their early 20s, women should be told about the benefits and limitations of breast self-examination (BSE). The importance of prompt reporting of any new breast symptoms to a health professional should be emphasized. Women who choose to do BSE should receive instruction and have their technique reviewed on the occasion of a periodic health examination. It is acceptable for women to choose not to do BSE or to do BSE irregularly.
		Clinical breast examination	For women in their 20s and 30s, it is recommended that clinical breast examination (CBE) be part of a periodic health examination, preferably at least every 3 years. Asymptomatic women aged 40 and over should continue to receive a clinical breast examination as part of a periodic health examination, preferably annually.
		Mammography	Begin annual mammography at age 40–50*
Colorectal <sup>†</sup>	Men and women, age 50+	Tests that find polyps and cancer:	Every 5 years starting at age 50
		Flexible sigmoidoscopy <sup>‡</sup> or Colonoscopy, or	Every 10 years, starting at age 50
		Double-contrast barium enema (DCBD) <sup>‡</sup>	Every 5 years, starting at age 50
		Tests that mainly find cancer: Fecal occult blood test (FOBT) with at least 50% test sensitivity for cancer, fecal immunochemical test (FIT) with at least 50% test sensitivity for cancer, <sup>‡,§</sup> or Stool DNA test (sDNA) <sup>‡</sup>	Annual, starting at age 50  Interval uncertain, starting at age 50
Prostate	Men, age 50+	Prostate-specific antigen test (PSA) with or without digital rectal exam (DRE)	Asymptomatic men who have at least 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about screening for prostate cancer after receiving information about the uncertainties, risks, and potential benefits associated with screening. Prostate cancer screening should not occur without an informed decision-making process.
Cervix	Women, age 21+	Pap test	Cervical cancer screening should begin approximately 3 years after a woman begins having vaginal intercourse, but no earlier than 21 years of age. Screening should be done every year with conventional Pap tests or every 2 years using liquid-based Pap tests. At or after age 30, women who have had three normal test results in a row may get screened every 2 to 3 years with cervical cytology (either conventional or liquid-based Pap test) alone, or every 3 years with an HPV DNA test plus cervical cytology. Women 70 years of age and older who have had three or more normal Pap tests and no abnormal Pap tests in the past 10 years and women who have had a total hysterectomy may choose to stop cervical cancer screening.
Endometrial	Women, at menopause	At the time of menopause, women at average risk should be informed about risks and symptoms of endometrial cancer and strongly encouraged to report any unexpected bleeding or spotting to their physicians.	
Cancer-related checkup	Men and women age 20+	On the occasion of a periodic health examination, the cancer-related checkup should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures.	

American Cancer Society: *Cancer facts and figures—2012*, Atlanta, 2012, American Cancer Society; ACOG Committee on Practice Bulletins-Gynecology. *Obstet Gynecol* 114(6):1409-1429, 2009.

\*Beginning at age 40, annual clinical breast examination should be performed before mammography.

<sup>†</sup>Individuals with a personal or family history of colorectal cancer or adenomas, inflammatory bowel disease, or high-risk genetic syndromes should continue to follow the most recent recommendations for individuals at increased or high risk.

<sup>‡</sup>Colonoscopy should be done if test results are positive.

<sup>§</sup>For FOBT or FIT used as a screening test, the take-home multiple sample method should be used. An FOBT or FIT done during a digital rectal exam in the doctor's office is not adequate for screening.

<sup>¶</sup>Information should be provided to men about the benefits and limitations of testing so that an informed decision can be made with the clinician's assistance.

**FIGURE 7-2** United States 2012 estimated new cancer cases (A) and estimated cancer deaths (B) in 10 leading sites by gender. Excludes basal and squamous cell skin cancers and in situ carcinomas except urinary bladder. (American Cancer Society: *Cancer facts and figures—2012*, Atlanta, 2012, American Cancer Society.)

define dietary fiber. Because fiber is associated with beneficial effects on digestion and elimination, fiber intake in the range of 10 to 13 g per 1000 calories consumed is generally recommended.

### Alcohol

Alcohol intake has been linked to a number of cancers, including breast, esophageal, laryngeal, and liver cancer. Alcohol may exert its cancer-promoting effects through impairment of the liver's ability to metabolize harmful substances and endogenous hormones. Moderate alcohol intake has been shown to increase estrogen levels, which may account for its promoting effects on breast cancer.<sup>9</sup> As a carbohydrate-dense substance, alcohol may contribute to cancer risk through its effects on insulin secretion. Insulin is a general growth factor for a number of tissues. Limiting alcohol intake may provide a modest reduction in cancer risk.

### Antioxidants

Until recently, the emphasis of cancer prevention has been on the identification and avoidance of cancer-causing agents. However, increasing interest has been shown in finding substances with cancer-protective properties. The fact that DNA damage is an important step in cancer initiation, coupled with the knowledge that oxygen free radicals can impart this damage, led to the idea that antioxidants may have protective effects for cancer. The specific agents tested in clinical trials included  $\beta$ -carotene, vitamin E, vitamin C, selenium, retinol, zinc, riboflavin, and molybdenum. None of the completed trials produced

convincing evidence to justify the use of traditional antioxidant-related vitamins or minerals for cancer prevention.<sup>10</sup>

Vitamin A and the antioxidant trio of vitamin E,  $\beta$ -carotene, and vitamin C have been most widely studied. The use of antioxidants to prevent cancer sounds like a good idea; however, several large-scale studies have failed to reveal a benefit and some have found that the risk of cancer may be increased.<sup>11,12</sup> At present, it may be prudent to consume a diet high in natural fruit and vegetable sources of antioxidants.

#### KEY POINTS

- The risk of developing cancer increases with age. It is estimated that men have almost a 1 in 2 lifetime chance of developing cancer, whereas women have a little more than a 1 in 3 chance.
- The development of many cancers is related to lifestyle, particularly tobacco use and nutrition. Smoking cessation is considered important in reducing cancer risk. Guidelines regarding nutrition are less clear. Limiting excessive calorie and alcohol intake while increasing intake of dietary fiber, fruit, and vegetables may be of benefit.

## GENETIC MECHANISMS OF CANCER

Despite much progress in our understanding of how mechanisms of growth control and cellular differentiation may go awry, there is still no simple answer to the question, "What causes cancer?" It is increasingly evident, however, that cancer is primarily a disorder of gene

\*Per 100,000 age adjusted to the 2000 U.S. standard population.

**Note:** Due to changes in ICD coding, numerator information has changed over time. Rates for cancer of the liver, lung and bronchus, and colon and rectum are affected by these changes.

**FIGURE 7-3** United States age-adjusted cancer death rates for selected sites in men (A) and women (B) from 1930 to 2007. (American Cancer Society: *Cancer facts and figures—2012*, Atlanta, 2012, American Cancer Society.)

**FIGURE 7-4** Annual cancer deaths attributable to smoking in males and females in the United States. (From Centers for Disease Control and Prevention: Annual smoking-attributable mortality, years of potential life lost, and productivity losses—United States, 2000-2004, *MMWR Morb Mortal Wkly Rep* 57[45]:1226-1228, 2008.)

expression. Early support for a genetic basis of cancer came from the observation that cancer often resulted from agents known to damage deoxyribonucleic acid (DNA). In the 1970s a number of potential cancer-causing agents (**carcinogens**) were identified by demonstrating their mutagenic potential.<sup>13</sup> The suggestion that mutant genes were the basis for cancer launched intense research to identify the cancer-causing gene or genes.

Cancer-critical genes are grouped into two broad classes, according to whether overactivity of the gene contributes to cancer (gain-of-function mutations) or whether underactivity is the problem (loss-of-function mutations). Both categories of genes result in similar effects in enhancing cell proliferation and survival.<sup>2</sup> Genes in the first category are called **proto-oncogenes**, which normally code for components of the cellular growth-activating pathways. A proto-oncogene in its mutant, overactive, or overexpressed form is called an *oncogene*. Genes in the second category of cancer-related genes are called **tumor suppressor genes**, which normally inhibit cell proliferation. Cancers may arise when tumor suppressor gene function is lost or abnormally inhibited. To achieve malignant transformation, a cell must generally suffer mutations in a combination of these growth regulatory genes. A cell thus transformed passes on these mutations to its progeny when it divides and forms a clone of abnormally proliferating cells. Numerous studies have begun to unravel the details of how proto-oncogenes and tumor suppressor genes may dysfunction and contribute to the malignant phenotype. In addition to the genes that regulate the cell cycle, two other categories of genes that monitor and maintain the genome contribute indirectly to the development of cancer. These are the DNA-repair genes and the genes that regulate apoptosis (see Chapter 4).

### Proto-Oncogenes

Proto-oncogenes were the first of the tumor-associated genes to be discovered, and hundreds have been described to date.<sup>2</sup> As often happens in the study of genes, a gene associated with a disease process is identified long before its normal cellular function is elucidated. Thus genes associated with cancer are traditionally named for the cancer in which they were first discovered (in mutant form)

rather than for their normal cellular function. Many of the first cancer-associated genes, called **oncogenes**, were initially identified in viruses and still retain the name reflecting their viral discovery. The term *proto-oncogene* was created to label the normal cellular gene that can be transformed into an oncogene by activating (gain-of-function) mutations. A representative list of known proto-oncogenes is shown in Table 7-4.

The majority of proto-oncogenes described to date code for components of cell-signaling systems that promote cell proliferation.<sup>2</sup> These components can be grouped into four broad categories: (1) growth factors, (2) receptors, (3) cytoplasmic signaling molecules, and (4) nuclear transcription factors (Figure 7-5). Excessive activity in any of these components may release the cell from environmental feedback and allow it to proliferate abnormally.

### Growth Factors (Mitogens)

The first proto-oncogenes to be discovered coded for growth factors. A great deal of intercellular communication is accomplished through the cell-to-cell transmission of growth factors. Growth factors are small peptides that are manufactured by cells and secreted into the extracellular space. They diffuse to nearby cells and interact with receptors on the target cell surface. Binding of growth factors to cell surface receptors activates signaling cascades within the cell that enhance proliferation. As a general principle, cells do not independently produce growth factors sufficient to stimulate their own proliferation. The proliferation signals must be produced by the cell's environment. The cell's environment also conveys growth-inhibiting signals. Overproduction of stimulatory growth factors by a mutant proto-oncogene can shift the balance of signals and produce excessive self-stimulated growth (**autocrine signaling**). Examples of tumor-secreted growth factors include platelet-derived growth factor (PDGF), transforming growth factor- $\alpha$  (TGF- $\alpha$ ), and epidermal growth factor (EGF). Certain cancer types typically secrete particular growth factors. For example, platelet-derived growth factor is commonly oversecreted in glial cell cancers (brain tumors) and connective tissue cancers (sarcomas).

**TABLE 7-4 EXAMPLES OF GAIN-OF-FUNCTION PROTO-ONCOGENES AND THEIR MECHANISMS OF ACTION**

FACTOR	TYPE OF CANCER
<b>Mitogens and Growth Factors</b>	
PDGF	Glioma (brain)
FGF	Melanoma
EGF	Breast
TGF- $\alpha$	Breast, numerous others
<b>Cell Membrane Receptors</b>

Cyclin-dependent kinase 4	Melanoma, sarcoma

EGF, Epidermal growth factor; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; TGF, transforming growth factor.

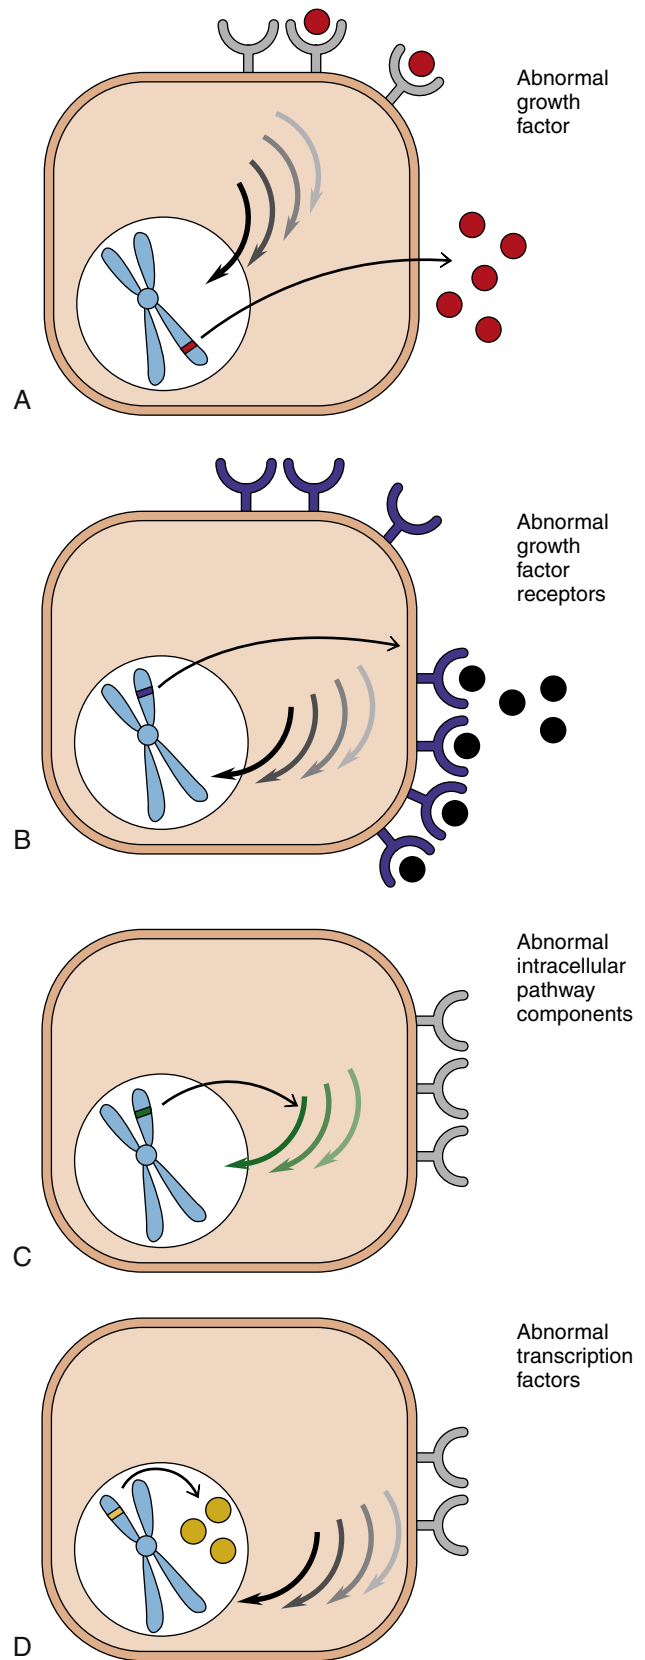

**Growth Factor Receptors**

Peptide growth factors (mitogens) cannot penetrate the cell membrane directly, so their presence at the cell surface must be transmitted intracellularly by cell surface receptors. Receptors are transmembrane proteins with the mitogen-binding area on the outside of the cell and an enzyme-activating area on the inside of the cell. These receptors are extremely specific; they will bind with only one particular mitogen. Binding activates a series of reactions within the cell that eventually leads to cell proliferation.

A mutational event may allow the expression of receptors that should not be present at all or allow excessive amounts of normally present receptors, or it may produce receptors with abnormally high affinity. All of these changes result in excessive responsiveness to the mitogens normally present in the cell's environment. Some mutant receptors may even be active in the absence of growth factors and spur the cell to divide despite the absence of environmental signals to do so. An important example of a receptor abnormality is the overexpression of human epidermal growth factor receptor type 2 (HER2) receptors in about 25% of breast cancers. The overactive receptors stimulate proliferation of tumor cells even when there is little or no epidermal growth factor bound to them.

**Cytoplasmic Signaling Pathways**

A third way in which oncogenes may facilitate proliferation is by the manufacture of excessive or abnormal components of the intracellular

**FIGURE 7-5** Possible effects of proto-oncogene activation on growth signaling pathways. **A**, Production of growth factors (mitogens). **B**, Production of growth factor receptors. **C**, Intracellular pathway disturbances. **D**, Activation of transcription factors for growth.

**FIGURE 7-6** Mechanisms of proto-oncogene activation. **A**, Retroviral insertion. **B**, Proto-oncogene mutation. **C**, Regulatory sequence mutation. **D**, Proto-oncogene amplification. *RT*, Reverse transcriptase.

signaling pathways. These pathways involve numerous enzymes and chemicals that normally function to transmit signals from activated receptors at the cell surface to the cell nucleus. A mutant proto-oncogene that codes for excessive or abnormal cytoplasmic signaling components could cause activation of the pathway even though no signal was received at the cell surface. The best understood example of this mechanism is mutations of the *ras* gene family. Proteins encoded by *ras* genes are monomeric G-proteins that transmit signals from receptors at the cell surface into the interior of the cell. The *ras* protein is active when it has guanosine triphosphate (GTP) bound to it, but it quickly hydrolyzes the GTP, thus automatically turning itself off after a brief period of activity. A mutation in the *ras* gene can code for a protein that is unable to hydrolyze GTP, so it remains persistently active and stimulates cell proliferation inappropriately. Mutations of the *ras* genes occur in about 20% of all human cancers, including leukemias and lung, ovarian, colon, and pancreatic cancer.<sup>1</sup>

### Transcription Factors

The entire proliferation pathway, including the growth factor (mitogen), the receptor, and the intracellular cascade, ultimately affects transcription of a set of genes in the nucleus that spur the cell to enter the S phase. A number of proto-oncogenes have been identified that code for transcription factors in the nucleus. Transcription factors are proteins that must be assembled at the promoter area to begin gene transcription (see Chapters 3 and 5). Transcription factors are normally sequestered and prevented from indiscriminate activity until appropriate signals cause their release. Mutations in transcription factor genes may cause overproduction of transcription factors or interfere with the normal mechanisms for keeping them in check. *Myc*, *jun*, and *fos* are examples of proto-oncogenes that code for nuclear transcription

factors. Abnormalities of the *myc* genes are found in numerous cancers, including lung and breast cancer, leukemia, and neuroblastoma.

### From Proto-Oncogene to Oncogene

Proto-oncogenes become activated oncogenes when mutations alter their activity so that proliferation-promoting signals are generated inappropriately. At least four general ways in which proto-oncogenes can be activated are known (Figure 7-6): (1) Oncogenes may be introduced into the host cell by a retrovirus; (2) a proto-oncogene within the cell may suffer a mutagenic event that changes its structure and function; (3) a DNA sequence that normally regulates proto-oncogene expression may be damaged or lost and allow the proto-oncogene to become abnormally active; and (4) an error in chromosome replication may cause extra copies of the proto-oncogene to be included in the genome (amplification).

In the early 1960s it was discovered that certain viruses were associated with cancer in various animal models. Researchers speculated that a virus could introduce a mutant, cancer-causing gene (oncogene) into the host's cells. Indeed, malignant cells containing the cancer-causing viruses were shown to have incorporated a small number of viral genes into their cellular DNA.<sup>14</sup> The presence of these oncogenes was required to maintain the malignant state of the cell.

Only a few types of human cancers are thought to be associated with viruses. The clearest associations involve viruses called *retroviruses*. At least three retroviruses are considered to be causative factors in some human cancers: Human immunodeficiency virus is associated with Kaposi sarcoma, Epstein-Barr virus with Burkitt lymphoma, and human T lymphocyte virus type I with adult T cell leukemia-lymphoma.

Retroviruses are composed of RNA and possess a unique enzyme—reverse transcriptase—that directs the synthesis of a DNA copy of the

**FIGURE 7-7** Overactivity of proto-oncogenes may be due to normal production of an abnormal protein (mutation in coding sequence) or excessive production of a normal protein (gene amplification or chromosome rearrangement).

viral RNA. The DNA copy can then be incorporated into the cellular DNA and become part of the host's genome. The degree of viral oncogene expression depends on where the oncogene is inserted in the host DNA. Insertion near a promoter sequence may result in continuous transcription of the oncogene. Viral oncogenes are not subject to normal DNA transcription controls and are thus not responsive to growth-suppressing signals. Where did the viral oncogenes originate? Apparently, the tendency of retroviruses to slip in and out of host genomes allows them to pick up some of the host's genes, namely, the growth-promoting proto-oncogenes.

Proto-oncogene expression is tightly regulated in a normal cell. A number of different mutations can affect proto-oncogene expression and activity. A point mutation in the coding region of the proto-oncogene can alter the structure of its protein product and make it hyperactive. An example of this mechanism is the abnormal *ras* protein described earlier. Even though the protein is synthesized in normal quantity, its activity is enhanced. Other mutations may lead to overproduction of a protein with normal structure. Gene amplification and chromosomal rearrangement during mitosis may release the proto-oncogene from its normal regulation and allow excessive transcription (Figure 7-7).

In summary, mutational events in the cell's genome may cause overexpression of normal proto-oncogene products or production of altered and hyperactive proteins. Most known oncogenes act by releasing the cell from its dependence on growth and survival signals in its environment. This effect usually is accomplished by gain-of-function abnormalities in the proliferation pathways that involve growth factors (mitogens), receptors, cytoplasmic signaling molecules, or nuclear transcription factors.

### Tumor Suppressor Genes

To become malignant, cells must devise ways to evade the normal inhibitory mechanisms that keep the brakes applied to cell division. It is not enough to simply overstimulate growth-promoting signals. Critical elements of the proliferation-inhibiting pathways are defective in most cancers. The components of the inhibitory machinery are specified by the so-called *tumor suppressor genes*. Tumor suppressor genes are difficult to study because they contribute to cancer only when they are not there. The first tumor suppressor gene to be discovered was the *Rb* gene, so named because of its role in retinoblastoma, a cancer of the eye.<sup>15</sup> A familial form of retinoblastoma is associated with the transmission of a genetic defect; a portion of chromosome 13 is missing, which is where the *Rb* gene is normally located. An absent *Rb* gene predisposes an individual to cancer, but cancer will not develop unless the other copy of the *Rb* gene (from the other parent) is also damaged (Figure 7-8).

Since the initial discovery of the *Rb* tumor suppressor gene, researchers have compiled an impressive list of other genes that appear to function as inhibitors of cellular proliferation (Table 7-5). As with the *Rb* gene, both copies of the tumor suppressor genes usually are inactivated when cancer develops. A person who inherits a defective copy of a tumor suppressor gene from one parent has a much higher risk of cancer than a person who inherits two healthy copies. Knowledge about the sequence of many of these genes provides the opportunity to screen individuals with familial cancers to determine whether they carry a defective gene. Detection of defective tumor suppressor genes is easier than determining their normal cellular functions, but steady progress is being made.

Why do tumor suppressor genes stop functioning? As with proto-oncogene activation, genetic mutations are the usual culprits. Chromosome deletions, point mutations, or chromosome loss through

**FIGURE 7-8** Both DNA copies (alleles) of the *Rb* tumor suppression gene must be dysfunctional for occurrence of retinoblastoma. Inheriting a defective *Rb* gene predisposes an individual to the development of cancer because only a single mutational event is required to inactivate *pRb* function. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 288.)

**TABLE 7-5 EXAMPLES OF TUMOR SUPPRESSOR GENES**

GENE	CHROMOSOME	
	LOCATION	CANCER
<i>Rb</i>	13q14	Retinoblastoma, sarcoma
<i>P53</i>	17p13	Li-Fraumeni syndrome, 50% of all tumors
<i>DCC</i>	18q21	Colorectal carcinoma
<i>APC</i>	5q21	Colorectal, stomach, pancreatic
<i>BRCA1</i>	17q21	Breast, ovarian
<i>BRCA2</i>	13q12	Breast, ovarian, prostate
<i>WT1</i>	11p13	Wilms tumor
<i>WT2</i>	11p15	Rhabdomyosarcoma
<i>NF1</i>	17q11	Neurofibromatosis type 1, astrocytoma
<i>NF2</i>	22q12	Neurofibromatosis type 2, meningioma
<i>VHL</i>	3p25	Renal cell carcinoma
<i>MEN1</i>	11q23	Multiple endocrine neoplasia
<i>MTS1</i>	9p21	Melanoma, leukemia, sarcomas, several carcinomas

nondisjunction may knock out tumor suppressor gene function. Tumor suppressor gene function may also be lost through an “epigenetic” process that “silences” the gene. Epigenetic influences do not change the DNA sequence (no mutation is required), but change the packaging of DNA and chemically modify it (e.g., methylation) so that the gene is inactivated. This inactivation can be passed on to daughter cells during mitosis.

### The *Rb* Gene

The *Rb* gene codes for a large protein in the cell nucleus (pRb) that has been labeled the “master brake” of the cell cycle (see Chapter 3). It blocks cell division by binding transcription factors (E2F) and thereby inhibiting them from transcribing the genes that initiate the cell cycle (Figure 7-9). The Rb protein can be induced to release the transcription factors when it is sufficiently phosphorylated. Proliferation-promoting signals in the cell increase cyclin-dependent kinase (cdk) enzymes and promote pRb phosphorylation, whereas growth-inhibiting signals prevent phosphorylation. Thus an inactivating mutation of the *Rb* genes removes one of the major restraints on cell division. Defective pRb is common to a number of different cancers.

**FIGURE 7-9** The Rb protein functions to bind transcription factors in the nucleus and keep them from participating in the transcription of cell cycle–related genes. pRb is induced to release its hold on the E2F transcription factors when it is sufficiently phosphorylated by cyclin-dependent kinases (*Cdk*). Cyclin-dependent kinases are activated by cyclin proteins that accumulate when growth factors bind to receptors and stimulate growth pathways. Other signals, such as transforming growth factor- $\beta$  (*TGF- $\beta$* ), inhibit the activity of cyclin/Cdk through activation of inhibitory proteins such as p16. A loss of pRb function removes the “major brake” on cell division. P, Phosphate group; *EGF*, epidermal growth factor.

### The *P53* Gene

The most common tumor suppressor gene defect identified in cancer cells involves *P53*, so named because of the protein’s molecular mass of 53 kilodaltons (also called TP53). More than half of all types of human tumors lack functional *P53*. The p53 protein, like pRb, inhibits cell cycling. Unlike pRb, however, normally very little p53 is found in cells, and it accumulates only after cellular, particularly DNA, damage. P53 is a transcription factor that binds to damaged DNA and regulates hundreds of genes.<sup>1</sup> P53 stalls cell division, presumably to allow time for DNA repair before DNA replication in the S phase (Figure 7-10). In the face of excessive damage (or other distress signals), p53 may direct the cell to initiate apoptosis. A defect in p53 function disrupts this important quality control system, allowing genetically damaged and unstable cells to survive and continue to replicate (see Figure 7-10). Genetically unstable cells have a propensity to accumulate more cancer-promoting mutations while they proliferate. The *P53* gene is important for therapeutic reasons as well. Chemotherapy- and radiation-induced cell death is mediated in large part by p53. These agents usually do not kill cancer cells directly; rather, they cause enough cellular damage in the target cell to trigger p53-mediated cell suicide. Cancer cells that lack functional p53 may therefore be resistant to some radiation and chemotherapeutic protocols.

### *BRCA1* and *BRCA2*

Many tumor suppressor genes have been identified through studies of inherited predisposition to certain types of cancer. The breast cancer genes *BRCA1* and *BRCA2* are important examples. Women with a family history of breast cancer and an inherited defect in the *BRCA1* gene have about a 50% risk of developing breast cancer.<sup>16</sup> The age of onset of inherited breast cancer is earlier than the onset of noninherited (sporadic) forms, and the prevalence of bilateral breast cancer is higher. Inherited forms of breast cancer account for only about 5% to 10% of all cases of breast cancer, but study of the genes involved is providing important insights into breast cancer biology in general.

Defects in numerous other tumor suppressor genes have been identified in certain types of cancers (see Table 7-5), including *APC* and *DCC* in

colorectal cancer, *NF1* and *NF2* in neurofibromatosis, and *VHL* in renal cell cancers. The functions of tumor suppressor genes are varied, but most appear to inhibit proliferation or induce apoptosis in defective cells.

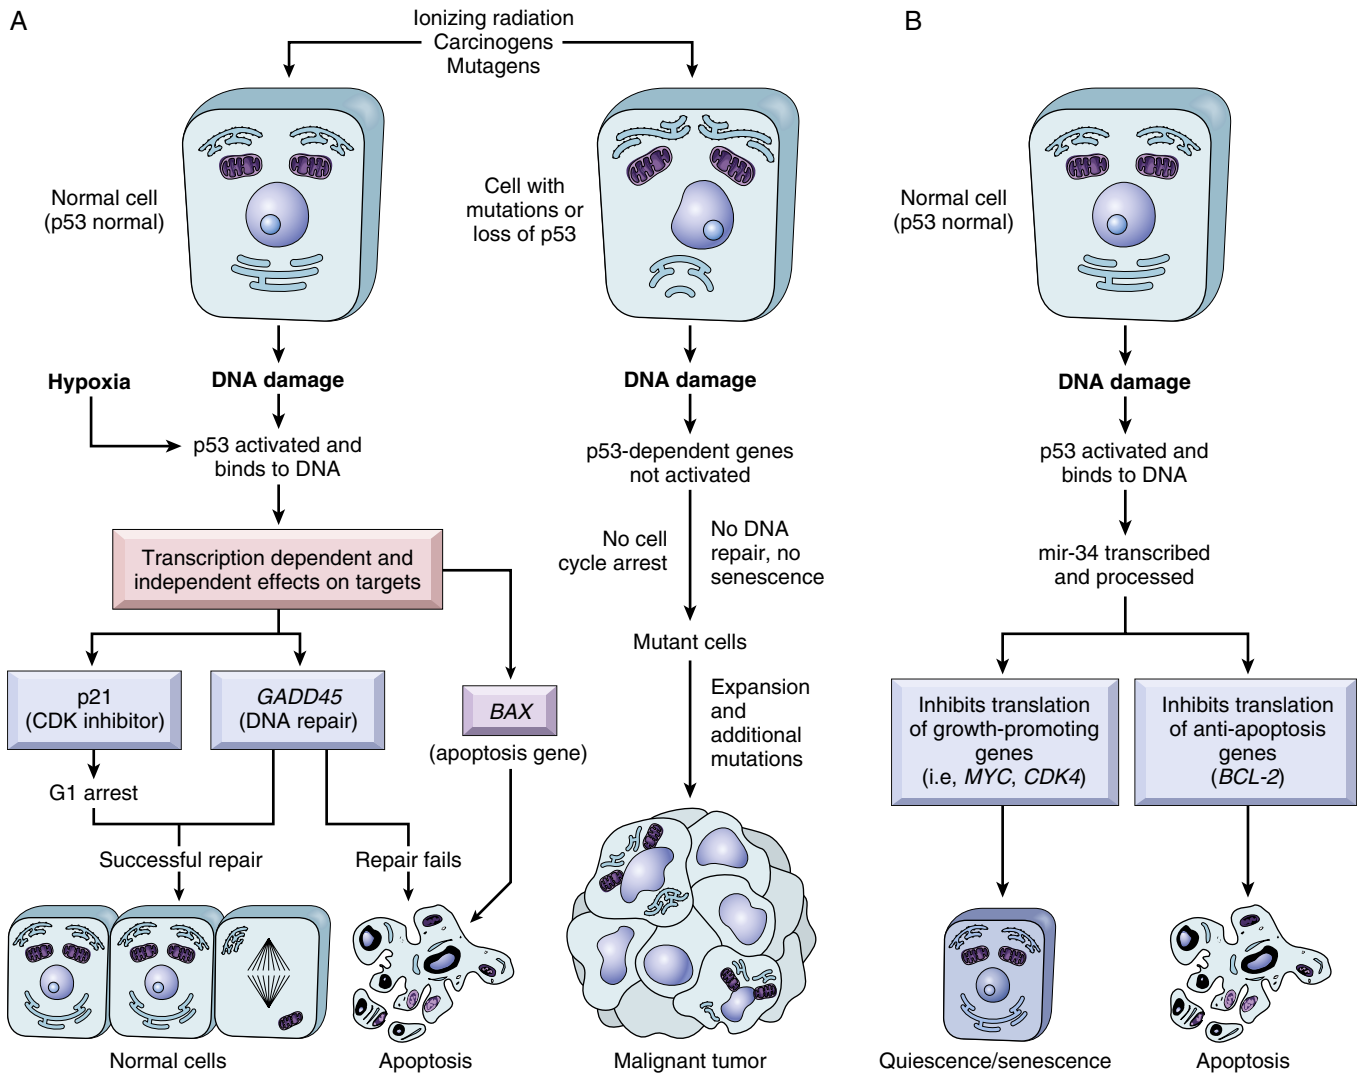

Figure 7-11 summarizes the major known cellular signaling pathways that are relevant to the development of cancer. The functions of oncogenes and tumor suppressor genes are shown to interact to determine cell proliferation, cell survival, and cell death. In general, any cellular alteration that promotes proliferation or inhibits cell death can contribute to an increased risk of tumor development.

#### KEY POINTS

- Cancer is thought to develop when proto-oncogenes become inappropriately activated in a cell or when tumor suppressor genes become inactivated. This change in gene function is usually due to mutations in the cell’s DNA.
- Mutant proto-oncogenes disrupt the intercellular communication pathway that normally regulates cell proliferation. This disruption may occur through abnormal production of growth factors, receptors, cytoplasmic signaling molecules, or nuclear transcription factors.
- Both copies of a tumor suppressor gene usually must be inactivated to eliminate its function. Tumor suppressor genes inhibit cellular proliferation in various ways. The Rb protein serves as a “master brake” on cell proliferation by inhibiting transcription factors. *P53* inhibits cell cycling when the cell is damaged to allow time for DNA repair. *P53* is also important in initiating apoptosis of damaged or unwanted cells.

### MULTISTEP NATURE OF CARCINOGENESIS

From the preceding discussion, it might seem that simply activating an oncogene in a normal cell or knocking out a tumor suppressor gene would be sufficient to transform it into a malignant cell. Such has not proved to be the case. Growth regulation of mammalian cells appears to be organized in such a manner that a single aberrant gene is unable to induce conversion to full malignancy. Different genes function in

**FIGURE 7-10** Role of *P53* (TP53) in maintaining the integrity of the genome. Damage to DNA in cells with functional *P53* stalls the cell cycle so that DNA can be repaired. If repair fails, then the cell undergoes apoptosis to prevent the proliferation of DNA-damaged cells. If the *P53* is not functional, genetically unstable cells may be allowed to survive and proliferate. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 291.)

distinct ways and may affect only a subset of the changes necessary to achieve full malignancy. For example, introduction of the *ras* oncogene into normal cells in culture causes them to show anchorage independence, but they are unable to form tumors when inoculated into an animal. Anchorage independence is a typical feature of most transformed cells and means that they are capable of proliferating even if they are not attached to a matrix. Normal cells will not divide and will initiate apoptosis if they do not have a space on the matrix on which to anchor themselves. Similarly, the *myc* oncogene allows cells to grow indefinitely in culture, but these immortal cells are still unable to induce tumor formation. However, when both the *ras* and the *myc* oncogenes are introduced into normal cells, they become fully malignant (Figure 7-12).<sup>17</sup>

These culture experiments support the clinical observation that carcinogenesis is a multistep phenomenon.<sup>2</sup> The steps of carcinogenesis have been labeled *initiation*, *promotion*, and *progression* (Figure 7-13).

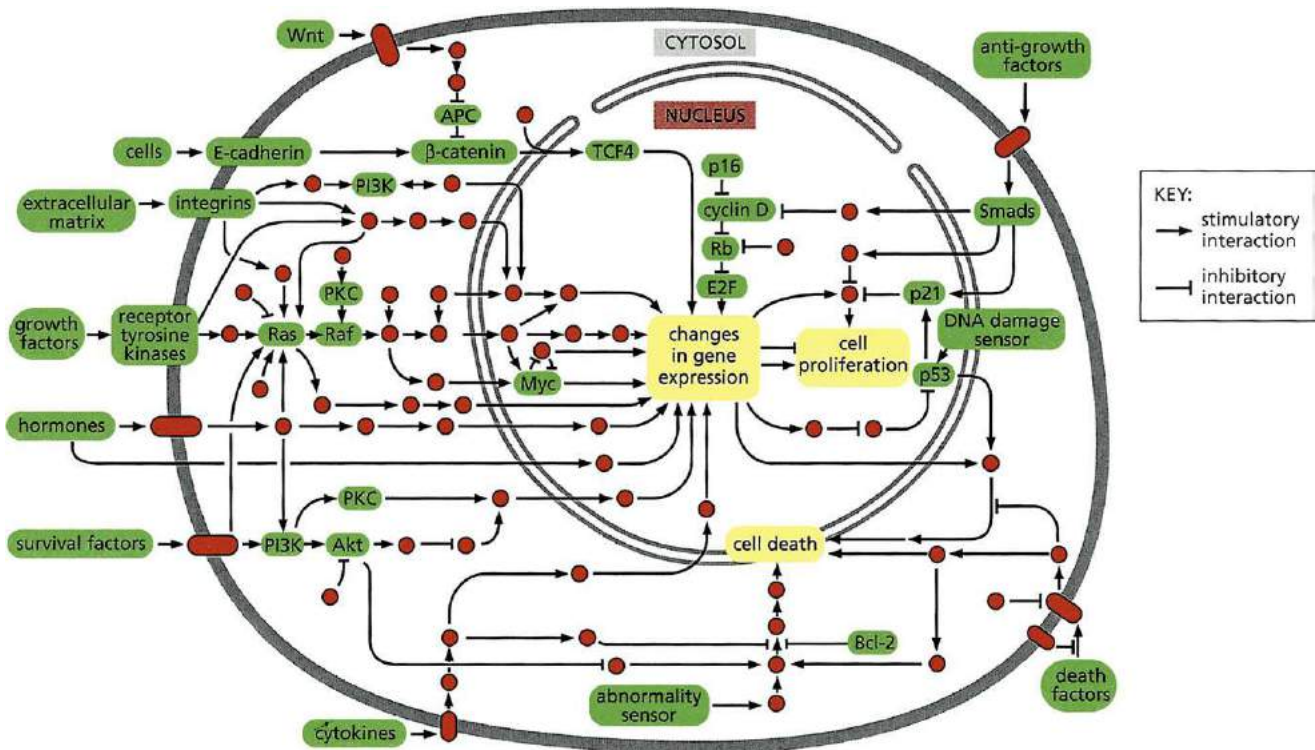

### Initiation

Initiating events are thought to be the genetic mutations that inappropriately activate proto-oncogenes and inactivate tumor suppressor

genes. However, the genetic mutations are not evident until the mutant cell proliferates. *Proliferation* is a requirement for cancer development, and nonproliferating cells are unlikely to cause cancer. It has been suggested that several mutations may be necessary to achieve full malignancy. The development of colorectal cancer is a well-documented example of these sequential changes (Figure 7-14). Each individual cancer is likely to have its own unique combination of mutations that eventually lead to malignant behavior.

A number of etiologic agents are considered important initiators of cancer. The term *carcinogen* is applied to agents and substances capable of inducing cancer. Some carcinogens are complete carcinogens in that they are capable of the initiation of genetic damage as well as the promotion of cellular proliferation, whereas many others are only partial carcinogens. Partial carcinogens are often promoters that stimulate growth but are incapable of causing genetic mutations sufficient to initiate cancer by themselves. Examples of known carcinogens are ultraviolet and ionizing radiation, certain viruses, asbestos, and numerous chemicals. Most known chemical carcinogens are encountered through repeated occupational exposure (Box 7-1).

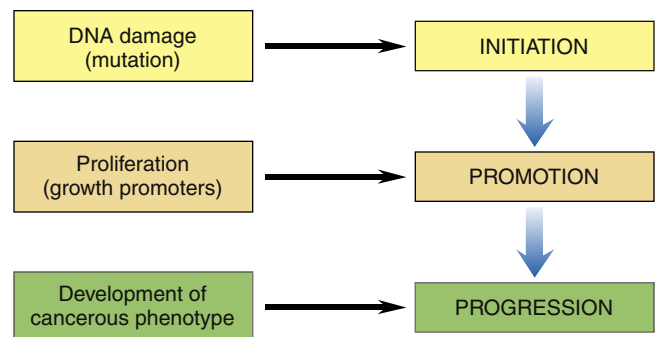

**FIGURE 7-11** Diagram of the major signaling pathways relevant to human cancer. Overactivity of proto-oncogenes and underactivity of tumor suppressor genes result in enhanced cell proliferation and inhibition of appropriate cell death. More than 100 proto-oncogene products and numerous tumor suppressor gene products have been identified. (From Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 1243.)

**FIGURE 7-12** Synergy between oncogenes may be necessary to initiate malignant growth. **A**, The *ras* gene only. **B**, The *myc* gene only. **C**, Synergy between *ras* and *myc* genes.

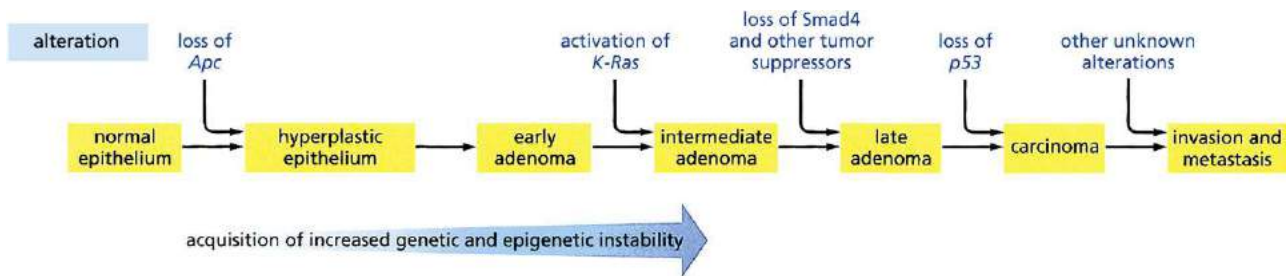

**Promotion**

Promotion is the stage during which the mutant cell proliferates. The transition from initiation to promotion may involve the activation of another oncogene or the inactivation of a tumor suppressor gene that

**FIGURE 7-13** Theoretical steps in the development of cancer include initiation, promotion, and progression.

has kept proliferation in check. Nonmutating factors may also be important in promoting cellular proliferation. Nutritional factors and infection may provide a stimulus for cellular proliferation. As previously described, proliferation is regulated by numerous hormonal growth factors. It is not surprising, then, that hormones may act as promoters of certain types of cancer. The relationship between estrogen hormones and breast, ovarian, and uterine cancer is an important example. Epidemiologic studies indicate that the greater the number of menstrual cycles experienced, the higher the risk of these types of cancer developing. Women with early menarche, late first pregnancy, lack of breast feeding, and late menopause have a greater risk of developing breast, uterine, and ovarian cancer. This enhanced susceptibility is thought to occur in part because of the greater lifetime estrogen exposure. Estrogen is a trophic hormone for these tissues and may therefore be viewed as having promoter effects. Treatment protocols using antiestrogen agents

**FIGURE 7-14** The development of colorectal cancer illustrates the concept of multistep carcinogenesis. Derangement of several genes is likely to occur in most types of cancer. (Redrawn from Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 1255.)

### BOX 7-1 MAJOR CHEMICAL CARCINOGENS

#### Direct-Acting Carcinogens

##### Alkylating Agents

$\beta$ -Propiolactone  
Dimethyl sulfate  
Diepoxybutane  
Anticancer drugs (cyclophosphamide, chlorambucil, nitrosoureas, and others)

##### Acyating Agents

1-Acetylimidazole  
Dimethylcarbamoyl chloride

#### Procarcinogens That Require Metabolic Activation

##### Polycyclic and Heterocyclic Aromatic Hydrocarbons

Benz[*a*]anthracene  
Benzo[*a*]pyrene  
Dibenz[*a,h*]anthracene  
3-Methylcholanthrene  
7,12-Dimethylbenz[*a*]anthracene

##### Aromatic Amines, Amides, Azo Dyes

2-Naphthylamine ( $\beta$ -naphthylamine)  
Benzidine  
2-Acetylaminofluorene  
Dimethylaminoazobenzene (butter yellow)

##### Natural Plant and Microbial Products

Aflatoxin B<sub>1</sub>  
Griseofulvin  
Cycasin  
Safrole  
Betel nuts

##### Others

Nitrosamine and amides  
Vinyl chloride, nickel, chromium  
Insecticides, fungicides  
Polychlorinated biphenyls

(tamoxifen) indicate that breast cancer risk may be reduced by blocking the effects of estrogen.<sup>18,19</sup> However, estrogen is not considered to be carcinogenic and does not cause genetic mutations.

A similar relationship has been identified for prostate cancer and testosterone hormones. In males, testosterone is secreted primarily from the testes under the influence of pituitary gonadotropins. Testosterone is a growth factor for the prostate gland and can act as a promoter of tumor formation in this tissue. This relationship is supported by the fact

that therapeutic blocking of testosterone activity in persons with prostate cancer can help shrink the tumor.

Tumor cells frequently produce more than the normal amount of telomerase, an enzyme that allows the cell to repair the ends of the chromosomes (telomeres).<sup>20</sup> Telomere shortening with each cell division normally limits the number of cell cycles in normal cells. Tumor cells must overcome this limit on cell division in order to achieve the immortality required to continue to divide. In the early 1970s it was discovered that normal somatic cells replicate only a finite number of times in culture: Fetal cells may replicate approximately 80 times, whereas cells from older individuals divide only 20 or 30 times.<sup>21</sup> Each time a cell divides, it must replicate its DNA, but DNA polymerase is unable to copy the DNA strands all the way to the very tips of the chromosomes (called *telomeres*). The telomere thus shortens slightly with each cell division until some critical length is reached and cell division stops (see Chapter 4). Stem cells and germ cells produce an enzyme called *telomerase* that promotes synthesis of the telomere ends and permits these cell types to replicate indefinitely, but normal somatic cells produce little of this enzyme. Most cancer cells begin to synthesize telomerase while they acquire the malignant phenotype, thus rescuing themselves from critical telomere shortening and gaining a mechanism for achieving immortality. In addition, the majority of cancers are deficient in *p53* activity, which allows them to escape apoptosis despite gross derangements in DNA structure.

### Progression

Progression is the stage during which the mutant, proliferating cells begin to exhibit malignant behavior. The mutations suffered during initiation are not sufficient to cause all the biochemical changes necessary for malignant behavior. The proliferating cells are genetically unstable and undergo chance mutations that give them a growth advantage. Clones of mutant cells exhibit a wide variation in phenotype. *Phenotype* refers to the cell's traits, such as morphology, metabolism, and biochemical composition. Cells whose phenotype gives them a growth advantage proliferate more readily. With each cycle of proliferation, an opportunity for chance variation arises. In the end, highly evolved tumor cells are generated that differ significantly from their normal ancestors. These cells have developed characteristics such as the presence of laminin receptors, lytic enzymes, and anchorage independence that enable them to behave malignantly.<sup>1</sup>

Cancer cells often have numerous abnormalities of chromosome structure, and the karyotype can be quite bizarre with bits and pieces of chromosomes attached in the wrong places and extra or missing chromosomes. An example of the chromosomes obtained from an ovarian cancer cell is shown in Figure 7-15. The color stains are specific for a particular chromosome, and each chromosome pair should be one color. Note the numerous multicolored chromosomes indicating multiple translocations of chromosome pieces.

**FIGURE 7-15** Fluorescent images from human ovarian cancer (CH1) cells. A representative karyotype of CH1 cell line shows the balanced  $t(15;20)$  chromosomes (*arrows*). The size of one of the chromosomes 2 (*arrowhead*) is slightly bigger than normal, which contains a duplication. (From Xueying Mao et al: Subtle genomic alterations and genomic instability revealed in diploid cancer cell lines, *Cancer Lett* 267[1]:49-54, August 2008.)

The fact that conversion from a normal cell type to a malignant cell type requires multiple steps implies many opportunities to intervene in the process. Prevention of the initiating mutation may be difficult inasmuch as carcinogens are ubiquitous; however, therapies to prevent promotion and progression could render the initial mutation harmless. As the biochemical processes governing promotion and progression become clearer, strategies for blocking these stages continue to be developed.

#### KEY POINTS

- Full expression of cancer in a host is a multistep process. These steps have been described as initiation, promotion, and progression. The initiating event is usually from genetic mutations. Promotion refers to the stage in which the mutant cell is induced to proliferate. Progression is the stage during which the mutant, proliferating cells acquire properties that allow malignant behavior.
- Malignant cells commonly produce telomerase, an enzyme that repairs the telomeres and may be a key for attaining immortality. The majority also have insufficient p53, which allows the tumor cells to escape apoptosis despite DNA damage.

## METASTASIS

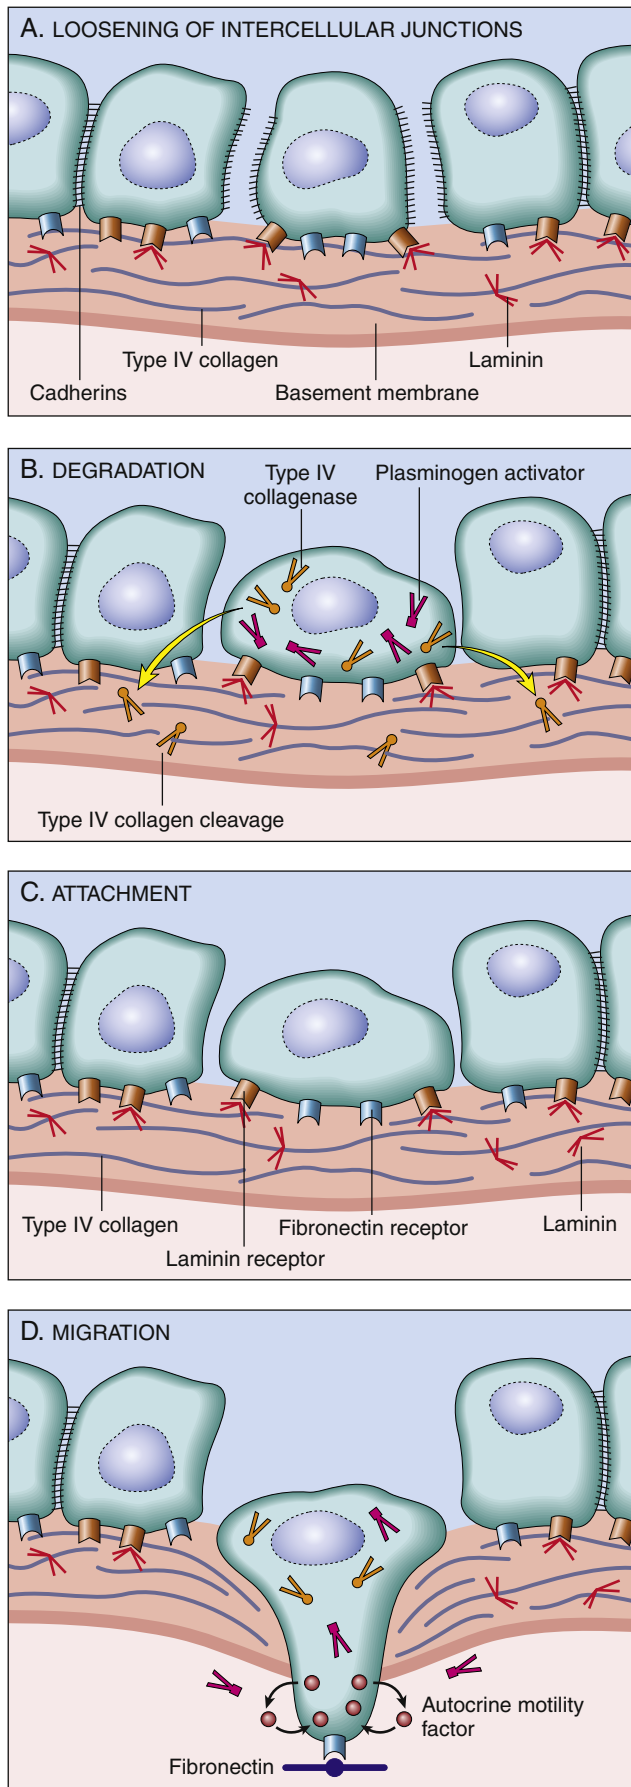

Metastasis is the process whereby cancer cells escape their tissue of origin and initiate new colonies of cancer in distant sites. For tumor cells to gain access to the blood or lymphatic circulation, they must first escape the basement membrane of the tissue of origin, move through the extracellular space, and penetrate the basement membrane of the vessel. This process is thought to involve loss of cell-to-cell adhesion and binding to matrix components such as laminin via specific laminin receptors on the tumor cell, followed by release of enzymes such as proteases and collagenases that digest the basement membrane.<sup>22</sup> The cancer cell then squeezes through the rift by amoeboid movement. The process is repeated at the vessel basement membrane to access the blood or lymphatic vessel. When the cell reaches the tissue to be colonized, it must again traverse the basement membranes by using similar mechanisms (Figure 7-16). Once in a new tissue setting, the cancer cell colony must acquire nutrients and a blood supply and cope with an environment that may differ

considerably from its origin. In general, less differentiated cancer cells are better able to adapt to foreign tissues and survive.

### Patterns of Spread

The survival of tumor cells in the circulation is not guaranteed. They may be detected by immune cells and destroyed, or they may undergo apoptosis unless they quickly find a matrix on which to adhere. Fewer than 1 in 10,000 of the cancer cells that enter the circulation survives to form a new tumor at a distant site.<sup>22</sup> Some tumor cell types appear to prefer specific target organs. Sometimes the pattern of metastasis is related to the circulatory flow. For example, metastatic tumors from the colon often seed the liver because they travel within the portal vein. The localization of most metastatic tumors is not so easily explained by blood flow patterns, and some tumor cells appear to “home” to specific targets. This homing tendency is poorly understood but may involve chemotactic signals from the organ to which the tumor cells respond. Cell surface receptors of the integrin and cell adhesion molecule families, which mediate cell-to-matrix and cell-to-cell adhesion, are likely to influence the choice of tissues that cancer cells invade. Dissemination via lymphatics is somewhat more predictable than distribution by blood flow. Generally, the lymph nodes that immediately drain the tissue of cancer origin are colonized first, and then the tumor cells tend to spread contiguously from node to node. Hodgkin disease, a lymphoma, is particularly noted for its orderly spread via the lymphatics.

Because tumor cells exhibit various degrees of differentiation or resemblance to the parent tissue of origin, it may be difficult to determine the metastatic cancer’s tissue of origin. **Tumor markers** are substances associated with tumor cells that may be helpful in identifying their tissue type. Identification of the tissue of origin has important implications for prognosis and selection of treatment options. Tumor markers rely on the retention of at least some characteristics of the parent tissue type. Some tumor markers are released into the circulation, whereas others must be identified through biopsy of the metastatic tissue. Enzymes and other proteins that are specific to a particular cell type are commonly used as tumor markers. For example, production of thyroglobulin protein is specific for thyroid tumor cells. Melanoma cells express the antigens HMB-45 and S-100, which is helpful in identification as melanocytes. Unfortunately, most tumor markers are not very specific for cancer because the normal cells in the

**FIGURE 7-16** Mechanisms of tumor invasion allow tumor cells to escape the site of origin, penetrate the basement membrane, and travel to distant sites. **A**, Tumor cells decrease cell-to-cell attachments via cadherins that allow detachment and migration toward the basement membrane. **B**, Enzymes that degrade proteins are released into the area to form a rift. **C**, The tumor cell migrates away from the site of origin using laminin and fibronectin receptors to pull through the tissue. **D**, Finally the cell moves through a rift in the matrix. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 299.)

tissue of origin also produce them. Tumor markers are most useful as indicators for further diagnostic evaluation and to track the tumor activity. An increasing blood concentration of a specific tumor marker may indicate progression and proliferation of the cancer cells (increased tumor burden). See Table 7-6 for other examples of antigen, hormone, isoenzyme, and immunoglobulin markers used to identify tumor cell types.

**TABLE 7-6 SELECTED TUMOR MARKERS**

**Hormones**

Human chorionic gonadotropin	Trophoblastic tumors, nonseminomatous testicular tumors
Calcitonin	Medullary carcinoma of thyroid
Catecholamine and metabolites	Pheochromocytoma and related tumors
Ectopic hormones	Paraneoplastic syndromes

**Oncofetal Antigens**

$\alpha$ -Fetoprotein	Liver cell cancer, nonseminomatous germ cell tumors of testis
Carcinoembryonic antigen	Carcinomas of colon, pancreas, lung, stomach, and heart

**Isoenzymes**

Prostatic acid phosphatase	Prostate cancer
Neuron-specific enolase	Small cell cancer of lung, neuroblastoma

**Specific Proteins**

Immunoglobulins	Multiple myeloma and other gammopathies
Prostate-specific antigen and prostate-specific membrane antigen	Prostate cancer

**Mucins and Other Glycoproteins**

CA-125	Ovarian cancer
CA-19-9	Colon cancer, pancreatic cancer
CA-15-3	Breast cancer

**New Molecular Markers**

p53, APC, and RAS mutants in stool and serum	Colon cancer
p53 and RAS mutants in stool and serum	Pancreatic cancer
p53 and RAS mutants in sputum and serum	Lung cancer
p53 mutants in urine	Bladder cancer

## Angiogenesis

Tumors cannot enlarge more than about 2 mm in diameter unless they grow blood vessels into the tumor mass to provide oxygen and nutrients. Angiogenesis is the process of forming new blood vessels. Most tumors do not induce angiogenesis until late in the stage of cancer development and so remain small and nonvascularized for years. The triggers that spur the cancer to begin angiogenesis are not completely understood. Tumor cells may begin to produce angiogenic factors such as vascular endothelial growth factor (VEGF) in response to hypoxia or other signals. VEGF stimulates proliferation of vascular endothelial cells, which then migrate to the tumor and orchestrate blood vessel development. Metastatic tumors must also initiate angiogenesis in their new locations or they will not survive. Therefore inhibition of angiogenesis is an important therapeutic goal to limit tumor growth and metastasis and continues to be an area of active research.

## Grading and Staging of Tumors

Grading and staging of tumors are done to predict the clinical behavior of a malignant tumor and to guide therapy. **Grading** refers to the histologic characterization of tumor cells and is basically a determination of the degree of anaplasia. Most grading systems classify tumors into three or four classes of increasing degrees of malignancy. A greater degree of anaplasia indicates a greater malignant potential. The correlation between the grade of the tumor and its biological behavior is not perfect. Some low-grade tumors have proved to be quite malignant.

The choice of treatment modality is usually influenced more by the stage of the tumor than by its histologic grade. **Staging** describes the location and pattern of spread of a tumor within the host. Factors such as tumor size, extent of local growth, lymph node and organ involvement, and presence of distant metastases are considered. Several staging systems exist; however, the international TNM (tumor, *node*, *metastasis*) system is used extensively as a general framework for staging tumors.<sup>23</sup> Particular staging criteria vary with tumors in different organ systems. Examples of staging criteria for breast and colon cancer are shown in [Tables 7-7 and 7-8](#).

In the past, tumor staging was based primarily on results of radiography and exploratory surgery. The availability of computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and other highly sophisticated imaging techniques has revolutionized cancer detection. These imaging modalities allow noninvasive exploration of the tissues of the entire body. The computer-generated images can then be scrutinized for any signs of abnormality that might signal the presence of hidden tumors. CT and MRI rely primarily on detection of differences in tissue density and are therefore not totally specific for tumors. They can, however, guide the selection of sites for exploration and biopsy and potentially reduce unnecessary surgery. Positron emission tomography is a promising staging technology because it facilitates cancer detection based on molecular and biochemical processes within the tumor tissues ([Figure 7-17](#)). PET may be used in certain clinical situations in which CT has known limitations, such as differentiation of benign from malignant lymph nodes or other lesions, differentiation of residual tumor from scar tissue, or detection of unsuspected distant metastases.

Antibodies can also be used to locate cancer cells in the body. Antibodies can be raised against specific antigens present on the surface of tumor cells. The antibodies are also bound to a tracer (e.g., a radioactive isotope such as iodine-125), which can be detected by imaging. Because methods for identifying tumor antigens and raising specific antibodies have improved, this technology provides the potential for finding very small numbers of tumor cells hidden in the body.

The results of the staging procedure will determine which of the mainstays of cancer treatment—surgery, radiation therapy, or

chemotherapy—may be used, singly or in combination, to destroy the cancer cells. Localized tumors may be managed with surgery and radiation therapy, whereas evidence of metastasis generally necessitates the addition of chemotherapy.

### KEY POINTS

- Malignant cells produce specialized enzymes and receptors to enable them to escape their tissue of origin and metastasize.
- The spread of tumors generally occurs by way of the bloodstream or lymphatics. Tumor cells often lodge in the capillary beds of the organs that drain them, such as liver and lung. Some tumors appear to “home” to certain tissues.
- Grading and staging are done to predict tumor behavior and guide therapy. Grading is the histologic characterization of tumor cells, whereas staging describes the location and pattern of tumor spread within the host.
- The TNM staging system is used to describe the tumor size, lymph nodes affected, and degree of metastasis.

## EFFECTS OF CANCER ON THE BODY

The effects of cancer on the host vary widely, depending on the location of the tumor and the extent of metastasis. Early-stage cancer may be asymptomatic. As the tumor increases in size and spreads through the body, a number of symptoms typically become apparent, including pain, cachexia, immune suppression, and infection. Once treatment has begun, patients may also suffer hair loss and sloughing of mucosal membranes. The American Cancer Society has published the seven warning signs of cancer as a way of encouraging the public to seek early evaluation of potential cancers ([Box 7-2](#)). The presentation of cancer in children differs from that in adults, and special warning signs have been identified for the pediatric population ([Box 7-3](#)).

Pain is a common and feared complication of the disease process. Pain may be due to invasion of metastatic cells into organs or bone and subsequent activation of pain and pressure receptors in these tissues. Tissue destruction and inflammation may contribute to cancer pain. Cancer treatment may contribute to overall pain because of procedures requiring biopsy and intravenous drug administration. Pain can usually be controlled through the use of analgesics. The use of patient-controlled analgesia has been effective in reducing patient fears of inadequate therapy for pain (see [Chapter 47](#)).

*Cachexia* refers to an overall weight loss and generalized weakness ([Figure 7-18](#)). Many factors contribute to cancer cachexia, including loss of appetite (anorexia) and increased metabolic rate. Anorexia accompanies many disease processes and may result from toxins released by the cancer cells or immune cells. Cancer patients may have aversions to specific foods and may feel full after only a few bites. Nausea and vomiting are common complications of cancer therapy and contribute to decreased nutrient intake. Despite the minimal nutrient intake, body metabolism remains high. Production of tumor necrosis factor (TNF) and other immune cytokines is thought to be important in producing the hypermetabolic state. Nutrients are mobilized from fat and protein stores in the body and consumed by the hypermetabolic cells (see [Chapter 42](#)). Some patients may require nutritional supplementation by enteral or parenteral routes.

Individuals with cancer often demonstrate deficits in immune system competence. Cancer cells secrete substances that suppress the immune system. Individuals with cancer may have reduced populations of T and B cells and may respond poorly to injected antigens. The mechanisms by which cancer cells depress immune responses are not well understood, but the prognosis for cancer recovery is poorer when the immune system is depressed. Immune cells, including cytotoxic T cells and natural killer (NK) cells, actively detect and destroy cancer cells.

TABLE 7-7 TNM STAGING CRITERIA FOR BREAST CANCER

**Primary Tumor (T)**

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget's should still be noted.
T1	Tumor $\leq 20$ mm in greatest dimension
T1mi	Tumor $\leq 1$ mm in greatest dimension
T1a	Tumor $> 1$ mm but $\leq 5$ mm in greatest dimension
T1b	Tumor $> 5$ mm but $\leq 10$ mm in greatest dimension
T1c	Tumor $> 10$ mm but $\leq 20$ mm in greatest dimension
T2	Tumor $> 20$ mm but $\leq 50$ mm in greatest dimension
T3	Tumor $> 50$ mm in greatest dimension
T4	Tumor of any size with direct extension to chest wall and/or to skin (ulceration or skin nodules). <b>NOTE:</b> Invasion of dermis alone does not qualify as T4.
T4a	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T4b	Ulceration and/or ipsilateral satellite nodules and/or edema (including peau d'orange) of the skin, which do not meet the criteria for inflammatory carcinoma
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma

**Lymph Node (N)**

NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastasis in ipsilateral level I, II axillary lymph node(s) that are clinically fixed or matted; or in clinically detected ipsilateral internal mammary nodes in the <i>absence</i> of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary level I, II lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically detected* ipsilateral internal mammary nodes and in the <i>absence</i> of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement, or in clinically detected* ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)

**Distant Metastasis (M)**

M0	No clinical or radiographic evidence of distant metastasis
cM0(i+)	No clinical or radiographic evidence of distant metastasis, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastasis
M1	Distant detectable metastasis as determined by classical clinical and radiographic means and/or histologically proven larger than 0.2 mm

**Stage Grouping**

Stage 0	Tis	N0	M0
Stage IA	T1	N0	M0
Stage IB	T0	N1mi	M0

Stage IV	Any T	Any N	M1

From Edge SB, Byrd DR, Compton CC, Fritz AG, Greene FL et al, editors: *AJCC cancer staging handbook*, ed 7, New York, 2010, Springer-Verlag, pp 440-443.

\**Clinically detected* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine needle aspiration biopsy with cytologic examination.

**TABLE 7-8 TNM STAGING CRITERIA FOR COLON CANCER**

**Primary Tumor (T)**

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intraepithelial or invasion of lamina propria
T1	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4a	Tumor penetrates to the surface of the visceral peritoneum
T4b	Tumor directly invades or is adherent to other organs or structures

**Regional Lymph Nodes (N)**

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1-3 regional lymph nodes
N1a	Metastasis in one regional lymph node
N1b	Metastasis in 2-3 regional lymph nodes
N1c	Tumor deposit(s) in the subserosa, mesentery, or nonperitonealized pericolic or perirectal tissues without regional nodal metastasis
N2	Metastasis in 4 or more regional lymph nodes
N2a	Metastasis in 4-6 regional lymph nodes
N2b	Metastasis in 7 or more regional lymph nodes

**Distant Metastasis (M)**

M0	No distant metastasis
M1	Distant metastasis
M1a	Metastasis confined to one organ or site (e.g., liver, lung, ovary, nonregional node)
M1b	Metastasis in more than one organ/site or the peritoneum

**FIGURE 7-17** PET scan that detects uptake of radioactively labeled glucose is overlaid onto a CT scan background image. The yellow spots in the abdomen and mediastinum are indicative of multiple metastases of non-Hodgkin lymphoma. (From Alberts B et al, editors: *Molecular biology of the cell*, ed 5, New York, 2008, Garland Science, p 1206. Courtesy Dr. Sanjiv Sam Gambhir.)

In addition to the general immunosuppressive effects of cancer, some cancer cells have developed ways to elude immune system detection.<sup>24</sup> For example, cancer cells can internalize their immunoreactive cell surface antigens. Some tumors escape detection because they are coated with normal extracellular matrix molecules such as glycoproteins. The glycoproteins physically conceal the antigenic tumor markers.

Bone marrow suppression contributes to the anemia, leukopenia, and thrombocytopenia that often accompany cancer. Bone marrow suppression may be due to invasion and destruction of blood-forming cells in the bone marrow, poor nutrition, and chemotherapeutic drugs. *Anemia* refers to a deficiency in circulating red blood cells. In addition to decreased production of blood cell precursors in the bone marrow, anemia may result from chronic or acute bleeding. The signs and symptoms of anemia, such as fatigue, increased heart rate, and increased respiratory rate, are related to a decrease in oxygen-carrying capacity.

*Leukopenia* refers to a decrease in circulating white blood cells (leukocytes). Malignant invasion of the bone marrow is a primary cause of leukopenia, with malnutrition and chemotherapy being contributing factors. A deficiency in white blood cells reduces the patient's ability to fight infection, which is a major cause of morbidity and mortality in cancer patients. Often the offending organism is *opportunistic*; it is unable to infect an immunocompetent host and becomes virulent only when a person is immunocompromised. Infections are very difficult to manage because the host is unable to mount an effective immune response. Infections are also difficult to prevent because the majority

### BOX 7-2 CANCER'S SEVEN WARNING SIGNS

- Change in bowel or bladder habits
- A sore that does not heal
- Unusual bleeding or discharge
- Thickening or lump in breast or elsewhere
- Indigestion or difficulty swallowing
- Obvious change in wart or mole
- Nagging cough or hoarseness

### BOX 7-3 CANCER'S WARNING SIGNS IN CHILDREN

- Continued, unexplained weight loss
- Headaches with vomiting in the morning
- Increased swelling or persistent pain in bones or joints
- Lump or mass in abdomen, neck, or elsewhere
- Development of whitish appearance in pupil of the eye
- Recurrent fevers not caused by infections
- Excessive bleeding or bruising
- Noticeable paleness or prolonged tiredness

**FIGURE 7-18** General emaciated appearance in cancer cachexia. (Courtesy Dr. P. Marazzi/Science Photo Library.)

of the infecting organisms are from the patient's own endogenous flora (e.g., skin, gastrointestinal tract). The development of severe leukopenia or infection during treatment may necessitate changes in the chemotherapeutic regimen to allow bone marrow recovery.

*Thrombocytopenia* is a deficiency in the number of circulating platelets, which are important mediators of blood clotting. Platelet deficiencies predispose to life-threatening hemorrhage. A platelet count of less than 20,000/mm<sup>3</sup> has been associated with spontaneous hemorrhage.

Anemia, leukopenia, and thrombocytopenia may be managed by administration of blood products containing red blood cells, white blood cells, and platelets, respectively. In fact, blood replacement therapy is used more often in cancer patients than in patients with any other medical condition. When chemotherapy is terminated, stem cells in the bone marrow generally recover and the production of blood cells resumes. In some cases, the production of red and white blood

cells can be enhanced by treating the patient with specific growth factors, such as erythropoietin (Epoen) or granulocyte-stimulating factors (Neupogen).

Hair loss and the sloughing of mucosal membranes are complications of radiation therapy and chemotherapy. Treatment is designed to kill the rapidly proliferating cancer cells, but normal cells with high growth rates such as mucosal epithelia and hair follicle cells are also damaged. Damaged mucosa is a primary source of cancer pain and anorexia, and may provide a portal for the invasion of organisms from the skin or gastrointestinal tract.

*Paraneoplastic syndromes* are symptom complexes that cannot be explained by obvious tumor properties and occur in 10% to 15% of patients with cancer. Many of the syndromes are associated with excessive production of hormones or cytokines by the tumor. Common paraneoplastic syndromes include (1) hypercalcemia, (2) Cushing syndrome secondary to excess adrenocorticotropic hormone (ACTH) secretion, and (3) hyponatremia and water overload secondary to excess antidiuretic hormone (SIADH, syndrome of inappropriate ADH) secretion. Small cell carcinoma of the lung is commonly the culprit for excess ACTH and ADH syndromes. Hypercalcemia (elevated concentration of serum calcium) is a paraneoplastic syndrome associated with abnormal production of parathyroid hormone-related protein (PTHrP) by the tumor cells. Unexplained hypercalcemia is regarded as evidence of cancer until proven otherwise. Hypercalcemia may be a consequence of metastatic bone cancer, and in this case it would be an expected finding rather than a paraneoplastic syndrome.

If left untreated, cancer has the potential to kill the host. The cause of death is multifactorial. Infection, hemorrhage, and organ failure are the primary causes of cancer death. The failure of cancer-ridden organs such as the liver, kidney, brain, and lung results in the loss of life-sustaining functions. Treatment for cancer can also be detrimental to the host by contributing to immunosuppression and platelet deficiencies. The cumulative effects of one or more of these factors may lead to death.

#### KEY POINTS

- Regardless of the type of malignancy, affected individuals exhibit characteristic signs and symptoms, including pain, cachexia, bone marrow suppression, and infection.
- Bone marrow suppression is manifested as anemia, leukopenia, and thrombocytopenia.
- Immunosuppression with consequent infection is a primary cause of cancer-associated death.

## CANCER THERAPY

The overall 5-year survival rate for patients with cancer is approximately 68%, with some types of cancer having much higher or lower rates.<sup>3</sup> Early detection of cancer, while it remains localized in the tissue of origin, is associated with the best prognosis for cure. Cure implies eradication of all cancer cells in the body and is different than the 5-year survival rate. Patients with metastatic invasion of regional lymph nodes still have a good opportunity for cure with appropriate therapy. Widespread invasion of multiple tissues and organs is associated with a poor prognosis, and therapy may be aimed at remission or palliation of symptoms rather than cure. The mainstays of cancer therapy are surgery, radiation therapy, and drug therapy. In some hormone-sensitive tumors (breast, prostate), hormonal blocking drugs may be used.

Immunotherapy and targeted molecular therapies have begun to emerge as important treatments for specific cancers. Traditional forms

of treatment are not selective for cancer cells and result in unavoidable damage to normal tissue. The immune system, on the other hand, is noted for its ability to make subtle distinctions between normal and abnormal or foreign cells. Recognition of tumor cells as different from their normal counterparts is the basis of tumor immunology. Recognition depends on the expression of abnormal molecules or antigens on the cancer cell surface. Unfortunately, most tumor-associated antigens are also expressed to some degree on normal cells, which makes it difficult to develop strategies to target cancer cells selectively.

Transplantation of stem cells from the bone marrow or peripheral blood is an increasingly important aspect of cancer treatment for leukemia, lymphoma, and some solid tumors. The choice of treatment depends largely on the results of the staging procedure. A greater degree of metastasis generally requires a more aggressive therapeutic approach.

### Surgery

The majority of patients with solid tumors are treated surgically, which can be curative in some localized cancers. The main benefit of surgery is removal of a tumor with minimal damage to other body cells. The surgeon generally removes a margin of normal-appearing tissue around the resected tumor to ensure complete tumor removal. Lymph nodes are subjected to biopsy and also removed if evidence of metastasis is present. Surgical resection of some tumors can be tricky if vital structures such as neurons or blood vessels are involved.

Surgery involves risks related to the effects of anesthesia, infection, and blood loss. The surgical procedure may be disfiguring or may result in loss of function. Surgical resection as the sole treatment for solid tumors is curative in a minority of patients because most patients already have undetectable metastases at the time of diagnosis.<sup>25</sup> Therefore, surgical resection is commonly accompanied by radiation therapy or chemotherapy. Even one remaining cancer cell could be sufficient to reinitiate tumor formation.

### Radiation Therapy

Ionizing radiation is used for two principal reasons: to kill tumor cells that are not resectable because of location in a vital or inaccessible area and to kill tumor cells that may have escaped the surgeon's scalpel and remain undetected in the local area. Radiation kills cells by damaging their nuclear DNA. Cells that are rapidly cycling are more susceptible to radiation death because there is little time for DNA repair. Radiation may not kill cells directly; rather, it may initiate apoptosis. The *P53* tumor suppressor gene is an important mediator of this response. Many tumors have mutant *P53* and may be less susceptible to radiation-induced cell death.

It is difficult to kill all the cells of a large tumor by irradiation because they are heterogeneous—they are in different phases of mitosis and are cycling at different rates. A single radiation dose large enough to kill all the tumor cells would be sufficient to kill the normal cells as well. Radiation is often administered in smaller doses over several treatments and is most effective at eradicating small groups of tumor cells. It is often used in combination with surgery. Radiation is also useful for palliative reductions in tumor size. Pain from bone and brain tumors may be effectively managed with radiation therapy that shrinks the tumor. Tumors with bleeding surfaces may be coagulated with radiation to decrease blood loss.

A certain degree of destruction of normal cells in the irradiated field is expected with radiation therapy. Radiation is best used when tumor cells are regionally located. Total-body irradiation to kill tumor cells in disseminated locations is not recommended because of the likelihood of life-threatening tissue damage, although it may be used in preparation for bone marrow or peripheral stem cell transplantation.

## Drug Therapy

Chemotherapy generally refers to the systemic administration of anti-cancer chemicals as treatment for cancers that are known or suspected to be disseminated in the body. Unlike surgery or radiation therapy, which is locally or regionally applied, parenterally administered chemotherapeutic drugs can find their cancer cell targets in areas throughout the entire body.

Most chemotherapeutic agents are cytotoxic because they interfere with some aspect of cell division. The more rapidly dividing cells are more susceptible to the killing effects of chemotherapeutic agents. In a large tumor mass, the rates of cell division are very diverse, with many slowly dividing cells. At any one time, only a portion of the tumor cells are in a cell cycle stage that is susceptible to chemotherapy. Several courses of chemotherapy are generally necessary to ensure that all tumor cells have been killed. It is difficult to kill slowly cycling tumor cells without also killing normal cells that are cycling at approximately the same rate. Small tumors are easier to eradicate because rates of cell division are generally faster. To prevent relapse, the “stem” cells that develop into clones of malignant cells must be destroyed. Unfortunately, stem cells may not divide as rapidly as other cells. Resection or irradiation to reduce tumor size may prompt the stem cells to divide, thus making them more susceptible to chemotherapy. Tumor cells with mutations of the *P53* gene may be resistant to chemotherapeutic agents that work by damaging DNA, so drugs that act by interfering with the cancer cell cycle in other ways may be more effective.

Chemotherapeutic agents are not selective for tumor cells, and a certain amount of normal cell death also occurs. Rapidly dividing cells, particularly those of the bone marrow, intestinal epithelia, and hair follicles, are most affected. Bone marrow depression is a most serious side effect inasmuch as it predisposes the patient to anemia, bleeding, and infection.

New approaches to cancer drug therapy have emerged that indirectly inhibit tumors rather than seeking to eradicate tumor cells directly. A promising approach is to interrupt the tumor’s blood supply. To proliferate, solid tumors must be supplied by a progressively expanding network of capillaries. The development of new capillaries, called *angiogenesis*, is accomplished by migration and growth of endothelial cells. Antiangiogenic drugs block the development of new capillaries.

## Immunotherapy

Harnessing the power of the immune system to fight cancer is a particularly appealing idea because of the potential for *specificity*. Current modes of immunomodulation primarily involve the use of interferons, interleukins, and monoclonal antibodies. These therapies are generally used as adjuncts to surgery, irradiation, and chemotherapy.

Interferons are glycoproteins produced by immune cells in response to viral infection. Interferons inhibit cell proliferation and are stimulatory to NK cells, T cells, and macrophages. Interferon- $\alpha$  has been used successfully to treat hairy cell leukemia (a rare B cell malignancy), chronic myelogenous leukemia, and multiple myeloma. Interferon therapy produces symptoms similar to those of a viral infection: fever, chills, and muscle aches.

Interleukins are peptides produced and secreted by white blood cells. They are also called lymphokines or cytokines. Interleukin-2 (IL-2) is an important cytokine secreted by activated T helper cells. It stimulates the proliferation of T cells, NK cells, and macrophages. IL-2 can be used to stimulate the growth of these immune cells in culture. Immune cells taken from a patient’s blood can be grown in culture in the presence of IL-2. Then the greatly expanded number of immune cells can be given back to the patient, along with intravenous infusions of IL-2. Such treatment has been associated with regression of some tumors (melanoma, renal cell carcinoma). Because IL-2 toxicity is high

and many individuals have severe allergic reactions, the benefit of therapy must be weighed against the risks for each individual situation.

The use of monoclonal antibodies (antibodies having identical structure) in cancer therapy is currently the subject of intense investigation. Monoclonal antibodies specifically bind with target antigens and can therefore be used in several ways as treatment for cancer. Antibodies can be used to deliver a cytotoxic drug preferentially to the cancer cell and thus minimize drug interactions with normal cells. Similarly, antibodies can be used to direct other cytotoxic cells, such as NK and T cells, to tumor cells lurking in the body. Antibodies can be attached to a radioactive label and injected into a patient to screen for recurrence of tumor growth. Antibodies can also be directed against cells that support tumor growth.

Monoclonal antibodies have been developed for management of several cancers. For example, nearly 25% of breast cancers have overexpression of the HER2 receptor on the surface of malignant cells. The monoclonal antibody trastuzumab specifically binds to this HER2 protein and helps immune cells to find and kill the tumor cells. A summary of monoclonal antibody agents and their main tumor protein targets is shown in Figure 7-19.

## Gene and Molecular Therapy

Because cancer is fundamentally a disorder of gene function, the use of gene therapy to alter the malignant behavior of cells may have high therapeutic potential.<sup>26</sup> As specific gene derangements are identified for particular tumors, gene therapy may be used to suppress overactive oncogenes or replenish missing tumor suppressor function. Current uses of gene therapy for cancer include genetic alteration of tumor cells to make them more susceptible to cytotoxic agents or immune recognition, and genetic alteration of immune cells to make them more efficient killers of tumor cells.

Tumor cells can also be made more recognizable to immune cells by insertion of genes that cause the tumor cells to express “foreign” proteins on their cell surface. This type of gene therapy has shown some benefit in melanoma and renal carcinoma. Replacement of genes for *P53* is an attractive therapy because tumor cells would be more susceptible to apoptosis. Gene replacement of other tumor suppressors such as *pRb* or *APC* in those tumors that are deficient could help inhibit tumor proliferation.

Gene therapy can be directed at cells other than tumor cells to enhance the body’s cancer defenses. One such approach involves harvesting immune cells from the cancer patient, inserting IL-2 genes, and then returning the genetically enhanced immune cells to the patient. The enhanced immune cells attack the tumor cells more vigorously than normal immune cells do and have been shown to persist in the body for 6 months or longer.

At present, gene therapy is limited by difficulty in delivering the new genes to the target cells. As methods improve, gene therapy will become an increasingly important part of cancer prevention and management.

Molecular therapies that target cytoplasmic signaling pathways have also been developed. For example, in chronic myelogenous leukemia a chromosomal rearrangement results in the abnormal production of an enzyme, BCR/ABL. This enzyme stimulates cell proliferation and contributes to the overproduction of leukemic cells. An agent that specifically inhibits this enzyme (Gleevec) has dramatically improved the management of this disease. Other drugs that specifically target abnormal tumor products are under development.

## Stem Cell Transplantation

Transplantation of hematologic stem cells is used to manage life-threatening disorders in which the patient’s bone marrow is incapable of manufacturing white blood cells, red blood cells, or platelets. Most often, nonfunctional marrow is a consequence of the high-dose

**FIGURE 7-19** Cancer cells express abnormal antigens (tumor-associated antigens) on their cell surface that can activate immune cells or be used as targets for monoclonal antibodies. Numerous medications are now available that use monoclonal antibodies to target cellular proteins relevant to several different types of cancer.

chemotherapy and radiation used to manage hematologic malignancies such as leukemia and lymphoma. Stem cell transplantation also has been applied to other malignancies (e.g., breast cancer) and to nonmalignant disorders (e.g., aplastic anemia, sickle cell anemia, and thalassemia). Stem cells can be harvested from aspirates of bone marrow or from the donor's peripheral bloodstream. Bone marrow is rich in stem cells, but the peripheral blood is poor. The stem cell donor can be a tissue-matched individual (allogeneic), an identical twin (syngeneic), or the patient in question (autologous). A closer match between donor and recipient is associated with a better outcome.

Before infusion of donor stem cells, the patient's own immune cells must be suppressed to prevent transplant rejection. It is also necessary to eliminate any residual malignant cells from the body to avoid relapse of the cancer. Both of these objectives are accomplished through high-dose chemotherapy and total-body irradiation regimens, which leave the patient susceptible to severe anemia, infection, and bleeding. The therapeutic goal of stem cell transplantation is to restore immune and hematopoietic function. It may take weeks to months for the infused stem cells to reestablish themselves and begin to proliferate in their new host. During this time, the transplant recipient requires intensive monitoring and management of complications.

The success of stem cell transplantation depends on a number of factors, including the age of the patient, closeness of tissue matching, stage of cancer, and general health status of the patient before transplantation. Transplantation is an expensive undertaking but may significantly improve disease survival rates in some malignancies.<sup>27</sup>

#### KEY POINTS

- Early detection of cancer while it remains localized is associated with the best prognosis for cure. The overall 5-year survival rate for patients with cancer is about 68%.
- The mainstays of cancer therapy are surgery, radiation therapy, and chemotherapy. Surgery and radiation therapy are effective for cancers that are localized. Chemotherapy is usually the treatment of choice for cancers known or suspected to be disseminated in the body.
- Cells that divide rapidly are the most susceptible to damage from radiation therapy or chemotherapy. However, in addition to cancer cells, rapidly dividing normal cells may be killed. Cells of the bone marrow, hair follicles, and gastrointestinal mucosa are particularly susceptible.
- Immunotherapy has the potential to specifically target cancer cells. At present, interferon, IL-2, and numerous monoclonal antibodies are being used to boost the immune system's ability to locate and destroy cancer cells.
- Gene and molecular therapy may be used to alter cancer cells to suppress oncogenes, enhance tumor suppressor genes, make tumor cells more susceptible to cytotoxic agents, or interfere with the function of cancer gene products.
- Transplantation of hematopoietic stem cells is an important adjunct to cancer therapy that provides a method to restore bone marrow function after high-dose irradiation or chemotherapy.

## SUMMARY

Neoplasia is abnormal cell proliferation of a benign or malignant nature. Benign tumors resemble their parent cells and are strictly local, whereas malignant tumors are anaplastic, invade local tissues, and may spread to distant sites (metastasize). The most important consideration for cancer management is the degree of cancer spread in the body, which can be determined by staging procedures. Cancer is managed by surgical removal, radiation therapy, chemotherapy, and immunotherapy.

Cancer cells have complex relationships with the host. The host immune system is capable of but not always successful in recognizing and killing cancer cells. Cancer cells exert immunosuppressive effects on the host and eventually cause pain, cachexia, and bone marrow suppression. If untreated, cancer has the potential to kill the host by multifactorial processes, including infection, hemorrhage, and organ failure. If treated, cancer has an overall 5-year survival rate of approximately 68%.

Cancer is an outcome of genetic predispositions and environmental carcinogens. Tobacco use and improper nutrition are the two most

studied carcinogenic lifestyle factors. Tobacco is clearly carcinogenic through its ability to cause genetic damage and to promote the growth of mutant cells.

Cancer is thought to develop when proto-oncogenes become inappropriately overactivated in the cell or tumor suppressor genes become inactivated. This change in activation is usually due to a mutational event in the cell's DNA. Oncogenes are believed to disrupt intercellular communication, which normally exerts growth-controlling effects on the cell. This disruption is accomplished primarily through the production of abnormal growth factors, growth factor receptors, cytoplasmic signaling molecules, or nuclear transcription factors that allow the cancer cell to manufacture its own growth-promoting signals. The tumor suppressor genes *Rb* and *P53* are important inhibitors of cell replication. The Rb protein binds and sequesters transcription factors, whereas p53 monitors the integrity of cellular DNA and may initiate apoptosis (cell suicide) when significant cell damage occurs. Loss of tumor suppressor gene function occurs in most cancers.

Infectious diseases can be caused by bacteria, viruses, fungi, and animal- or insect-borne parasites that enter the body by penetrating natural barriers. Viruses are the single most common cause of infectious diseases worldwide.<sup>1</sup> Although treatments are available for many of these diseases, development of resistant strains complicates successful treatment in some cases.

A variety of pathogens inhabit different environments such as hospitals, the food supply, water, animals, and humans. For example,

many hospitalized patients are at risk for the development of sepsis, an overwhelming infection that may lead to shock, multiple organ failure, and death. The methods for preserving the food supply have an impact on transmission of infections, as do the location, density, and sanitary practices of a population. Globalization of the world's population, with the associated rapidity and extent of air travel, has major implications for the worldwide spread of infectious agents before the infected individual becomes symptomatic or identifiable.

Infection with pathogenic microorganisms has become a tool of war and terrorism in the world. Whether it is anthrax spores sent through the mail or the threat of smallpox being introduced into an unimmunized population, methods of preventing infection have a key role in the defense of humanity.

Medications that inhibit the immune response in populations such as transplant or cancer patients, and the use of immunomodulators for treatment of diseases like rheumatoid arthritis, increase the likelihood of **opportunistic** infections. Excessive use of antibiotics in humans and domesticated animals has contributed to the emergence of treatment-resistant infections. Health care professionals have a vital role in the prevention, early detection, and management of infections.

## EPIDEMIOLOGIC CONCEPTS

**Epidemiology** is the study of the causes, distribution, and control of disease in populations. Epidemiology evaluates where, when, and to whom a health event happens and quantifies the risk associated with a particular event.<sup>2</sup> The risk to a population for development of disease varies with the population. For example, in a low-income population the risks are related to poor water supply, poor sanitation, and inadequate nutrition. In affluent populations the risks of decreased physical activity, increased body fat, and poor urban air quality are more important<sup>3</sup> (Figure 8-1). Epidemiology is discussed in more detail in Chapter 1.

One of the first attempts to identify the cause of an infection and develop a method to prevent it was conducted by Benjamin Jesty in England in the mid-1700s. He noticed that milkmaids who developed cowpox from working with cows did not develop smallpox disease. He deduced that there was a connection between cowpox and smallpox. He exposed his wife and children to cowpox to protect them from smallpox and provided an example of the successful use of epidemiological principles and inoculation to prevent disease.<sup>4</sup>

Jesty also performed basic statistical analyses of the numbers of people who developed infections and the numbers who did not, using the concepts of prevalence and incidence. The prevalence of a disease is the number of people who have that disease during a year (e.g., the number of people living with human immunodeficiency virus [HIV] infection). The number of people who develop a new infection in a

year is the incidence. The number of new cases within a given population is the incidence rate (e.g., 10 cases per 1000 persons).<sup>5</sup> A variety of other statistics can be used for surveillance, monitoring, and investigation of outbreaks.<sup>6</sup>

An infectious disease that has a fairly constant presence in a community and changes little from year to year, such as the sexually transmitted disease *Chlamydia*, is classified as **endemic**. A significant increase in new infections in a certain population, such as a measles outbreak at a university, is termed an epidemic. An epidemic that has spread to a large geographic area is a **pandemic**. The bubonic plague, which caused 100 million deaths worldwide in the 1300s, was a pandemic.

The study of infectious diseases requires the evaluation of many factors to determine the association of a disease with its cause. The United States Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have pivotal roles in identifying diseases, tracking their natural history, and defining protocols for their control and prevention. An example of how these organizations can control disease is the virtual eradication of smallpox. The World Health Organization, with the cooperation of other health organizations such as the Centers for Disease Control and Prevention, mandated immunizations for all those susceptible to the disease that were living in or traveling to areas where smallpox was prevalent. This immunization program, coupled with the lack of a viral host other than humans, led to the eradication of smallpox, except in the laboratory. Only the fear of the reintroduction of the virus into the population in a bioterrorism attack or biological warfare may mandate the continued immunization of susceptible populations such as health care workers, emergency personnel, and the military.

## Transmission of Infection

**The transmission of infection or disease** requires an unbroken chain of events to enable one host to infect another<sup>7</sup> (Figure 8-2). Disease-causing organisms (**pathogens**) must live and reproduce in a reservoir. The reservoir may be a human, as in the influenza virus; an animal, as in rabies; an insect, as in West Nile virus; or soil, as in enterobiasis (pinworm infestation).

The **pathogen** must have a portal of exit and a mode of transmission from the reservoir to a susceptible host. The portal of exit

**FIGURE 8-1** Traditional risks to a population compared to modern risks. (From World Health Organization: *Global health risks: mortality and burden of disease attributable to selected major risks*, 2009, available at [www.who.int/healthinfo/global\\_burden\\_disease/GlobalHealthRisks\\_report\\_full.pdf](http://www.who.int/healthinfo/global_burden_disease/GlobalHealthRisks_report_full.pdf).)

is usually closest to the breeding site of the organism. For example, *Neisseria gonorrhoeae*, the organism that is responsible for gonorrhea, usually resides in the urethra of an infected male and in the vaginal canal of an infected female. The microorganism is transmitted to others by sexual contact.

Control of disease acquisition depends on breaking the chain of transmission in one or more places<sup>8</sup> (Figure 8-3). A pathogen can be vulnerable in one or more links of the transmission chain. The goal of epidemiology is to identify these vulnerabilities and exploit them to stop disease transmission.

The ability of a pathogen to cause disease is influenced by the ability to communicate the infection, in other words the ability to spread and cause the disease. The ability to invade and multiply within the host is termed infectivity. Some pathogens have a greater ability to spread and multiply in the host, increasing their infectivity. This difference in the mechanism of action can make one pathogen much better at causing disease (pathogenicity) and some can cause very severe disease (virulence). The ability to cause disease is also influenced by the access to a host. For example, respiratory diseases caused only by exposure to droplets are much more easily transmitted than a disease that requires direct contact. Some pathogens produce toxins or endotoxins that can markedly increase the toxigenicity of the organism.<sup>9</sup>

Transmission of infection is defined as any mechanism by which an infectious agent is spread through the environment to another person.<sup>7</sup> These mechanisms can be either direct or indirect. There are three direct transmissions. The most common transmission occurs through the exchange of body fluids (droplets) from kissing or sexual intercourse. In this type of transmission droplets are spread from an infected host to the conjunctiva or mucous membranes of a second

host. The second type of direct transmission occurs from the bite of an animal (e.g., rabies) or from soil (e.g., systemic mycosis) transmitting the inoculant. The third type of direct transmission occurs through the placenta when diseases such as HIV are transmitted directly to the fetus.<sup>6</sup>

Indirect transmissions occur as vehicle-borne, vector-borne, or air-borne transfers. A vehicle-borne transfer occurs when an infectious agent is transported to the host. The vehicle could be food, water, clothing, plasma, or tissues. The agent does not require any development or multiplication and is delivered without change with the vehicle. Airborne transmission occurs with aerosols including suspensions of particles (smaller than the size of droplets), which can be carried great distances from the source for transmission. Examples are outbreaks of measles and legionnaires disease. Vector-borne transmission can occur as a mechanical or biological transfer. The mechanical transfer occurs when an insect carries an infectious agent on its feet or proboscis (Figure 8-4). In this transfer the agent does not require multiplication or development before transfer. This is in contrast to biological vector-borne transport. In this type of transmission the agent propagates and there is cyclic development before the arthropod can transmit the disease.<sup>6</sup>

The human body also contains a variety of microorganisms that colonize the body and are called normal flora. These flora occur naturally and have a role in defense by occupying space, competing for nutrients, stimulating cross-protective antibodies, and reducing or containing the growth of potentially disease-causing bacteria or fungi. These organisms can become pathogens and cause disease if the host defenses are altered, as in the case of patients receiving chemotherapy. For example, *Staphylococcus epidermidis* is commonly present on the skin. With an injury to the skin, or injection through the skin, this

FIGURE 8-2 Chain of transmission of microorganisms from host to victim.

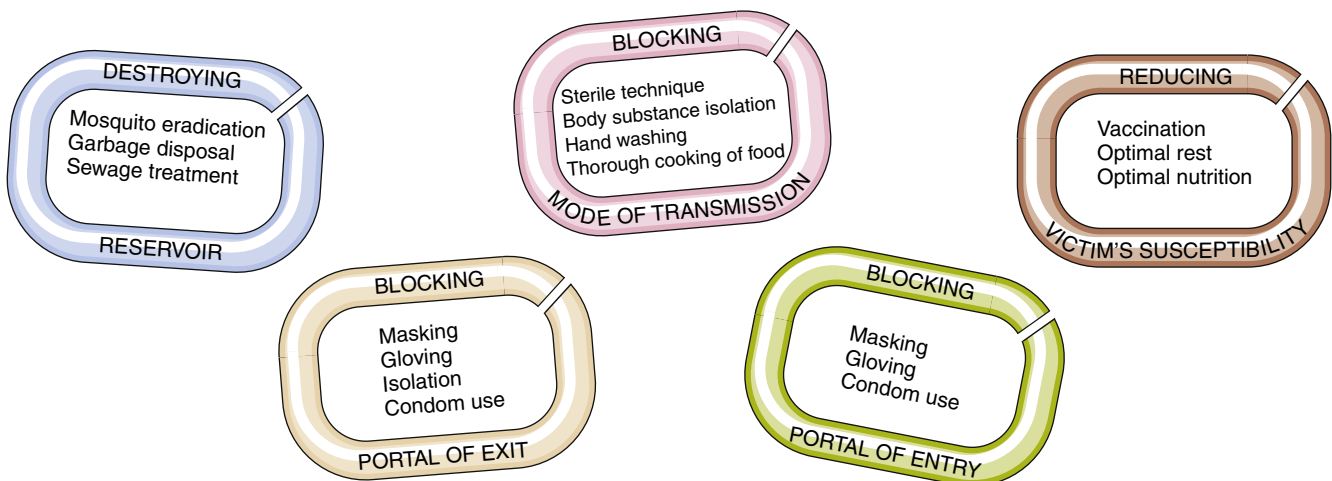

FIGURE 8-3 Breaking the chain of transmission of microorganisms from host to victim.

normal bacterial flora can be introduced to a different space in the body and then become an infectious agent.<sup>10</sup>

Destroying nonhuman reservoirs and vectors of the pathogen can break the chain of transmission. For example, controlling the number of mosquitoes with insecticides and other biological means is a method used to curb the spread of malaria and West Nile virus. Immunization of domesticated animals against rabies eliminates one reservoir of potential rabies transmission. Distribution of clean needles in the intravenous drug user community is aimed at removing a common transmission vector (contaminated needles) for HIV, the causative pathogen responsible for acquired immunodeficiency syndrome (AIDS).

**FIGURE 8-4** A female *aedes aegypti* mosquito as it breaks the surface of the host. (Courtesy James Gathany, Centers for Disease Control and Prevention, Atlanta.)

Blocking the portal of exit can also block transmission of the pathogen. Having patients with tuberculosis wear face masks while they move through the hospital and implementing respiratory isolation techniques to stop transmission are interventions aimed at blocking the portal of exit. Standard precautions are infection-control guidelines designed to block the pathogen's portal of exit, route of transmission, and portal of entry.<sup>2</sup> Hand washing is one of the most effective ways to break the chain of transmission by blocking an important mode of transmission—contaminated hands. Many factors influence the risk of exposure to foreign materials and the occurrence of infection (Table 8-1).

### Role of Host

The body's defense system is responsible for identifying foreign materials and neutralizing or eliminating them without injuring its own tissues.<sup>6</sup> Responses to a pathogen can be either innate or specific. Innate responses occur on the initial exposure to the antigen, whereas a specific response is slow to develop and more efficient on subsequent exposures. Immune responses can be modified by the characteristics of the host, including genetics, age, metabolism, anatomic, and physiologic and environmental factors<sup>6,11</sup> (Table 8-2). Host immune systems are discussed in greater detail in Chapter 9.

### Host Characteristics

#### Physical and Mechanical Barriers

Intact physical barriers act as a blockade to foreign material entering the body (Figure 8-5). Epithelial cells of the skin and those that line the gastrointestinal, genitourinary, and respiratory tracts are tightly linked and provide an initial barrier to infection. Because the intestinal epithelial cell half-life is 30 hours, the constant shedding of the epidermis and mucosal membranes aids in the removal of any microorganisms that

**TABLE 8-1 OVERVIEW OF HUMAN DEFENSES**

CHARACTERISTICS	INNATE IMMUNITY		
	BARRIERS	INFLAMMATORY RESPONSE	ADAPTIVE (ACQUIRED) IMMUNITY
Level of defense	First line of defense against infection and tissue injury	Second line of defense; occurs as response to tissue injury or infection	Third line of defense; initiated when innate immune system signals cells of adaptive immunity
Timing of defense	Constant	Immediate response	Delay between primary exposure to antigen and maximum response; immediate against secondary exposure to antigen
Specificity	Broadly specific	Broadly specific	Response is very specific toward "antigen"
Cells	Epithelial cells	Mast cells, granulocytes (neutrophils, eosinophils, basophils), monocytes/macrophages, natural killer (NK) cells, platelets, endothelial cells	T lymphocytes, B lymphocytes, macrophages, dendritic cells
Memory	No memory involved	No memory involved	Specific immunologic memory by T and B lymphocytes
Peptides	Defensins, cathelicidins, collectins, lactoferrin, bacterial toxins	Complement, clotting factors, kinins	Antibodies, complement
Protection	Protection includes anatomic barriers (i.e., skin and mucous membranes), cellular components, and secretory molecules or cytokines (e.g., lysozymes, low pH of stomach and urine, and ciliary activity)	Protection includes vascular responses, cellular components (e.g., mast cells, neutrophils, macrophages), secretory molecules or cytokines, and activation of plasma protein systems	Protection includes activated T and B lymphocytes, cytokines, and antibodies

From McCance K, Huether S: *Pathophysiology: the biologic basis for disease in adults & children*, ed 6, St Louis, 2010, Mosby.

are attached to their surfaces.<sup>9</sup> In addition, the high fat content of the skin inhibits the growth of bacteria and fungi. Changes in this barrier are sometimes the route for normal flora to become infectious.<sup>12</sup>

The mucous membrane linings of the gastrointestinal and genitourinary tracts provide a barrier separating the sterile internal body from the external environment. The lungs are protected with a layer of mucous lining. The sticky consistency of mucus traps microorganisms, and the cilia sweep the microorganisms from the body. The mucociliary system and alveolar macrophages are important for ridding the lungs of trapped microorganisms. Mechanisms such as coughing, sneezing, and urinating help to remove particles trapped on mucous membranes of the body.<sup>9</sup>

Biochemical barriers enhance the effectiveness of the mechanical barriers. The acidic environment of the skin, urine, and vagina inhibits bacterial growth. The secretion by the stomach of hydrochloric acid (with a pH of 1 to 2) results in the killing of microorganisms. Saliva, mucus, tears, and sweat contain antimicrobial chemicals such as lysozyme, an enzyme that destroys cell walls of gram-positive bacteria.<sup>9</sup> Lactoferrin is a

mucosal protein that keeps bacterial replication low by reducing the availability of free iron needed for bacterial growth. Sebaceous gland secretions act as antifungals. Immunoglobulins (immunoglobulin A [IgA], immunoglobulin G [IgG]) are present in many of the body's secretions and prevent entry of bacteria and viruses through mucous membranes.<sup>13</sup> (See Chapter 9 for a discussion about immunoglobulins.)

Removal or degradation of the body's mechanical and biochemical barriers creates a setting in which infection is likely. For example, burn victims who have lost portions of their skin barrier are at high risk for infection. Cellular changes induced by smoking reduce the number of cilia in the respiratory tract. The normal action of cilia in the respiratory tract in removing foreign particles is blocked by endotracheal tubes. Hospitalized patients who have incisions or intravenous and urinary catheters are at risk for infection because their skin barrier has been breached. When a urinary catheter is in place, flushing of bacteria from the urinary tract opening (meatus) is bypassed.

**Risk Factors**

**Nutritional status.** The World Health Organization (WHO) reports that inadequate nutrition is a general risk factor for disease and is a particularly important factor in tuberculosis (TB) infection.<sup>14</sup> Protein-energy malnutrition is associated with defects in cell-mediated immunity (specific), impaired intracellular destruction by neutrophils, reduced complement activity, and decreased levels of secretory IgA.<sup>15</sup> At the time of an illness, nutrition is negatively affected by decreased appetite, malabsorption, diarrhea, diversion of nutrients for immune responses, and urinary nitrogen loss, further exacerbating a malnourished state. The presence of fever increases the metabolic rate, requiring more energy and micronutrients. Malnutrition exists because of the lack of available clean and safe food. Contributing factors include decreased financial resources, inadequate housing, potentially unsafe water supplies, and the lack of or accessibility to health care.

Micronutrients are also important in immune function. Vitamin A contributes to maintenance of the epithelium and vitamin E is an antioxidant that supports the development and function of T cells.<sup>16</sup> Vitamin D supports innate and adaptive immunity and promotes immune protection against tuberculosis by increasing macrophage defenses.<sup>9</sup> Decreased availability of zinc results in a reduction in neutrophil and natural killer cell function, complement activity, and lymphocyte activity. Iron deficiency is associated with decreased cell-mediated immunity and reductions in neutrophil action. Iron deficiency is one of the most common deficiencies worldwide.<sup>17</sup>

**Age.** Age is also a variable in the ability to resist infections. Viruses such as mumps, polio, or Epstein-Barr virus (EBV) cause less severe infection in infants, whereas others such as rotaviruses result in severe illness in infants. These age-related factors may reflect the availability of immune factors or the maturity of the immune system.<sup>12</sup> T-cell function appears to be impaired in newborns, with the majority of the immune response provided by maternal IgG that crossed the placenta. As this immunity fades over approximately the first 6 months of life, these newborns are more at risk of serious infection. Those infants who are breast feeding will obtain secretory IgA, which does provide additional protection.<sup>13</sup> Immunity tends to decline in the elderly, resulting in reduced antibody responses to new antigens. The immune system may become disregulated as evidenced by the increased frequency of autoimmune diseases with age.<sup>13</sup>

**Chronic illness and immunosuppression.** Chronic illnesses such as diabetes, cancer, heart disease, and renal failure are associated with an increased risk of infection. Deaths in patients with chronic illnesses are frequently directly related to an infectious process. Diabetes alters the host's ability to resist infection. Phagocytosis is impaired with hyperglycemia, and detection of the pain of infection may be delayed because of

**TABLE 8-2 HOST CHARACTERISTICS INFLUENCING INFECTION**

Exposure	Host Health
Animals, humans, insects, parasites	Intact immune system
<b>Environmental</b>	Absence of chronic disease such as diabetes
Water, toxins, pollutants, radiation, sewage	Absence of genetic abnormality
<b>Hygiene</b>	<b>Nutritional Status</b>
Toileting, hand washing, dental care, bathing	Adequate intake of proteins, vitamins, and minerals
<b>Social Behaviors</b>	<b>Antibiotic Exposure</b>
Illicit drug use, alcohol, smoking	Recent use, noncompletion of course

neuropathies. The invasiveness of the microorganisms is increased when exposed to hyperglycemic environments. This increased risk of infectious disease in a population with chronic disease is multifactorial and includes the nature of their chronic disease, medications, treatments, exposure to health care settings, and the innate genetics of the individual.

Immunocompromised patients have an increased risk of severe, rapidly progressing infections that may be unresponsive to usual treatments. Infection with pathogens that are usually not pathogenic is an indicator that a person is immunocompromised. The immunocompromised status might be a result of genetic disorders (such as hypogammaglobulinemia) or may be acquired (such as in patients who have undergone a splenectomy). The prevalence of people with transplants and medication-induced immunosuppression is increasing. Antirejection medications such as corticosteroids, cyclosporine, and tacrolimus contribute to immunosuppression in transplant patients.<sup>18</sup> People who take corticosteroids and immunomodulators to suppress inflammatory and autoimmune diseases are also at high risk of infection. Human immunodeficiency virus (HIV) disease is an important chronic condition that predisposes to a variety of other infections (see Chapter 12).

The physiologic response to chronic stress is thought to contribute to risk for infection. The neurohormonal alterations lead to changes in the levels of cortisol and other stress hormones that may affect immune responsiveness (see Chapter 2).

### Role of Immunization

**Immunization** of a population is the most effective means to reduce morbidity and mortality from vaccine-preventable diseases such as hepatitis A, hepatitis B, influenza, and pneumococcal infections.<sup>18</sup> There are two goals of immunization. The first is to confer immunity to a host by direct exposure to the altered pathogen. The second is to decrease the number of susceptible hosts in the population, thereby limiting the possibility of transmission of the disease. By this method, known as *herd immunity*, the disease can be controlled or eliminated without immunizing everyone, as long as a high enough percentage of the population is immunized. The number of susceptible hosts in the population decreases as immunization rates increase. When a critical percentage of the susceptible population is immunized, the chain of transmission is broken and the disease outbreak averted. If the percentage of adequately immunized individuals drops, epidemics may result.

Immunization with preformed antibodies to the infectious agent provides immediate immunity. Immunizations with killed vaccines such as influenza provide immunity without the risk of infection from the agent. This type of vaccination may require several doses spaced at intervals to allow for continued development of an antibody level sufficient to prevent disease.<sup>12</sup> The increased prevalence of pertussis infection in recent years demonstrates the importance of continued monitoring of vaccine use. Historically, the last pertussis dose was given with the last tetanus dose of a teenaged child. Increasing occurrence rates precipitated a CDC recommendation for a booster dose for adults ages 19 to 64 years.<sup>18</sup> The CDC provides updates and recommendations for immunizations for adults, children, and travelers ([www.cdc.gov](http://www.cdc.gov)).

### Role of Environment

Multiple environmental factors affect the prevalence and transmission of various infections and infestations. For example, parasitic infections are facilitated by hot and humid climates, overcrowded living conditions, the presence of insect vectors in bed linen or clothing, improper sewage disposal or treatment (such as the use of raw human sewage as fertilizer), the lack of clean water, and the consumption of contaminated raw or undercooked meat or vegetables.

Infections may be transmitted by inhalation of polluted dust or air. For example, the fungus *Coccidioides immitis*, which causes valley fever,

is pandemic in the southwestern United States. Toxoplasmosis is caused by inhalation or ingestion of dirt, sand, or litter dust contaminated with cat feces that contain the causative protozoon *Toxoplasma gondii*. The plague is still a disease of concern in many countries. It is caused by the bacterium *Yersinia pestis*, which is carried by a rodent flea.<sup>19</sup> There are multiple examples of foodborne illness such as *Salmonella*, with outbreaks related to improper processing, storage, or cooking of meats and raw produce.<sup>20</sup>

The risk factors for tuberculosis (TB) include crowded living conditions, poor nutrition, frequent contact with those who have TB, and extremes of age (i.e., infants and elderly). Those with reduced immune function attributable to HIV infection, medications, or other risks as previously listed are also at risk for TB.<sup>21</sup>

There are periodic outbreaks of diseases that occur related to travel, shipments of food products, and vaccination levels. Monitoring of travel from those countries with known endemic vaccine-preventable diseases is important to prevent global transmission. SARS (severe acute respiratory syndrome) was identified in 2003 in a businessman traveling from China to Vietnam. The diagnosis was made by WHO physician Dr. Carlo Urbani. This life-threatening disease required the skills of the WHO to identify it as a new and different disease. Unfortunately, Dr. Carlo Urbani died from this disease as did the original patient. This coronavirus, which is transmitted as a respiratory virus, is believed to have originated from small mammals in China and developed into a lethal disease. It is a tribute to the WHO and cooperating agencies that SARS was identified as a global health threat, and a travel advisory was issued.<sup>22,23</sup>

#### KEY POINTS

- Epidemiology is the study of health events and disease, their distribution, and associated causative factors in a defined population. Goals of epidemiology are to define a disease, identify outbreaks, assist in the development and evaluation of treatment protocols, and develop prevention strategies.
- Transmission of disease requires a chain of events that includes passing of the pathogen from the reservoir of the infection through a portal of exit to a susceptible host through a portal of entry by a circumscribed mode of transmission.
- The host has several lines of defense to prevent and fight infection. The skin and mucous membranes provide a first line of defense through mechanical and biochemical barriers. Epithelial shedding, ciliary action, acidic secretions, and enzymes help remove or destroy microorganisms before they gain access to the body.
- Malnutrition may depress immune function because many components require adequate proteins, vitamins, and minerals for synthesis. Immunoglobulins, complement factors, and clotting factors require adequate protein metabolism by the liver.
- Chronic illnesses such as diabetes and cardiovascular disease predispose to infection because circulation of immune components may be impaired and a high-glucose medium may enhance bacterial growth.
- Trauma, burns, invasive instrumentation, antibiotics, and immunosuppressive therapies, which may accompany acute illnesses, predispose an individual to infection by altering normal host defenses.
- The very young and very old are more susceptible to infection because of immature or degenerating immune function.
- Stress is associated with increased secretion of corticosteroids, which are believed to depress immune function. Exogenous steroids and other immunosuppressive therapies (radiation, antibiotics, anticancer drugs, and anti-rejection drugs) also increase the risk of infection.
- Immunizations alter the susceptibility of the host by stimulating the immune system to create antibodies to the pathogen.
- Environmental factors influence the likelihood of exposure and infection by microorganisms. Sanitation, air quality, living conditions, and climate are important factors.

**FIGURE 8-6** This depiction of the interactions of host, microbe, and environment provides a framework for understanding infectious processes.

## HOST-MICROBE RELATIONSHIP

### Normal Microbial Flora

The ability of the human body to resist infection requires an intact defense system. Host and environmental factors such as nutrition, age, illness, air quality, sanitation, and stress may alter the host's resistance to infection. In addition, characteristics of the pathogen such as virulence, toxins, adherence, and invasiveness may allow it to evade the human defense system and colonize.<sup>11</sup> This relationship between the host, the infectious agent, and the environment, as shown in Figure 8-6, is the framework for understanding infectious processes.<sup>1</sup>

Large numbers of microorganisms reside on the skin and in the gastrointestinal tract and vagina of the human host. These microbes can have a symbiotic relationship or just a neutral relationship to the host. Residents are those that are continually present on or in the host. Transients are acquired and may be present briefly but are removed either by host immunity or because the environment is not suited to their continued presence. Variable quantities of available nutrients, pH variability, and microbial resistance to local antibacterial substances such as bile and lysozymes influence the presence of flora (Table 8-3).

In the intestinal tract, the mouth and oral pharynx have large numbers of anaerobes, whereas the stomach, because of the presence of gastric hydrochloric acid and peptic enzymes, is inhospitable to bacteria. In the colon the quantity of bacteria is markedly increased. These primarily include anaerobes such as *Bacteroides* and *Clostridium*. The respiratory tract (beginning with the nares) contains *Staphylococcus* and *Streptococcus*, and may also potentially have pathogenic bacteria such as pneumococci, meningococci, and *Haemophilus* species. The areas below the larynx, including the trachea and bronchi, have only transient bacteria, as do the eustachian tubes. The genitourinary tract is sterile beyond the distal 1 cm of the urethra. The organisms at this site vary by age in women because of the influence of estrogenic hormones.<sup>12</sup>

Normal flora can cause an opportunistic infection when they reach certain areas of the body. For example, a common cause of urinary

**TABLE 8-3 CLASSES OF ORGANISMS INFECTIOUS TO HUMANS**

CLASS	SIZE	SITE OF REPRODUCTION	EXAMPLE
Viruses	20-300 nm	Intracellular	Poliomyelitis
Chlamydiae	200-1000 nm	Intracellular	Urethritis
Rickettsiae	300-1200 nm	Intracellular	Rocky Mountain spotted fever
Mycoplasmas	125-350 nm	Extracellular	Atypical pneumonia
Bacteria	0.8-15 mcg	Skin Mucous membranes Extracellular Intracellular	Staphylococcal wound infection Cholera Streptococcal pneumonia Tuberculosis
Fungi	2-200 mcg	Skin Mucous membranes Extracellular Intracellular	Tinea pedis (athlete's foot) <i>Candida</i> (e.g., thrush) Sporotrichosis Histoplasmosis
Protozoa	1-50 mm	Mucosal Extracellular	Giardiasis Sleeping sickness
Helminths	3 mm to 10 m	Intracellular Extracellular	Trichinosis Filariasis

From McCance K, Huether S: *Pathophysiology: the biologic basis for disease in adults & children*, ed 6, St Louis, 2010, Mosby.

tract infection is the migration of *Escherichia coli* from the colon into the urinary tract. If the host has reduced defenses or immune dysfunction, then normal flora can invade to become an opportunistic infection.<sup>12</sup>

### Microorganism Characteristics

#### Virulence

Microorganisms possess certain characteristics that assist in their penetration and survival in the host despite the presence of an intact defense system. Virulence, toxin production, microbial adherence, and invasiveness are microorganism factors that influence the development of infection in the host.

#### Adherence

The ability to adhere to the contact surface is critical for the success of a microorganism. This ability is affected by the surface hydrophobicity, the net surface charge, the binding molecules on the bacteria (ligands), and the interaction with the host cell. Many bacteria, such as *E. coli*, have pili, which are hairlike structures that extend from the bacterial cell wall and help to increase attachment of the bacteria to host cells. Other bacteria, such as *Streptococcus pyogenes*, have hairlike appendages called fimbriae that extend from the cell surface and promote attachment.<sup>24</sup>

#### Invasion

Access to the host by invasion of the epithelium is important for many bacteria. These bacteria move through cellular junctions to more central tissues (e.g., *Salmonella*). Others invade certain types of cells and enter a host cell. They may stay in a vacuole (made of the host cell

membrane) and may multiply in the host cell. Improvements in *in vitro* studies with tissue cultures are adding to our knowledge about these processes.<sup>24</sup>

### Toxins and Exotoxins

Some bacteria produce a lipopolysaccharide termed a toxin. The toxins are further delineated as exotoxins (excreted by a living cell, with high concentrations in liquid) or endotoxins (an integral part of the cell wall, which is released upon cell death and sometimes during cell growth). An example is tetanus, which is caused by the toxin of *Clostridium tetani*. (Vaccines that are made to prevent these types of diseases are then called toxoids.) When the toxins are released, they have specific effects throughout the body. For example, tetanus causes release of a toxin that attaches to receptors of the motor neurons. The toxin migrates to the spinal cord and then to the brainstem with resulting paralysis. Some toxins are so powerful that very small quantities are required to produce severe effects.<sup>24</sup>

### Bacterial Enzymes

Tissue-degrading enzymes are produced by some bacteria. These enzymes degrade certain body tissues, promoting continued disease. For example *Staphylococcus aureus* secretes coagulase, which coagulates plasma and contributes to the formation of fibrin walls around the lesions caused by these bacteria. This allows the bacteria to persist in the cellular environment. The coagulase also causes deposits of fibrin on the bacteria itself, leading to improved protection from phagocytosis.<sup>24</sup>

Other bacteria produce hyaluronidase, which is an enzyme that breaks down hyaluronic acid. This acid is present in connective tissue. This action helps dissemination of the bacteria through the tissues. Some bacteria are able to produce substances that are cytolytins. These cytolytins can dissolve red blood cells, tissue cells, or leukocytes. For example, group A streptococci produce streptolysin O, which lyses red blood cells.<sup>24</sup>

### Antiphagocytic Factors

Some bacteria develop an outside coating on their surface to prevent phagocytosis. The coating can be made of host cell components or a polysaccharide capsule. In this way they are not as recognizable to leukocytes.<sup>24</sup> Development of a microbial slime layer also facilitates adherence and improves survival of the pathogen. A thin layer of peptidoglycan is created that can participate in the development of pili or flagella on some organisms.<sup>24</sup>

The identification of the production of biofilm by bacteria has changed many facets of patient treatment and prevention of disease. The biofilm is a collection of interactive bacteria that are attached to a solid surface or to each other. This collection is then encased in a polysaccharide matrix. This slimy coat on solid surfaces can involve a single species or several species. These bacteria can then be protected from the host's immune mechanisms. Measures to prevent the collection of this biofilm can reduce infection rates.<sup>24</sup>

### Endospores

Several of the bacteria are capable of creating endospores. In responses to the depletion of nutrients such as carbon, nitrogen, or phosphorus, the cell forms an internal spore. These spores are in a resting state that is markedly resistant to heat, chemical agents, and desiccation. When the environment is more favorable spores are reactivated. Common bacteria with this ability include *Bacillus* and *Clostridium*.<sup>24</sup>

### Mobility

The ability to move (locomotion) is a characteristic of bacteria that have a single flagellum, multiple flagella in a single location on the cell, or flagella over the entire cell. The flagella are made of proteins and give the cell a spinning movement. The movement is directed to swim toward nutrients in the environment. This movement, called *chemotaxis*, can also be seen to avoid a repellent in the environment.<sup>24</sup>

### Antimicrobial Resistance

There are four known mechanisms of bacterial resistance to drugs. Bacteria can produce enzymes that inactivate drugs (e.g.,  $\beta$ -lactamase can inactivate penicillins). Bacteria can create a modified target that is no longer as susceptible to the antibiotic. A reduction in permeability of the bacteria to the drug prevents entry through the bacterial wall. Bacteria can employ an export mechanism that uses an ion gradient ( $H^+$ ) to actively pump out the drug.<sup>13</sup> Usually these resistant properties develop by chance mutations in the organisms; however, some bacteria may be able to transmit their resistance to other bacteria through gene transfer.

Resistant infections occur because of natural genetic differences in the population of organisms that affect their susceptibility to antibiotics. The susceptible strains die and the resistant strains emerge following exposure to antibiotics, creating a drug-resistant infection. Excessive use of antibiotics and subtherapeutic dosing contribute to the development of resistant infections. Relatively resistant microorganisms survive a low-dose antibiotic course to become the dominant species and may then be transmitted to other individuals.

The emergence of vancomycin-resistant *Enterococcus* (VRE) and methicillin-resistant *S. aureus* (MRSA) among others is a troubling development in infectious disease management. The emergence of MRSA was the result of a mutation of the organism and selection of resistant strains in response to antibiotics. The ability of *S. aureus* to become antibiotic resistant was first recognized following the introduction of penicillin (Table 8-4).<sup>13</sup> Multidrug-resistant tuberculosis has also emerged as has antiviral medication resistance, making treatment more difficult.

In summary, virulence and invasiveness factors include a variety of mechanisms that microorganisms have evolved to elude and block host defenses or assist in host invasion. These characteristics contribute to the pathogenicity of the microorganism by enabling it to penetrate natural barriers, resist death by phagocytosis, or survive antimicrobial therapy (e.g., MRSA). Examples include bacterial enzymes, encapsulation, mutation, mobility, endospore formation, and resistance to phagocytosis and antimicrobial therapy.

**TABLE 8-4 HISTORICAL PROGRESSION OF STAPHYLOCOCCUS AUREUS RESISTANCE TO ANTIBIOTICS**

ANTIBIOTIC AND YEAR INTRODUCED	YEAR RESISTANCE APPEARED

Methicillin, 1959	Late 1960s

Data from Morita MM: Methicillin-resistant *Staphylococcus aureus*: past, present and future, *Nurs Clin North Am* 28:625-637, 1993; Rosenberg J: Methicillin-resistant *Staphylococcus aureus* (MRSA) in the community: who's watching? *Lancet* 346:132-133, 1995.

**KEY POINTS**

- A number of microorganisms are considered resident flora because they live on or in the host without causing disease. Resident flora benefit the host by synthesizing molecules and inhibiting the growth of nonresident microorganisms. If the host's immune system is compromised, resident flora may become pathogenic and cause opportunistic infection.
- Microorganisms possess characteristics that enhance their pathogenic potential. Adherence is improved by the presence of adhesion molecules, slime layers, and pili. Escape from immune detection and destruction is enhanced by encapsulation, spore formation, mutation, use of flagella, and toxin production. Microorganisms that possess these characteristics are more virulent and thus more likely to cause disease.
- Drug resistance occurs when microorganisms undergo chance mutations that allow them to survive in the presence of an antibiotic. When the antibiotic is present, these resistant strains emerge to become the dominant species in an individual and may be transmitted to others, causing resistant infections.

**TYPES OF PATHOGENIC ORGANISMS**

Box 8-1 summarizes primary pathogens associated with specific infections in the human host. Photographic examples of pathogenic organisms are shown in Figure 8-7.

**Bacteria**

Bacteria are single-celled rigid wall organisms that have no internal organelles (Figure 8-8). Some live in the intestines of humans, and other animals, and participate in digestion. Others live in the soil and are responsible for its fertility. They degrade dead tissue into useful components for other organisms to use. Among the countless types of bacteria that exist, only a small percentage is known to be harmful to humans.<sup>12</sup>

“True bacteria” have a variety of shapes including cocci (spherical), bacilli (rod shaped or comma-shaped rods, e.g., *Pseudomonas aeruginosa* vibrio), or spiral (twisted rod shaped, e.g., *Spirillum*). Those classified as cocci are also seen in clusters, chains, pairs, or tetrads. The

Microscopic Morphology of Bacteria

B

C

**FIGURE 8-8** Types of microorganisms. **A**, Bacteria. **B**, Virus. **C**, Fungus. (**A**, from Mahon CR, et al: *Textbook of diagnostic microbiology*, ed 4, Philadelphia, 2011, Saunders; **B** and **C**, from Nisengard RJ, Newman MG: *Oral microbiology and immunology*, ed 2, Philadelphia, 1994, Saunders.)

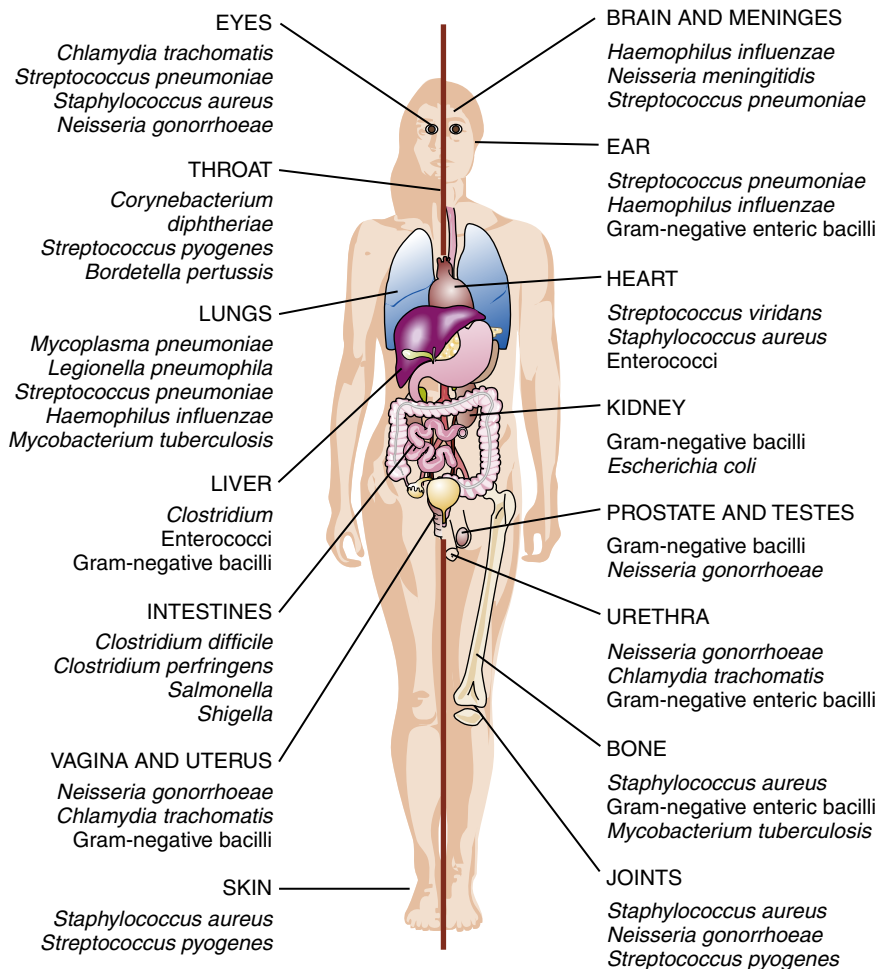

majority of bacteria that cause disease in humans are one of these true bacteria. Filamentous bacteria may have branching structures that resemble fungi. *Mycobacterium tuberculosis* would be an example.<sup>9</sup>

*Spirochetes* (the majority of which are anaerobic) possess a motile spiral filament (e.g., *Treponema pallidum* [Figure 8-9]). Bacteria of the genus *Mycoplasma* do not have a rigid cell wall and are pleomorphic (many formed) in shape. They are some of the smallest of the bacteria; an example is *Mycoplasma pneumoniae*, which causes an atypical pneumonia. *Rickettsia* is a genus consisting of intracellular parasites that can have a variety of shapes. This group is usually spread by vectors; an example is Rocky Mountain spotted fever caused by *Rickettsia rickettsii* transmitted by ticks. *Chlamydia* are also intracellular parasites but have a more complex life cycle, with *Chlamydia trachomatis* as an example.<sup>9</sup>

Bacteria are classified not only by morphology (shape) but also by the response to gram staining. Gram staining separates bacteria into gram-positive organisms, which appear dark purple under the microscope; gram-negative organisms, which appear pink; or acid-fast organisms, which resist staining but once stained resist discoloration. Further differentiation of bacteria is based on nutritional requirements (such as

**FIGURE 8-9** Spirochetes (e.g., *Treponema pallidum*): immunohistochemistry of the muscular layer in the small intestine of a newborn with congenital syphilis. Multiple spirochetes are shown in red (both cross-sections and entire treponemes can be noted [×100]). (Courtesy Jeannette Guarner, MD, and Sherif R. Zaki, MD, PhD, Centers for Disease Control and Prevention, Atlanta.)

**FIGURE 8-10** Examples of pathogenic bacteria classified according to the part of the human body that they commonly infect.

whether the organism is anaerobic or aerobic), on colony characteristics, and on resistance.

Figure 8-10 depicts examples of pathogenic bacteria and the areas that they commonly infect. Once they have penetrated the initial defense mechanisms, the bacteria multiply and create a colony. In an attempt to contain and eliminate the invading bacteria, an acute inflammatory reaction occurs. Phagocytic cells such as neutrophils and macrophages are recruited to the area, where they ingest and destroy the microorganisms. If these responses are insufficient to contain the infection, the bacteria move through the body in natural currents of fluids (i.e., bloodstream, lymph system, or interstitial fluids). Bacteria may move through the lymph system to the lymph nodes where they stimulate an immune response. If they are present in sufficient numbers to overwhelm the lymph nodes, circulating clumps of bacteria (emboli) can cause bacteremia and microabscesses. In severe cases, sepsis, hypotension, organ system failure, and death can occur (see Chapter 20).

## Viruses

**Viruses**, the smallest known infective agents, range in size from 20 to 300 nm. They consist of a protein shell called the capsid and a core of genetic material made of either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). The capsid can be in many shapes including helical, icosahedral, or large pleiomorphic shapes. Some viruses also have a protective envelope surrounding the capsid. This envelope is acquired from the cell membrane of the infected host cell.

Viruses are classified as RNA or DNA viruses, and as either single-stranded (ss) or double-stranded (ds). Some RNA viruses, called retroviruses, contain the enzyme reverse transcriptase and can convert their RNA into DNA that can be incorporated into the host's DNA. The HIV virus is an example of a retrovirus (see Chapter 12). A comparison of viruses, transmission characteristics, and resulting disease processes is presented in Table 8-5.

DNA viruses (e.g., herpes simplex virus) enter the nucleus of the host cell and produce messenger RNA (mRNA) using the host cell's enzymes. Viral proteins are then formed from the messenger RNA, and the DNA of the virus is replicated by host polymerases. DNA and proteins are assembled into new viruses in the host cell. The RNA viruses replicate within the cytoplasm and most produce mRNA that is then translated into proteins and genomic RNA, from which new viruses are created.

Transmission of a virus occurs from one infected person to another or from an animal reservoir (zoonotic infection). The steps of the viral life cycle include attachment to the target cell as the initial step. The virus then penetrates the cell membrane in various ways. Once inside the host cell, the virus uses the host cell's materials to produce new viral components. The virus may be released from the host cells by budding from the cell's surface (Figure 8-11). Viruses that do not manufacture an envelope are usually released by *lysing* the host cell, thus destroying it.<sup>25</sup> A comparison between viruses and other microorganisms is presented in Table 8-6.

TABLE 8-5 HUMAN DISEASES CAUSED BY SPECIFIC VIRUSES

BALTIMORE CLASSIFICATION	FAMILY	VIRUS	ENVELOPE	MAIN ROUTE OF TRANSMISSION	DISEASE	
dsDNA	Adenoviruses	Adenovirus	No	Droplet contact	Acute febrile pharyngitis	
	Herpesviruses	Herpes simplex type 1 (HSV-1)	Yes	Direct contact with saliva or lesions	Lesions in mouth, pharynx, conjunctivitis	
		Herpes simplex type 2 (HSV-2)	Yes	Sexually, contact with lesions during birth	Sores on labia, meningitis in children	
		Herpes simplex type 8 (HSV-8)	Yes	Sexually?, body fluids	Kaposi sarcoma	
		Epstein-Barr virus (EBV)	Yes	Saliva	Mononucleosis, Burkitt lymphoma	
		Cytomegalovirus (CMV)	Yes	Body fluids, mother's milk, transplacental	Mononucleosis, congenital infection	
		Varicella-zoster virus (VZV)	Yes	Droplet contact	Chickenpox, shingles	
ssDNA	Papovaviruses	Papillomavirus	No	Direct contact	Warts, cervical carcinoma	
dsRNA	Reoviruses	Rotavirus	No	Fecal-oral	Severe diarrhea	
ssRNA+	Picornaviruses	Coxsackievirus	No	Fecal-oral, droplet contact	Nonspecific febrile illness, conjunctivitis, meningitis	
Hepatitis A virus	Flaviviruses		No	Fecal-oral	Acute hepatitis	
Poliovirus			No	Fecal-oral	Poliomyelitis	
Rhinovirus				No	Droplet contact	Common cold
			Hepatitis C virus	Yes	Blood, sexually	Acute or chronic hepatitis, hepatocellular carcinoma
			Yellow fever virus	Yes	Mosquito vector	Yellow fever
			Dengue virus	Yes	Mosquito vector	Dengue fever
			West Nile virus	Yes	Mosquito vector	Meningitis, encephalitis
		Togaviruses	Rubella virus	Yes	Droplet contact, transplacental	Acute or congenital rubella
		Coronaviruses	SARS	Yes	Droplets in aerosol or direct contact	Severe respiratory disease
ssRNA-		Caliciviruses	Norovirus	No	Fecal-oral	Gastroenteritis
	Orthomyxoviruses	Influenzavirus	Yes	Droplet contact	Influenza	
	Paramyxoviruses	Measles virus	Yes	Droplet contact	Measles	
		Mumps virus	Yes	Droplet contact	Mumps	
		Parainfluenza	Yes	Droplet contact	Croup, pneumonia, common cold	
			Respiratory syncytial virus (RSV)	Yes	Droplet contact, hand-to-mouth	Pneumonia, influenza-like syndrome
	Rhabdoviruses	Rabies virus	Yes	Animal bite, droplet contact	Rabies	
	Bunyaviruses	Hantavirus	Yes	Aerosolized animal fecal material	Viral hemorrhagic fever	
	Filoviruses	Ebola virus	Yes	Direct contact with body fluids	Viral hemorrhagic fever	
		Marburg	Yes	Direct contact with body fluids	Viral hemorrhagic fever	
Arenavirus		Lassa virus	Yes	Aerosolized animal fecal material	Viral hemorrhagic fever	
ssRNA+ with RT	Retroviruses	HIV	Yes	Sexually, blood products	AIDS	
dsDNA with RT	Hepadna viruses	Hepatitis B virus	Yes	All body fluids	Acute or chronic hepatitis, hepatocellular carcinoma

AIDS, Acquired immunodeficiency syndrome; DNA, deoxyribonucleic acid; ds, double-stranded; HIV, human immunodeficiency virus; RNA, ribonucleic acid; RT, reverse transcriptase; SARS, severe acute respiratory syndrome; ss single-stranded.

**Fungi**

**Fungi** are eukaryotic microorganisms with the ability to form complex structures with thick rigid cell walls. They can grow as a mold with branched filaments or as a meshwork-type structure. Yeasts are a type of fungi with ovoid or spherical shapes. In contrast to bacteria, which have no organelles, the cytosol of fungi does contain

organelles. Infections caused by fungi are called mycotic infections, or **mycoses**. Fungi cause infection first by colonizing the area. The fungus adheres to and proliferates on the site of infection. The next phase requires invasion of the epithelium. Anything that breaks the integrity of the skin (e.g., maceration) facilitates the invasion. Polymorphonuclear leukocytes attempt to phagocytize and digest the

**FIGURE 8-11** Scanning electron micrograph of HIV-1-infected T4 lymphocyte. Large numbers of HIV virions are budding from the plasma membrane of the lymphocytes. (Courtesy Centers for Disease Control and Prevention, Atlanta.)

invading fungi. Neutrophils, monocytes, and eosinophils can destroy fungi in the body.

Certain fungi live in the body as normal flora (e.g., *Candida*). When the body's defense mechanisms are compromised, they can overgrow and cause local or systemic infections. Patients who have been given antibiotics lose some of their normal flora along with the targeted pathogen. The fungi that are not affected by the antibiotic overgrow to fill that niche. Some patients suffering from AIDS, leukemia, alcoholism, drug abuse, and malnutrition or those being treated with immunosuppressive agents lack a well-functioning immune system that prevents fungi from overgrowing, and are therefore more susceptible to fungal infections (opportunistic fungi). When the environment contains more nutrients on which the fungi can grow, such as the hyperglycemic bloodstream of a diabetic patient or the vaginal tract of a female taking antibiotics, fungi can overgrow and cause infections. *Pneumocystis carinii* was reclassified as a fungus in 2006, and renamed to *Pneumocystis jiroveci*. This opportunistic infection is commonly associated with HIV disease.<sup>9</sup>

Superficial mycoses, such as those caused by dermatophytes (e.g., tinea pedis), occur only on superficial, dead, keratinized tissue like hair, epidermis, and nails. Cutaneous fungi do not invade the tissues but do result in an inflammatory response, as in tinea pedis (athlete's foot). Subcutaneous mycoses occur when fungi are introduced into subcutaneous tissues and can be seen in ulcers or abscesses on the skin. Systemic infections are invasive to lungs and other organs (e.g., *Cryptococcus neoformans*). Systemic treatment is used more commonly for the immunocompromised patient or for the patient with disseminated disease because skin infection is usually self-limited. Topical antifungal drugs may be used to treat these superficial infections. Table 8-7 summarizes some examples of fungal infections.

Systemic mycoses may occur in both healthy and immunocompromised hosts. Because the fungi causing systemic infections are usually found in soil, these infections tend to be endemic to certain regions where the fungus is found. Infection is caused by inhalation of dust containing the fungus. Because of the endemic nature of these fungi, large segments of the population in the area may have been exposed and infected without any symptoms. If symptoms develop, they are usually self-limiting and mild. However, for those with compromised immune systems, the disease becomes severe and disseminated. Examples of systemic mycoses are histoplasmosis, blastomycosis, and coccidiomycosis.<sup>12</sup> *Histoplasma capsulatum* is a fungus that commonly occurs in soil in the central and eastern United States. *Histoplasma* also occurs in soil rich with chicken feces or bat guano. Humans and animals exposed to dust storms in endemic areas or contaminated with these feces are most likely to be infected. They may also have positive histoplasmin skin tests and may show calcified sites of infection in their lungs.<sup>12</sup>

### Parasites

Parasites establish themselves with another organism and benefit from the other organism. They range in size from a small unicellular protozoan to large worms. Parasites are representative of four families of the animal kingdom: protozoa, or single-celled animals (Figure 8-12); nemathelminths, or roundworms; platyhelminths, or flatworms; and arthropoda, or invertebrate animals with jointed appendages. These parasites live on or in the human body during some part of their life cycle. Parasites and protozoa are rarely transmitted by human contact; usually they are disseminated through a vector where the parasite or protozoan spends part of its life cycle. For example, malaria (*Plasmodium* sp.) is transmitted by mosquitoes. Many of the protozoal infections are transmitted through contaminated water or food and require ingestion (e.g., *Giardia lamblia*). Some parasites have specific surface glycoproteins that influence their ability to enter macrophages.

Host resistance depends on macrophages, neutrophils, eosinophils, and platelets, which kill both protozoa and worms. T cells are required to develop immunity against these organisms. The symptoms of parasitic infection depend on the area in which the infestation develops. Protozoan infestation (amebiasis) of the gastrointestinal tract produces cramping, abdominal pain, and bloody diarrhea. Infestation of the blood produces fever, chills, rigor, and later anemia, all of which are associated with malaria (*Plasmodium* infection). Acute pruritus and rash occur after infection of the skin with *Sarcoptes scabiei* (scabies).<sup>9</sup>

Identification of the infectious agent is usually accomplished either by visualization of the adult parasite, by direct observation of the area (inspection of the skin or hair), or by microscopic examination of blood, feces, or tissue samples. Table 8-8 summarizes various parasitic infections of humans, including the common name, location, symptoms, and mode of transmission.

**TABLE 8-6 COMPARISON OF VIRUSES AND OTHER MICROORGANISMS**

ORGANISM	GROWS IN NONLIVING MEDIA	CONTAINS BOTH DNA AND RNA	CONTAINS RIBOSOMES	SENSITIVE TO ANTIBIOTICS
Bacteria	Yes	Yes	Yes	Yes
Mycoplasmas	Yes	Yes	Yes	Yes
Rickettsiae	No	Yes	Yes	Yes
Chlamydiae	No	Yes	Yes	Yes
Viruses	No	No	No	No

TABLE 8-7 FUNGAL INFECTIONS

INFECTION	DISTRIBUTION	MODE OF TRANSMISSION VECTOR		SYMPTOMS	LOCATION OF INFECTION	
					PRIMARY SITE(S)	SECONDARY SITE(S)
Cryptococcosis	Everywhere	Inhalation	Pigeon feces	Fever, cough, weight loss, pleuritic pain, CNS disturbances	Pulmonary system	Meninges, skin, bone
Candidiasis	Normal flora	Ever present	N/A	Mucocutaneous pain and pruritus at site of infection	Fungemia, endocarditis	Kidneys, eyes, heart
Phycomycosis (mucormycosis)	Everywhere	Inhalation, ingestion, wound contamination	Decayed matter, soil	Rhinocerebral mucormycosis: destruction of CN II, IV, V, VI; erosion of carotid artery; meningitis; brain abscess Pulmonary mucormycosis: dyspnea, chest pain, hemoptysis	Nose, brain, lung	Rare
Histoplasmosis	River valleys (e.g., California), southwestern USA (Arizona, Nevada)	Inhalation	Bird and bat feces	Flulike: cough, fever, myalgias, weight loss, anemia, leukopenia, thrombocytopenia, painful oropharyngeal ulcers	Pulmonary system	Bone marrow
Coccidioidomycosis (San Joaquin Valley fever)	Semi-arid USA (e.g., California), southwestern USA (Arizona, Nevada)	Inhalation	Dust, dirt	Cough, fever, pleuritic chest pain, weight loss, dyspnea, chest pain, CNS disturbances	Pulmonary system	Skin, bone, joints, meninges
Blastomycosis	Southeastern USA, south central USA, midwestern USA, Great Lakes region	Inhalation	Unknown	Flulike: pleuritic chest pain, arthralgias, erythema nodosum, weight loss, fever, cough, chest pain	Pulmonary system	Skin, bone, joints, male GU tract
Aspergillosis	Everywhere	Inhalation	Decaying vegetation	Dyspnea, chest pain, hemoptysis, wheezing	Pulmonary system	Brain, kidney, liver

CN, Cranial nerve; CNS, central nervous system; GU, genitourinary; N/A, not applicable.

**KEY POINTS**

- Microorganisms responsible for infections in humans include bacteria, viruses, fungi, and parasites.
- Bacteria are characterized according to shape (cocci, rods, spirals), reaction to stains (gram negative, gram positive, acid fast), and oxygen requirements (aerobic, anaerobic).
- Viruses are small pieces of genetic material (DNA, RNA) with associated proteins and lipids. The smallest infective agents known, viruses are intracellular pathogens that use the host's energy sources and enzymes to replicate. Viral replication may or may not destroy the host cell. DNA viruses may be incorporated directly into the host genome. RNA viruses serve as templates for the production of viral RNA and proteins.
- Retroviruses are RNA viruses that contain a special enzyme called *reverse transcriptase* that mediates the synthesis of a DNA copy of the RNA virus. The DNA can then be incorporated into the host genome and passed on to daughter cells when the cell divides.
- Fungal infections can be superficial (e.g., ringworm, athlete's foot), subcutaneous (e.g., sporotrichosis), or systemic (e.g., histoplasmosis). Systemic fungal infections tend to be more serious and usually do not occur unless the host's immune system is compromised.
- Parasites include protozoa, helminthes (roundworms, flatworms), and arthropods. Manifestations of parasitic infections vary depending on the organism and site of infection. Common sites of parasitic infestation are the skin and gastrointestinal tract.

TABLE 8-8 PARASITIC INFECTIONS

PARASITIC AGENT	COMMON NAME OF DISEASE	LOCATION OF INFECTION	SYMPTOMS	MODE OF TRANSMISSION
<b>HELMINTHS (WORMS)</b>				
<b>Nematodes (Roundworms)</b>				
<i>Ancylostoma duodenale</i>	Hookworm	Blood vessels of gut	Anemia	Skin penetration
<i>Ascaris lumbricoides</i>	Giant roundworm	Small intestine, lungs	Pneumonitis (rare), intestinal obstruction (rare)	Oral (fecal contamination), autoinfection
<i>Enterobius vermicularis</i>	Pinworm	Cecum	Anal pruritus	Oral
<i>Onchocerca volvulus</i>	River blindness	Skin, eye	Blindness	Insect inoculation
<i>Strongyloides stercoralis</i>	Strongyloidiasis	Small intestine, lungs	Eosinophilia, urticaria, rash, abdominal pain, pneumonitis	Skin penetration, autoinfection
<i>Trichinella spiralis</i>	Trichinosis	Muscles	Muscular pain, eosinophilia, fever, periorbital edema	Oral (infected meat)
<i>Trichuris trichiura</i>	Whipworm	Intestine	Rectal prolapse	Oral (fecal contamination)
<i>Wuchereria bancrofti</i>	Filariasis	Lymphatics	Elephantiasis	Insect (mosquito)
<b>Trematodes (Flukes)</b>				
<i>Clonorchis sinensis</i>	Liver fluke	Liver	Biliary obstruction (rare)	Oral (raw fish)
<i>Fasciola hepatica</i>	Liver fluke	Liver	Fever, right upper quadrant abdominal pain, eosinophilia	Oral
<i>Fasciolopsis buski</i>	Intestinal fluke	Liver	Abdominal pain, diarrhea	Oral
<i>Paragonimus westermani</i>	Lung fluke	Lung, intestine	Eosinophilia, cough, chest pain, bronchitis	Oral (poorly cooked freshwater crab or crayfish)
<i>Schistosoma haematobium</i>	Blood fluke	Urinary tract	Acute: rash, fever, cough, chest pain, chills	Skin inoculation
<i>Schistosoma japonicum</i>	Blood fluke	Mesenteric blood vessels	Hepatomegaly, splenomegaly	Skin inoculation
<i>Schistosoma mansoni</i>	Blood fluke	Mesenteric blood vessels	Lymphadenopathy, eosinophilia	Skin inoculation
<b>Cestodes (Tapeworms)</b>				
<i>Diphyllobothrium latum</i>	Fish tapeworm	Intestine	Megaloblastic anemia	Oral (poorly cooked fish)
<i>Taenia saginata</i>	Beef tapeworm	Intestine	Mild abdominal pain	Oral (poorly cooked beef)
<i>Taenia solium</i>	Pork tapeworm	Intestine	Mild abdominal pain	Oral (poorly cooked pork)
<i>Echinococcus granulosus</i>	Hydatid cyst	Lung, liver	Cholestasis, liver congestion and atrophy, biliary obstruction	Oral (inoculation with sheep, cattle, or dog feces)
<b>PROTOZOA</b>				
<i>Entamoeba histolytica</i>	Amebic dysentery	Intestine	Bloody, mucoid diarrhea; colicky abdominal pain	Contaminated water, raw vegetables
<i>Plasmodium</i> spp.	Malaria	Liver, erythrocytes	High fever, chills, rigor, anemia, headache, malaise, chest pain, abdominal pain	Female <i>Anopheles</i> mosquito
<i>Leishmania</i> spp.	Kala azar; cutaneous leishmaniasis	Reticuloendothelial cells of body disseminates to spleen, liver, bone marrow, lymph glands	Chronic: abdominal discomfort, ascites, fever, weakness, pallor, weight loss, cough Acute: sudden fever, chills	All transmission accomplished through bite of sandflies after biting specific infected mammals
<i>Trypanosoma</i> spp. <i>T. cruzi</i>	Chagas disease	Bloodstream	Local inflammation, lymphadenopathy, muscular necrosis including myocardium (heart failure), esophagus, and colon (dilation); fever, malaise, anorexia, edema of face	Insects—hematophagous <i>Triatoma</i> (blood drinking)
<i>T. brucei</i>	African sleeping sickness	Bloodstream	Fever, malaise, headache, rash, CNS disturbances	<i>Glossina</i> flies (tsetse flies)
<i>Toxoplasma gondii</i>	Toxoplasmosis	Throughout body	Acute: usually asymptomatic Immunosuppressed: encephalitis, myocarditis, pneumonitis	Eating raw or undercooked meat, poultry, or dairy foods; oral inoculation with cat feces

TABLE 8-8 PARASITIC INFECTIONS—cont'd

PARASITIC AGENT	COMMON NAME OF DISEASE	LOCATION OF INFECTION	SYMPTOMS	MODE OF TRANSMISSION
<i>Giardia lamblia</i>	Epidemic diarrhea	Intestine	Newborn: impaired vision, neurologic disorders Acute: self-limited diarrhea; occasionally malabsorption with weight loss	Fecal contamination of water; person to person
<i>Trichomonas vaginalis</i>	Trichomoniasis (vaginitis)	Vagina	Irritation, discharge	Sexually transmitted
<b>ECTOPARASITES</b>				
<b><i>Pediculus humanus</i></b>				
<i>Var. corporis</i>	Body louse	All hair-covered parts of body	Pruritus Nits at base of hair shaft	Person to person, by fomites
<i>Var. capitis</i>	Head louse	Head area		
<i>Pediculus pubis</i>	Pubic louse	Pubic area		
<i>Sarcoptes scabiei (var. hominis)</i>	Scabies	Skin	Pruritus, worse at night; linear burrows in folds of fingers, elbows, knees, axillae, pelvic girdle	Person to person
Maggots (larvae of dipterous flies)	Myiasis	Necrotic tissue	Depends on location of infestation	Dipterous flies
Chiggers (mites)		Skin	Intense pruritus, hemorrhagic papules	Inhabit dogs, rabbits, cats, rats; foul cheese, flour, house dust
Ticks		Skin	Can transmit tick paralysis, Lyme disease	Reside in wooded and grassy areas

## SUMMARY

The process of transmission of infection can be thought of as a chain with links that flow from the host or reservoir of the microorganism to the next susceptible victim. The goal of infection control is to block transmission of the microorganism to susceptible victims by severing the chain at one or more links.

Four basic types of microorganisms exist: bacteria, or single-celled organisms with cellular organelles that allow them to live independently in the environment; viruses, or tiny genetic parasites that require the host cell to replicate and spread; fungi that may cause superficial or systemic mycotic infections; and parasites, which include protozoa, roundworms, flatworms, and arthropods. These organisms can be helpful or harmful to the host. When harmful, a microorganism is considered pathogenic. The study of pathogenic organisms and the way that they spread is called *epidemiology*.

The host-microbe relationship is determined by the characteristics of both the microorganism and the host. Microorganism factors that affect the relationship include the requirement for the microbe to kill the host cell in order to propagate, the reaction of the host to the invading microorganism and its endotoxins, and the ability of the microorganism to live independently from the host in the environment. Multiple host factors such as the integrity of barriers to transmission, nutritional status, age, and drug regimen all have an impact on this relationship.

Health care professionals have a key role in the prevention, surveillance, and early detection of infectious processes in hospital and community settings. The identification of high-risk individuals who are more susceptible to infection will assist in earlier detection of the manifestations of infection. Management of infections requires optimizing the client's host defense system and is supplemented by targeted pharmacologic and nutritional interventions.

## KEY QUESTIONS

- What are the major organs and cellular components of the body's defense against foreign antigens?
- How do immune cells communicate through cell-to-cell interactions and through secreted cytokines?
- How do innate and adaptive immune mechanisms differ?
- How do macrophages, granulocytes, and lymphocytes work together to locate, recognize, and eliminate pathogens?
- What is the role of MHC class I and II proteins in cell-mediated immunity?
- Why is an immune response usually more effective on subsequent exposure to an antigen than after the first exposure?
- How do noncellular immune system components, including antibodies, complement, and clotting factors, aid the immune response?

### INTEGRATED FUNCTION AND REGULATION OF THE IMMUNE SYSTEM, 189

- Integrated Response to New Antigen, 189
- Regulation of Immune Function, 192

The immune system is a complex network of cells and tissues that work together to protect the body against foreign invaders. The wide variety of potential pathogens requires a defense system that is diversified and adaptable. Several types of white blood cells (WBCs) are of primary importance in localizing, recognizing, and eliminating foreign substances. These immune cells are strategically situated in diverse locations so that pathogens may be detected quickly. The dispersed nature of these defensive cells necessitates a complex system of intercellular communication to effectively mobilize reinforcements to areas of need. A tremendous amount of information has accumulated about how immune cells communicate and the processes that enable them to migrate to particular locations. The impact of this research goes far beyond the traditional immune disorders such as immunodeficiency diseases and hypersensitivity reactions. The immune system has been implicated in the pathogenesis of disorders as diverse as atherosclerosis, myocardial infarction, shock, diabetes, and stroke. Therefore, an understanding of immune function is fundamental to the study of a wide variety of diseases. This chapter describes the organs and cells that constitute the immune system, the mechanisms of action of innate and adaptive defenses, and the communication processes whereby immune cells achieve a coordinated response. Underreactions and overreactions of the immune system, immune system malignancies, and human immunodeficiency virus disease are described in Chapters 10, 11, and 12, respectively.

## COMPONENTS OF THE IMMUNE SYSTEM

The structures of the immune system include (1) skin and mucous membranes; (2) the mononuclear phagocyte system; (3) the lymphoid system, including spleen, thymus gland, and lymph nodes; and (4) bone marrow. All these structures are inhabited by different types of WBCs (leukocytes) that mediate **inflammation** and **immunity**. Leukocytes are responsible for locating and eliminating pathogens and foreign molecules. They are aided in their task of bodily defense by a number of chemical mediators, including **complement**, **kinins**, clotting factors, **cytokines**, and **chemokines**.

Components of the immune system are often categorized into specific or innate defenses according to the mechanisms whereby antigens are recognized. Innate defenses require no previous exposure to mount an effective response against an **antigen**, and a wide variety of different antigens are recognized. Natural killer (NK) cells and phagocytic cells such as **neutrophils** and **macrophages** are mediators of innate defenses. In contrast, specific defenses respond more effectively on second exposure to an antigen (adaptive) and are highly selective in the ability to recognize antigens. B lymphocytes (B cells) and T lymphocytes (T cells) are the agents of specific immunity.

Although separating immune components into specific and innate systems is helpful for studying inflammation and immunity, it is an artificial division because they function in a highly integrated manner.

The approach used in this chapter is to first describe the major components of the immune system, discuss innate and specific adaptive defenses separately, and then summarize the integrated function of the entire system and its regulation.

## EPITHELIAL BARRIERS

The skin and mucous membranes are sometimes called the “first line of defense” because they are frequently the initial sites of microbial invasion. Intact epithelia in skin and mucous membranes provide mechanical and chemical barriers that prevent microorganisms from gaining access to the body’s tissues. The skin epithelium produces antimicrobial peptides called *defensins* that can kill a wide variety of bacteria and fungi. The intestinal epithelium produces another form of bactericidal peptide called *cryptocidins* that prevent bacteria from colonizing the intestinal wall.<sup>1</sup> Resident microorganisms may aid in providing this line of defense by making conditions inhospitable for pathogens (see Chapter 8). Disruption of the normal epithelial barriers increases the likelihood that pathogens will successfully establish an infection. Physical trauma (e.g., burns, lacerations, erosions) and biochemical alterations (e.g., pH changes, increased glucose concentration, decreased enzyme production) predispose to infection. Pathogens that breach the skin or mucous membranes are generally first detected by cells of the mononuclear phagocyte system. These cells are thought to originate from monocytes produced in the bone marrow. Specialized antibody-secreting cells also locate to the mucous membranes where they produce antibodies of the immunoglobulin A (IgA) class. IgA antibodies bind antigens on the mucosal surface and prevent them from entering more deeply into the tissues.

## MONONUCLEAR PHAGOCYTE SYSTEM

The mononuclear phagocyte system (previously called the reticuloendothelial system) is composed of dendritic cells, monocytes, and macrophages that are widely distributed throughout the body. Monocytes from the circulating blood migrate to organs and tissues to become macrophages. Macrophages are found throughout the body and are assigned various names according to the tissues in which they are located, such as alveolar macrophages in the lungs, microglial cells in the brain, Kupffer cells in the liver, and histiocytes in connective tissue (Figure 9-1). Dendritic cells are a monocyte-derived cell type that specializes in capturing and presenting antigens to T cells. Dendritic cells are strategically located in subcutaneous and submucosal tissues.

Macrophages and dendritic cells are often the first immune system cells to encounter a pathogen or foreign antigen after it has entered the body, and they are instrumental in communicating news of the invasion to other immune cells. This communication is accomplished through secretion of chemical signaling molecules called *cytokines* and

**FIGURE 9-1** Cells of the mononuclear phagocyte system. (Redrawn from Schindler LW: *Understanding the immune system*, NIH Pub No. 92-529, Bethesda, MD, 1991, U.S. Department of Health and Human Services, p 9.)

by presentation of captured antigen to the specific, adaptive immune cells. Dendritic cells specialize in antigen presentation and are able to migrate quickly to lymphoid tissues when they have captured antigens. Macrophages have many other roles in the immune response in addition to their sentry function. Macrophages are powerful phagocytes, each capable of ingesting numerous microbes. Macrophages are called on to clean up the area in which dead neutrophils and inflammatory debris have accumulated after an inflammatory reaction, and they have a role in wound healing.

## LYMPHOID SYSTEM

The primary lymphoid organs are the bone marrow and thymus gland, which are the structures where lymphocytes develop. All types of lymphocytes are produced from stem cells in the bone marrow (Figure 9-2). T lymphocytes then migrate to the thymus for development, whereas B lymphocytes and NK cells stay in the marrow to develop. NK cells are a population of lymphocytes that lack both T-cell and B-cell markers. NK cells are produced and released from the bone marrow and function in innate immune responses. NK cells are found mainly in the circulation and spleen. Once mature, T and B lymphocytes migrate to the secondary lymphoid organs where they await activation by antigens. Secondary lymphoid organs include the tonsils, spleen, lymph nodes, and Peyer patches (Figure 9-3).

### Primary Lymphoid Organs

Bone marrow is contained in all the bones of the body. The primary function of bone marrow is **hematopoiesis**, or the formation of blood cells. There are two kinds of bone marrow: red and yellow. Hematopoiesis is

carried out by red (functioning) marrow. By adulthood, red marrow is confined to the pelvis, sternum, ribs, cranium, ends of the long bones, and vertebral spine. Yellow or fatty bone marrow is found in the remaining bones. It normally does not contribute to hematopoiesis in the adult, but can be recruited to become red marrow again under conditions of increased need for hematopoiesis.<sup>2</sup>

B lymphocytes (B cells) are produced and develop in the bone marrow. B cells migrate from the outer edges toward the center of the bone marrow as they develop. Pre-B cells are subjected to a highly selective quality control process, and less than 25% of the developing B cells are allowed to survive. During migration through the bone marrow, immature B cells are exposed to self antigens. B cells that do not bind to any antigens continue to develop into mature B cells. If immature B cells encounter antigens to which they bind while still in the bone marrow, a series of events is triggered to induce self-tolerance. The immature B cell is stimulated to reactivate the genetic recombination machinery in an attempt to produce a new B-cell receptor (BCR) that does not bind to self antigens. If this receptor editing attempt fails to alter binding sufficiently, the immature B cell will undergo apoptosis in the bone marrow.<sup>3</sup> Mature B cells that leave the bone marrow to colonize secondary lymphoid organs are called *naïve* B cells because they have not yet encountered antigen.

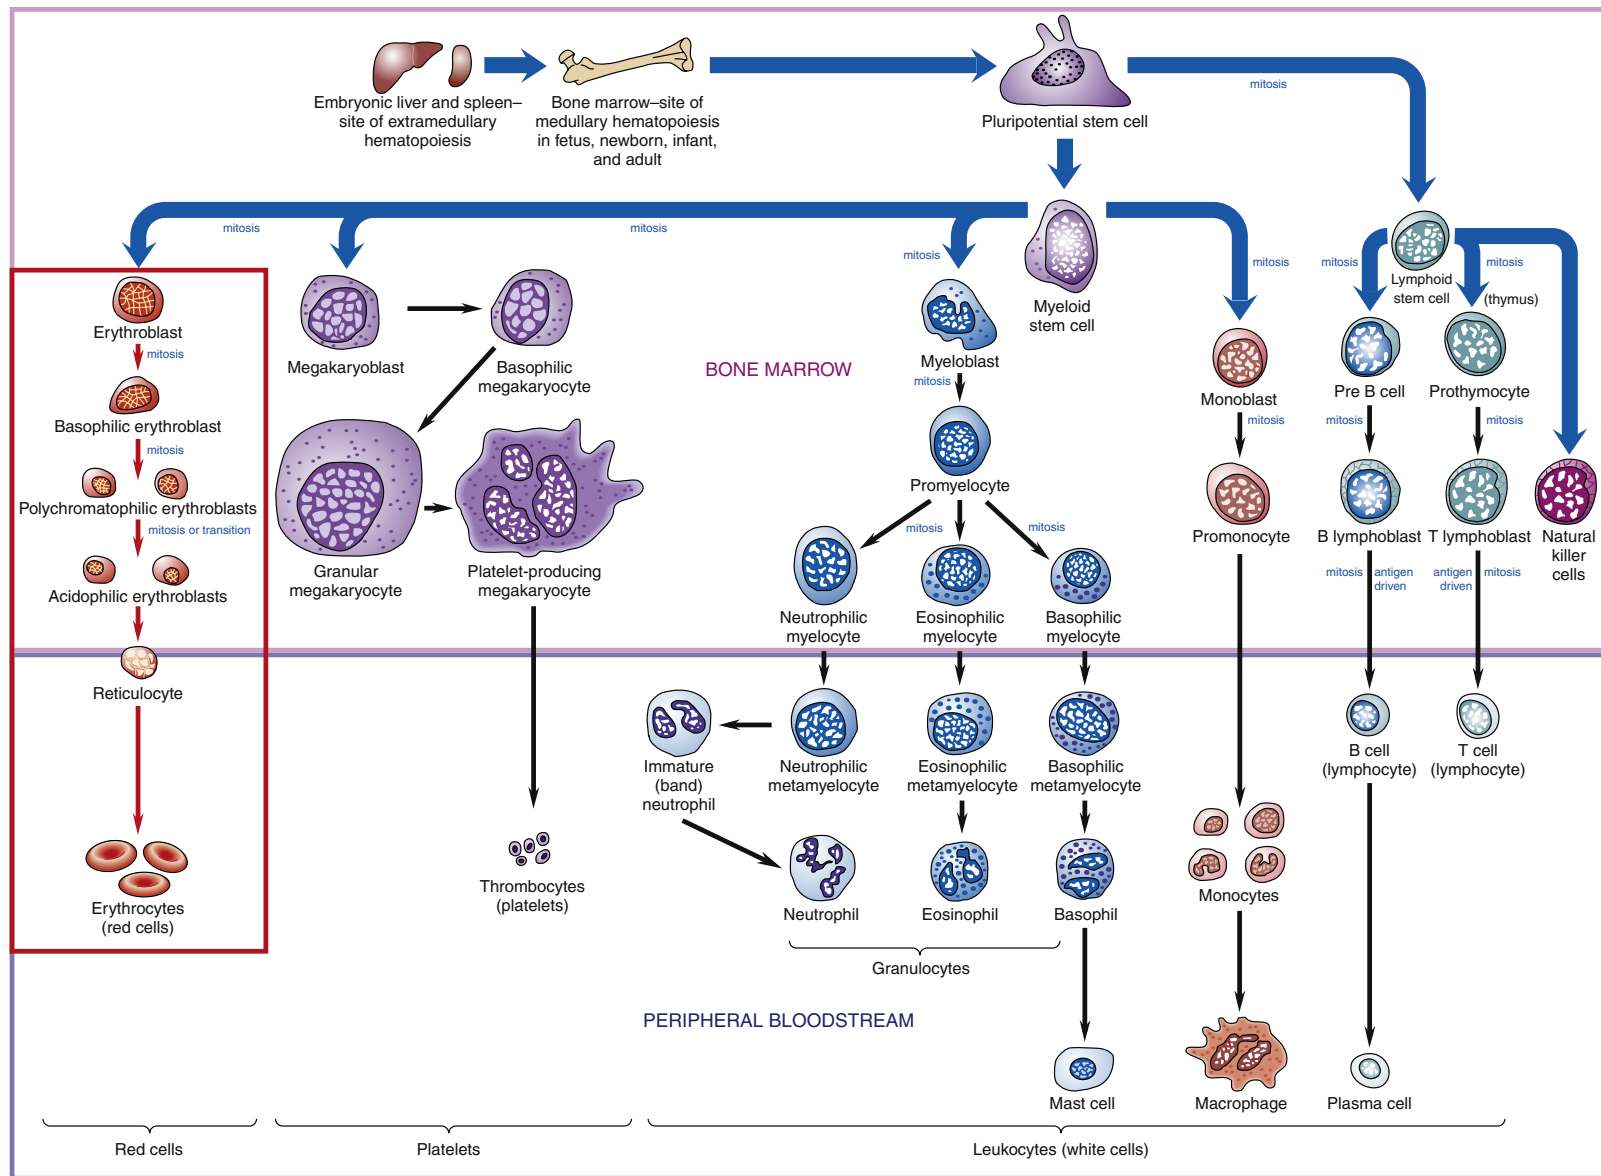

T lymphocytes (T cells) develop in the thymus, which is located in the anterior mediastinum overlying the heart. Pre-T cells initially enter the outer aspect (cortex) of the thymus lobules, and many die while they migrate to the center (medulla) of the thymus. The selection process for T cells is even more rigorous than that for B cells; only about 5% of the cells entering the thymus survive to reenter the circulation and colonize secondary lymphoid organs. The thymus is relatively large at birth and steadily atrophies after puberty.<sup>4</sup> The thymus produces interleukin-7 (IL-7), a cytokine that promotes T cell proliferation.

### Secondary Lymphoid Organs

Once mature, lymphocytes leave their primary lymphoid organs and travel through the blood to localize in peripheral, or secondary, lymphoid tissues, including lymph nodes, spleen, tonsils, and Peyer patches in the intestine. These naïve T cells and B cells express specific receptor proteins on their cell surfaces that allow them to migrate or “home” to specific locations in lymph tissue. Most mature T lymphocytes are in constant circulation through lymphatic tissues and the bloodstream. It has been estimated that a lymphocyte makes a circuit from the blood to tissues to lymphatics and back to the bloodstream once or twice per day.<sup>3</sup> Antigens can be carried to the naïve cells in the lymph nodes by the specialized antigen-presenting dendritic cells. When exposed to an appropriate antigen, T cells and B cells migrate toward each other within the lymph nodes and begin to proliferate. Activated T cells may then migrate to lymph vessels and travel to the bloodstream, where they are dispersed throughout the system. The majority of B cells stay in the lymph node, where they mature into antibody-secreting plasma cells. Lymphocyte recirculation and homing is regulated by binding interactions between various types of cell adhesion molecules (CAMs) including selectins, integrins, and addressins.<sup>3</sup>

### Tonsils

Tonsils are aggregates of lymphoid tissue located in the mouth and pharynx. The tonsils are strategically located at the entrance to the digestive and respiratory tracts, where they are likely to encounter microorganisms. Unlike lymph nodes, tonsils have no afferent (incoming) lymphatic vessels. They do have efferent lymphatic drainage so that activated lymphocytes from the tonsils can migrate to other lymphoid organs. Tonsils normally make an important contribution to

**FIGURE 9-2** Maturation of human blood cells showing pathways of cell differentiation from the pluripotent stem cell to mature granulocytes, monocytes, lymphocytes, thrombocytes, and erythrocytes. Production begins in embryo blood islands in the yolk sac. As the embryo matures, production shifts to the liver, spleen, and bone marrow. In an adult, nearly all hematopoiesis occurs in the bone marrow. The two major differentiation pathways are the myeloid pathway and the lymphoid pathway. The lymphoid pathway produces lymphocytes, whereas the myeloid pathway produces granulocytes, monocytes, platelets, and red blood cells.

FIGURE 9-3 Principal organs of the lymphoid system.

immune function; however, they may occasionally become chronically infected, and surgical removal (tonsillectomy) is then helpful.

### Spleen

The spleen is located under the diaphragm on the left side of the body. It measures about 12 cm in length, which makes it the largest of the lymphoid organs. The spleen provides an important filtering function for blood. The tissue structure of the spleen is similar to that of lymph nodes. It is surrounded by a capsule of connective tissue and filled with a meshwork of red pulp and localized masses of lymphocytes called *white pulp*. Within the red pulp are many blood-filled sinuses lined with macrophages. Macrophages filter out foreign substances and old red blood cells. Lymphocytes located in the white pulp are in a strategic position to come in contact with blood-borne antigens. Lymphocytes thus activated in the spleen can migrate to other lymphoid organs via efferent lymphatics. Like the tonsils, the spleen does not have afferent lymphatic vessels.

### Lymph Nodes and Lymphatics

The lymphatic vessels begin with small, closed-ended lymphatic capillaries in direct contact with the interstitial fluid surrounding cells and tissues. Lymphatics pick up fluid and proteins that escape the bloodstream and return them to the circulation by way of the right lymphatic and thoracic ducts. Along the way from lymphatic capillaries to the thoracic ducts, lymph flows through specialized structures called *lymph nodes*. Lymph nodes are found primarily in the neck, axilla, thorax, abdomen, and groin. They often become tender and palpable when responding to foreign invaders. Projections of connective tissue called *trabeculae* divide the interior of the lymph node into compartments (Figure 9-4). Lymph nodes contain large numbers of B and T lymphocytes and macrophages. B cells are the predominant cell type in

the cortical follicles, whereas T cells predominate in the area just under the cortex called the *paracortex*. The central region, or medulla, is populated by macrophages, B cells, and plasma cells (antibody-secreting B cells). Lymph fluid flows through the nodes in a way that allows these immune cells to filter, detect, and react to foreign material.

### Peyer Patches

Aggregates of lymphoid tissue can be found scattered throughout the body, particularly in the gastrointestinal, respiratory, and urogenital tracts. These structures are analogous to lymph nodes, but they are not encapsulated and contain primarily B cells. Because of their location, these structures have been termed *mucosa-associated lymphoid tissue* (MALT) or *gut-associated lymphoid tissue* (GALT). These structures, also called *Peyer patches*, are of particular importance in producing antibodies to microorganisms that tend to invade mucosal tissue.

## LEUKOCYTES

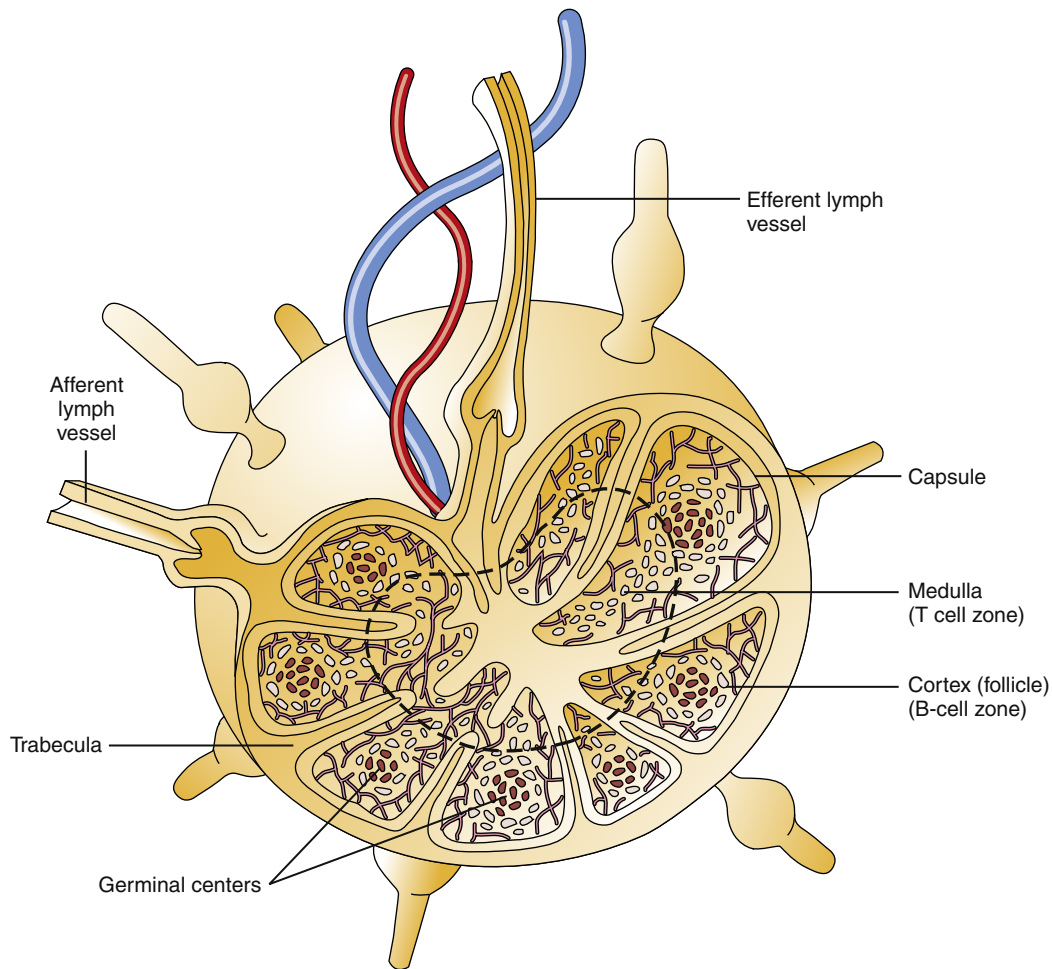

Leukocytes, or WBCs, are the primary effector cells of the immune system. Each of the different types of leukocytes found in blood has a special job to perform. All leukocytes, as well as red blood cells and platelets, are formed from stem cells in the bone marrow. Stem cells can produce daughter cells that differentiate along several different pathways to become mature cell types (see Figure 9-2). The first major differentiation step produces either a lymphoid stem cell or a myeloid stem cell. Lymphoid stem cells further differentiate to form B and T lymphocytes and NK cells. Myeloid stem cells can produce a variety of cell types, including red blood cells, platelets, monocytes, dendritic cells, and **granulocytes**. Monocytes that migrate from the blood into tissues are called *macrophages*. Granulocytes are further divided into neutrophils, eosinophils, and basophils. Basophils are precursors of the mast cells located in tissues.

Development of these cell types is influenced by hormonal signaling molecules called *cytokines*. Cytokines are produced locally in the bone marrow and by various other cells. Certain cytokines stimulate stem cell growth, proliferation, and differentiation into particular cell types. The WBC count and differential are commonly measured laboratory tests used to evaluate white blood cell production. A normal WBC count and differential are shown in Table 9-1. The general features of each of the WBC types are summarized in the following sections.

### Neutrophils

Neutrophils are circulating granulocytes that are also known as *polymorphonuclear leukocytes* (polys or PMNs). They account for 60% to 80% of the total WBC count. Neutrophils normally have two to five nuclear lobes and coarse, clumped chromatin. Neutrophils arise from bone marrow stem cells and undergo several stages of maturation. As illustrated in Figure 9-2, these stages, from least to most mature, are myeloblast, promyelocyte, metamyelocyte, band cell, and mature segmented neutrophil.

Neutrophils stored in the bone marrow outnumber, by about 10-fold, the quantity of circulating neutrophils. An adult produces more than  $1 \times 10^{11}$  neutrophils each day.<sup>1</sup> These stored neutrophils are released into the circulation, where they have a half-life of 4 to 10 hours. Neutrophils that are not recruited into tissues within about 6 hours undergo programmed cell death (apoptosis). Neutrophils are early responders to an acute bacterial infection and arrive in large numbers very quickly. They are phagocytes that engulf and degrade microorganisms. Circulating neutrophils have receptors on their cell surfaces that enable them to bind to endothelial cells in areas of inflammation. These receptors, called *L-selectins*, allow neutrophils to adhere and roll along

**FIGURE 9-4** Schematic drawing of a typical lymph node showing afferent and efferent lymph vessels, as well as B-cell and T-cell zones.

**TABLE 9-1 LEUKOCYTE PROPORTIONS AND FUNCTIONS**

TYPE	PERCENTAGE*	ROLE IN INFLAMMATION
Neutrophils	60-80	First to appear after injury, phagocytosis
Lymphocytes	20-30	Immune response
Monocytes (macrophages)	3-8	Phagocytosis
Eosinophils	1-6	Allergic reactions, parasite infection
Basophils	0-2	Contain histamine, mediate type I allergic reactions, initiate inflammation

\*Total white cell count, 3500 to 10,000/ $\mu$ L.

the capillary surface.<sup>5</sup> Other interactions between neutrophil integrin receptors and extracellular matrix then facilitate movement of neutrophils through the capillary wall and into the tissue. Neutrophils are attracted to areas of inflammation and bacterial products by **chemotactic** factors such as complement fragments and cytokines. This process is discussed in more depth in the section titled Inflammation.

Initially during an acute infection, **neutrophilia**, or an increase in the number of circulating neutrophils, occurs as the bone marrow releases stored neutrophils. As neutrophils are consumed and demand exceeds production, an increase in the number of immature (band) neutrophils occurs. Bands are identified by their lack of nuclear segmentation. This increase in band cells is referred to as a “shift to the left of normal” (Figure 9-5). Traditionally, the band count has been used to differentiate bacterial from viral infections, and a greater shift to the left is viewed as a more severe infection. The utility of using the band count for these purposes has been called into question because the specificity is poor.<sup>6</sup>

Neutrophils produce potent chemical mediators that enable them to destroy microorganisms. Numerous toxins released by neutrophils have been identified, including oxidizing free radicals, defensins, and proteolytic enzymes, such as elastase.<sup>7</sup> Because of the ability to generate free radicals and release enzymes, neutrophils can cause extensive damage to normal tissue during their inflammatory response.

### Eosinophils

**Eosinophils** are circulating granulocytes that have two nuclear lobes and stain brilliant red-orange with eosin. They constitute 1% to 6% of the total WBC count. Eosinophils mature in the bone marrow (3 to 6 days) and circulate in the blood for about 30 minutes. They have a half-life of 12 days in tissue. Eosinophils arise from myeloid stem cells and undergo a maturation process similar to that of neutrophils.

**FIGURE 9-5** Inflammatory cytokines stimulate the release of more immature neutrophils, called *bands*, from the bone marrow. An increased ratio of bands to mature neutrophils is termed a “shift to the left.” This clinical term evolved from the practice of listing bands to the left of mature cells on the laboratory report sheet. A shift to the left is commonly seen with acute bacterial infections.

Eosinophils are particularly associated with an increase in number during allergic reactions and infection by intestinal parasites. The role of eosinophils in allergic reactions is less well characterized than that of mast cells. Eosinophils are recruited into areas of inflammation by the chemokine eotaxin, which is produced by epithelial cells.<sup>3</sup> Eosinophils release inflammatory chemicals, such as lysosomal enzymes, peroxidase, major basic protein, and cationic protein. The primary function of eosinophils is to kill parasitic helminths (worms). Helminths are too large to be phagocytosed by neutrophils or macrophages, and their exterior is resistant to attack by complement or mast cell products. Eosinophils produce specialized molecules such as major basic protein and eosinophil cationic protein, which may be more effective against helminths.<sup>1</sup> Eosinophils recognize helminths that have been opsonized (coated) with IgE antibody. They bind to the IgE and then release their stored chemicals onto the surface of the opsonized helminth. Parasitic infections are a significant problem in much of the world, with one third of the population being affected.

### Basophils and Mast Cells

**Basophils** are granulocytes characterized by granules that stain blue with basophilic dyes. Basophils account for 0% to 2% of the total leukocyte count. Basophils are structurally similar to mast cells. Mature basophils circulate in the vascular system, whereas mast cells are found in connective tissue, especially around blood vessels and under mucosal surfaces. When stimulated by cytokines, mature basophils can migrate to connective tissue, but once in the tissue, basophils (then called mast cells) do not reenter the circulation.

The average basophil life span is measured in days, whereas mast cells can live for weeks to months. Mast cells and basophils have IgE

receptors that allow them to bind and display IgE antibodies on their cell surfaces. When an appropriate stimulus occurs, such as antigen binding to the IgE antibodies, mast cells and basophils release granules (**degranulate**) containing proinflammatory chemicals.

Mast cell and basophil granules contain histamine, platelet-activating factor, and other vasoactive amines that are important mediators of immediate hypersensitivity responses (Figure 9-6). Degranulation of mast cells and basophils begins the inflammatory response that is characteristically associated with allergic reactions. Mast cells and basophils are also involved in wound healing and chronic inflammatory conditions (see Chapter 10).

**FIGURE 9-6** Micrograph of a mast cell showing a large yellow nucleus and numerous packets containing histamine, which are colored red. (Roitt IM, Brostoff Male, DK: *Immunology*, ed 3, St Louis, 1993, Mosby.)

**FIGURE 9-7** Scanning electron micrograph of a macrophage (red) attaching to and phagocytizing bacteria (yellow). ## Monocytes and Macrophages

Monocytes and macrophages, like granulocytes, originate from bone marrow stem cells of the myeloid lineage. Monocytes are immature macrophages and account for about 5% of the total WBC count. Monocytes circulate in the bloodstream for about 3 days before they enter tissue to become macrophages. As described earlier, macrophages are found in widespread locations as part of the mononuclear phagocyte system.

Phagocytosis by macrophages is similar to that by neutrophils except that neutrophils are short-lived and die in the process of fighting infection. Macrophages, in contrast, may live for months to years and can migrate in and out of tissue. Macrophages are more efficient phagocytes than neutrophils and can ingest several times as many microorganisms (Figure 9-7). Macrophages are capable of cell division and may proliferate at the site of inflammation.

Macrophages are covered with a variety of receptor proteins on their cell surface (Figure 9-8). Some of these receptors help macrophages locate antigens that have been coated by antibodies. These receptors are called *Fc receptors* because they bind to the part of an antibody called the *constant fragment*, or *Fc*. Macrophages also have receptors for the complement component C3b. Complement, like antibodies, can coat an antigen and make it more recognizable to macrophages. Coating of antigen by antibodies or by complement is called **opsonization**. Macrophages have receptors that help them recognize bacteria directly. These innate pattern-recognition receptors bind to particular molecules prevalent in the bacterial cell wall. For example, mannose receptors and numerous Toll-like receptors on macrophages allow them to recognize common microbial structures (see Figure 9-8).

**FIGURE 9-8** Macrophage surface receptors. Macrophages display receptors for a number of extracellular molecules that enhance their function such as cytokines, complement, selectins, integrins, and antibody (*Fc*). Toll-like receptors recognize patterns of microbial components and trigger intracellular signaling cascades in the macrophage. *IFN-γ*, Interferon- $\gamma$ ; *IL*, interleukin; *LPS*, lipopolysaccharide.

**FIGURE 9-9** Macrophages are of central importance in initiating inflammation and recruitment of other leukocytes to areas of need. Macrophages secrete a variety of cytokines that induce inflammation and chemotaxis. Some macrophage cytokines stimulate the growth and differentiation of other white blood cell types.

Other receptors, called *selectins* and *integrins*, help macrophages adhere to capillary walls, and enter and move through tissue. Integrin receptors bind to proteins in the extracellular matrix and help macrophages target or “home” to certain areas.

In addition to their phagocytic function, macrophages have important secretory function. Some of the substances secreted by macrophages are cytokines, which help to coordinate the activities of other immune cells (Figure 9-9). Macrophage cytokines include IL-1, IL-6, IL-12, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ). These cytokines promote inflammation, as well as the activity of other WBCs, including neutrophils and lymphocytes (see the section titled Cytokines and Chemokines).

Macrophages secrete a number of proteins that are important in wound healing. Some of these proteins are enzymes that degrade tissue (e.g., collagenase, elastase, plasminogen activator), whereas others stimulate the growth of new granulation tissue (e.g., fibroblast growth factor, angiogenic factors).

A third function of macrophages, in addition to phagocytosis and secretion, is antigen presentation. For T cells to recognize antigens, these antigens must first be processed and presented on the surface of an antigen-presenting cell such as dendritic cells, macrophages, or B cells. Macrophages accomplish this task by first engulfing the antigen, then processing it into smaller pieces, and finally combining the antigen fragments with special membrane proteins. The antigen complexes are then displayed on the macrophage cell surface, where T lymphocytes (T helper cells) can recognize and become activated by them. Antigen presentation is explored in more detail in the section titled Specific Adaptive Immunity.

### Dendritic Cells

Dendritic cells are derived in the bone marrow from the same progenitor cells that produce monocytes and macrophages (Figure 9-10) and are structurally and functionally similar to macrophages (Figure 9-11). Dendritic cells derive their name from an unusual shape that has extensive projections from the surface. Dendritic cells are located

throughout the body as part of the mononuclear phagocyte system. They function primarily as antigen-presenting cells, capturing antigen in tissues and then migrating to lymphoid areas to present antigen to T cells. Some types of dendritic cells produce chemical messengers called *type I interferon* (IFN- $\alpha$  and IFN- $\beta$ ) in response to viral infections. Type I interferons suppress the viral replication machinery in nearby cells and help stop the local spread of the virus.

### Lymphocytes

The three major types of lymphocytes are NK cells, T cells, and B cells. NK cells function in innate immunity, whereas B and T lymphocytes are the cells responsible for specific, adaptive immunity. B and T cells have the capacity to proliferate into “memory cells,” which provide long-lasting immunity against specific antigens. NK, T, and B cells are derived from a common lymphoid stem cell in the bone marrow that is stimulated to proliferate by bone marrow–derived cytokines including IL-7. T cells then migrate to the thymus, where they mature. B cells remain in the bone marrow during their maturation phase. NK cells are released into the circulation. Together NK, B, and T lymphocytes compose approximately 20% of the total WBC count. Mature NK cells circulate and populate the spleen, whereas T and B cells migrate to secondary lymphoid organs.

Structurally, lymphocytes are small, round cells with a large, round nucleus. Despite their relatively uniform appearance, lymphocytes can be sorted into a number of subpopulations based on characteristic surface proteins called *cluster of differentiation (CD) markers*. More than 350 different CD markers have been identified thus far, with different immune cell types displaying different combinations on their cell surfaces. Lymphocytes have many complex and differentiated functions, and only the major lymphocyte subtypes are discussed in this chapter.

### Natural Killer Cells

NK cells have no B- or T-cell markers and are not dependent on the thymus for development. NK cells are considered to be innate immune

**FIGURE 9-10** Development of dendritic cells from a myelomonocytic progenitor cell and precursor cells in common with monocytes and macrophages. (Redrawn from Nairn R, Helbert M: *Immunology for medical students*, ed 2, St Louis, 2007, Mosby, p 81.)

**FIGURE 9-11** Dendritic cell morphology. **A**, Light micrograph of resting dendritic cells from the bone marrow. **B**, Scanning electron micrograph of a mature dendritic cell showing extensive projections of the cell membrane. (From Abbas AK, et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 115. Courtesy of Dr. Y-J Liu, MD, Anderson Cancer Center, Houston, TX.)

cells because they can effectively kill tumor cells and virally infected cells without previous exposure. NK cells kill their target cells by a mechanism similar to that used by cytotoxic T cells. Unlike T and B cells, NK cells can respond to a variety of antigens and are therefore not specific for a particular antigen. Like neutrophils and macrophages, NK cells recognize antibody-coated target cells with their Fc receptors. This process is called *antibody-dependent cell-mediated cytotoxicity* (ADCC). NK cells also target virally infected cells and tumor cells. They are thought to be able to recognize virally infected cells through innate pattern-recognition receptors; however, only those cells that lack certain normal self proteins on their cell surface (major histocompatibility complex I, or MHC I, proteins) are targeted for killing.<sup>3</sup> Cells that display normal MHC I on their cell surfaces are protected from NK cell cytotoxicity, but will be susceptible to killing by cytotoxic T cells that recognize viral antigen displayed on the MHC I proteins.

### T Lymphocytes

Two major classes of T lymphocytes can be differentiated by the presence or absence of CD4 and CD8 surface proteins (Figure 9-12). T cells that possess CD4 proteins (CD4<sup>+</sup>) are called T helper cells. T helper cells interact with antigens presented on the surface of specialized antigen-presenting cells such as dendritic cells, macrophages, and B cells. T helper cells can be further divided into subclasses called T<sub>H</sub>1, T<sub>H</sub>2, and T<sub>H</sub>17 based on the types of cytokines that they secrete (Figure 9-13). The T<sub>H</sub>1 subset of T helper cells develops in response to IL-12 from macrophages and, when activated, secretes cytokines that activate other T cells (IL-2) and macrophages (interferon- $\gamma$  [IFN- $\gamma$ ]). T<sub>H</sub>2 cells develop in response to IL-4 from activated T helper cells and secrete cytokines that stimulate B-cell proliferation and antibody production (e.g., IL-4, IL-5, IL-10, IL-13).<sup>8</sup> The T<sub>H</sub>17 subclass, as its name implies, secretes IL-17, which is a proinflammatory cytokine.

**FIGURE 9-12** Two major classes of T lymphocytes can be differentiated by CD markers on the cell surface. T helper cells have CD4 markers, whereas cytotoxic T cells have CD8 markers. CD4 cells can be further differentiated into  $T_H1$ ,  $T_H2$  and  $T_H17$ , which secrete different cytokines. CD8 cells are cytotoxic T cells.

**FIGURE 9-13** Three types of T helper cells,  $T_H1$ ,  $T_H2$ , and  $T_H17$  secrete different cytokines.  $T_H1$  cells secrete interleukin-2 and interferon- $\gamma$ , which stimulate T cells and macrophages.  $T_H2$  cells secrete a number of cytokines that affect B cells.  $T_H17$  cells secrete a proinflammatory cytokine, IL-17.  $T_H1$ ,  $T_H2$ , and  $T_H17$  cells inhibit the release of cytokines from one another and thus help regulate the immune response. *IFN- $\gamma$* , Interferon- $\gamma$ ; *IL*, interleukin.

**FIGURE 9-14** Scanning electron micrograph of activated T cells (blue) and a tumor cell (red). (From Nairn R, Helbert M: *Immunology for medical students*, ed 2, St Louis, 2007, Mosby, p 3. With permission from BSIP Lecaue and the Science Photo Library.)

The presence of CD8 protein (CD8<sup>+</sup>) on a T lymphocyte characterizes it as a cytotoxic T cell. Cytotoxic T cells recognize antigen presented in association with surface proteins that can be found on all nucleated cells of the body (MHC I). When a CD8<sup>+</sup> T cell recognizes a foreign antigen on a cell, the antigen-presenting cell is killed, thus the name *cytotoxic T cell*. CD8<sup>+</sup> cells are particularly effective at destroying virally infected cells, foreign cells, and mutant cells (Figure 9-14). Proliferation of activated cytotoxic T cells is enhanced by T helper cell cytokines, particularly IL-2.

### B Lymphocytes

B cells are distinguished from other lymphocytes by their ability to produce antibodies and by the presence of antibody-like receptors (B-cell receptors [BCRs]) on their cell surfaces. Each B cell carries many copies (100,000) of identical BCRs and is able to respond to only 1 antigen **epitope**<sup>9</sup> (Figure 9-15). B cells require “help” from T helper cells to respond efficiently to protein antigens. B cells bind and internalize the protein antigen, and then process and present it to T helper cells. T cells that recognize the presented peptides bind to and are activated by the B cell. T-cell help is provided to the B cell by physical cell-to-cell contact through coreceptor binding, as well as through secreted cytokines. Some B cells can respond to nonprotein antigens such as bacterial carbohydrate and lipid molecules. B-cell responses to nonprotein antigens are T-cell independent because T cells respond only to peptide antigens. Exposure to antigens stimulates B cells to mature into antibody-secreting plasma cells and memory cells. B-cell memory cells form a reserve of cells that can quickly mount an immune response on subsequent exposure to the same antigen. Memory cells are able to survive for months to years, whereas most antibody-secreting plasma cells live for only a few days. Plasma cells are able to secrete antibodies at a rate of about 2000 per second per cell.<sup>9</sup> Memory B cells and plasma cells develop in germinal centers located in secondary lymphoid organs, including the lymph nodes and spleen. A few long-lived plasma cells inhabit the bone marrow and continue to produce a low level of antibody, which provides immediate protection on second exposure to the same antigen. The mechanisms of specific adaptive immunity are explored later in the chapter.

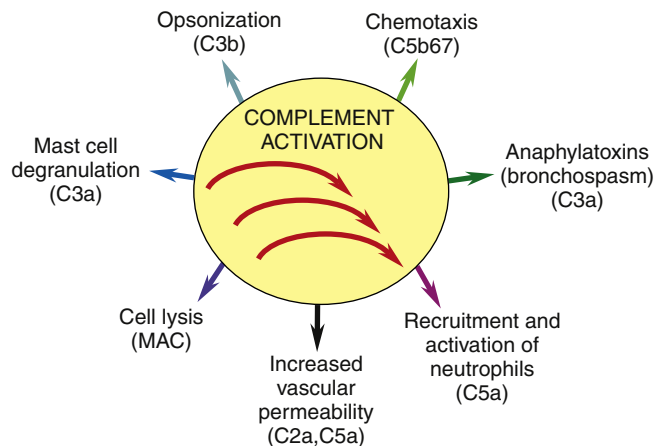

## CHEMICAL MEDIATORS OF IMMUNE FUNCTION

### Complement

The complement system consists of about 20 plasma proteins that interact to enhance inflammation, chemotaxis, and lysis of target cells.

**FIGURE 9-15** Typical B cell showing a number of identical B-cell receptors (BCRs) on the cell surface. Each BCR is capable of binding to two identical antigen epitopes.

**FIGURE 9-16** Activation of the complement cascade results in the production of products that perform a variety of functions to augment the immune response. MAC, Membrane attack complex.

Complement proteins are synthesized in the liver and by macrophages and neutrophils. They circulate in the blood in an inactive form. Activation of the complement cascade occurs via three different pathways: classical, alternative, and lectin. In all three pathways, the inactive complement proteins are converted to their active form in a sequence of reactions. Major actions of complement proteins include cell lysis, facilitation of phagocytosis by opsonization, inflammation, and chemotaxis (Figure 9-16).

**FIGURE 9-17** Complement cascade. The cascade is activated by the first complement molecule, C1, which binds an antigen-antibody complex. This event begins a domino effect, with each of the remaining complement proteins performing its part in the attack sequence. The end result is a hole in the membrane of the offending cell and destruction of the cell. Activation of the complement cascade results in the formation of membrane attack complexes that insert in the cell membrane. These pore-like structures allow sodium and water influx, which causes the cell to swell and rupture. (Redrawn from Schindler LW: *Understanding the immune system*, NIH Pub. No. 92-529, Bethesda, MD, 1991, U.S. Department of Health and Human Services, p 11.)

The classical pathway is usually triggered by IgG or IgM antibody-antigen complexes. The alternative pathway can be initiated on first exposure to an antigen. Lipopolysaccharide, in bacterial cell walls, and bacterial endotoxin are effective triggers of the alternative pathway. In the classical pathway, an antibody hooked onto an antigen combines with C1, the first of the complement proteins. This step sets in motion a domino effect called the *complement cascade* (Figure 9-17). The alternative pathway begins with the activation of C3. The alternative pathway can be activated on first exposure and is part of the innate immune response.<sup>10</sup> The lectin pathway also can be triggered on first exposure. Lectin is a circulating biomolecule that binds mannose on bacterial cell walls and triggers complement activation at C2 and C4. C3 spontaneously degrades into active C3b fragments in plasma. If microbial cell surfaces are present, the C3b fragment can bind directly to the microbe. Two other complement proteins, factors B and D, combine with C3b to initiate the alternative pathway. C3 is the most important and plentiful of the complement proteins. C3 divides into two fragments called C3a and C3b. C3a is a proinflammatory protein that causes histamine release from mast cells, contraction of smooth muscle, and increased endothelial cell permeability. C3b initiates the next step in the cascade by cleaving C5 into its active fragments C5a and C5b. Complement protein fragment C5a is both a powerful inflammatory chemical and a potent chemotactic agent. C5a chemotaxis stimulates neutrophils and monocytes to migrate to the inflamed tissue. C5a also activates

neutrophils by triggering their oxidative activity and increasing their glucose uptake.

The C5b fragment combines with C6, C7, C8, and multiple units of C9 to form a large porelike structure (C5b6789) called the *membrane attack complex*. The membrane attack complex has a direct cytotoxic effect by attacking cell membranes and disrupting the lipid bilayer. This action allows free movement of sodium and water into the target cell, which causes it to rupture (see Figure 9-17). The complement system is a potent inflammatory and cytotoxic system that is carefully regulated by eight known inhibitory factors.<sup>3</sup> Normal host cells produce membrane and inhibitory plasma proteins that prevent complement binding to their surface (e.g., C1 inhibitor, protein S).

### Kinins

Bradykinin and kallidin are two of the many kinins present in the body. Kinins are small polypeptides that cause powerful vasodilation. They are especially active in the inflammatory process. The kinin system is linked to the clotting system via the Hageman factor (XII) and is activated with the activation of clotting.<sup>1</sup> The first step in this process is the conversion of factor XII to factor XIIa (Figure 9-18). Factor XIIa converts a substance known as prekallikrein to kallikrein. Kallikrein converts precursor substances known as kininogens to kinins. The most prevalent is kallidin, which is then converted to bradykinin. Activated kinins cause increased vascular permeability, vasodilation, and

**FIGURE 9-18** Common linkage of the kinin and coagulation systems through the activation of factor XII (Hageman factor). *XIIa*, Activated factor XII.

smooth muscle contraction. Kinins are also responsible for pain, which is one of the classic signs of inflammation.

### Clotting Factors

The blood coagulation cascade's major purpose is to stop bleeding. It is also intimately involved in inflammation and triggering of the kinin system. The key linkage between the inflammatory response and clotting system is activated factor XII (Hageman factor) (see Figure 9-18). (The blood coagulation cascade is discussed in detail in Chapter 14.) Activation of the coagulation cascade results in the formation of insoluble fibrin strands, which provide an effective barrier to the spread of infection. Clot formation also activates the fibrinolytic cascade, which splits fibrin proteins. Some of the fibrin degradation products are chemotactic signals for neutrophils.

### Cytokines and Chemokines

Cytokines are polypeptide signaling molecules that affect the function of other cells by stimulating surface receptors. Cytokines function in a complex intercellular communication network. WBC cytokines have previously had many names, including monokines, lymphokines, and interleukins, depending on their cell of origin. The number of known cytokines is large and growing; they can be grouped according to their source and function (Table 9-2).

Macrophages and T helper cells are the main sources of immune system cytokines. These cytokines generally function as chemotactic factors (chemokines), antiviral factors, mediators of inflammation, hematopoietic factors, or activation signals for specific types of WBCs. The major cytokines produced by macrophages are shown in Figure 9-9. T helper cells of the  $T_H1$  subclass produce two main cytokines, IL-2 and IFN- $\gamma$ , whereas  $T_H2$  cells secrete a number of cytokines important to B-cell function (see Figure 9-13). Cytokines function to enhance and coordinate both innate and specific immune defenses. They are discussed in more detail in the sections that follow.

#### KEY POINTS

- The primary lymphoid organs are the thymus and bone marrow. T cells develop in the thymus, whereas B cells develop in the bone marrow. Mature lymphocytes then migrate to secondary lymphoid structures, including the spleen and lymph nodes.

- Blood cells are produced in the bone marrow in response to specific hematopoietic growth factors. Granulocytes (neutrophils, basophils, eosinophils) and monocytes (macrophages) are phagocytic cells that provide innate protection. Lymphocytes (B cells, T cells) are specific cells that react only to particular antigens. NK cells are lymphocytes that lack T cell and B-cell markers and function in innate immune responses. Other blood components produced by bone marrow are erythrocytes and platelets.
- Neutrophils are the most numerous WBCs in blood. A large storage pool lies in the bone marrow and can be mobilized in response to antigen. Neutrophils are the predominant WBC type mobilized in early infection. They migrate to the area by following chemotactic factors and perform phagocytic functions. During acute bacterial infection, larger numbers of immature neutrophils (bands) are released into the blood, which is termed a "shift to the left." Chronic infections may produce a shift to the right with more segmented neutrophils than normal.
- Monocytes located in tissue are called *macrophages*. Monocytes and macrophages are distributed in strategic locations throughout the body, including the skin, lungs, gastrointestinal tract, liver, spleen, and lymph. Macrophages are powerful phagocytes and are predominant in late inflammation.
- T lymphocytes, the major effectors of cell-mediated immunity, interact with specific antigens on cell surfaces. They are important in immunity against foreign, infected, or mutant cells. In addition, they secrete cytokines that boost the immune response of B cells and other cell types. T cells are composed of two main subtypes called CD4 (helper) and CD8 (cytotoxic). B lymphocytes are the major effectors of antibody-mediated immunity.
- The complement system consists of about 20 plasma proteins that interact in a cascade fashion to produce important mediators of inflammation and immunity. The cascade can be activated by microbial antigens (alternative pathway) or by antigen-antibody complexes (classical pathway).
- Cytokines are peptide factors released by immune cells. They have many functions, including as inflammatory mediators, chemotaxins, intercellular communication signals, growth factors, and growth inhibitors. Macrophages and lymphocytes are important sources of immune cytokines.

### INNATE DEFENSES AND INFLAMMATION

Inflammation occurs when cells are injured, regardless of the cause of the injury. It is a protective mechanism that also begins the healing process. The inflammatory response has three purposes: (1) to neutralize and destroy invading and harmful agents, (2) to limit the spread of harmful agents to other tissue, and (3) to prepare any damaged tissue for repair. Inflammatory reactions increase capillary permeability such that phagocytic cells, complement, and antibodies can leave the bloodstream and enter tissues where they are needed.

Five cardinal signs of inflammation have been described: (1) redness (rubor), (2) swelling (tumor), (3) heat (calor), (4) pain (dolor), and (5) loss of function (functio laesa). The suffix *-itis* is commonly used to describe conditions associated with inflammation. For example, appendicitis, tendonitis, and nephritis refer to inflammation of the appendix, tendon, and kidney, respectively.

Inflammation can be caused by many conditions. Any injury to tissue will evoke an inflammatory response. Injury can arise from sources outside the body (exogenous) or from sources inside the body (endogenous). Surgery, trauma, burns, and skin injury from chemicals are all examples of exogenous injuries. Endogenous injuries may result from tissue ischemia such as myocardial infarction or pulmonary embolism.

Inflammation and infection are commonly confused because they often coexist. Under normal conditions, infection is always accompanied by inflammation; however, not all inflammation involves an

TABLE 9-2 SELECTED IMMUNE CYTOKINES AND THEIR FUNCTIONS

CYTOKINE	ORIGIN	FUNCTION
IFN- $\alpha$	Macrophages and induced by RNA or DNA viruses and by single- or double-stranded polyribonucleotides	Inhibits virus replication, toxic to cancer cells, stimulates leukocytes, facilitates NK cell activity, produces fever, increases B- and T-cell activity
IFN- $\beta$	Fibroblasts and induced by RNA or DNA viruses and by single- or double-stranded polyribonucleotides	Inhibits virus replication, toxic to cancer cells, facilitates NK cell activity, produces fever
IFN- $\gamma$	T cells ( $T_H1$ and $CD8^+$ ) and NK cells	Inhibits virus replication, promotes antigen expression, activates macrophages, inhibits cell growth, induces myeloid cell lines, promotes B cell switch to IgG
IL-1	Mononuclear phagocyte	Stimulates T cells and macrophages, induces acute phase reaction of inflammation, produces fever; similar to TNF and endogenous pyrogen
IL-2	T helper cells ( $T_H1$ )	Promotes growth of T cells, enhances function of NK cells, assists T-cell maturation in thymus and B-cell proliferation
IL-3	T cells, endothelial cells, fibroblasts, other cells	Induces proliferation and differentiation of other lymphocytes, pluripotent stem cells, mast cells, and granulocytes
IL-4	T helper cells ( $T_H2$ )	Promotes T-cell/B-cell interactions, promotes synthesis of IgE by B-cell and $T_H2$ cell growth, promotes mast cell and hematopoietic cell growth
IL-5	T helper cells ( $T_H2$ )	Promotes growth and differentiation of B cells to secrete IgA, induces differentiation of eosinophils
IL-6	Mononuclear phagocytes, T helper cells ( $T_H2$ ), tumors, and nonlymphoid cells (e.g., endothelium)	Promotes immunoglobulin secretion by B cells, induces fever, promotes release of inflammation factors from liver cells, promotes differentiation of hematopoietic stem cells and nerve cells
IL-7	Stromal cells in bone marrow	Stimulates immature lymphocytes to divide to produce B and T cells
IL-8	Macrophages	Enhances inflammation and chemotaxis (CXCL chemokine)
IL-9	$T_H2$ cells	Enhances growth of T helper cells
IL-10	T cells and macrophages	Inhibits activation of macrophages and dendritic cells, inhibits IL-12 production
IL-11	Stromal cells in bone marrow	Stimulates platelet production
IL-12	Macrophages, dendritic cells	Enhances $T_H1$ cell activities and release of IFN- $\gamma$ by T cells and NK cells
IL-13	$T_H2$ cells	Stimulates B-cell growth and IgE production, suppresses macrophages
IL-14	T cells	Induces B-cell proliferation
IL-15	Macrophages (esp. viral infection)	Similar actions to IL-2, enhances proliferation of T cells ( $CD8$ ) and NK cells
IL-16	$CD8^+$ T cells	$CD4^+$ cell chemotaxis, suppresses viral replication of HIV
IL-17	$CD4^+$ T cells	Stimulates production of colony-stimulating factors and chemokines
IL-18	Macrophages in response to microbes	Increases NK cell proliferation and secretion of IFN- $\gamma$ by $T_H1$
IL-19	Macrophages	Stimulates macrophage IL-1 secretion
IL-20	Monocytes	Stimulates hematopoietic stem cells
IL-21	$T_H2$ and $T_H17$ cells	Activates B cells, stimulates production of NK cells
IL-22	$T_H17$ cells	Epithelial cells, increased barrier function, defensin production
IL-23	Macrophages and dendritic cells	Similar to IL-12, stimulates cell-mediated immunity
IL-24	Monocytes, T cells	Monocyte inflammatory cytokine production
IL-25	$T_H2$ cells	Stimulates production of cytokines by $T_H2$ cells
IL-26	T cells, monocytes	Uncertain
IL-27	Macrophages and dendritic cells	Inhibits $T_H1$ cells
TNF- $\alpha$	Macrophages	Induces leukocytosis, fever, weight loss, inflammation, necrosis of some tumors; stimulates lymphokine synthesis; activates macrophages; toxic to viruses and tumor cells
TNF- $\beta$	T cells	Inhibits B-cell and T-cell proliferation
G-CSF, M-CSF, GM-CSF	Macrophages, T cells, fibroblasts	Stimulates granulocyte and monocyte production in bone marrow
TGF- $\beta$	T cells, macrophages	Inhibits T cells, B cells, and macrophages
<b>Chemokines</b>		
CXCL 1-16	Macrophages and various cells in tissues	Recruitment of neutrophils, macrophages, lymphocytes
CCL 1-28	Macrophages and various cells in tissues	Recruitment of neutrophils, macrophages, lymphocytes

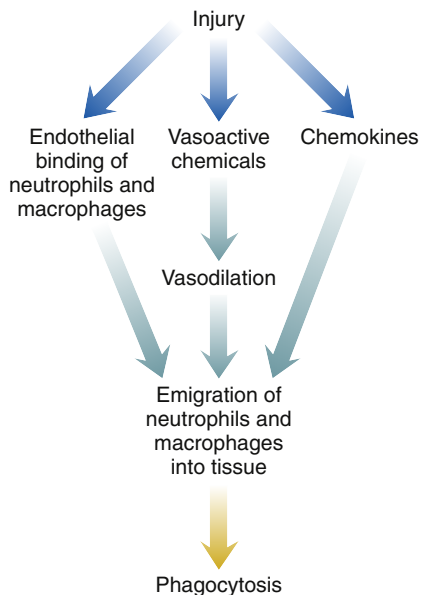

GM-CSF, Granulocyte-macrophage colony-stimulating factor; HIV, human immunodeficiency virus; IFN, interferon; IL, interleukin; NK, natural killer; TNF, tumor necrosis factor; TGF, transforming growth factor.

infectious agent. For example, inflammation can occur with sprain injuries to joints, myocardial infarction, sterile surgical incisions, thrombophlebitis, and blister formation as a result of either temperature extremes or mechanical trauma.

Inflammation may be categorized as either acute or chronic. Acute inflammation is short in duration, lasting less than 2 weeks, and involves a discrete set of events. Chronic inflammation tends to be more diffuse, extends over a longer period, and may result in the formation of scar tissue and deformity.

## INFLAMMATION

The inflammatory response is remarkably the same, regardless of the cause. Events in the inflammatory process include (1) increased vascular permeability, (2) recruitment and emigration of leukocytes, and

**FIGURE 9-19** Tissue injury stimulates the release of a number of chemical mediators that promote vasodilation, chemotaxis, and binding of neutrophils and macrophages to area capillaries. These events facilitate the emigration of neutrophils and macrophages into the tissue, where they begin phagocytosis.

(3) phagocytosis of antigens and debris. The inflammatory response is outlined in Figure 9-19.

### Increased Vascular Permeability

Immediately after injury, the precapillary arterioles around the injured area contract briefly, which causes a short period of vasoconstriction. The amount of vasoconstriction depends on the degree of vascular injury and is usually of little significance.<sup>11</sup> Vasoconstriction is followed by a prolonged period of vasodilation caused by release of chemical mediators from injured tissues.

Vasoactive chemicals released during the inflammatory process include histamine, prostaglandins, and leukotrienes (Table 9-3). Mast cells are an important source of these inflammatory chemicals. Mast cells in the area of injury degranulate and release packets of histamine and other inflammatory chemicals. One of the early actions of these mediators is to vasodilate and cause endothelial cells to begin contraction and rounding up, thus increasing capillary permeability. The greater volume of blood increases the amount of pressure within the blood vessels (hydrostatic pressure). The increased pressure along with increased permeability pushes fluid out of the blood vessels and into the surrounding tissue, contributing to local swelling. Because of the dilated blood vessels and open capillaries, more blood is carried to the injured area and contributes to the redness, pain, heat, and swelling of inflammation (Figure 9-20).

Histamine is an early mediator of this inflammatory response. It is such a potent vasodilator that it can cause significant reductions in blood pressure when released in excessive amounts. Histamine also causes bronchial constriction and mucus production. Histamine receptor blocking agents are widely used in allergic reactions, such as skin reactions and hay fever, to suppress these inflammatory actions of histamine.

Prostaglandins and leukotrienes are phospholipid compounds formed from arachidonic acid. The prostaglandins involved in inflammation contribute to vasodilation and increased permeability (Figure 9-21). Prostaglandin D<sub>2</sub> also acts as a chemotactic factor and stimulates neutrophil emigration. Prostaglandins cause pain by enhancing the sensitivity of pain receptors.<sup>11</sup> They arise from the cyclooxygenase pathway and can be inhibited by drugs that block enzymes in this pathway, such as aspirin.

Five types of leukotrienes are generated from the lipoxygenase pathway: A<sub>4</sub>, B<sub>4</sub>, C<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>. Leukotriene B<sub>4</sub> is a potent chemotactic agent that causes aggregation of leukocytes; leukotrienes C<sub>4</sub>, D<sub>4</sub>, and E<sub>4</sub>

\*Proteases and oxygen-based free radicals derived from neutrophils are believed to mediate a sustained increase in permeability by means of their damage to endothelial cells.

are inflammatory and cause smooth muscle contraction, bronchospasm, and increased vascular permeability.<sup>11</sup> Leukotriene receptor blocking agents can be used to inhibit the inflammatory actions of these chemicals.

During the early phase of tissue inflammation, platelets move into the site and adhere to exposed vascular collagen. The platelets release fibronectin to form a meshwork trap and stimulate the intrinsic

clotting cascade to help reduce bleeding. Platelets release a number of peptide growth factors, including platelet-derived growth factor and insulin-like growth factor.<sup>12</sup> Platelet-derived growth factor stimulates fibroblast cell proliferation, and insulin-like growth factor type 1 is a potent vascular endothelial cell chemotactic factor. Triggering of the blood coagulation cascade also occurs and leads to the formation of a fibrin clot. Usually, early clot formation occurs within several minutes. Fibrin is also deposited in the lymph system, where it causes lymphatic blockage. Lymphatic blockage “walls off” the area of inflammation from the surrounding tissue and delays the spread of toxins.

The vascular changes that occur soon after injury are beneficial to the injured tissue because irritating or toxic agents are diluted by the fluid that leaks out of the blood vessels into surrounding tissue. In addition, when the fluid leaves the blood vessels, the remaining blood becomes viscous (thick) and circulation is slowed, facilitating neutrophil emigration.

### Emigration of Leukocytes

As blood flows through areas of inflammation, neutrophils move to the sides of the blood vessels and roll along the endothelium of the vessel wall. This process is referred to as *margination* or *pavementing*. Normally, neutrophils slide past the capillary endothelial cells and do not stick. Injured tissue triggers the expression of adhesion molecules on the surface of endothelial cells, and the adhesion molecules bind to receptors on neutrophils (Figure 9-22). These receptors, called *selectin* and *chemokine receptors*, help neutrophils stick and roll along the

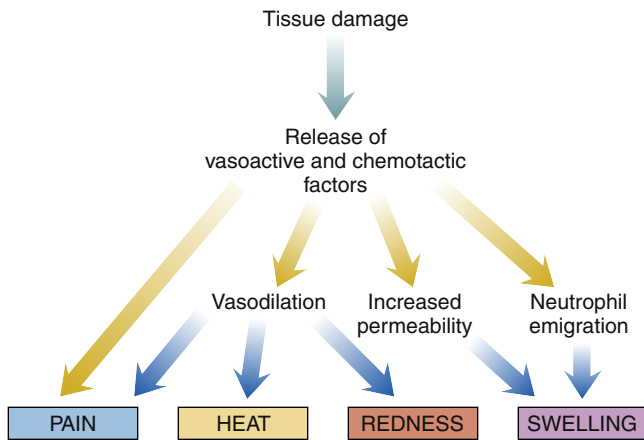

FIGURE 9-20 Cardinal signs of acute inflammation result mainly from vasodilation and increased vascular permeability.

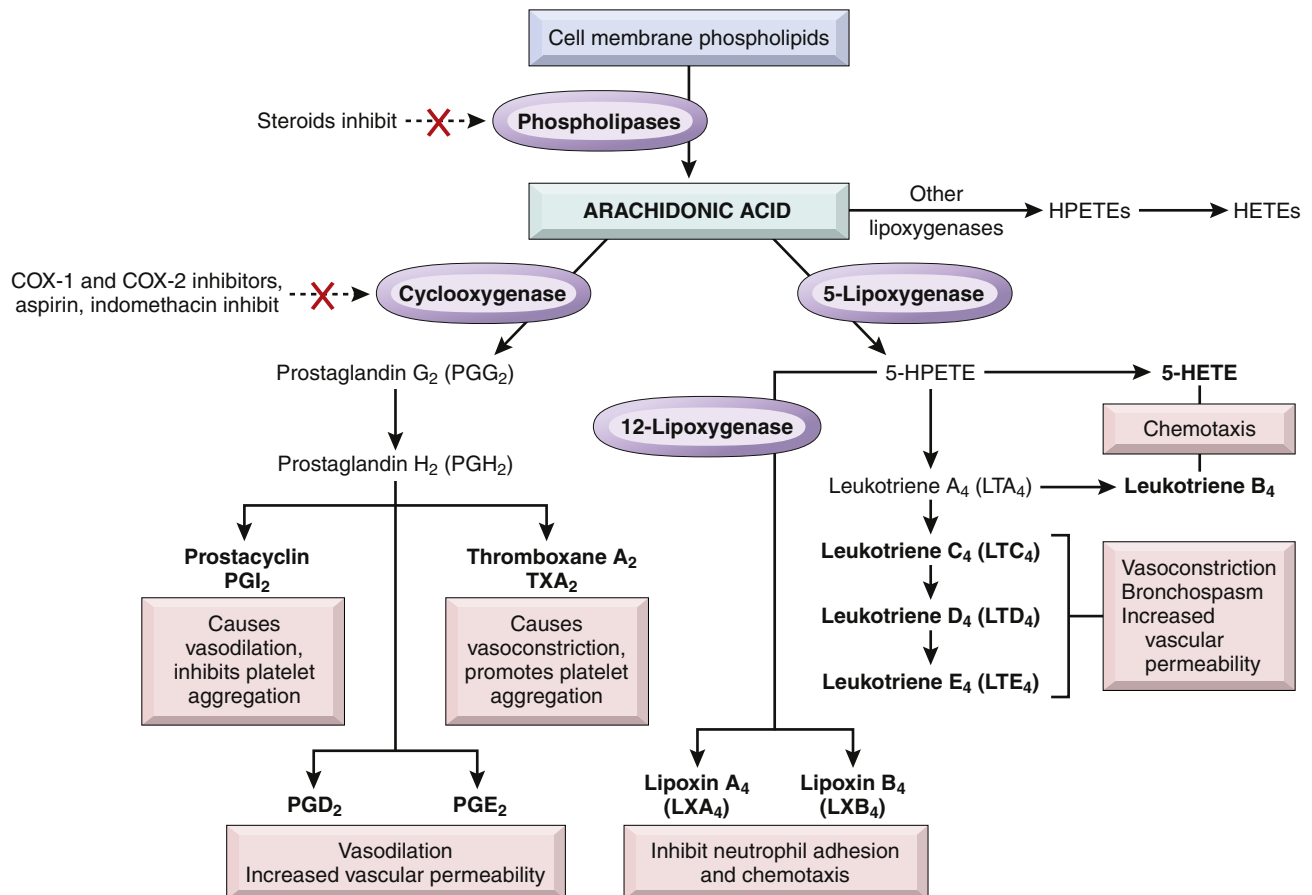

FIGURE 9-21 Generation of prostaglandins, thromboxane, and leukotrienes from arachidonic acid, and roles in inflammation. HETEs, Hydroeicosatetraenoic acids; HPETEs, hydroperoxyeicosatetraenoic acids. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 58.)

**FIGURE 9-22** Emigration of neutrophils from the bloodstream into tissue is mediated by receptor interactions with the capillary endothelium. With inflammation and injury, endothelial cells begin to express binding molecules on their cell surfaces (selectins). Leukocytes also have selectins, which can bind to endothelial adhesion proteins. The selectin interactions cause the leukocytes to stick and roll. Chemokines on the surface of endothelial cells interact with neutrophils (and macrophages) to increase the binding affinity of integrin receptors on leukocytes. Firm attachment and diapedesis through the capillary wall is facilitated by integrins, which allow the neutrophils to bind to endothelial cells and extracellular matrix and then pull themselves into the tissue. *IL*, Interleukin; *TNF*, tumor necrosis factor.

capillary endothelial surface.<sup>5</sup> Binding to and subsequent movement through the capillary wall are accomplished by another group of receptors called *integrins*. Chemokines present on the endothelium enhance the binding affinity of integrins so the neutrophil can attach firmly to the vessel wall. The process of passing through the blood vessel walls and migrating to the inflamed tissue is referred to as *emigration* or *diapedesis*. Diapedesis begins within a few minutes to hours of injury. Even though the spaces between endothelial cells lining the vessels are much smaller than the neutrophils, neutrophils are able to slide through a small portion at a time.

Neutrophils are attracted to the inflamed tissue by a process called **chemotaxis**. Biochemical mediators that attract neutrophils include bacterial toxins, degenerative products of the inflamed tissue, the C5a complement fragment, and other substances. Neutrophils are thus guided through the tissue to an area of injury by these chemicals. Because neutrophils are highly mobile, they are first on the scene to begin phagocytosis and production of collagenase to degrade dead tissue. Monocytes are slightly slower to arrive at an area of inflammation but use a similar process of emigration to gain entry to the area of tissue injury.

Eosinophils and NK cells also respond to the site of inflammation. Eosinophils are rich in chemical mediators such as hydrolases and peroxidases, which may contribute to the inflammatory process. NK cells are most effective in recognizing virally infected cells and opsonized microbes.

### Phagocytosis

Once neutrophils and monocytes (macrophages) enter the tissue, they begin the process of phagocytosis (Figure 9-23). These cells produce a wide variety of enzymes that digest protein structures. Some of these enzymes include lysozyme, neutral proteases, collagenase, elastase, and

acid hydrolases. Neutrophils and macrophages specialize in collagen and extracellular matrix degradation. Peptide bonds are cleaved in the extracellular matrix by collagenase, elastase, proteinase, and gelatinase. If the microbe is small enough to be internalized, it will be captured by the phagocyte and endocytosed into a phagosome. The phagosome then merges with a lysosome containing degradative enzymes. Large antigens may trigger the neutrophil to release its degradative enzymes extracellularly, causing damage to local tissues.

Oxidizing agents, the most destructive of the inflammatory cell products, are formed as a result of the phagocyte oxidase enzyme system on the membrane of the lysosome. Neutrophils are capable of synthesizing and assailing microorganisms with these oxidizing agents, which include the following oxygen radicals: superoxide ( $O_2^-$ ), hydrogen peroxide ( $H_2O_2$ ), and hydroxyl ions ( $OH^-$ ). Oxidizing agents directly attack cell membranes and thereby increase permeability. Nitric oxide products may also be produced by inducible nitric oxide synthase (iNOS) and function in concert with oxygen radicals to attack microbial molecules<sup>1</sup> (see Figure 9-23).

Because acute inflammation can cause severe tissue damage, it is not surprising that a system of inactivators is present. An important inhibitor of inflammatory damage is  $\alpha_1$ -antiprotease. Antiproteases are made in the liver and circulate continuously in the bloodstream.  $\alpha_1$ -Antiprotease inhibits the destructive proteases released from activated neutrophils. A deficiency of antiproteases can predispose an individual to inflammatory tissue destruction.

Neutrophils have a limited capacity to phagocytose foreign and inflammatory debris. Once the neutrophil leaves the circulation to fight an infection, it is unable to return and will die at the site. When phagocytosis is incomplete, a collection of dead neutrophils, bacteria, and cellular debris, called *pus*, may form at the site. Macrophages are left with the job of removing spent neutrophils and preparing the site

**FIGURE 9-23** Neutrophils and macrophages have a number of different receptors on their surface that enable them to bind to components of microbes or to opsonins like IgG and complement. Bound microbes are internalized into phagosomes that fuse with lysosomes containing numerous enzymes. Some of these enzymes degrade proteins (proteolytic), and others such as oxidase and inducible nitric oxide synthase (*iNOS*) produce free radicals that attack molecular bonds. When phagocytes are strongly stimulated or microbes are too large to internalize, the lysosomal enzymes may be activated or released at the cell surface, causing tissue damage and inflammation. *ROS*, Reactive oxygen species.

for healing. A predominance of monocytes and macrophages in an inflamed area signals the beginning of chronic inflammation.

### Chronic Inflammation

Macrophages are essential for wound healing because of their phagocytic and debridement functions. Macrophages produce proteases that help in removing foreign protein from the wound. Macrophages also release tissue thromboplastin to facilitate hemostasis and stimulate fibroblast activity. Macrophages secrete other peptide growth factors such as angiogenic factor, which encourages the growth of new blood vessels. Macrophages also phagocytose spent neutrophils and their degradation products so they do not interfere with healing. Prolonged inflammation may impair healing and result in an accumulation of macrophages, fibroblasts, and collagen, called a *granuloma*. Granulomas are usually evident on examination of tissue biopsy as clusters of macrophages surrounding particulate matter or resistant microbes such as *Mycobacterium tuberculosis*. Fibrosis and scarring are evident because normal parenchyma is replaced with fibrous tissue.

### HEALING

Healing of tissues following inflammation can occur in different ways over time. Usually the reconstructive phase begins 3 to 4 days after injury and persists for 2 weeks. The major cells involved in this phase include fibroblasts, endothelial cells, and myofibroblasts.

Fibroblasts are found all over the body and are thought to originate in mesenchymal primitive tissue. They synthesize connective tissue and are able to migrate. Fibroblasts are stimulated to make collagen, proteoglycans, and fibronectin by a variety of growth factors.<sup>12</sup> Macrophages secrete lactate and release growth factors that stimulate fibroblasts. Fibroblasts respond to contact and density inhibition and thereby facilitate orderly cellular growth. Myofibroblasts develop at the wound edge and induce wound contraction.

Endothelial cells grow into the connective tissue gel stimulated by angiogenic substances. They usually develop capillary beds from existing vessels. The new capillaries can transport nutrients for tissue repair and wound healing. However, because the new capillaries are leaky, they contribute to continuing edema.

Regeneration of damaged tissue into the preexisting tissue type requires survival of the basement membrane and tissue stem cells. Some cell types regenerate constantly; among these types are the epithelial cells of the skin and mucous membranes, bone marrow cells, and lymphoid cells. Cells of the liver, pancreas, endocrine glands, and renal tubules are also able to regenerate when necessary. However, some cell types, such as neurons and muscle cells, regenerate poorly. The maturation phase of wound healing occurs several weeks after the injury and may last for 2 years or more. It is characterized by wound remodeling by fibroblasts, macrophages, neutrophils, and eosinophils. Wound remodeling is the process of collagen deposition and lysis with debridement of the wound edges. During this phase the wound changes color from bright red to pink to whitish. As long as a wound is pink, the maturation phase is not completed.

## INFLAMMATORY EXUDATES

Exudate is fluid that leaks out of blood vessels, combined with neutrophils and the debris from phagocytosis. Exudates may vary in composition, but all types have similar functions, including (1) transport of leukocytes and antibodies, (2) dilution of toxins and irritating substances, and (3) transport of the nutrients necessary for tissue repair.

*Serous exudate* is watery, has a low protein content, and is similar to the fluid that collects under a blister. This type of exudate generally accompanies mild inflammation. With mild inflammation, the permeability of the blood vessels is not greatly changed. As a result, only some protein molecules escape from vessels, and serous exudate, with a low protein content, develops. Small amounts of red blood cells may leak into the serous fluid with capillary injury, resulting in a pink-tinged drainage called *serosanguineous* drainage.

With greater injury, more inflammation occurs and the blood vessels become more permeable. Because of this increased permeability, more protein can pass through the vessel walls. Fibrinogen, a large protein molecule, can pass through a highly permeable blood vessel wall. *Fibrinous exudate* is sticky and thick and may have to be removed to allow healing; otherwise, scar tissue and adhesions may develop. However, in some instances fibrinous exudate may be beneficial. In the case of acute appendicitis, fibrinous exudate may actually wall off and localize the infection and prevent its spread.

*Purulent exudate* is called pus. Purulent exudate generally occurs in severe inflammation accompanied by bacterial infection and is primarily composed of neutrophils, protein, and tissue debris. Large pockets of purulent exudate, called abscesses, must generally be removed or drained for healing to take place.

*Hemorrhagic exudate* has a large component of red blood cells. This type of exudate is usually present with the most severe inflammation. Hemorrhagic exudate occurs with severe leakage from blood vessels or after necrosis or breakdown of blood vessels.

## SYSTEMIC MANIFESTATIONS OF INFLAMMATION

Inflammation is associated with both localized and systemic signs and symptoms. The localized symptoms, described previously, occur with both acute and chronic inflammation. Depending on the magnitude of injury and the resistance of the individual, localized inflammation can lead to systemic involvement. Systemic responses include fever, neutrophilia (increased blood neutrophil count), lethargy, and muscle catabolism. Three macrophage-derived cytokines—IL-1, IL-6, and TNF- $\alpha$ —are responsible for most of the systemic effects of inflammation.<sup>11</sup>

TNF- $\alpha$  and IL-1 act on the brain to raise body temperature, induce sleep, and suppress appetite. By raising the set point for body temperature, these cytokines induce conservation of heat through vasoconstriction, as well as increased heat production through shivering. An increase in body temperature is assumed to improve the immune response; however, the mechanism is unclear. IL-1 is responsible for stimulating the release of neutrophils from bone marrow storage sites, thus producing neutrophilia. All three cytokines act on skeletal muscle to enhance protein catabolism, which provides an available pool of amino acids for efficient antibody production by plasma cells.

The liver is an important target for IL-1, IL-6, and TNF- $\alpha$ . These cytokines induce the liver to release a number of proteins collectively called *acute phase proteins*, which include complement components, clotting factors, and protease inhibitors (Figure 9-24). Two of the most important acute phase proteins are C-reactive protein (CRP) and serum amyloid A. CRP binds to phospholipids on bacterial cell membranes and acts as an opsonin to facilitate phagocytosis.<sup>3</sup>

**FIGURE 9-24** The liver is a target for three important cytokines: interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ). In response to these cytokines, the liver releases a number of proteins, collectively called *acute phase proteins*. *vWB*, von Willebrand factor.

When the liver releases acute phase proteins, the level of fibrinogen in the serum is increased. Fibrinogen coats the surface of red blood cells and reduces their charge so that they aggregate more readily. A blood test called the *erythrocyte sedimentation rate* (ESR, “sed rate”) provides a simple measure of the level of inflammation in an individual. Thus an elevated ESR indicates the presence of inflammation in the body. The greater the inflammation, the faster the red blood cells precipitate to the bottom of a test tube and the higher the ESR. The ESR is a nonspecific but clinically useful indicator of inflammation. Serum CRP activity is also used as a nonspecific indicator of inflammation in a manner similar to the ESR.

### KEY POINTS

- Previous exposure to foreign antigens is not required for the activation of innate immune defenses. Inflammation is an important aspect of innate immunity that involves localization of harmful agents and the movement of phagocytic cells to the area. Classic manifestations of inflammation are redness, swelling, heat, pain, and loss of function.
- Inflammatory chemicals such as histamine, prostaglandins, and leukotrienes are released from injured tissues, mast cells, macrophages, and neutrophils. These chemicals increase vascular permeability, vasodilate, and attract immune cells to the area (chemotaxis).
- Phagocytes migrate to the inflamed area, collect at the side of the vessel, and squeeze through into the tissue. Emigration of neutrophils and macrophages is facilitated by chemokines, selectins, and integrins present on the surface of endothelial cells and leukocytes. Neutrophils arrive in large numbers in acute bacterial infection and begin active phagocytosis. Neutrophils and macrophages produce proteolytic enzymes and oxidizing agents to destroy and digest antigens. With chronic inflammation, macrophages and lymphocytes predominate.
- Healing is mediated by growth factors released from platelets and immune cells that stimulate fibroblasts to divide and manufacture extracellular matrix proteins. Endothelial cells respond to angiogenic growth factors by forming capillary networks.

- Inflammatory exudate functions to transport immune cells, antibodies, and nutrients to the tissue and dilute the offending substances. Serous exudate is watery and low in protein; fibrinous exudate is thick, sticky, and high in protein; purulent exudate contains infective organisms, leukocytes, and cellular debris; and hemorrhagic exudate contains red blood cells.
- Systemic manifestations of inflammation include fever, neutrophilia, lethargy, muscle catabolism, increased acute phase proteins (CRP), and increased ESR. These responses are attributable to the IL-1, IL-6, and TNF- $\alpha$  released from macrophages and inflamed tissues.

## SPECIFIC ADAPTIVE IMMUNITY

The specific immune system uses remarkably effective and adaptive defense mechanisms capable of recognizing foreign invaders, destroying them, and retaining a memory of the encounter such that an even more effective defense (adaptive) will be achieved after subsequent exposure. As previously described, B and T lymphocytes are the cellular mediators of specific adaptive immunity. B cells are said to provide “humoral” immunity because the antibodies they produce are found in body fluids, or “humors.” T cells provide “cell-mediated” immunity because they recognize antigen presented on the surface of cells. To achieve immunity against specific antigens, B and T lymphocytes must be capable of recognizing an enormous range of foreign antigen yet not be reactive to self tissues.

Differentiation between self and nonself requires a complex lymphocyte development process in which self-reactive lymphocytes are destroyed and potentially useful lymphocytes are preserved. The MHC proteins have a primary role in enabling lymphocytes to react to foreign antigen while remaining tolerant to self antigen. Self-tolerance is not always effectively maintained, and impairment in self-tolerance can result in the development of autoimmune disorders (see Chapter 10).

## MAJOR HISTOCOMPATIBILITY COMPLEX

A cluster of genes on chromosome 6 is known as the **major histocompatibility complex (MHC)**. In humans, the MHC is also known as the **human leukocyte antigen (HLA)** complex. The proteins made by these genes are displayed on the surface of body cells and mark them as “self.” The MHC contains three classes of genes: I, II, and III (Figure 9-25). Class I and II genes code for proteins that display or “present” antigens on the surface of cells. Antigen presentation is a vital first step in the initiation of an immune response. T lymphocytes cannot recognize foreign antigens unless they are displayed on MHC proteins on the surface of a cell. Class III genes code for a variety of proteins, many of which are of importance to inflammatory reactions, including several complement proteins.

A great deal of **polymorphism** is found in the MHC class I and II genes, which means that it is very unlikely that one individual will have exactly the same MHC genotype as another individual. For example, three gene loci for MHC class I proteins (A, B, C) are located on each chromosome 6, and an individual inherits one chromosome from each parent for a total of six MHC class I genes. Each of these genes has many different forms (alleles) such that each of the six is likely to be different (Figure 9-26). Related individuals will generally be more similar but not identical (unless identical twins). The “matching” of MHC gene expression is an important consideration for tissue and organ transplantation. The closer the match is, the less likely that the host will reject the transplant. An individual also receives six MHC class II genes that are expressed on specialized antigen-presenting cells, such as dendritic cells, macrophages, and B cells. Because of the potential for

**FIGURE 9-25** Major histocompatibility complex genes are categorized into three main groups known as class I, II, and III. Class I and II genes code for antigen-presenting proteins, whereas class III genes code for a heterogeneous group of proteins, many of which serve immune functions.

**FIGURE 9-26** Each individual receives six class I major histocompatibility complex (MHC) genes including pairs of A, B, and C genes. One member of the pair is inherited from each parent. MHC class I genes are expressed in all nucleated cells of the body. Each individual also receives six class II MHC genes, three from each parent. However, class II proteins are composed of 2 polypeptide chains such that an individual may have 10 to 20 different MHC class II protein molecules. Class II MHC proteins are expressed on the surface of specialized antigen-presenting cells like macrophages, dendritic cells, and B cells. The structure of an individual’s MHC proteins is assessed to determine the “tissue type” when matching for tissue transplantation procedures.

mixing and matching of class II MHC gene products, an individual may express 10 to 20 different MHC class II proteins.<sup>1</sup> The MHC class I and II proteins on the surface of cells display both self and foreign antigens for inspection by T cells. Cells displaying foreign antigens stimulate an immune response, whereas those displaying self antigens do not. Genetic diversity in MHC gene expression is believed to be important to the preservation of a species because new pathogens are likely to encounter at least some individuals with MHC genotypes that can recognize and eliminate these pathogens.

## ANTIGEN PRESENTATION BY MHC

Nucleated cells in the body are capable of expressing MHC class I proteins on their cell surfaces, whereas only certain specialized cells, primarily dendritic cells, macrophages, and B cells, are able to express MHC class II proteins. Cytotoxic T cells are able to recognize antigen

**FIGURE 9-27** Nearly all nucleated cells of the body are able to process and display antigen in association with major histocompatibility complex (MHC) class I protein. The antigens come from the intracellular compartment, and a common source of foreign antigen is viral infection. The viral proteins made within the cell's cytoplasm are processed into peptide fragments in the proteasome and then enter the endoplasmic reticulum (ER) through TAP transporters. There they combine with MHC class I proteins. The MHC class I–antigen complex then shuttles to the cell surface within a vesicle. When the vesicle combines with the plasma membrane, the MHC class I–antigen complex is displayed on the cell surface. CTL, Cytotoxic T lymphocyte; TAP, transporter associated with antigen processing. (Redrawn from Abbas AK et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 131.)

bound to MHC class I proteins, whereas T helper cells recognize antigen bound to MHC class II proteins. T cells are screened during development in the thymus so that they recognize and are tolerant to self MHC proteins and do not react to self peptides displayed by self MHC proteins. This concept is explored further in the section Mechanisms of Cell-Mediated Immunity. The sources of antigen, mechanism of antigen processing, and T-cell response to antigen are quite different for MHC I and MHC II reactions.

### MHC Class I Presentation

Nucleated cells continuously produce MHC class I proteins on the rough endoplasmic reticulum (ER), where they are combined with various peptide fragments that are present in the cytoplasm. These peptides result from degradation of normal intracellular proteins. The MHC I–peptide complexes are cycled to the cell surface for inspection by T cells. Normal MHCs displaying normal cellular proteins are ignored by T cells. If abnormal proteins are produced in the cell, then the MHC I–peptide complex will be recognized as foreign and an immune response will occur. The peptide antigens presented on MHC I are of intracellular origin. Because viruses are able to gain access to cells directly, viral protein is a common source of foreign MHC class I antigens. Abnormal intracellular proteins produced by mutant cells may also be presented on MHC I, thus targeting them for immune destruction. Before intracellular proteins can be presented at the cell surface, they must be processed and transported to the ER, where they are combined with newly synthesized MHC class I protein (Figure 9-27). Peptide fragments are generated in the cytoplasmic proteasomes and escorted through the ER by special transporters called *transporters associated with antigen processing* (TAPs). The TAPs are located near

the MHC I complexes on the ER membrane and target the peptides to the MHC I–binding cleft. The MHC I–binding cleft can accommodate peptide fragments of 8 to 11 amino acids<sup>1</sup> (Figure 9-28). The MHC I–antigen complexes then travel to the cell membrane, where they are displayed. Recognition of foreign antigen in association with the MHC I protein on the cell surface targets the presenting cell for destruction by cytotoxic T cells. When the cytotoxic T cell binds to the MHC I–antigen complex, it is stimulated to release enzymes and pore-forming proteins (perforins) that lyse the target cell. Cytotoxic T cells can only recognize an antigen if it is physically bound to an MHC class I molecule. Cytotoxic T cells are thus said to be MHC class I restricted.

### MHC Class II Presentation

MHC class II proteins are used to present antigens obtained from extracellular sources. Extracellular antigens must first be engulfed by the antigen-presenting cell. Cells of the monocyte-macrophage lineage, dendritic cells, and B cells are responsible for presenting antigen by MHC II. Macrophages and dendritic cells obtain foreign antigens by phagocytosis and are thus able to process and present a large number of different antigens. They are said to be “nonspecific” for this reason. B cells, on the other hand, are very particular about the antigens that they engulf. The antigen must specifically bind to the BCR to be ingested by a B cell. Each B cell has only one type of BCR and therefore processes and presents only one specific antigen. The specificity of the BCR corresponds to the antibody that the activated B cell will produce. The process of B-cell activation is explored in the section titled Mechanisms of Humoral Immunity.

After the antigen-presenting cell has ingested an antigen, it is degraded into fragments within the cellular phagosomes (endocytic vesicle). MHC

**FIGURE 9-28** Schematic (A) and ribbon (B) diagrams of the class I major histocompatibility complex molecule. Note that the peptide-binding cleft is formed from one polypeptide chain that restricts the size of peptide in the pocket to 8 to 11 amino acids. (From Abbas AK et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 123.)

II proteins are synthesized on the rough ER and pick up an antigen from the phagosome on their way to the plasma membrane (Figure 9-29). The class II MHC molecule is formed by two protein chains, and the binding cleft is more flexible than that of MHC I proteins (Figure 9-30). Peptides displayed by MHC class II proteins range in size from 10 to 30 amino acids.<sup>1</sup> The MHC II–antigen complexes are then displayed at the cell surface where T helper cells can detect them. T helper cells can only recognize a foreign antigen if it is physically bound to an MHC II protein. T helper cells are thus said to be MHC II restricted. Naive T cells located in lymph nodes are usually presented with antigen by dendritic cells. Dendritic cells populate the body surfaces and mucous membranes. When they engulf antigen, they break their tissue attachments and migrate to lymph nodes where they interact with T helper cells.

## MECHANISMS OF CELL-MEDIATED IMMUNITY

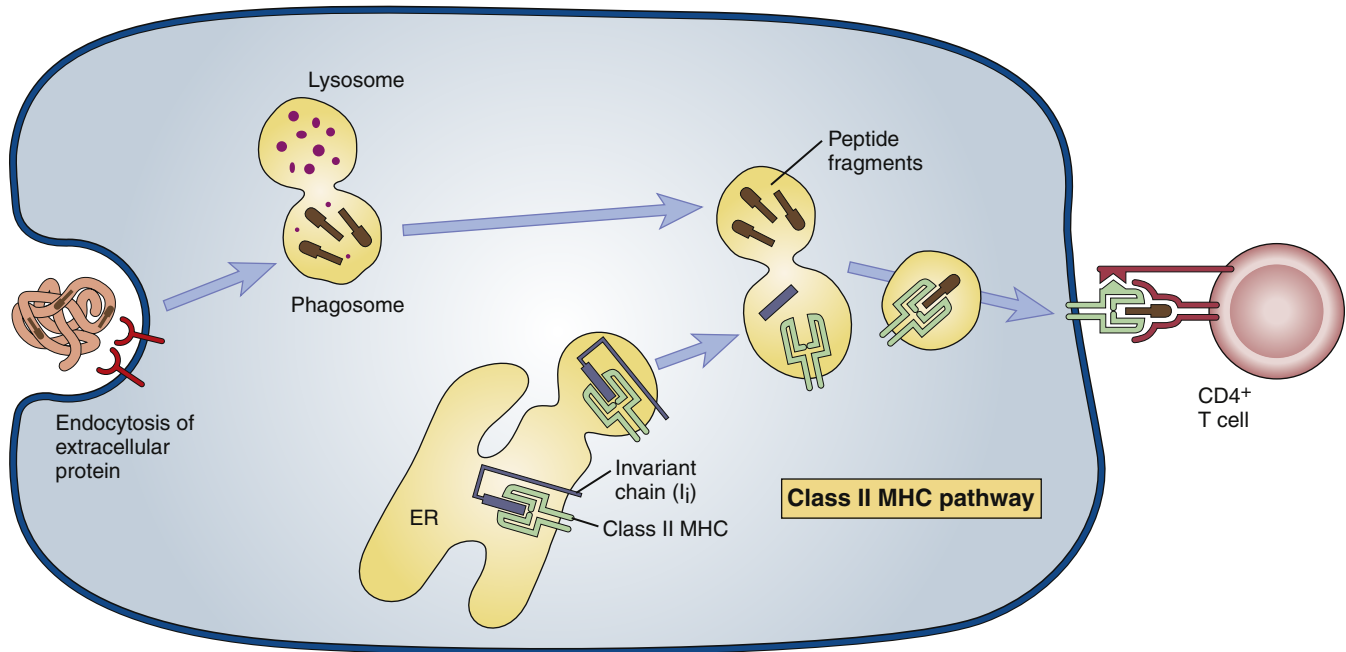

T cells are able to recognize foreign antigen displayed on the surface of antigen-presenting cells through specialized receptors called *T cell receptors* (TCRs). Each T cell has tens of thousands of identical TCRs on its cell surface.<sup>9</sup> Each T cell is thus able to recognize and respond to only a single antigenic epitope. This property is what makes T cells specific. The binding specificity of the TCR is randomly determined by recombination and rearrangement within the genes that code for the TCR-binding domain. Billions of different TCR amino acid sequences are possible, thus providing a tremendous diversity of potential antigen-binding specificities. This diversity increases the likelihood that one or more T cells will have the right TCRs to allow recognition of any of the various pathogens that may gain access to the body. The drawback to this random approach is that many TCRs will be useless or may bind self antigens. A rigorous selection process occurs in the thymus such

that self-reactive T cells are eliminated. This selection process requires at least two steps. In the first, T cells must demonstrate an ability to recognize self MHC proteins displayed on the surface of specialized thymic cells. Portions of the TCR must make appropriate contact with the MHC protein, or the T cell will not be able to respond to antigens presented on the cell surface.<sup>13</sup> The expression of either CD4 or CD8 on the T cell helps determine which class of MHC the T cell must fit. T cells that do not have functional TCRs undergo apoptosis in the thymus. The second requirement is that the TCR does not bind tightly to MHC proteins that are displaying normal self-derived peptides. Tight binding to self peptides also triggers the cell to initiate apoptosis. T cells that pass these tests migrate to secondary lymphoid tissues to await foreign antigens. Exposure of a T cell to its corresponding antigen results in expansion of the T cell into a clone of cells that all recognize the same antigen. This process ensures that useful T cells are maintained in the body as memory cells, whereas T cells that do not encounter antigen will not proliferate. Members of the T-cell clone migrate to lymphoid organs throughout the body, where they can respond rapidly should the same antigen reenter the system. The life span of mature T cells is long, but the numbers of memory cells in a clone will decline over time. However, intermittent exposure to the antigen is likely to occur and will stimulate proliferation and maintain immunity.

The two major types of T cells, T helper cells and cytotoxic T cells, react very differently to activation of their TCRs by antigen and are therefore described separately in the following sections.

### T Helper Cells (CD4<sup>+</sup>)

T helper cells recognize antigen in association with MHC class II molecules. The CD4 protein is needed to enable T helper cells to bind the MHC II protein, whereas the TCR recognizes the specific antigen being

**FIGURE 9-29** Only specialized cells are able to obtain extracellular antigen for processing and presentation in association with major histocompatibility complex (MHC) class II protein. These cells are primarily dendritic cells, macrophages, and B cells. The antigen is first engulfed into a vesicle called a *phagosome*, which fuses with a lysosome. Enzymes within the phagosome break the protein into pieces. MHC II molecules are synthesized on the endoplasmic reticulum (ER) and then transported to the phagosome in a vesicle. The binding cleft of the MHC II protein is complexed with a blocking protein to prevent it from retrieving peptide before it reaches the phagosome. The phagosome and vesicle fuse, and the MHC II loses its blocking protein and picks up an antigen peptide. The complex then migrates to the cell surface and combines with the cell membrane. The MHC II–antigen complex is then displayed on the cell surface. (Redrawn from Abbas AK et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 130.)

**FIGURE 9-30** Schematic (A) and ribbon (B) diagrams of the class II major histocompatibility complex (MHC) molecule. Note that the peptide-binding cleft is formed from 2 separate polypeptide chains, which allows the size of peptide in the pocket to be 10 to 30 amino acids. (From Abbas AK et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 125.)

**FIGURE 9-31** T helper cells can recognize and bind antigen in association with major histocompatibility complex (MHC) class II molecules. The T cell receptor (TCR) on the T helper cell binds to the antigen, and the CD4 protein recognizes the MHC class II protein. Binding is very specific because the TCR must match the antigen fragment precisely. Once binding is achieved, CD3 and  $\zeta$  proteins associated with the TCR are activated to initiate intracellular enzyme cascades. Major signaling pathways in activated T cells are shown. These ultimately result in activity of transcription factors and changes in gene activity. *AP-1*, Activation protein-1; *DAG*, diacylglycerol; *IP<sub>3</sub>*, inositol 1,4,5-trisphosphate; *NFAT*, nuclear factor of activated T cells; *NF $\kappa$ B*, nuclear factor kappa B; *PIP<sub>2</sub>*, phosphatidylinositol 4,5-bisphosphate; *PLC $\gamma$* , phospholipase C- $\gamma$ .

presented (Figure 9-31). Binding of the TCR to its corresponding antigen generates a signaling cascade in the cytoplasm of the T helper cell. The TCR is linked to this signaling cascade through another protein called CD3. Stimulation of CD3 results in the activation of enzymes (kinases) in the cytoplasm that mediate the production of two second messengers: inositol trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG) (see Chapter 3). Inositol trisphosphate initiates a rise in the concentration of intracellular calcium ions, which also act as second messengers to change cell behavior. Other protein kinases turn on the genes for cytokines (e.g., IL-2, IFN- $\gamma$ , and others), IL-2 receptors, and other cell surface proteins. As previously mentioned, the subtypes of T helper cells (i.e., T<sub>H1</sub>, T<sub>H2</sub>, and T<sub>H17</sub>) secrete somewhat different amounts and

types of cytokines. These cytokines provide the “help” that T helper cells give to other cells of the immune system. For example, IL-2 activates helper and cytotoxic T cells, NK cells, and macrophages; and IFN- $\gamma$  is a potent activator of macrophages. IL-2 and IFN- $\gamma$  are the main cytokines secreted by T<sub>H1</sub> cells. The cytokines secreted by T<sub>H2</sub> cells have stimulatory effects on B cells (e.g., IL-4, IL-5, IL-6, IL-13). In addition, when a B cell is serving as the antigen-presenting cell, T helper cells provide specific B cell help through direct cell-to-cell contact by receptor proteins.

### Cytotoxic T Cells (CD8<sup>+</sup>)

Cytotoxic T cells recognize antigen displayed in association with MHC class I protein. The CD8 protein is needed to facilitate binding to the

**FIGURE 9-32** Cytotoxic T cells are able to recognize and bind antigen in association with major histocompatibility complex (MHC) class I molecules. The T cell receptor on the cytotoxic T cell binds to the antigen, and the CD8 protein recognizes the MHC I protein. Binding is specific. Binding of a cytotoxic T cell to its target stimulates granules containing perforin and granzymes to migrate to the cell contact site. Perforins then assemble into pores on the target cell, through which the granzymes can enter the target cell cytoplasm. The granzymes interrupt the cellular DNA and trigger apoptosis. *FasL*, Fas ligand (CD95L); *ICAM*, intercellular adhesion molecule; *LFA*, leukocyte function–associated antigen; *TCR*, T cell receptor.

MHC I, whereas the TCR specifically recognizes the presented antigen (Figure 9-32). Binding of the TCR to its corresponding antigen triggers a number of responses in the cytotoxic T cell. This process is similar to that described for T helper cells and involves signal transduction through CD3 proteins. Antigen binding by cytotoxic T cells is not sufficient to activate them. Cytotoxic T cells also require costimulation by IL-2 cytokines. IL-2 is secreted primarily by activated T helper cells ( $T_H1$ ). Thus, cytotoxic T cells require cytokine “help” before they proliferate effectively. Cytokines are generally not enough to induce significant proliferation of target cells unless other coactivators are also presented by target cells (see Figure 9-32). Once activated, cytotoxic T cells proliferate into memory cells as well as effector cells. Effector cells accomplish their cytotoxic functions in two ways: through perforins and through CD95.

Perforins are proteins manufactured in the cytotoxic T cell and stored in granules (vesicles) within the cytoplasm. A number of proteolytic enzymes (granzymes) are located in the granules along with the perforins. Binding to the target cell causes the granules to migrate to the contact site, where they are released onto the target cell membrane. The perforins assemble into pores, which then allow the granzymes to move into the target cell. Granzymes degrade DNA and trigger target cell death (apoptosis).

Perforins function in a similar manner to the complement membrane attack complex previously described. It is not entirely clear how the cytotoxic T cell manages to escape injury in this process. Presumably, the perforins and granzymes are focused on the target cell in some controlled manner.

The CD95 protein on cytotoxic T cells is called the *CD95 ligand* (CD95L) or the *Fas ligand* (*FasL*).<sup>14</sup> It can bind specifically to complementary CD95 proteins (Fas) found on the surface of target cells.

Normal, healthy cells do not express CD95 and are not recognized by cytotoxic cells. Binding of the CD95L to CD95 triggers programmed cell death (apoptosis) of the target cell (see Figure 9-32). This system is thought to be particularly important in culling senescent cells and self-reactive lymphocytes.

## MECHANISMS OF HUMORAL IMMUNITY

B cells are responsible for antibody-mediated (humoral) immunity. B cells have two major subpopulations: memory cells and plasma cells. Memory B cells contain antigen receptors and function in a manner similar to memory T cells. In other words, memory of exposure to an antigen is stored in a clone of memory B cells. When exposed to the same type of antigen in the future, these memory B cells are able to respond rapidly with appropriate antibodies.

Some B cells differentiate into short-lived antibody-producing factories called *plasma cells*. All of the plasma cells in a clone secrete antibodies with identical antigen-binding specificity (monoclonal antibody). The secreted antibodies circulate in the blood and body fluids and bind specifically to the antigen that triggered their production. Once antigen is cleared, the population of plasma cells declines and the antibody concentration (titer) falls. However, some long-lived plasma cells migrate to the bone marrow where they continue to secrete a level of antibody sufficient to provide immediate protection upon the next exposure to the same antigen.<sup>1</sup>

### Antigen Recognition by B Cells

During their development in the bone marrow, B cells begin to express BCRs on their cell surfaces. The structure of the antigen-binding area on the BCR is randomly determined in a manner similar to that

**FIGURE 9-33** Two major classes of genes are responsible for coding for the variable (*V*) and constant (*C*) regions of an antibody. Variable genes code for the antibody region that binds to antigen. Constant genes form the stem of the antibody and are the same for any antibody of a given class.

described for TCRs. Each BCR is coded for by two distinct types of genes: one for the variable region, which makes up the antigen-binding site, and one for the constant region, which is essentially the same for all antibodies of a given class (Figure 9-33). The structure of the BCR bound to the B-cell surface is similar to the structure of IgM. Rearrangement, recombination, and selective splicing of variable region genes allow for great diversity of BCR binding specificities. The potential number of different BCR structures is enormous. Some of these combinations are unsuitable for BCR assembly, and it has been estimated that a typical human B-cell population can recognize approximately  $10^{11}$  different antigenic epitopes.<sup>3</sup> As is the case with T cells, useful B cells—ones activated by antigen—will be preserved in the body, whereas B cells that encounter no antigen will not proliferate. Binding of an antigen to the B cell results in the cross-linking of two surface BCR proteins and initiates an intracellular cascade. These cascades activate transcription factors within the B cell (NF $\kappa$ B, NFAT, AP-1) that regulate genes involved in proliferation and differentiation of the B cell (Figure 9-34).

The growth and activity of B cells that recognize protein antigens are regulated by helper T cells. Binding of antigen to the B cell's BCR is a necessary but insufficient stimulus to produce an effective B-cell clone in most cases. To be effectively activated, the B cell must engulf some of the antigen, process it, and present it to T helper cells. This activity will initiate cell-to-cell contact between the B cell and its complementary T-cell helper. A number of receptor interactions bind the T cells and B cells together, in addition to the main MHC II–TCR interaction, and include CD80–CD28 and CD154–CD40 (Figure 9-35). These cell-to-cell binding interactions stimulate intracellular signaling pathways in the B cell (and T helper cell) that promote clonal expansion and differentiation. B cells also require certain cytokines to proliferate and begin antibody synthesis. B cells are quite dependent on T cell help during the initial exposure to antigen (primary response), but less so on subsequent exposures. Some types of B cells have BCRs that bind nonprotein antigens, such as bacterial carbohydrates and lipids. Because T cells only recognize peptides, these types of B-cell responses are T-cell independent. Other costimulatory signals, such as the

complement fragment C3d on the antigen, may provide the necessary costimulation to achieve a B-cell response and antibody production. It is doubtful that memory cells are formed in this process<sup>1</sup> (Figure 9-36).

### Antibody Structure

Each antibody (immunoglobulin) molecule contains two identical light polypeptide chains joined by disulfide bonds to two identical heavy polypeptide chains. The geometry of the relationship between the heavy (H) and light (L) chains forms a Y-like structure. The H chains form the stem of the Y, and the L chains are on the outside of the arms of the Y. The antigen-binding end of the antibody is often called *Fab* (antigen-binding fragment), whereas the stem is called *Fc* (constant fragment). It is the structure of the constant fragment that determines the antibody class.

Antibodies are differentiated into five classes: IgG, IgM, IgA, IgD, and IgE. The structure and properties of the immunoglobulin classes are listed in Table 9-4. IgG and IgE circulate as single molecules or monomers; IgA is a dimer (two antibodies joined together); and IgM consists of five antibody molecules joined together to form a pentamer. IgD is found mainly on the B-cell plasma membrane and does not circulate in significant quantity. IgD is thought to participate in signal transduction across the B-cell membrane along with the BCR. Different antibody classes serve different immune functions in the body.

IgG, the most common type of immunoglobulin, accounts for 75% to 80% of all immunoglobulins. It is found in nearly equal proportions in the intravascular and interstitial compartments and has a long half-life of about 3 weeks.<sup>15</sup> IgG is the smallest of the immunoglobulins and can more easily escape the bloodstream to enter the interstitial fluid surrounding tissues.

IgM accounts for about 10% of circulating immunoglobulins and is predominantly found in the intravascular pool.<sup>15</sup> Its large pentamer structure prevents it from migrating through the capillary wall. IgM has a half-life of 10 days. It is the first immunoglobulin to be produced on exposure to antigens or after immunization and is the major antibody found on B-cell surfaces. IgM is the antibody class that works best to activate complement, which is important for cytotoxic functions in the immune system. Only one molecule of IgM is needed to activate complement, whereas two molecules of IgG are needed to activate complement.

IgA is produced by plasma cells located in the tissue under the skin and mucous membranes. IgA is primarily found in saliva, tears, tracheobronchial secretions, colostrum, breast milk, and gastrointestinal and genitourinary secretions. Transport of IgA into secretions is facilitated by binding to a secretory component produced by epithelial cells. This complex is called *secretory IgA* (Figure 9-37). The half-life of IgA is about 6 days.<sup>15</sup>

IgD is found in trace amounts in the serum (1%) and is located primarily on the membranes of B cells along with IgM. IgD has a half-life of 3 days.<sup>15</sup> IgD functions as a cellular antigen receptor acting to stimulate the B cell to multiply, differentiate, and secrete other specific immunoglobulins.

IgE is found bound by its Fc tail to receptors on the surface of basophils and mast cells (Figure 9-38). Only trace amounts of IgE are identified in the serum. IgE has a half-life of 2 days.<sup>13</sup> It has a role in immunity against helminthic parasites (worms) and is responsible for initiating inflammatory and allergic reactions (e.g., asthma, hay fever). IgE functions as a signaling molecule and causes mast cell degranulation when antigen is detected at the mast cell surface (see Chapter 10).

### Class Switching and Affinity Maturation

During the course of an antibody response, the class of antibody manufactured by a particular B cell usually changes. The antigen-binding

**FIGURE 9-34** Major signaling pathways in B cells. Cross-linking of two surface B-cell receptors initiates intracellular pathways that subsequently activate several transcription factors leading to altered gene activity. *AP-1*, Activation protein-1; *DAG*, diacylglycerol; *IP $_3$* , inositol 1,4,5-trisphosphate; *NFAT*, nuclear factor of activated T cells; *NF $\kappa$ B*, nuclear factor kappa B; *PIP $_2$* , phosphatidylinositol 4,5-bisphosphate; *PLC $\gamma$* , phospholipase C- $\gamma$ .

site does not change significantly and remains specific for the particular antigen that initiated the response. To switch class, the B cell selects different constant region genes to splice to the antigen-binding fragment. Thus, most B cells begin by using genes that code for IgM and IgD. Then the B cell switches to produce IgG, IgE, or IgA.<sup>16</sup> The triggers that determine the class of antibody a particular B cell will produce are not completely understood. Some cytokines have a role in class switching. For example, IFN- $\gamma$  promotes IgG production, IL-4 promotes IgE production, and transforming growth factor- $\beta$  (TGF- $\beta$ ) promotes IgA production<sup>16</sup> (Figure 9-39).

Knowledge about the normal progression of class switching may be helpful in determining whether an infectious process is acute or chronic. For example, a person newly infected with hepatitis B virus would be expected to have primarily IgM antihepatitis B antibodies, whereas in chronic or previous infection, B cells would switch class to produce mainly IgG. The relative concentrations of antihepatitis B IgM and IgG can help identify the time of onset of the infection.

Over the course of a B cell antibody response, the affinity with which the antibodies bind to antigen often increases. This is thought to occur because of a process called *affinity maturation* during which B cells undergo a hypermutation response producing random changes in the antigen-binding pocket of the BCR.<sup>17</sup> Those that bind antigen most avidly are stimulated to proliferate to a greater extent. Thus, the antibodies formed later in an immune response are more efficient in binding antigen at lower and lower concentrations. Affinity maturation occurs in specialized germinal centers in the lymph nodes.

### Antibody Functions

Antibodies function in a number of ways to enhance the localization and removal of antigens from the body. These functions can generally be summarized as precipitation, agglutination, neutralization, opsonization, and complement activation. Precipitation and agglutination occur because each arm of the immunoglobulin Y structure can bind an antigenic epitope. This structure allows the antibodies and antigens to bind together into large insoluble complexes that precipitate out of

**FIGURE 9-35** Activation of a B cell requires T helper cell “help.” This help is given through a number of cell-to-cell interactions via receptors, as well as through the secretion of cytokines that stimulate B-cell growth and differentiation.

**FIGURE 9-36** In response to nonprotein antigens (T-cell independent), B cells can be activated by complement opsonins on the microbial antigen. The complement-receptor (*CR*) interaction provides a costimulatory signal to the B-cell receptor–antigen signal. (Redrawn from Abbas AK et al: *Cellular and molecular immunology*, ed 7, Philadelphia, 2012, Saunders, p 161.)

body fluids (Figure 9-40). Agglutination refers to the same process as applied to cellular antigens rather than soluble antigens. It is efficient for phagocytic cells to find the large complexes and clear them from the system.

Antibodies can function as antitoxins by neutralizing bacterial toxin. This role is accomplished by binding the toxins before they can

interact with cells or by covering the active portions of the toxin and inactivating it. Some antibodies are effective opsonins. They coat the foreign antigen and thereby make it more recognizable to phagocytic cells. Macrophages, neutrophils, eosinophils, and NK cells have receptors for the Fc ends of the antibodies, which help them bind to opsonized antigens. Antibodies thus make the innate phagocytic processes

more efficient. Antibodies (IgG and IgM) bound to foreign antigens on cell membranes also can activate the complement cascade and trigger the release of chemotaxins and inflammatory mediators and the formation of the membrane attack complex.

## PASSIVE AND ACTIVE IMMUNITY

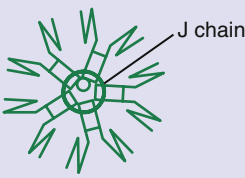

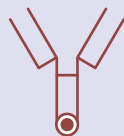

Immunity is a state of resistance against infection from a particular pathogen. Immunity is provided primarily by adequate levels of

circulating antibodies. Specific serum antibody concentrations can be measured by a blood test called an *antibody titer*. A sufficiently high antibody titer confers immunity by removing pathogens from the body before they cause signs and symptoms of illness. Immunity can be achieved passively or actively.

## Passive Immunity

Passive immunity involves the transfer of plasma (sera) containing preformed antibodies against a specific antigen from a protected or

immunized person to an unprotected or nonimmunized person. As a treatment, this is indicated in the following situations: (1) when B cell immunodeficiency exists; (2) when highly susceptible persons are exposed to a disease without adequate time for active immunization; and (3) when antibody injection may alleviate or suppress the effects of an antigenic toxin.

Passive transfer of antibodies can occur in a variety of ways. In the fetus, certain maternal IgG antibodies can cross the placental barrier. Most of the time these antibodies are beneficial and assist the newborn

in resisting pathogens. However, in some cases these antibodies can be damaging to the fetus, as occurs in hemolytic disease of the newborn. In this disorder, maternal antibodies bind to and lyse fetal red blood cells (see Chapters 10 and 13).

Antibody, complement, and macrophage function is deficient at birth. Newborns who are breast fed may have improved immune function. Newborns receive IgA antibodies through breast milk. The infant's immature gastrointestinal tract and low proteolytic enzyme activity do not destroy all protein, which allows some of the IgA antibodies to be

**FIGURE 9-38** Mast cells bind IgE antibody with their Fc receptors ( $Fc_{\epsilon}RI$ ) and display the IgE on the cell surface, where they are available to bind antigens.

**FIGURE 9-40** Large antigen (Ag)-antibody complexes tend to precipitate out of solution, which makes it easier for phagocytic cells to find and eliminate the antigens.

**FIGURE 9-39** Activated B cells undergo class switching from IgM to IgG, IgE, or IgA. Class switching is influenced by the presence of specific cytokines. *IFN*, Interferon; *IL*, interleukin; *TGF*, transforming growth factor. **FIGURE 9-41** Time phases in the immune response. The primary response takes much longer to develop and declines rapidly. On second exposure, a much quicker and greater antibody response is achieved.

absorbed. These antibodies assist the infant in defending against bacterial and viral infections during infancy. It has been hypothesized by some researchers that IgA antibodies in breast milk may modify the ways that proteins cross the infant's highly permeable intestinal mucosa and help prevent food allergies in later life (see Pediatrics Consideration box).<sup>18</sup>

Another method of passive immunity, called serotherapy, involves direct injection of antibodies into an unprotected person. The unprotected individual can receive a variety of substances, including immune globulin (human) such as IgG; specific immune globulins like hepatitis B immune globulin (human) or rabies immune globulin (human); plasma containing all human antibodies; or animal antibodies such as diphtheria antitoxin, tetanus antitoxin, botulism antitoxin, and antirabies serum.

Human immune globulin contains mostly IgG with traces of IgA and IgM. It is a sterile, concentrated protein solution that contains antibodies from the pooled plasma of many adults. It can be administered intramuscularly or intravenously, depending on the product. Human immune globulins may be used as prophylaxis against hepatitis B and as therapy for the following conditions: antibody deficiency disorders, pediatric acquired immunodeficiency syndrome, and hypogammaglobulinemia after bone marrow transplantation.

Animal antibodies are given in specific situations only when necessary because of significant allergic risks with animal sera. Patients who have specific animal allergies or a history of asthma, allergic rhinitis, or other allergies are highly susceptible to serum sickness, anaphylaxis, or acute febrile reactions. Serum sickness occurs when antibodies bind to foreign proteins in the injected sera, forming immune complexes that precipitate into capillaries and joints and cause inflammation. Animal antibodies may be given to ameliorate toxins or venoms, such as those associated with botulism, diphtheria, rabies, tetanus, and snake and spider bites.

### Active Immunity

Active immunity confers a protected state attributable to the body's immune response as a result of active infection or immunization. The development of active immunity requires the maturation and maintenance of memory B cells. On second exposure to antigen, the antibody response is much greater and more rapid (Figure 9-41). Exposure to antigen can be achieved through active infection or through immunization. The immune system must be exposed to the

antigen at a sufficient dose for an adequate length of time to stimulate an immune response.

Immunization tricks the immune system into responding to a perceived infection. Vaccines contain altered microorganisms or toxins that retain their ability to stimulate the immune system (antigenic properties) but do not have pathogenic properties. Vaccines can contain live and attenuated (altered) or killed infectious agents.

Vaccines that contain live, altered viruses or bacteria cause active infection but little injury to the vaccinated individual. These vaccines mimic a natural immune response, activating B and T cells, and provide good humoral and cellular immunity with longer lasting memory and often lifetime immunity. Examples of vaccines registered in the United States are listed in Box 9-1.

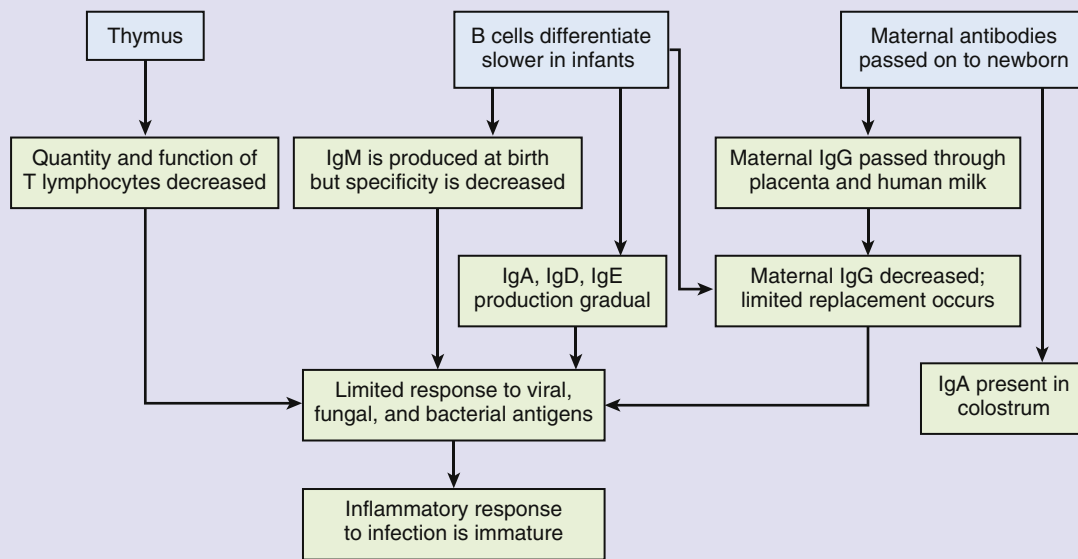

### KEY POINTS

- Specific immunity refers to functions of B and T lymphocytes. Each lymphocyte recognizes and reacts to only one particular antigen. On initial exposure to an antigen, lymphocytes undergo clonal expansion; consequently, many lymphocytes are distributed throughout the body to recognize and react to that particular antigen. These cells are called *memory cells*. Subsequent exposure results in a much faster and larger lymphocyte response.
- T lymphocytes are able to bind antigens only when they are displayed on the surface of cells. Cytotoxic T cells (CD8<sup>+</sup>) react to cells that have foreign MHC class I proteins on their surface. T helper cells (CD4<sup>+</sup>) bind to cells that have MHC class II proteins on their surface. MHC class II proteins are found on antigen-presenting cells (B cells, dendritic cells, and macrophages). These cells engulf foreign antigens and combine the antigens with MHC class II proteins on their cell surface.
- T cells, which mature in the thymus, have two major subgroups: T helper cells and cytotoxic T cells. T helper cells perform a central role in specific immunity. Activation of T helper cells results in secretion of the cytokines necessary for clonal expansion of T and B lymphocytes. Cytotoxic T cells locate and lyse abnormal cells through the actions of perforins.
- B and T cell functions are interdependent. T cells cannot respond to soluble antigens. B cells can process free antigen and present it to T cells. On first exposure, B cells are minimally activated by antigen unless they are stimulated by cytokines and coreceptors from T cells.

## PEDIATRIC CONSIDERATIONS

### Changes in the Immune System in Infants

The immune system is immature in an infant. Infants generally do not produce immunoglobulin (Ig) until the beginning of the second month of life and then production is slow (Hockenberry and Wilson, 2011). IgM is produced at birth but specificity is decreased, limiting the infant's ability to fight some antigens. IgM reaches adult levels by 9 to 12 months. IgA, IgD, and IgE begin gradual production in the second month of life and reach adult levels around early childhood.

Infants rely on maternal antibodies for production until their own immune system can mature. Maternal IgG is passed through the placenta and breast milk and for the first 3 months provides protection to the infant from antigens to which the mother has been exposed. IgG levels decline after 4 months and remain low until 6 months of age. Forty percent of infants achieve adult levels of

IgG by 1 year of age with the remaining reaching adult IgG levels by 4 years of age. IgA is present in the colostrum and believed to protect the infant's gastrointestinal tract until more IgA can be produced.

The thymus is large in infants and decreases in size over childhood. By the end of adolescence, the thymus shrivels and its function declines. The infant's immune response is immature resulting in a limited response to viral, fungal, and bacterial antigens in the infant.

Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children*, ed 8, St Louis, 2011, Mosby.

- B lymphocytes mature in bone marrow and lymph tissue. B cells have receptors on their surfaces that can bind antigens. Each B cell binds only one particular antigen. With appropriate T helper cell "help," antigen binding causes the B cell to divide (clonal expansion). Some of the daughter cells become plasma cells, which actively produce and secrete antibodies. Other daughter cells (memory cells) resemble the original cell and are distributed in lymph throughout the body. On subsequent exposure to the antigen, antibody production is rapid.
- Antibodies are proteins that specifically bind a particular antigen. Antibodies have several functions, including precipitation, agglutination, neutralization, opsonization, and complement activation.
- The five major antibody classes are IgG, IgM, IgA, IgD, and IgE. Antibody class is determined by the structure of the Fc portion. IgG is the most prevalent antibody class (75%). IgM is the first kind to be produced on antigen exposure. IgA is found primarily in body secretions. IgD is present on the B-cell membrane and functions in signal transduction. IgE binds to basophil and mast cell membranes and mediates inflammation and allergy.
- Administration of preformed antibodies confers passive immunity. Passive immunity provides immediate but temporary protection. Active immunity occurs when individuals are exposed to antigen that stimulates their own lymphocytes to produce memory cells. Active immunity confers long-term protection but may take several weeks to develop.

## INTEGRATED FUNCTION AND REGULATION OF THE IMMUNE SYSTEM

The innate and adaptive cells of the immune system work interdependently to protect the host from foreign antigens. Efficient interdependent function depends on a complex communication network that allows coordination of various immune components. One of the reasons that the immune system uses such a complex communication system is to ensure that normal healthy tissue is not injured. The destructive powers of the immune system must be tightly regulated to avoid undue tissue damage. These regulatory controls can be affected by aging and disease. The effects of aging on immune function are described in Geriatric Considerations: Changes in the Immune System. In the following sections, major events in the immune response to a new antigen are summarized and mechanisms of immune regulation are described.

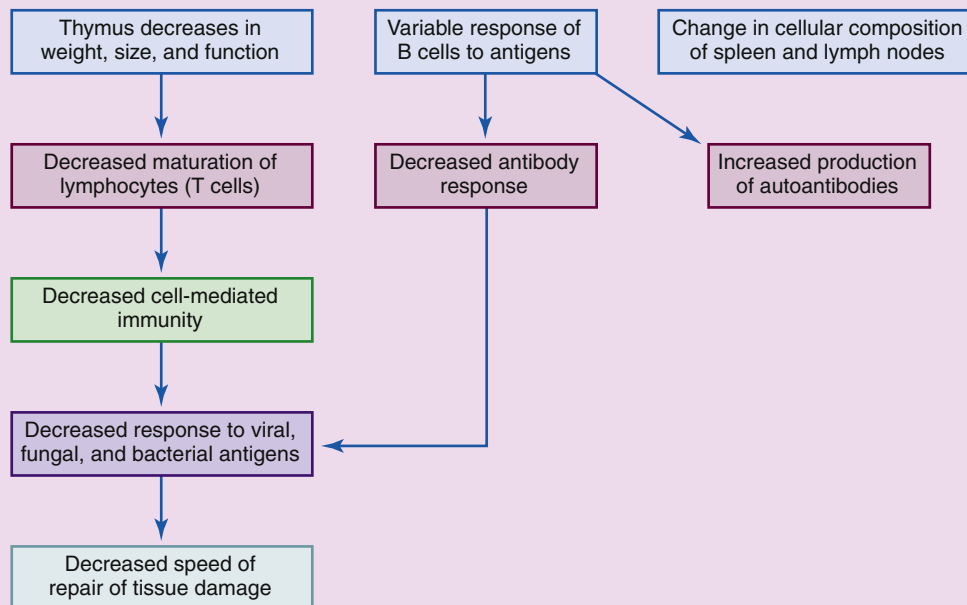

## INTEGRATED RESPONSE TO NEW ANTIGEN

A new antigen entering the body through the skin or mucous membranes will generally encounter tissue macrophages and dendritic cells stationed in strategic locations in the body as part of the mononuclear phagocyte system. Macrophages initiate activity of both innate and

**GERIATRIC CONSIDERATIONS*****Changes in the Immune System***

In the elderly, immune system function is altered with a decreased ability to respond to antigenic stimulation. The elderly are able to respond to infections with previously produced “remembered” antibodies. However, they are less able to respond to new antigens. As a result of these changes, there is decreased speed of repair of tissue damage and increased vulnerability to disease. The cells of the immune system in elderly persons are not able to proliferate or reproduce as effectively as those in younger persons. Although the total number of T cells remains the same, T-cell function is decreased. T cells are less able to

proliferate and have decreased cytotoxicity. Antibody production also decreases, especially antibodies such as IgG. There is also a rise in autoantibody production, which may influence the increase in autoimmune disease in the elderly. Thymus size decreases after puberty, causing a decline in thymic hormone production, decreased T-cell differentiation, and reduced T cell–related B-cell differentiation. Usually thymic hormone secretions stop after age 60 years. However, the role of thymus involution in elderly immune system changes is currently uncertain.

**FIGURE 9-42** Diagram showing the integrated function of a number of immune components. Note that the macrophage is at the center of many immune functions, including chemotaxis and inflammation, presentation of antigen to T cells, and phagocytosis of antibody-antigen complexes. *BCR*, B-cell receptor; *MHC*, major histocompatibility complex; *NK*, natural killer; *TCR*, T cell receptor; *WBC*, white blood cell.

specific immune components (Figure 9-42). First, activated macrophages release cytokines that initiate inflammation and chemotaxis. Some of these cytokines ( $\text{TNF-}\alpha$ ,  $\text{IL-1}$ ) induce capillary endothelial cells to express selectins and integrin ligands that help circulating leukocytes adhere to the capillary wall (margination) and then move into the tissue locations of antigens (emigration). Neutrophils, macrophages, and NK cells are attracted to the infected area by chemotactic factors, some of which are released by macrophages, whereas others are products of the complement cascade and tissue injury. The complement cascade is activated by the alternative pathway on primary exposure to an antigen. Complement fragments C3a and C5a are potent inflammatory agents. Complement activation also results in the formation of membrane attack complexes that directly lyse cellular antigens.

Tissue injury associated with the infectious process also activates both the coagulation cascade, which forms a fibrin meshwork to help

entrap and localize the agent, and the kinin system, which promotes vasodilation to increase blood flow to the area. A number of other vasodilatory chemicals may be released from mast cells in the area when they degranulate. These inflammatory chemicals lead to the classic manifestations of inflammation: warmth, swelling, redness, pain, and loss of function. Neutrophils, macrophages, and NK cells that emigrate to the tissue find their targets through innate receptors on their cell surfaces. Thus, they are as effective on first exposure to an antigen as they are on subsequent exposures. These receptors bind to complement opsonins and molecules expressed on microbes such as lipopolysaccharide and mannose. NK cells release cytotoxins onto their targets; macrophages and neutrophils phagocytose and digest their targets.

Dendritic cells and macrophages ingest protein antigens to process and present them to T helper cells in association with MHC class II proteins. Dendritic cells move from the tissue and travel to the T-cell

zones of lymph nodes. Activation of T helper cells results in the secretion of a variety of cytokines that boost the growth and activity of many immune cells, including macrophages, neutrophils, NK cells, cytotoxic and T helper cells, and B cells. Some of the cytokines produced by activated T cells and macrophages stimulate stem cells in the bone marrow to produce more WBCs (neutrophilia). Other cytokines affect the brain (inducing fever, lethargy, and anorexia) and the liver (producing acute phase proteins).

Meanwhile, certain B cells that encounter the antigen in the lymph nodes will have the correct BCR to bind and internalize it. Internalized antigen is then processed and presented to T helper cells in association with B-cell MHC II proteins. Complementary T helper cells then bind the B cell (via MHC II–TCR–CD4 interactions) and provide help to the B cell through the secretion of cytokines and through coreceptor-mediated second-messenger signals. B cells thus activated proliferate into a clone of cells, with some becoming memory cells and others becoming plasma cells. Plasma cells synthesize and secrete antibodies that specifically bind the antigen. Significant antibody production takes 10 to 14 days to occur, and the infected individual may have signs and symptoms of illness during this time.

Antibodies enhance the function of innate phagocytic cells by collecting antigen into large complexes that are easier for nonspecific cells to locate and phagocytose. Activated T helper cells also secrete cytokines such as IL-2 and IFN- $\gamma$ , which enhance the effectiveness of macrophages. After the antigen is cleared from the body, macrophages perform clean-up functions to remove inflammatory debris and dead neutrophils from the tissue. Macrophages also secrete enzymes and growth factors that stimulate tissue healing.

After the primary infection, B and T memory cells populate the body in much larger numbers and can mount an effective immune response very quickly on second exposure. The individual then has immunity for the particular pathogen because the antigen will usually be cleared from the system before significant illness occurs.

If the infectious agent is a virus, the sequence of events is somewhat different. Virally infected cells initiate cytotoxic T cell activity, which serves to kill the infected cells. Natural killer cells are important for detecting and destroying virally infected cells that have down-regulated their MHC I proteins, making themselves invisible to cytotoxic T cells.<sup>19</sup> Helper T cell responses and B-cell production of antibody to the virus occur by the processes previously described. However, neutrophils are less important in the response to viral infection.

## REGULATION OF IMMUNE FUNCTION

The mechanisms that promote inflammation and enhance immune function are much better understood than those that negatively regulate these processes. However, the mechanisms for inactivating an immune response and keeping inflammation in check are just as important. The destructive powers of the immune system can cause severe tissue damage unless carefully controlled.

Inhibition of immune responses occurs in a number of different ways. The process of inducing tolerance to self antigens is of primary importance. Because both T and B lymphocytes produce antigen-binding receptors by a random process, generation of self-reactive lymphocytes cannot be prevented. As previously mentioned, B and T cells are subjected to a rigorous selection process as they mature in the bone marrow and thymus, respectively. Several theories have been proposed to explain how self-reactive cells are detected and eliminated. The clonal deletion theory suggests that cells in the thymus process and present self antigens to developing T cells. Those lymphocytes that avidly bind self antigens are triggered to initiate programmed cell death (apoptosis).<sup>20</sup> There appears to be a critical time in fetal

development when self antigens begin to be differentiated from foreign antigens. Before that time, antigens introduced into the fetus will be viewed as “self” and tolerance to them will develop. By the same token, self antigens that are not presented to T cells in the thymus may be viewed as foreign. This situation may occur with certain so-called sequestered antigens as would be found in the interior of the eye or testes. If these antigens are later released by trauma, an immune response may be directed against them.

Clonal deletion may not rid the body of all self-reactive lymphocytes; therefore many safeguards are in place to prevent their activation. A complex process of antigen processing and presentation is required before T and B cells can be effectively activated. A certain “dose” of antigen must be present to achieve an effective response.<sup>1</sup> Antigen in very high concentration appears to cripple lymphocyte responsiveness and may initiate apoptosis. Self antigens may be present in such high quantity that reactive lymphocytes are killed. Because dendritic cells, macrophages, and B cells are important antigen-presenting cells, they can exert some influence on T cell activation by controlling the dose of antigen presented. Certain cytokines are known to influence the production of MHC proteins and can therefore alter the amount of antigen to which T cells are exposed.

B-cell activation requires a number of costimulatory signals from different sources. This complexity helps ensure that B cells will be activated appropriately. These signals include antigen binding to the BCR, T helper binding to the B cell MHC class II protein, expression of costimulatory ligands and receptors, and secretion of cytokines that promote B-cell growth and differentiation into memory cells and plasma cells. In addition, B cells are subject to negative feedback by circulating antibodies. Circulating IgG antibodies can bind to special receptors (Fc) on the B-cell membrane and inhibit B-cell activity.<sup>21</sup> As B cells switch from IgM to IgG and soluble IgG-antigen complexes begin to accumulate, the immune complexes can bind to the Fc receptors on B cells and block further antibody production (Figure 9-43).

Another mechanism of immune suppression is accomplished through cells that secrete inhibitory chemicals. Some subtypes of CD4 T cells may perform regulatory functions. They can inhibit immune responses by secreting immunosuppressive cytokines such as IL-10 and TGF- $\beta$ .

Control of the complement, kinin, and clotting systems is achieved by a number of inhibitory binding proteins. C1 inhibitor, a glycoprotein, inhibits both Hageman factor (factor XII) and activated portions of C1. Other portions of the complement system are regulated by other binding proteins (e.g., factor I, factor H, and S protein). S protein is of particular importance. It prevents the complement membrane attack complex from attaching to and lysing cell membranes.

The production of oxygen free radicals by neutrophils can be inhibited through a number of antioxidant enzymes, including superoxide dismutase, glutathione peroxidase, and catalase. Vitamin E and  $\beta$ -carotene are fat-soluble vitamins that react with oxygen free radicals and prevent membrane damage. Uric acid and vitamin C neutralize oxidizing agents in the cytoplasm.<sup>22</sup> Neutrophils also release proteolytic enzymes that injure tissues. Protease inhibitors synthesized by the liver, such as  $\alpha_1$ -antitrypsin, help reduce excessive protease destruction.

The neuroendocrine system also has a role in immune regulation. Immune cells have receptors for glucocorticoid hormones and a number of neuropeptides, including enkephalins, endorphins, adrenocorticotrophic hormone, oxytocin, somatostatin, and substance P.<sup>23,24</sup> It is a well-known phenomenon that stress and depression can lead to reduced immune function. Some of these hormones are believed to be responsible for this effect. The immune system also affects the nervous

**FIGURE 9-43** IgG antibody can bind to antigen to form antigen-antibody (Ag-Ab) complexes that attach to special Fc receptors on the surface of B cells. Binding of the antigen-antibody complexes in this manner inhibits B-cell production of antibody. This process is called *negative-feedback regulation*. BCR, B-cell receptor.

system through secreted cytokines such as IL-1 and TNF- $\alpha$ , which induce sleep and malaise.

One of the most important mechanisms of terminating an immune reaction is the elimination of the inciting antigen. As the antigen is cleared, levels of many of the cytokines and costimulators are reduced so that “survival signals” are no longer given to lymphocyte populations and they undergo apoptosis.

## SUMMARY

Cells and tissues throughout the body participate in defense against foreign antigens. Some components of the immune system are able to react to a large number of foreign invaders upon first exposure. These innate components are essential for protecting the body while the specific immune defenses are being activated. Innate defenses include physical and biochemical barriers of the skin and mucous membranes, cells of the mononuclear phagocyte system, neutrophils, NK cells, and a large number of chemical mediators such as complement, clotting factors, kinin, and cytokines. Immunity to specific antigens is provided by B and T lymphocytes. T helper cells are important regulators of the

immune system because they secrete cytokines that enhance T cell, B cell, and macrophage function.

## KEY POINTS

- Specific and innate immune cells work together to protect the body from foreign antigens. Macrophages and dendritic cells play a central role because they are commonly the first immune cells to encounter the antigen. Macrophages secrete cytokines that stimulate WBC production and help WBCs locate the area. Tissue reactions activate the clotting cascade and kinin system, which help to localize the antigen and promote movement of fluid and immune cells into the tissue.
- Macrophages and dendritic cells are antigen-presenting cells that engulf and display antigen on their cell surface in association with MHC class II proteins. T helper cells are specifically activated by these antigen-presenting cells. T helper cells secrete cytokines that promote the production of WBCs in the marrow, initiate proliferation of mature B and T cells, and stimulate the phagocytic potential of macrophages and neutrophils.
- B-cell proliferation and antibody secretion usually require T cell help. B cells internalize and present antigen to T cells, which then stimulate B-cell proliferation. B cells secrete antibodies that help phagocytic cells localize and destroy antigens.
- The immune response to primary exposure is slow and often insufficient to prevent illness. Memory cells that develop during primary exposure can mount a more effective response on subsequent exposure and usually prevent manifestations of illness.
- T and B lymphocytes must be tolerant to self. T lymphocytes capable of reacting with self tissue are thought to be destroyed or permanently inactivated during development in the thymus. One theory suggests that lymphocytes must come in contact with all self antigens during development, and those that do not specifically bind self antigens are allowed to survive.
- B cells are subject to careful regulation by T helper cells and by negative feedback from high concentrations of circulating antigen-antibody complexes.
- Mechanisms to inhibit and control the immune response include activation of regulatory T-cell cytokines, complement inhibitors, circulating antiproteases, and antioxidants as well as degradation of inflammatory mediators.

## KEY QUESTIONS

- What are the potential mechanisms whereby erroneous reaction of the immune system with self tissue leads to autoimmune diseases?
- How do type I, II, III, and IV hypersensitivity reactions differ according to the immune cell types involved and the mechanism of tissue injury?
- What are the common features of autoimmune disorders and certain types of hypersensitivity disorders?
- How are hypersensitivity disorders detected, prevented, and treated?
- How do the etiologic processes of primary and secondary immune deficiency disorders differ?
- What are the clinical features of the common immunodeficiency disorders?

## CHAPTER OUTLINE

- Common Variable Immunodeficiency, 212*

**Secondary Immunodeficiency Disorders, 212**

The purposes of the immune system are to defend the body against invasion or infection by foreign substances called **antigens**, and to patrol for and destroy cells that are abnormal or damaged. Normally, the immune system works efficiently to accomplish these purposes, but in some situations inappropriate immune responses lead to disease.

These disorders can be divided into two general categories: (1) excessive immune responses and (2) deficient immune responses. The category of excessive immune responses includes disorders in which the immune system is overfunctioning or hyperfunctioning. Examples are autoimmunity and hypersensitivity disorders.

The category of deficient immune responses includes disorders in which the immune response is ineffective because of disease-causing genotypes or secondary/acquired dysfunction. Examples of deficient immune responses are severe combined immunodeficiency (SCID) syndrome, DiGeorge syndrome, and selective immunoglobulin A (IgA) deficiency. Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) is a primary acquired immunodeficiency disorder that is discussed in Chapter 12. The secondary immunodeficiencies associated with white blood cell malignancies are included in Chapter 11.

### EXCESSIVE IMMUNE RESPONSES

Excessive immune response disorders result from a functional increase in the activity of the immune system involving multiple, interacting immune cells. Autoimmunity and hypersensitivity are types of excessive immune response disorders. They are often related, and both may be present in patients with excessive immune responses. It may be helpful to think of autoimmunity as a way of describing the *etiologic process*, or cause, of abnormal excessive immune responses toward self tissues. Hypersensitivity disorders describe *mechanisms* of injury, or how the injury occurs, which may or may not involve autoimmunity. Autoimmunity is a general term that is used when the immune system attacks its own tissues. Most autoimmune reactions toward self tissues are mediated through type II (cytotoxic) and III (immune-complex) hypersensitivity mechanisms. For this reason, many autoimmune diseases also are considered hypersensitivity reactions. For example, myasthenia gravis is both an autoimmune disease and a type II hypersensitivity reaction. Immune complex glomerulonephritis is both an autoimmune disease and a type III hypersensitivity reaction. When hypersensitivity reactions occur in response to foreign antigens, such as bee venom, they are not autoimmune.

The causes of immune system overreactions are poorly understood. Interplay between genetic factors, including major histocompatibility complex (MHC) genes, and environmental factors is thought to be important in the development of autoimmune disorders. Most hypersensitivity disorders have familial tendencies also, but the specific genes and environmental agents remain to be discovered. Some evidence suggests that excessive immune responses may be the result of glucocorticoid resistance in target tissues. For example, the number of glucocorticoid receptors in circulating leukocytes is decreased 50% in patients with rheumatoid arthritis. This decrease in receptors would prevent adequate suppression of leukocyte activity and could further enhance inflammation.

### AUTOIMMUNITY

**Autoimmunity** occurs when the immune system recognizes a person's own cells ("self") as foreign and mounts an immune response that injures self tissues. It is a failure of self tolerance. Identification and tolerance of self antigens occur during embryonic development. The adaptive immune response is the responsibility of antigen-specific

T cells and B cells that learn to identify "self" in the thymus and bone marrow.<sup>1</sup> The thymus gland is principally responsible for eliminating self-reactive cells.<sup>1</sup> During this time, aggressive or intolerant self-reactive (autoreactive) lymphocytes are eliminated or suppressed (see Chapter 9). However, a small number of T cells escape thymic control, and move into the peripheral circulation. The immune system has other peripheral "checkpoints" to detect, limit, and control these "self" or "auto" reactive T cells.<sup>1</sup> Autoimmune diseases result when self tolerance is lost and reactions between self antigens and the immune system occur causing dysregulation of proinflammatory and anti-inflammatory mediators, cytokines, CD4<sup>+</sup> and CD8<sup>+</sup> T cells, B cells, and ubiquitin-editing enzyme A20 in dendritic cells.

Several theories have been proposed to explain how various immune system components and environmental triggers might interact to produce autoimmunity. However, no single theory can fully explain the loss of self tolerance that occurs in autoimmune diseases. A number of genetic and environmental factors interacting together contribute to the development of autoimmunity. The triggers for autoimmunity are not known exactly because autoimmune diseases are mediated by a variety of mechanisms, biochemical and cellular events, and responses to those events.

The theory of antigenic mimicry emphasizes the similarities between certain molecular segments of foreign antigens called *epitopes* and the person's own cells. For example, all cells, whether self or foreign, are composed of proteins, carbohydrates, nucleic acids, and lipids. Certain viruses and bacteria evolve to look like "self" and use "molecular mimicry" to slip past the immune system defenses. Self cells with the same or similar molecular segments as these foreign epitopes can "fit" lymphocyte receptors. Therefore, these self antigens or autoantigens can be attacked as foreign under certain circumstances when the normal cell has been altered, such as by a viral infection that stimulates the immune response.<sup>2</sup> The persistent presence of these autoantigens then acts as a constant source of stimulation to the immune system.<sup>2</sup> A recent study of the molecular mimicry theory established an epidemiologic association between *Campylobacter jejuni* enteritis and the subsequent development of Guillain-Barré syndrome.<sup>2</sup> This theory is also suggested as a cause of rheumatic heart disease attributable to cross-reactions between streptococcal antigens and human proteins.<sup>3</sup> In both cases, autoantigens have been identified following exposure to bacterial or viral infection.

Another theory proposes that release of sequestered antigens triggers the autoimmune response. This theory suggests that certain self antigens are isolated from the immune system within an organ during the neonatal period. They are not in contact with antigen-processing cells during the embryonic period when self tolerance usually occurs. These hidden self antigens or sequestered proteins that are normally sheltered from immune recognition occur in sites such as the cornea of the eye, the testicles, or other areas not drained by lymphatics. If and when these sites are damaged later in life, the hidden or sequestered proteins are exposed to the immune system, which does not recognize them as self. Therefore, the damaged cells are attacked.

A number of T cell theories of autoimmunity have been proposed, including thymus gland defects, decreased suppressor T cell function, and altered T helper cells. The theories attributing autoimmunity to thymus gland defects state that maturation and differentiation of T cells are affected either by decreased hormone secretion or by failure of the thymus to expose T cells to all self products. The thymus gland is responsible for exposing developing T cells to self products produced in the thymus or carried to the thymus gland. If some self products are not exposed to the developing T cells, the product will not be recognized as self and will subsequently be attacked. However, recent evidence demonstrates that not all T cells mature in the thymus. Thus

not all T cells may experience or “learn” to recognize “self.”<sup>4</sup> This lack of exposure to self products is thought to be a major factor in the development of generalized autoimmune diseases such as systemic lupus erythematosus (SLE). Thymus dysfunction in “programming” self-tolerance to pancreatic insulin-secreting islet  $\beta$  cells along with increased effector T cells and decreased regulatory T cells is thought to be the cause of autoimmune type 1 diabetes mellitus.<sup>5</sup>

The theory attributing autoimmunity to decreased or lost regulatory/suppressor T cell (Treg) activity states that decreased numbers of Treg cells fail to repress immunoglobulin activity. It is unclear in this theory if Treg cells are lost or if they are “reprogrammed” when exposed to inflammation.<sup>6</sup> Some data suggest that Treg cells lose their forkhead box p3(FOXP3) protein and are transformed into effector T cells.<sup>6</sup> It is also unclear if this disruption in the number of, or activity of, T cells may also be the result of genetic mutations. For example, a mutation of the transcription factor (FOXP3) causes impaired development and function of CD4<sup>+</sup> T cells, which can lead to autoimmune inflammation. T helper cells 22 (Th22 cells) are a newly identified subset of T cells that are important mediators of chronic inflammation and autoimmunity by inducing the production of inflammatory cytokines (IL17a, IL17f, IL22, IL26) by CCR6<sup>+</sup> cells.<sup>7</sup>

A number of B cell theories of autoimmunity also have been proposed. The theory attributing autoimmunity to escape of B cell tolerance proposes that certain B cells lose their responsiveness to suppressor T-cell messages. The B cell activation theories, which are well supported clinically and experimentally, suggest that extrinsic factors or intrinsic, genetic B cell defects cause autoantibody production and an increase in the number and activity of B cells. A number of extrinsic factors, including viruses, bacteria, antibiotics, proteolytic enzymes, and lipopolysaccharides, have been found to be B-cell activating factors that could trigger autoantibody production.

Research has linked mast cells to autoimmunity as well as hypersensitivity. Mast cells reside in most mucous membranes waiting for foreign proteins or bacteria to invade. Their cell membranes are studded with bacteria-sensing proteins, called Toll-like receptors, which cause release of up to 10,000 different chemicals in response to activation. Mast cells release the cytokine interleukin-1 (IL-1), attracting and enlisting inflammation-inducing cells to joints and leaking fluid into joints in the autoimmune disease of rheumatoid arthritis. They are also thought to be involved in development of irritable bowel syndrome and other functional gastrointestinal disorders.

### Genetic Factors

Genetic predisposition seems to be an important factor in the development of autoimmune disorders. Gender, which is genetically determined, also influences the expression of autoimmune disorders. The

exact mechanisms of gender and genetic influence on autoimmune expression have not been established, but the relationship is significant. Females are at significantly higher risk for developing autoimmunity compared to males. Different cytokine profiles can be associated with autoimmunity. Those with genetically low levels of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and high levels of IL-10 may be more tolerant than those with normal levels.

The role of genetics is also supported by the observation that certain human major histocompatibility complex (MHC) genes located on chromosome 6p21 (also called human leukocyte antigen [HLA] genes) are frequently associated with certain autoimmune disorders (Table 10-1). The MHC gene region demonstrates a high level of polymorphism. One of the strongest correlations of MHC molecules with autoimmune disease is the linkage between the HLA-B27 phenotype and ankylosing spondylitis. In this case, 95% of all people with ankylosing spondylitis have a positive B27 phenotype. However, not everyone with a positive B27 phenotype develops ankylosing spondylitis, both because of differences in the way antigen is presented to the immune system and because of environmental factors. Other diseases are associated with different MHC phenotypes, but the correlation between risk for disease and presence of the disease marker is much lower. For example, Addison disease is associated with the HLA-DR3 phenotype, but it has only a 6% risk correlation. Juvenile rheumatoid arthritis is strongly associated with HLA-DR5.

There may also be disease-causing genotypes or genetic factors affecting expression of immune factors. For example, the lymphoid protein tyrosine phosphatase nonreceptor type 22 gene is associated with type 1 diabetes and other autoimmune disease. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is involved in acute and chronic inflammation, autoimmunity, and malignancies. Of special interest is the *FOXP3* gene, which is expressed by CD4<sup>+</sup> regulatory T cells. *FOXP3* deficiency is associated with both primary immune deficiency disorders and autoimmune disorders owing to its effect on regulatory T-cell immune function.

### Environmental Triggers

Chronic or multiple viral or bacterial infections may trigger the development of autoimmune disease in susceptible persons. Viruses can activate B cells, decrease the function of T cells, contribute to the development of antigenic mimicry, or insert viral components on cell surfaces and trigger immune reactions. For example, Epstein-Barr virus, cytomegalovirus, and bacteria such as *Campylobacter jejuni* and *Helicobacter pylori* have been frequently cited as potential triggers of autoimmune disease.

Environmental stress and occupational stress can affect the immune system because of their relationship to the neuroendocrine system,

**TABLE 10-1 MAJOR HISTOCOMPATIBILITY GENES AND AUTOIMMUNE DISEASE**

DISEASE	HLA (MHC) ANTIGEN	FREQUENCY IN PATIENTS (%)	FREQUENCY IN CONTROLS (%)	RELATIVE RISK
Ankylosing spondylitis				
Caucasians	B27	89	43	69
Japanese	B27	85	<1	207
Rheumatoid arthritis	DR4	68	25	3.8
Graves disease	Dw3	56	25	3.7
Type 1 diabetes mellitus	DR3/DR4 heterozygous			33
Systemic lupus erythematosus	DR4	73	33	5
Narcolepsy	DR2	100	34	358

Data from Tierney LM, McPhee SJ, Papadakis MA, editors: *Current medical diagnosis and treatment*, ed 46, New York, 2007, Lange/McGraw-Hill.

leading to inflammation or lymphokine release that activates T cells. Neuroendocrine and immune system interaction during life stress, such as shift work or workplace stress, promotes the synthesis and overproduction of proinflammatory cytokines. In genetically susceptible persons, this increase in systemic and local proinflammatory cytokines may affect the system's balance enough to trigger autoimmune disease. There are also other linkages between the neuroendocrine and immune systems.

Although the etiology of autoimmunity continues to be investigated, the mechanisms whereby autoantibodies injure tissues are better understood. The autoantibodies produced by autoimmune disorders affect tissue by the mechanisms described for type II and type III hypersensitivity reactions found later in this chapter.

## Pharmacotherapies

Immunosuppressive therapy is a common treatment for autoimmune disease. Because autoimmunity is expressed in different ways, the immunosuppressive treatment for each type of autoimmune disease is individualized, depending on disease expression. Immunosuppressive therapy, including corticosteroids and certain cytotoxic chemotherapeutic agents, has become an increasingly important treatment choice. These drugs are essential for inhibiting excessive or aberrant immune responses. The ideal immunosuppressive medication would be an agent that inhibits only the abnormal immune response without limiting the positive and protective functions of the immune system or causing any organ toxicity. Unfortunately, no immunosuppressive medication with these specific properties yet exists.

Immunosuppressive agents include corticosteroids, tumor necrosis factor inhibitors, immunomodulators, and cytotoxins. Corticosteroids decrease the number of lymphocytes and decrease antibody formation, as well as alter the functional activities of lymphocytes. They also have many other activities as a result of their glucocorticoid function. Corticosteroids tend to be used in the treatment of many autoimmune diseases and are the oldest of the immunosuppressive drugs. The adverse effects that occur during corticosteroid use often limit their extended use over time. The common side effects include hypercorticism with changes in fat distribution and buffalo hump formation, suppression of the HPA axis (hypothalamic-pituitary-adrenal axis), congestive heart failure, hypertension, emotional changes, thinning of skin, petechiae, diabetes mellitus, menstrual irregularities, electrolyte imbalances, liver and pancreatic dysfunction, exophthalmos, glaucoma, loss of muscle mass, and muscle weakness. Because corticosteroids affect the HPA system, gradual withdrawal by tapering the dose over time is necessary when discontinuing long-term therapy.

Cytotoxins, such as methotrexate, are used to manage autoimmune disorders because of their ability to kill actively proliferating lymphocytes after they are transformed from their resting  $G_0$  state. The key to the use of cytotoxins is to effectively apply their killing activity without damaging the rest of the body. Cyclosporine (Sandimmune) is a more selective immunosuppressant that reversibly suppresses T-helper cells in the  $G_0$  or  $G_1$  phase of the cell cycle without killing them. As a result, it inhibits the development of killer or cytotoxic T cells without decreasing the numbers of cells. It also impairs the ability of T cells to respond effectively to foreign antigens. It is used to suppress reactions during tissue or organ transplantation. Frequent side effects include edema, hypertension, headache, hirsutism, elevated triglyceride levels, gastrointestinal effects, nephropathy, infection, emotional changes, gynecomastia, leukopenia, anemia, and hepatotoxicity.

Tumor necrosis factor (TNF) inhibitors or immunomodulators, such as etanercept (Enbrel) or infliximab (Remicade), are used as

disease modifiers that bind to and block the activity of TNF- $\alpha$  and TNF- $\beta$ . They may also modulate TNF-mediated responses, such as leukocyte migration and expression of adhesion molecules. The most common side effects of TNF inhibitors include headache, gastrointestinal changes, injection site skin reactions, respiratory tract infections, edema, dizziness, dyspepsia, and weakness.

Therapeutic plasmapheresis is another type of therapy occasionally used in the management of autoimmune diseases. Plasmapheresis is analogous to dialysis and involves the selective filtering or removal of plasma or a plasma cell type as well as protein-bound toxic substances. The patient's whole blood is filtered, blood cells and platelets are returned, and the plasma component containing the autoantibodies is removed and replaced with 5% albumin or another colloid solution. According to the American Society for Apheresis, this type of therapy has been effective in the management of diseases such as myasthenia gravis, thrombocytopenia purpura, multiple sclerosis, and Rh-negative hemolytic disease of the newborn. Plasmapheresis is generally well tolerated; however, there are both major and minor risks involved in the process. Some of the risks include insertion of large intravenous (IV) catheters to perform the procedure, decrease in serum ionized calcium concentration, shifts of fluid levels, and risks of infection and bleeding from loss of coagulation factors.

### KEY POINTS

- Autoimmune disorders occur when the immune system erroneously reacts with "self" tissues. These disorders are thought to be polygenic and multifactorial; however, the exact etiologic process is unknown.
- The antigenic mimicry theory involves the alteration of viruses or bacteria to look like "self" and the precipitation of immune reactions.
- The theory involving release of sequestered antigens suggests that self antigens that do not come in direct contact with lymphocytes during fetal development may cause autoimmune reactions if they are subsequently released from sequestration.
- Abnormal production of subclasses of T lymphocytes, particularly suppressor T cells, has been proposed as a reason for the development of autoimmunity, as well as the development of abnormal B cells that do not respond to suppressor T cell signals.
- Genetic factors such as female gender and MHC genes are associated with certain autoimmune disorders.
- Autoantibodies injure body tissues through the mechanisms described for type II and type III hypersensitivity reactions.

## HYPERSENSITIVITY

**Hypersensitivity** is a normal immune response that is inappropriately triggered or excessive or produces undesirable effects on the body. The basic mechanism that triggers hypersensitivity is a specific antigen-antibody reaction or a specific antigen-lymphocyte interaction. Four classes or types of hypersensitivity are differentiated. Each type is characterized by a specific cellular or antibody response. Hypersensitivity types I, II, and III are mediated by antibodies produced by B lymphocytes. Type IV hypersensitivity is mediated by T cells. Hypersensitivity reactions are specific to a particular antigen and usually do not occur on first exposure to the antigen. Although the diseases or syndromes associated with each type differ in their clinical signs and symptoms, the underlying pathophysiologic process is similar within each type. In [Table 10-2](#) the four major types of hypersensitivity are contrasted. The complex interactions between immune system inflammatory mediators, cytokines, T cells, B cells, and mast cells characterize hypersensitivity reactions.

TABLE 10-2 THE FOUR TYPES OF HYPERSENSITIVITY

CHARACTERISTIC	TYPE I: ATOPIC, ANAPHYLACTIC	TYPE II: CYTOTOXIC, CYTOLYTIC	TYPE III: IMMUNE COMPLEX (ARTHUS REACTION)	TYPE IV: DELAYED HYPERSENSITIVITY
Mediated by:	IgE	IgM or IgG	IgG	T <sub>DTH</sub> lymphocytes
Complement activation	No	Yes	Yes	No
Immune response	Ag plus IgE, leading to mast cell degranulation	Surface Ag and Ab, leading to killer cell cytotoxic action or complement-mediated lysis	Ag-Ab complex in tissues; complement activated and PMNs attracted	Ag-sensitized T cells release lymphokines, leading to inflammatory reactions, and attract macrophages, which release mediator
Peak action	15-30 min	15-30 min	6 hr	24-48 hr
Serum transferability	Yes	Yes	Yes	No
Cell transferability	No	No	No	Yes (T cells)
Genetic mechanisms	Familial High IgE level HLA-linked <i>Ir</i> genes General hyperresponsiveness	HLA linked in some cases	Familial (autoimmune) HLA specificities	Unknown
Causes of reaction	T-cell deficiency Abnormal mediator feedback Environmental factors and Ag	Exposure to Ag or foreign tissue, cells, or graft	Persistent infection—microbe Ag Extrinsic environmental Ag Autoimmunity—self Ag	Intradermal Ag Epidermal Ag Dermal Ag
Manifestation (examples)	Asthma, rhinitis, atopic eczema, bee sting reaction	ABO transfusions, hemolytic disease of newborn, myasthenia gravis	Glomerulonephritis, SLE, farmer's lung arthritis, vasculitis	Guillain-Barré disease, tuberculin test, contact dermatitis, multiple sclerosis

Ab, Antibody; Ag, antigen; DTH, delayed-type hypersensitivity; Ig, immunoglobulin; HLA, human leukocyte antigen; PMN, polymorphonuclear leukocyte; SLE, systemic lupus erythematosus.

## Type I Hypersensitivity

**Etiology.** Genetic mechanisms influence type I hypersensitivity with strong genetic or hereditary linkage regarding the IgE response to antigens (allergens). This genetic component involves both the ability to respond to an allergen and the general ability to produce an IgE antibody response. For example, children born to two allergic parents have a 50% chance of being allergic. Children born to one nonallergic and one allergic parent have a 30% chance of being allergic. It has been identified that total IgE concentration is higher in patients with atopic rhinitis or asthma compared to nonatopic patients.<sup>8</sup>

**Pathogenesis.** Type I hypersensitivity is also known as immediate hypersensitivity, because the reaction is immediate. It is a sensitization reaction characterized by signs and symptoms of an allergic reaction that usually occurs 15 to 30 minutes after exposure to an antigen (allergen).

At the cellular level, immunoglobulin E (IgE) is the principal antibody mediating this reaction. IgE is produced by specialized plasma B cells and circulates in very small amounts in the blood. When an individual is exposed to an allergen, selected plasma B cells produce allergen-specific IgE. It usually takes repeated exposures to the allergen to cause significant levels of IgE to be present in the blood. Environmental pollutants may play a role by increasing mucosal permeability and enhancing antigen (allergen) entry into the body. This increased entry would subsequently increase IgE responsiveness.

Mast cells and basophils are the principal effector cells, although there are many other cells with histamine and other inflammatory mediators that can be involved in the reaction. These may include neutrophils, eosinophils, lymphocytes, macrophages, epithelial cells, and endothelial cells. Mast cells are found throughout the body in all loose connective tissue. They are covered with IgE receptors—up to 500,000 on their cell surfaces—and they are filled with vesicles or granules

containing potent vasoactive, proinflammatory chemical mediators (especially histamine) that produce inflammation when they are released. The IgE receptors on mast cells bind the Fc portion of an IgE antibody. The IgE antigen-binding sites are then displayed on the mast cell surface, where they can bind to antigens that pass by the mast cell (Figure 10-1). This process makes the mast cells responsive to particular antigens.

The initial incident during a type I hypersensitivity response is the cross-linking of two IgE receptors to one antigen on the mast cell located at the site of the allergen's entry into the body (see Figure 10-1). Cross-linking of IgE and the antigen causes an increase in intracellular calcium (Ca<sup>2+</sup>) concentration that results in immediate, massive, local mast cell degranulation of preformed and newly formed proinflammatory mediators. The release of mediators causes an inflammatory response.

Mast cells, basophils, and other effector cells release many chemicals. Some of the mediators are preformed and stored in vesicles, such as histamine, heparin, proteolytic enzymes, and chemotactic factors. Other mediators are formed during the degranulation process. Examples of newly formed mediators include superoxide, prostaglandins, thromboxanes, leukotrienes, bradykinin, and interleukins (see Chapter 9).

One of the most important mediators of type I hypersensitivity is histamine. Histamine binds to H<sub>1</sub> (histamine 1), H<sub>2</sub>, H<sub>3</sub>, and H<sub>4</sub> receptors, which are located on many types of cells. Mast cells have receptors for H<sub>1</sub>, H<sub>2</sub>, and H<sub>3</sub>, with H<sub>1</sub> receptors being the most active. Basophils express predominantly H<sub>2</sub> receptors, whereas neutrophils and eosinophils have both H<sub>1</sub> and H<sub>2</sub> receptors. Recent evidence shows that H<sub>1</sub> and H<sub>2</sub> receptors are present on monocytes and macrophages, with an increase in H<sub>1</sub> receptors when monocytes differentiate into macrophages. Histamine binding to H<sub>1</sub> receptors triggers increased vascular

FIGURE 10-1 Type I hypersensitivity reaction.

permeability, vasodilation (flushing), urticaria formation (hives), smooth muscle constriction (bronchoconstriction), increased mucus secretion and pruritus (increased itching), and increased gut permeability. The activation of  $H_2$  receptors has opposing effects to  $H_1$  receptors in some tissues and causes smooth muscle relaxation in the lower airways, augments gastric acid secretion from parietal cells, and in high

concentrations has an inhibitory effect on inflammatory cells, decreasing degranulation and decreasing neutrophil chemotaxis. The  $H_3$  receptors are located in the brain, in the spinal cord, and on sensory neurons such as postganglionic cholinergic nerves in lung bronchi. The  $H_4$  receptors are found on immune system cells such as dendritic cells, eosinophils, T cells, monocytes, macrophages, and natural killer cells as well as in hematopoietic cells such as the spleen, thymus, bone marrow, and blood leukocytes.  $H_4$  receptors are highly attracted to histamine and are also involved in chemotaxis and inflammatory responses.

The proteolytic enzymes kininogenase and trypsin activate the kinin pathway and C3 activates the complement cascade via the alternative pathway. Heparin decreases clot formation. The chemotactic factors recruit or activate other inflammatory and immune cells. Leukotrienes cause smooth muscle contraction and increase vascular permeability.

**Clinical manifestations.** Manifestations of an immediate hypersensitivity reaction vary in severity and intensity. For many people, type I hypersensitivity reactions are annoying, such as hives (urticaria), seasonal allergic rhinitis, eczema, or mild bronchoconstriction. In other people, the symptoms are more problematic, including tightening of the throat, localized edema, wheezing, and tachycardia, such as is associated with localized angioedema reactions or severe airway reactions. In a very small number of highly allergic people, the type I hypersensitivity reaction can be expressed as a life-threatening allergic reaction known as anaphylaxis such as that associated with bee stings and seafood or peanut allergic reactions. Common allergenic medications, insects, and foods that can trigger type I hypersensitivity reactions are listed in Box 10-1.

**Treatment.** Treatment for type I hypersensitivity primarily involves pharmacologic management with antihistamines,  $\beta$ -adrenergics, corticosteroids, anticholinergics, and anti-immunoglobulin E therapy (IgE blocker therapy). Antihistamines such as diphenhydramine (Benadryl) are used to block the effect of histamine. This action decreases vascular permeability and bronchoconstriction.  $\beta$ -Adrenergic sympathomimetics are used to decrease bronchoconstriction and bronchospasm. **Epinephrine** is an adrenergic agent ( $\alpha$ ,  $\beta_1$ , and  $\beta_2$ ) given subcutaneously or intravenously during acute allergic reactions, especially after food or bee sting reactions. Most patients with severe allergies to food or insect bites are given prescriptions for epinephrine in the form of EpiPen with an autoinjector. Corticosteroids are used to decrease the inflammatory response. Anticholinergics are used to block the parasympathetic system and thus allow greater sympathetic activity. This action indirectly causes bronchodilation. Anti-immunoglobulin E therapy (omalizumab) may be used for persons with severe persistent asthma. Omalizumab (Xolair) is a subcutaneously injected, monoclonal anti-IgE antibody that binds to the IgE molecule, thus inhibiting the binding of IgE to mast cells and basophils and promoting down-regulation of IgE receptors. It is used to improve asthma control in patients with moderate to severe persistent asthma not controlled with inhaled corticosteroids. It is used in children 12 years or older and in adults.

**Prevention.** Some protective, proactive actions taken during pregnancy are thought to decrease the likelihood that type I hypersensitivity will develop in children from families with a history of allergies. These actions include avoiding foods to which the mother is allergic, limiting excesses of one type of food during the last trimester of pregnancy, avoiding whole eggs during the last month before delivery and while breast feeding, and limiting cow's milk to two glasses per day. Other actions that may be helpful during the child's infancy include avoiding exposure to environmental pollution, breast feeding for a minimum of 6 months, supplementing the child's diet with non-cow's milk products such as soy milk, giving solid foods only after the infant is 6 months old, keeping the infant's room as free of dust and molds as possible, and keeping pets (dogs, cats, birds) out of the home.

**Pharmacotherapeutic prevention.** Another avenue for prevention of type I hypersensitivity reactions involves the use of desensitization therapy (immunotherapy). Desensitization, or immunotherapy, is more successful in patients with hay fever than in those with other types of allergies. It involves both environmental control of external allergens and titrated pharmacologic exposure to allergens. Environmental control involves a systematic plan to decrease exposure to house dust, molds, and animal dander. Pets are kept out of the house. The person must avoid food allergens, wool carpets, goose down or feather pillows, dried plants, and exposure to other animal and vegetable products. The person is urged to use air conditioning and electronic air filters.

Pharmacologic desensitization involves injecting a person with sufficient antigen (allergen) on a regular basis over a course of months or years, followed by periodic maintenance or booster therapy. Gradually the dose is increased until the person can tolerate the allergen without a type I hypersensitivity reaction. The goal of this therapy is a change in immunoglobulins so that there is an increase in IgG- and IgA-blocking antibodies, no increase in IgE during allergy season, decreased basophil reactivity, and decreased lymphocyte reactivity to allergens.

## Type II Hypersensitivity

**Etiology and pathogenesis.** Type II hypersensitivity, also known as tissue-specific, cytotoxic, or cytolytic hypersensitivity, is characterized by antibodies that attack antigens on the surface of specific cells or tissues. Often the reaction is immediate (15 to 30 minutes after

**TABLE 10-3 DISEASE AND AUTOANTIBODIES ASSOCIATED WITH TYPE II HYPERSENSITIVITY**

DISEASE	ANTIGEN/AUTOANTIBODY
Type 1 diabetes	Islet cells
Insulin-resistant diabetic states	Insulin receptor
Myasthenia gravis	Acetylcholine receptor
Addison disease	Adrenal epithelial cells
Autoimmune hemolytic anemia	Red blood cell membrane
Immune thrombocytopenic purpura	Platelet membrane
Autoimmune neutropenia	Neutrophil antigens
Pernicious anemia	Intrinsic factor, gastric parietal cells
Lymphocytic thyroiditis	Thyroglobulin
Graves disease	Receptor for thyroid-stimulating hormone
Pemphigus vulgaris	Desmosomes
Hyperacute graft rejection	Donor antigens

exposure to the antigen). However, it can occur over time, such as in thyroiditis or myasthenia gravis. The mechanisms that encompass type II tissue-specific hypersensitivity all occur after the binding of antibody to tissue-specific antigens. The reaction is mediated by the complement system and a variety of effector cells, including tissue macrophages, platelets, natural killer cells, neutrophils, and eosinophils. IgG and IgM are the principal antibodies. Examples of this type of hypersensitivity reaction include ABO transfusion reactions, hemolytic disease of the newborn, myasthenia gravis, thyroiditis, hyperacute graft rejection, and autoimmune hemolytic anemia (Table 10-3). Transfusion reactions, hemolytic disease of the newborn, and graft rejection are examples of **isoimmunity (alloimmunity)**, a condition in which the immune system reacts against antigens on tissues from other members of the same species.

The initial mechanism during a type II hypersensitivity response is exposure to antigen on the surface of foreign cells. The Fab portion of IgG or IgM antibodies binds to antigens on the target foreign cell to form an antigen-antibody complex (Figure 10-2). (Refer also to Chapter 9 for a discussion of IgG and IgM antibodies.) The Fc region of the IgG or IgM antibodies protrudes away from the cell membrane surface. The Fc region then acts as a bridge between the antigen and complement or the effector cells. This antigen-antibody binding with Fc bridging is the key and leads to lysis of the cell by one of several mechanisms. One mechanism is complement-mediated lysis. Complement-mediated lysis occurs through the classical pathway for activation of complement. The classical pathway of complement generates the activated complement component C3b via splitting of C4 and C2 by C1 (Chapter 9). The activated complement component C3b is bound to the target cell by the Fc region of IgG or IgM. C3b increases opsonization, which in turn increases the capacity of the system to allow lysis by other effector cells or by complement itself. Lysis of the foreign cell by complement occurs via the C5-C9 membrane attack complex (MAC), which disrupts the plasma membrane of the cell.

## Transfusion Reaction

An example of this type of mechanism is an acute hemolytic blood transfusion reaction. It occurs when a person receives blood from someone with a different blood group type (Table 10-4). In this case, the recipient of the blood transfusion has antibodies to the donor's

**FIGURE 10-2** Type II hypersensitivity reactions.

red blood cell (RBC) antigens. For example, if a person with type A blood having type A antigens and anti-B antibodies incorrectly receives type B blood with B antigens and anti-A antibodies, the anti-B antibodies will attach to the surface of the infused type B red blood cells and the anti-A antibodies in the infusion will attach to the surface of the circulating type A red blood cells. This event will stimulate the destruction of large numbers of red blood cells. The resulting signs and symptoms of this major blood group reaction include fever, chills, flushing, tachycardia, hypotension, low back pain, pleuritic chest pain, nausea, vomiting, restlessness, anxiety, oliguria, and headache. The reaction may progress to anaphylaxis, shock, and death.

Transfusion reactions are not always immediate. They may be delayed from a few days to 2 weeks especially in persons requiring

periodic transfusions such as in sickle cell anemia or thalassemia.<sup>9</sup> In many cases, antibodies occur as a result of blood component exposure from multiple transfusions. Delayed reactions can also occur as a result of transplantation. In delayed transfusion reactions, often the mechanism of action is related to differences in erythrocyte (RBC) antigens between blood donors rather than differences in the major ABO blood groups.<sup>9</sup> There are many hundreds of RBC antigens that have been identified; fortunately, most of them are rare. In the case of sickle cell anemia, RBC antigens between blood donors of European descent and patients of Afro-Caribbean descent can result in the development of alloantibodies when exposed.<sup>9</sup> The resulting type II hypersensitivity reaction causes the destruction of both the donor's and the recipient's RBCs along with the symptoms of acute hemolysis and severe vaso-occlusive crisis.

TABLE 10-4 MAJOR BLOOD GROUPS

BLOOD GROUP				
PHENOTYPE	GENE LOCI	FREQUENCY (%)	ANTIGENS	ANTIBODIES IN SERUM
A	1	42	A	Anti-B
B	1	8	B	Anti-A
AB	1	3	A and B	None
O	1	47	H	Anti-A, anti-B
<b>Other Major Blood Group Systems</b>				
Rhesus (Rh)		Three closely linked loci: Major antigen = RhD	C, D, E, c, d, e	
		Rh+	85	Cde, CDE
		Rh-	15	Cde, CdE
Kell		1	K or k	
		K	9	K
		K	91	k
MN		1	M or N	
		MM	28	MM
		MN	50	MN
		NN	22	NN
Duffy		1	Fy <sup>a</sup> , Fy <sup>b</sup> , Fy	
		Fy <sup>a</sup> Fy <sup>b</sup>	46	Fy <sup>a</sup> , Fy <sup>b</sup>
		Fy <sup>a</sup>	20	Fy <sup>a</sup>
		Fy <sup>b</sup>	34	Fy <sup>b</sup>
		Fy	0.1	Fy

### Hemolytic Disease of the Newborn

A second mechanism for antigen-antibody binding in type II hypersensitivity reactions is direct destruction by Fc-bearing effector cells, such as macrophages. The macrophage can link to exposed Fc antibody regions. Once this bridging occurs, the foreign cell is phagocytized and destroyed by lysosomes within the effector cell. This can be mediated with or without complement involvement. An example of this type of mechanism is hemolytic disease of the newborn (erythroblastosis fetalis).

This condition occurs during pregnancy when an Rh-negative mother is sensitized to the Rh-positive red cell group antigens of her fetus because of exposure during her current or a previous pregnancy. The mother's IgG Rh-positive antibodies cross the placental barrier and attack the red blood cells of the fetus. The mother's exposure occurs when mixing of fetal and maternal blood takes place. This can occur during an episode of antepartur bleeding or trauma to the placenta, during birth, or during miscarriage of an Rh-positive child. Of these situations, the most likely time for mixing of fetal and maternal blood is at the time of delivery. After this exposure, Rh-positive antibodies gradually develop in the mother and can affect her subsequent children. It takes as little as 1 cm<sup>3</sup> of fetal blood exposure for antibodies to Rh-positive red blood cells to develop in the mother. Usually, the first Rh-positive child is not affected unless placental tearing or leakage into the mother's circulation occurs during pregnancy.

Antibody screens are routinely performed during pregnancy to determine a mother's Rh status including indirect Coombs test and identification of specific antibodies. If the mother is Rh-negative, RhoGAM is administered at 28 weeks, after any prenatal bleeding, and at delivery for prevention of Rh-positive antibodies. RhoGAM contains antibodies against Rh antigens on fetal blood cells and is given to the mother to destroy fetal cells that may be present in her circulation before her immune system becomes activated and begins to produce anti-Rh antibodies. RhoGAM is not effective if the mother already has a positive antibody titer for fetal Rh antigens.

If the mother is Rh-negative, already has fetal Rh antibodies (i.e., is sensitized), and is carrying an Rh-positive fetus, she will not exhibit any significant physiologic effects except some discomfort from potential polyhydramnios. The mother may experience psychological distress. Most of the symptoms of Rh sensitization occur in the fetus, including signs of anemia, hypoxia, decreased fetal activity, ascites, congestive heart failure, and an elevated baseline heart rate of 180 beats/minute or greater with late decelerations. As a result, there is frequent fetal surveillance by 26 weeks' gestation including assessment of fetal heart rate, biweekly performance of nonstress tests, execution of serial amniocenteses to measure levels of bilirubin, and/or direct evaluation of fetal hemoglobin and hematocrit levels by means of percutaneous umbilical blood sampling. If fetal anemia becomes severe any time after 18 weeks' gestation, an intrauterine blood transfusion may be necessary to try to prolong the time the fetus is able to stay in utero. After 34 weeks, the fetus is often taken by cesarean section.

### Myasthenia Gravis

A third mechanism for antigen-antibody binding is seen in myasthenia gravis, an autoimmune disease of the neuromuscular junction. In this case, antibodies form primarily to the acetylcholine receptor (AChR), and less frequently to muscle-specific kinase (MuSK) or low-density lipoprotein receptor-related protein 4 (Lrp4) on muscle membrane surfaces, primarily the motor end-plate<sup>10</sup> (Figure 10-3). With antigen-antibody formation at the receptor site, complement is activated and disrupts the muscle cell membrane. Effector cells are not thought to be involved in this type II hypersensitivity reaction. The thymus gland is believed to be the site of anti-acetylcholine receptor antibody development.<sup>11</sup> It also sustains the autoimmune, hypersensitivity reaction.<sup>11</sup> The loss of acetylcholine stimulation at the motor end-plate causes the extreme muscular weakness associated with myasthenia gravis. The major symptoms of myasthenia gravis include ptosis, diplopia, and muscle weakness after exercise that resolves with rest.

**FIGURE 10-3** Type II hypersensitivity reaction in a person with myasthenia gravis. Having limited receptors available for acetylcholine impairs neuromuscular transmission.

### Graves Disease and Thyroiditis

A fourth mechanism for antigen-antibody binding in type II hypersensitivity reactions is also mediated by effector cells. The effector cells in this case do not directly engulf and destroy the complex because the tissue is too large for this process. Therefore, the effector cells, such as neutrophils, bind to the target cells and block the receptors from normal functioning, causing injury to or malfunction of the involved tissue. Lymphocytic thyroiditis and Graves disease (toxic diffuse goiter) are examples of this type of disorder. In Graves disease, the autoantibody attacks the thyroid-stimulating hormone (TSH) receptor and causes the cells to malfunction, producing excess thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ) by stimulation of the cells. This causes the symptoms of hyperthyroidism including tachycardia, fatigue, weight loss, tremor, heat intolerance, diarrhea, and emotional/mental changes.

### Hyperacute Graft Rejection

Another type II hypersensitivity mechanism for antigen-antibody binding that involves both effector cells and complement is the hyperacute graft rejection that affects transplanted tissues. It occurs when the transplanted donor tissue has an antigen to which the recipient has preformed antibodies. For example, when tissue from a blood type A or B donor is transplanted into a blood type O recipient, the recipient has anti-A and anti-B antibodies. These antibodies will immediately attack the foreign transplanted tissue.

Onset begins immediately after revascularization of the transplanted tissue. At this time, the blood supply from the patient is established in the newly transplanted organ. The patient's antibodies attack the foreign protein antigens and form an antigen-antibody complex. Effector cell infiltration and complement-mediated lysis of donor tissues, inflammation, vascular thrombosis, and hemorrhage occur. The reaction happens so quickly that within 48 hours after transplantation the graft tissue is no longer functioning.

To prevent hyperacute graft rejection, tissue and blood typing of donors and recipients of transplanted tissue is extensive. Lists of potential recipients are matched to donors through organ donation

laboratories both regionally and nationally. Only rarely has hyperacute graft rejection occurred because of an error in tissue or blood typing.

### Type III Hypersensitivity

**Etiology.** Type III hypersensitivity results from failure of the immune and phagocytic systems to effectively remove antigen-antibody immune complexes and is not tissue specific. It is also known as an immune complex reaction. Type III hypersensitivity is characterized by antigen-antibody complex deposition into tissues, with consequent activation of complement and a subsequent self-sustaining inflammatory reaction. It is not an immediate reaction; it occurs over a period of several hours or longer (i.e., glomerulonephritis) and is often ongoing.

Three possible scenarios can precipitate type III hypersensitivity. First, a recent history of infection or persistent low-grade infection by a microbial or viral agent can stimulate a weak antibody response. The continuing nature of persistent infection or untreated/undertreated infection provides a source of circulating antigen. The antigen and antibody response leads to chronic immune complex production. These immune complexes are not successfully removed from the blood and are deposited in many sites, including blood vessels, glomeruli, and joints. Second, an extrinsic environmental antigen from molds, plants, or animals can be inhaled into the lung, where it is exposed to antibody in the body fluid. This inhalation of antigen causes antigen-antibody complex formation in alveoli with immune complex deposition in the alveolar walls. Third, an autoimmune process can develop in which autoantibodies attack self antigens. In this case, the body forms both parts of the immune complex. Autoantibodies to either circulating or tissue-fixed self antigens may be produced. Because the self antigens persist over time, chronic immune complex production and deposition in tissues take place.

The mechanism of injury in type III hypersensitivity reactions is from activation of complement and other proinflammatory mediators in response to the antigen-antibody complex deposition. The antibody-antigen complex deposition does not cause the injury. The tissue injury is caused by an inflammatory reaction to the antibody-antigen complex. Therefore, it is not a tissue-specific reaction. The onset of this reaction occurs up to 6 or more hours after exposure to the antigen. IgG and IgM are the principal antibodies. The principal effector cells are neutrophils and mast cells. The principal mediator of the reaction is complement. Examples of type III hypersensitivity reaction include systemic lupus erythematosus, immune complex glomerulonephritis, serum sickness, and drug-induced vasculitis. Diseases associated with type III hypersensitivity are listed in Table 10-5.

**Pathogenesis.** Type III hypersensitivity reactions tend to be ongoing with variations in symptoms based on the fluctuation of antibody to antigen ratios, the amount of complement available to mediate the inflammation, and the dynamic nature of the antibody-antigen reaction. It is sometimes difficult to differentiate between type II and type III hypersensitivity reactions. The key differences between a type II and a type III reaction are the location of antigen and the mechanism of injury. As previously described, type II reactions occur in response to tissue-specific antigen located on cell surfaces and involve direct cell death or malfunction from the antigen-antibody reaction. Type III hypersensitivity reactions involve antigens forming antigen-antibody complexes that precipitate out of the blood or body fluid and are deposited into tissues.

Type III hypersensitivity reactions involve a sequential process that begins with interaction between a circulating soluble antigen and soluble antibody or between an insoluble antigen and a soluble antibody. Depending on the concentration of antigen and antibody, multiple cross-linking of antigen and antibody occurs and immune complexes

are formed. Most immune complexes are removed effectively before they can cause injury. In type III hypersensitivity, the immune complexes are not removed, which causes an inflammatory process and thus leads to tissue injury.

When both antigen and antibody are small or intermediate in size and soluble, the immune complex precipitates out of the body fluid and is deposited into tissues. When only the antibody is soluble, the antibody reacts with fixed antigen in the tissues. Then the antibody within the complex links with the complement system by its Fc receptors (Figure 10-4).

Activation of the classic complement cascade causes release of C3a and C5a, as well as the membrane attack complex. C3a stimulates the release of histamine from mast cells, indirectly increasing vascular permeability and vasodilation. Bronchial smooth muscle contraction

occurs, resulting in bronchial constriction, wheezing, and coughing. C3a also causes the endothelial cells to become more round, thereby increasing vascular permeability. The increased vascular permeability leads to edema formation, which provides more space for the movement of cellular inflammatory components. It also dilutes and limits the duration of action of mediators. C5a is an even more powerful component than C3a. It causes a powerful release of proinflammatory mediators with actions that are identical with those of C3a. It is also a powerful chemotactic agent for neutrophils and causes a respiratory burst within neutrophils in which oxygen consumption is increased to 50 times normal along with increased glucose uptake and procoagulant activity.

As a result of the activation of complement, neutrophils, macrophages, and mast cells are attracted to the area and are activated. These cells begin lysis and destruction of tissue via the release of cytokines and the inflammatory response. The inflammation causes tissue destruction, scarring, and further reaction of the immune system against the damaged tissue (see Figure 10-4). The persistence of the inflammation is due to the ongoing release of autoantigen particles in the damaged tissue that stimulate autoreactive B cells, leading to the formation and deposition of more immune complexes.<sup>12</sup>

**Tissue deposition.** Antigen-antibody complex deposition in tissues is affected by a number of factors including size and clearance rate.<sup>12</sup> Smaller immune complexes are able to circulate for longer periods, which may increase the immune response. However, small complexes also can be removed more easily because they can pass through the glomerular basement membrane. The very large complexes can be phagocytized more easily because they are easily marked or fixed by complement and bound to red blood cells. The large complexes can then be transported to the liver, where they are phagocytized by the reticuloendothelial system—particularly the Kupffer cells in the liver—and easily removed from the system. However, large complexes can become stuck in the kidney where they are unable to cross the glomerular basement membrane.

Increased vascular permeability as a result of histamine or other vasoactive mediator release is also hypothesized to be an important factor in tissue deposition. Researchers have found that small immune complexes can be deposited in tissues treated with vasoactive mediators. Sites of increased turbulence and blood pressure tend to have increased immune complex deposition. These sites include the glomerular capillaries, joint linings, ciliary body, pulmonary alveolar membranes, and vascular endothelial linings, especially around curves or bifurcations.

Intermediate-sized immune complexes tend to be deposited because they do not fix complement well, do not bind with red blood cells well

**TABLE 10-5 DISEASES ASSOCIATED WITH TYPE III HYPERSENSITIVITY**

DISEASE	ANTIGEN
Immune complex glomerulonephritis	GBM, exogenous antigens, drugs
SLE	Double-stranded DNA, DNA-histone complex, Sm, RNP, Ro:SSA, La:SSB, centromere
SLE-associated glomerulonephritis	Double-stranded DNA, DNA-histone complex, Sm, RNP, Ro:SSA, La:SSB
Acute allergic alveolitis	Various puffball spores from moldy dwellings
Farmer's lung disease	Thermophilic <i>Actinomyces</i> from contaminated hay or grains
Chemical worker's lung	Isocyanates
Still disease—postinfectious arthritis	RANA, or none identified
Rheumatoid arthritis	RANA
Serum sickness	Lymphocytes or thymocytes from heterologous serum
Henoch-Schönlein purpura	Upper respiratory tract viruses, drugs (antibiotics and thiazides), foods (milk, fish, eggs, rice, nuts, beans), and immunizations
Drug-induced vasculitis	Drugs (antibiotics and thiazides)
Polyarteritis nodosa	Antineutrophil cytoplasmic
Wegener granulomatosis	Antineutrophil cytoplasmic
Goodpasture syndrome	GBM

GBM, Glomerular basement membrane; La, Lane; RANA, rheumatoid arthritis nuclear antigen; RNP, ribonucleoprotein; Ro, Robert; SLE, systemic lupus erythematosus; Sm, Smith; SS, single stranded.

**FIGURE 10-4** Type III hypersensitivity reaction.

after fixation, and are not readily removed by the mononuclear phagocyte system. Large numbers of any size immune complex can be deposited if they are so numerous that the phagocytic cells are overwhelmed. Deposition of immune complexes also depends on their immunoglobulin class and the affinity between the antigen and antibody. Finally, deposition may be affected by the type of antigen or by the relationship between the immune complex and sites with increased collagen. Because DNA and collagen have strong affinity, an increased quantity of DNA-anti-DNA immune complexes may be deposited in collagen membranes, such as in the kidney. The electrical charge of the immune complex may affect where it is deposited. For example, a positively charged immune complex may be attracted by a negatively charged basement membrane.

### Immune Complex Glomerulonephritis

**Etiology.** Immune complex glomerulonephritis (an inflammatory renal disorder) is an example of a type III hypersensitivity reaction typically occurring 10 to 14 days after infection with a *Streptococcus* or *Staphylococcal* bacterial strain. It involves the interaction of soluble exogenous antigen with soluble antibody and is the cause of most glomerulonephritis cases. The circulating immune complex is then deposited in the glomerular capillary wall and mesangium.

**Clinical manifestations and treatment.** This deposition causes damage to the glomerular basement membrane with resultant proteinuria, hematuria, hypertension, oliguria, and red cell casts in the urine (see Chapter 27). In some types of glomerulonephritis, the patient may have nephrotic syndrome and acute renal failure that may progress to chronic renal failure.

Treatment of glomerulonephritis involves the use of corticosteroids and other medications to decrease inflammation. Antihistamines and antiserotonins have been tried in attempts to decrease vasoactive mediators and vascular permeability. Anticoagulants and antiplatelet medications such as aspirin, as well as plasmapheresis, are currently being studied. In plasmapheresis, plasma is removed from the blood and fresh frozen plasma or albumin is used to replace the withdrawn plasma.

### Systemic Lupus Erythematosus

**Etiology.** Systemic lupus erythematosus (SLE) is another example of a type III hypersensitivity reaction caused by autoantibody production. SLE tends to occur more frequently in women than in men (ratio of 7:1) and with an incidence of 20 cases per 100,000 persons. It is primarily characterized by the development of antibodies against nuclear antigens such as DNA, deoxyribonucleohistone, and RNA. Production of autoantibodies to red blood cells, neutrophils, platelets, lymphocytes, and other organs or tissues may also occur.

In SLE, antinuclear antibodies (ANAs) and anti-DNA autoantibodies attach to components of the nucleus to form immune complexes that are deposited on collagen-rich tissues, including the glomerular basement membrane and the dermal-epidermal junction. The exact mechanism causing cell damage and the release of nuclear components and subsequent development of antinuclear and anti-DNA antibodies is not known. However, once formed, the autoantibodies can react with DNA and nuclear components from damaged cells anywhere in the body. The resulting inflammatory response causes increased cell damage and further antigen-antibody immune complex formation, thus leading to a cyclic process. The immune complex deposition and resulting inflammatory response cause the signs and symptoms of SLE.

**Clinical manifestations.** SLE can affect any organ system and, as such, it can present with a variety of signs and symptoms. Because of the variable presentation, diagnostic specific criteria based on the presence of specific signs, symptoms, and laboratory findings have been developed. Kidney involvement is common and may lead to nephritis and glomerulonephritis. Skin symptoms are wide ranging and include malar

“butterfly” rash, erythematous rash on exposed skin, purpura, alopecia, mucosal ulcerations, subcutaneous nodules, and splinter hemorrhages. The malar butterfly rash occurs across the nose onto the cheeks in approximately 26% of patients with acute SLE. The butterfly rash can be flat or raised and always spares the nasolabial folds. The rash that occurs on sun-exposed skin can be superficial to indurated and is nonpruritic. It can occur on the face, chest, shoulders, extensor surfaces of the arms, and backs of the hands. The color ranges from red to reddish purple. Most patients have symptoms of arthritis or polyarthralgia. Other symptoms include pleurisy, pericarditis, restrictive pulmonary disease, retinal changes, thrombocytopenia, anemia, and gastrointestinal ulceration. Central nervous system involvement includes neuritis, seizures, depression, or psychosis. A positive ANA test is usually present with positive anti-DNA (antibody to native DNA) and anti-Sm (antibody to Smith nuclear antigen) (see Chapter 52 for more information).

**Treatment.** Treatment of SLE depends upon the organ system affected and includes administration of nonsteroidal antiinflammatory agents such as aspirin, systemic corticosteroids, and antimalarials such as hydroxychloroquine (Plaquenil). Antimalarials are a cornerstone of treatment for SLE because of their effectiveness. The major side effect of antimalarials is ocular toxicity, which can be prevented by limiting therapy to 10 years or less, not exceeding 6.5 mg/kg/day dosages, and undergoing yearly ophthalmic evaluations. Other side effects include myopathy, pigmentation changes, gastrointestinal effects, liver enzyme changes, dizziness, and emotional changes. Corticosteroids decrease inflammation and provide immunosuppression, which can decrease symptoms and add to the patient’s quality of life. If the patient does not respond to corticosteroids, immunosuppressives or cytotoxic agents can be used. Antibiotics are commonly prescribed because of frequent infections secondary to immune system compromise. There are new biological therapies being developed to target cytokines, and decrease immune system activation. Sunscreens with maximum sun protection factor (SPF) values are necessary to prevent photosensitivity reactions. Patients are also encouraged to avoid direct sunlight from 10 AM until at least 3 PM.

### Type IV Hypersensitivity

Type IV hypersensitivity is also known as delayed hypersensitivity. Delayed hypersensitivity is characterized by tissue damage resulting from a delayed cellular reaction to an antigen. Unlike other hypersensitivity reactions, primary antibody involvement is absent. The principal mediators are lymphocytes, including T helper cells (Th) that mediate the reaction by releasing lymphokines (cytokines) and/or antigen-sensitized cytotoxic T cells (Tc) that can directly kill cells. The principal effector cells are lymphocytes and macrophages, with mast cells involved in the early phases. Neutrophils are not involved in type IV hypersensitivity reactions. This reaction is slow in onset, beginning 24 hours after exposure and lasting up to 14 days after exposure. Clinical manifestations may linger for an even longer period.

Type IV hypersensitivity reactions involve a series of events evolving gradually. Mast cell degranulation occurs early in the evolution of a delayed hypersensitivity reaction, followed by lymphocyte and macrophage invasion. The mast cells are gatekeepers that regulate leukocyte migration in the microvasculature. Unlike that occurring in type I hypersensitivity reactions, the mast cell degranulation is more limited and localized. The reaction is also limited by the action of suppressor T cells, which inhibit other T-cell actions. The justification and the method for mast cell activation in this type of hypersensitivity reaction is not well understood. However, the combined action of mast cell and T cell mediators recruits other T cells and macrophages to the site.

Several types of delayed hypersensitivity reactions are recognized, including cutaneous basophil hypersensitivity (Jones-Mote

sensitivity), contact hypersensitivity, tuberculin-type hypersensitivity, and granulomatous hypersensitivity.

### Cutaneous Basophil Hypersensitivity

Cutaneous basophil is the most rapid type of delayed hypersensitivity reaction. It is a lymphocyte-mediated basophil reaction. Soluble antigen that has been injected intradermally or antigens introduced into the dermis trigger T-cell activation and subsequent release of cytokines and activation of basophils, which infiltrate the area. The reaction peaks with skin swelling in 24 hours and can last 7 to 10 days. An example of this type of hypersensitivity is skin graft reactions and rejection.

### Contact Hypersensitivity

Contact hypersensitivity is the most familiar type IV hypersensitivity. It is an immune or inflammatory response to a wide variety of plant oils, chemicals, ointments, clothing, cosmetics, dyes, and adhesives.

Contact hypersensitivity is an epidermal phenomenon. As a delayed reaction, it peaks in 48 to 72 hours. The reaction is slow because the skin-penetrating antigen is very small and in an incomplete form. This incomplete, lipid-soluble antigen is called a **hapten**. The hapten must first penetrate the epidermis, where it links with a normal body protein, called a *carrier*. Only after the hapten combines with the carrier is it a complete antigen—often called a hapten conjugate.

The complete antigen is processed by dermal dendritic cells located in the suprabasal epidermis. The dermal dendritic cells move to the local lymph channel, where they migrate to the regional lymph node. Within the lymph node, the dermal dendritic cells display the now processed complete antigen to CD4<sup>+</sup> T cells in the paracortex. Then the antigen-sensitized CD4<sup>+</sup> T cells release lymphokines, which initiate an inflammatory response and attract other effector cells. The primary lymphokines include IL-2, IL-3, interferon, TNF, and macrophage-stimulating factors (Figure 10-5).

FIGURE 10-5 Type IV hypersensitivity reaction.

Lymphokines (cytokines) and prostaglandins are important in contact hypersensitivity. The presentation of antigen to T cells causes the lymphokine cascade of vasoactive and cytoactive substances. These substances cause inflammation as well as activation of other cells. After about 72 hours, the reaction begins to decrease because of degradation of the antigen and production of prostaglandin E, which inhibits IL-1 and IL-2 production.

After primary exposure or immunization, a cellular reaction takes place at each subsequent exposure site. Cross-reactivity with related substances also occurs in contact hypersensitivity. For example, a person with contact dermatitis to nickel will react when exposed to a variety of nickel alloys, including the metal in earrings, zippers, snaps, and belt buckles. Skin symptoms resulting from contact dermatitis include redness (erythema), edema, pruritus, and blisters. People with sensitivities may also experience respiratory symptoms if exposed to aerosolized haptens. This situation could occur when a person is downwind from burning poison ivy or burning tires. Delayed hypersensitivity reaction (type IV) caused by exposure to the compounds in latex gloves is an occupational risk in surgeons and nurses who work in operating rooms.

Patch testing for diagnosis of contact hypersensitivity is indicated when symptoms persist despite avoidance of the suspected agent and with appropriate use of topical therapy. There are several types of patch tests including open and closed testing used by dermatologists and allergists. In open patch testing, the suspected allergen is applied twice daily to the upper arm and left uncovered for 2 days. In closed patch tests, the suspected allergen is applied to the skin away from the original site of eruption and is covered with an adhesive bandage. The bandage is then removed in 2 days. The results are graded according to response. A 1+ positive patch test response involves erythema of the entire area of exposure. Patchy pustular responses are not positive and are irritant reactions. A 2+ patch test response involves erythema and vesicles. A 3+ patch test response involves erythema, vesicles, and bullae.

### Tuberculin-Type Hypersensitivity

Tuberculin-type hypersensitivity occurs when someone who has been previously infected by tuberculosis is exposed to tuberculin antigen in a tuberculin test. It is a dermal phenomenon that peaks in 48 to 72 hours. The person experiences erythema, induration, and inflammation at the site of the intradermal injection. Because the amount injected is so small, the reaction disappears when the antigen has degraded. However, people with severe reactions may experience tissue necrosis at the site.

### Granulomatous Hypersensitivity

Granulomatous hypersensitivity reaction is a primary defense against intracellular infections and represents a chronic type IV hypersensitivity reaction. It is a protective defense reaction that eventually causes tissue destruction because of persistence of the antigen. In this type of hypersensitivity, antigen is not destroyed within the macrophages, either because of failure of lysosome-phagosome fusion, as in tuberculosis and leprosy, or because of the resistance of various materials to internal lysozymes, as in retained suture material or talc. In an effort to protect the host, lymphocytes and macrophages actually cause the tissue damage by releasing cytokines and stimulating an inflammatory response.

Antigen is engulfed and ingested by macrophages attempting to destroy the antigen, but these actions are unsuccessful in type IV hypersensitivity. The macrophages form a core of inflammatory cells that include lymphocytes, tissue histiocytes, eosinophils, plasma cells, giant cells, and epithelioid cells. This collection of inflammatory cells

**TABLE 10-6 GRANULOMATOUS DISEASE ASSOCIATED WITH TYPE IV HYPERSENSITIVITY**

DISEASE	BACTERIUM
Tuberculosis	<i>Mycobacterium tuberculosis</i>
Leprosy	<i>Mycobacterium leprae</i>
Histoplasmosis	<i>Histoplasma capsulatum</i>
Coccidioidomycosis	<i>Coccidioides immitis</i>
Brucellosis	<i>Brucella abortus</i> <i>Brucella suis</i> (less common) <i>Brucella melitensis</i> (less common)
Tularemia	<i>Francisella (Pasteurella) tularensis</i>

develops into a ball-like mass called a granuloma. The predominant cell in the granuloma is the macrophage. Epithelioid cells originate from macrophages and are large, flat cells with a large amount of endoplasmic reticulum. When epithelioid cells fuse, they form multinucleated giant cells. This core is surrounded by lymphocytes. Gradually, fibroblastic activity and increased collagen synthesis cause the granuloma to become fibrotic with scar formation. Often, central necrosis occurs within the granuloma and is called *caseous* or *cheesy necrosis*. Patients with granulomatous diseases have a variety of symptoms. Granulomatous diseases and the pathogens associated with them are listed in Table 10-6.

Testing for granulomatous diseases also involves skin testing. For example, the tuberculin skin test (i.e., Mantoux or purified protein derivative [PPD]) identifies infection but is not diagnostic of active disease. The test involves *intradermal* injection of 0.1 ml of PPD into the volar surface of the left forearm. There should be a clear bleb at the site of the test. The skin test is then read in 48 to 72 hours. A negative PPD skin test is one in which there is either no reaction or only redness at the site. A positive result is one in which there is equal to or greater than 10 to 15 mm of induration (or tissue firmness) at the site. In patients with HIV a positive result is equal to or greater than 5 mm of induration. However, if the HIV patient's CD4<sup>+</sup> cell count is low (<200 cells/μL), or if the patient is febrile or elderly, there may be no reaction to any skin testing. This is called anergy and causes a false negative in many cases.

### KEY POINTS

- Type I hypersensitivity is an immediate allergic or anaphylactic type of reaction mediated primarily by sensitized mast cells. The reaction is initiated when IgE antibodies located on the mast cell membrane are bound by antigen, with subsequent cross-linking of IgE receptors. Mast cell degranulation releases chemicals that mediate the signs and symptoms of anaphylaxis. Released histamine, kinin, prostaglandins, interleukins, and leukotrienes cause increased vascular permeability, vasodilation, hypotension, urticaria, and bronchoconstriction. Examples of type I reactions include drug reactions, bee sting reactions, and asthma.
- Type II hypersensitivity occurs when antibodies are formed against antigens on cell surfaces, usually resulting in lysis of target cells. Cell lysis may be mediated by activated complement fragments (membrane attack complex) or by phagocytic cells that are attracted to target cells by the attached antibodies. Examples include transfusion reactions, erythroblastosis fetalis, myasthenia gravis, and hyperacute graft rejection.
- Type III hypersensitivity reactions occur when antigen-antibody complexes are deposited in tissues and result in the activation of complement and subsequent tissue inflammation and destruction. Antigen-antibody

complexes activate the complement cascade and subsequently attract phagocytic cells to the tissue. History of persistent low-grade infections, inhalation of antigens into alveoli, and autoimmune production of antibodies may result in chronic production of antigen-antibody complexes. Examples include glomerulonephritis and SLE.

- Type IV hypersensitivity reactions are T-cell mediated and do not require antibody production, in contrast to type I, II, and III reactions. Sensitized T cells react with altered or foreign cells and initiate inflammation. Contact dermatitis, tuberculin reactions, transplant rejection, and graft-versus-host disease are examples.

## DEFICIENT IMMUNE RESPONSES

Deficient immune responses result from a functional decrease in one or more components of the immune system. These disorders can affect lymphocytes, antibodies, phagocytes, and complement proteins. Two types of immune deficiency are differentiated: primary and secondary. Primary disorders are immune deficiencies not attributable to other causes; these may be congenital or acquired. Examples of primary immunodeficiency disorders include severe combined immunodeficiency (SCID) syndrome, DiGeorge syndrome, selective IgA deficiency, and AIDS. Persons with a primary immunodeficiency can be predisposed to multiple deficiencies, as in agammaglobulinemia or SCID, or can have a single phenotype deficiency predisposing to a specific infection, such as disorders of the IL-12–interferon- $\gamma$  (IFN- $\gamma$ ) circuit, which predispose to infections caused by mycobacteria.<sup>14</sup> Secondary immunodeficiency disorders are a consequence of non-immune system disorders or treatments that secondarily affect

immune function. Examples of secondary disorders include those associated with hyperlipidemia or malnutrition, medical treatments such as cancer chemotherapy, or biopsychosocial stress such as post-surgical immune system problems.

## PRIMARY IMMUNODEFICIENCY DISORDERS

Primary immunodeficiency disorders (PIDs) include congenital phenotypes that result from abnormal development or maturation of immune cells, as well as acquired primary disorders of immune cells such as HIV/AIDS. AIDS is described in Chapter 12 and only the congenital forms of primary immunodeficiency are included here. The classic view of primary congenital immunodeficiency disorders is that they are rare genetic disorders that are often sex linked. The most common primary disorders are listed in Table 10-7. However, there are strong genetic epidemiologic data suggesting that most people have some inborn errors of immunity that may vary in clinical significance and severity. This novel observation is changing how we view immunodeficiency (Table 10-8).<sup>13</sup> The first clinical indicators of immunodeficiency disorders are the signs and symptoms of infection, and the disorders are often first suspected when an individual has severe recurrent, unusual, or unmanageable infections.

### B-Cell and T-Cell Combined Disorders

#### Severe Combined Immunodeficiency Disorders

**Etiology and pathogenesis.** (SCIDs) are inherited primary immunodeficiency disorders and are characterized by the absence or dysfunction of T cells affecting both cellular and humoral adaptive immunity.<sup>14</sup> Depending on the genetic defect, B cells may be present (T-B+) or absent (T-B-), and there is wide phenotypic and immunologic variability.<sup>14</sup> As

TABLE 10-7 PRIMARY CONGENITAL IMMUNODEFICIENCY DISORDERS

DISORDER	FUNCTIONAL DEFICIENCY	ERROR
Bruton X-linked agammaglobulinemia	B cells; antibody	<i>BTK</i> gene mutant
Common variable (acquired) hypogammaglobulinemia	B cells; antibody	Unknown: possible <i>CARMA1</i> variant and <i>BOB1</i> variant
Selective IgA deficiency	B cells; IgA antibody	Unknown: possible alterations in transmembrane activator, calcium modulator, and cycophilin ligand interactor gene
Secretory component deficiency—chronic mucocutaneous candidiasis	B cells; secretory IgA antibody	Autosomal recessive deficiency in IL-17RA; autosomal dominant deficiency of IL-17F
Selective IgM deficiency	IgM antibody	Unknown
Selective deficiency of IgG subclasses	IgG antibody subclass	Unknown
Transient hypogammaglobulinemia of infancy	Low antibodies	Unknown
X-Linked lymphoproliferative disease or Duncan X-linked lymphoproliferative disease	Anti-Epstein-Barr virus–linked antigen antibody	Mutations in <i>SH2D1A</i> and <i>XIAP (BIRC4)</i>
DiGeorge syndrome (congenital thymic hypoplasia or aplasia)	Primarily T cells	Chromosome 22q11.2 Deletion syndrome
Autosomal recessive SCID	T cells, antibody	Defects of <i>JAK3</i>
X-Linked recessive, T-B+ SCID	T cells, antibody	Defects of <i>IL2RG</i> gene
T-B- SCID (reticular dysgenesis)	T cells, antibody, granulocytes	Mutations of <i>RAG1</i> or <i>RAG2</i>
MHC class II expression deficiency (rare lymphocyte syndrome)	T cells, antibody	Impaired gene regulation and lack of HLA class II gene expression Probable: class II transactivator and regulatory factor X5
Wiskott-Aldrich syndrome (immunodeficiency with eczema and thrombocytopenia)	Antibody, T cells	Defect of short arm of X chromosome at Xp11.3 mutation of <i>WASP</i> gene
Chédiak-Higashi syndrome	Natural killer cells, phagocytic cells, granulocytes, platelets	Autosomal recessive disorder; <i>CHS1/L4ST</i> gene on chromosome 1
Chronic granulomatous disease of childhood	Phagocytic cells (neutrophils)	Mutations in genes <i>CYBA</i> , <i>NCF-1</i> , <i>NCF-2</i> , <i>CYBB</i>

*BTK*, Bruton tyrosine kinase; *JAK*, Janus kinase; *MHC*, major histocompatibility complex; *SCID*, severe combined immunodeficiency; *WASP*, WAS protein.

TABLE 10-8 PARADIGM SHIFT IN PRIMARY IMMUNODEFICIENCIES

PRIMARY IMMUNODEFICIENCIES	CONVENTIONAL VIEW	CONTEMPORARY VIEW
<b>Patient and Population Levels</b>		
Frequency	Rare	Common
Occurrence	Familial	Sporadic
Age at onset	Childhood	Adulthood
Prognosis	Spontaneously worsening	Spontaneously improving
<b>Phenotype Level</b>		
Disease-defining clinical phenotypes	Opportunistic infections	Other infections and phenotypes
Number of phenotypes per patient	High	Low (even single)
Number of episodes per patient	High	Low (even single)
Disease-causing cellular phenotypes	Hematopoietic	Nonhematopoietic
<b>Genotype Level</b>		
Disease-causing genes per patient	One (monogenic, mendelian)	A few (oligogenic, major genes)
Mode of mendelian inheritance	Autosomal and X-linked recessive	Autosomal dominant
Clinical penetrance	Complete	Incomplete
Mutations	Inherited from parental genome	Germ line de novo or somatic

From Casanova JL, Abel L: Primary immunodeficiencies: a field in its infancy, *Science* 317(5838):618, 2007.

such, these disorders vary in their severity and clinical features. T-B+ SCID is caused by mutations in cytokine-mediated signaling. The majority of these patients have X-linked SCID caused by mutations in the *IL2RG* gene that is responsible for encoding common  $\gamma$  chain, which is needed by several cytokine receptors.<sup>14</sup> Other T-B+ SCID patients have mutations in one of the four *CD3* genes.<sup>14</sup> T-B- SCID patients have a defect caused by mutations of recombination activating genes 1 or 2 (*RAG1* or *RAG2*), both of which are involved in the process of antigen receptor gene assembly. The three major types of SCIDs are classical SCID, atypical SCID, and Omenn syndrome.

The most severe form of T-B- SCID, called classical SCID or *reticular dysgenesis*, is characterized by failure of all white blood cell development. Infants with reticular dysgenesis have failure of both lymphocyte and granulocyte development. Although the fetus grows normally, the infant is severely affected with absent lymphoid tissue, absent T lymphocytes, and absent immunoglobulins. The T-B+ SCID X-linked recessive type is the most common type (50% of cases), affecting boys more often than girls. These infants lack circulating T cells and usually have a normal to increased number of B cells that do not function normally. The enzymes or other essential components necessary for immune cell functioning are deficient, particularly enzymes linked with purine nucleoside phosphorylase or adenosine deaminase metabolism. As a result, the infant accumulates toxic metabolites of purine or adenosine that affect lymphocytes. Antibody titers are decreased because of lack of antibody formation after immunization. T cells are low in number (less than 1000/ $\mu$ L) or absent. Some infants have increased numbers of B cells, but they are unable to function normally because of poor antibody production with decreased synthesis of IgG, IgM, and IgA. Generally, most patients have small, hypoplastic thymus glands indicative of poor or absent T cell development. Because complete failure of lymphoid and myeloid stem cells during fetal development is not generally compatible with life, many infants die in utero or shortly after birth.

**Clinical manifestations and treatment.** Infants with these syndromes are usually ill within 3 months of age and often have thrush, severe *Candida* diaper dermatitis, or infections causing otitis, pneumonia, and diarrhea. They are prone to sepsis, opportunistic infections with such pathogens as *Candida albicans* or *Pneumocystis jiroveci* (*carinii*), infections with such viruses as cytomegalovirus (CMV) or herpesvirus, and common childhood diseases such as varicella and measles.

Because of their severity, infections in infants with SCID are medical emergencies. T-B- SCID patients have an overall worse outcome than T-B+ SCID patients.<sup>14</sup>

Infants suspected of having SCID should be placed in protective isolation and all staff involved in the infants' care should be vigilant about following proper hand washing procedures and avoiding exposure to infections. Breast feeding is encouraged if the mother is CMV negative and without active infection. Curative therapy involves hematopoietic stem cell transplantation with either umbilical cord blood or bone marrow preferably from HLA-haploidentical siblings.<sup>14</sup> Other therapies include chemotherapy conditioning regimens, long-term immunoglobulin therapy, enzyme replacement therapy, and gene therapy.<sup>14</sup>

### Wiskott-Aldrich Syndrome

**Etiology and pathogenesis.** Wiskott-Aldrich syndrome is an X-linked immunodeficiency disorder that affects both T cells and B cells. The gene deficiency is caused by a mutation of the WAS protein (*WASP*) gene and has been mapped to the short arm of the X chromosome at Xp11.23. The *WASP* gene is involved in cytoplasmic signaling and in reorganization of the actin cytoskeleton. In this syndrome, IgM concentration is decreased. Other antibody concentrations are variable, with IgE and IgA levels usually elevated and IgG level normal to low. This antibody variability is the result of increased antibody catabolism. Platelet deficiency is also associated with Wiskott-Aldrich syndrome. T cells are present but function deficiently. Affected infants have particular difficulty mounting immune responses to protein and polysaccharide antigens, including bacterial cell walls (e.g., *Pseudomonas aeruginosa*, *Staphylococcus pneumoniae*).

**Clinical manifestations and treatment.** Wiskott-Aldrich syndrome is clinically characterized by the presence of eczema, thrombocytopenic purpura, and infection. Affected children are prone to pneumococcal infections, including pneumonia, meningitis, otitis media, and sepsis. They are also subject to renal disease, malignancies, and systemic autoimmunity.<sup>15</sup> The average age of these infants at death is 3.5 years without treatment.

Infants with Wiskott-Aldrich syndrome are treated with antibody replacement therapy, and antibiotic therapy. Bone marrow transplantation, stem cell transplantation, and gene therapy are options used to manage this disorder in affected children.

## T-Cell Disorders

### DiGeorge Syndrome or 22q11.2 Deletion Syndrome

**Etiology and pathogenesis.** 22q11.2 Deletion syndrome, previously known as DiGeorge syndrome, or thymic hypoplasia, is a developmental T-cell disorder associated with total or partial loss of thymus gland function. The development of this syndrome is caused by a chromosomal 22q11.2 deletion (del 22q11). It is the most common microdeletion syndrome with an estimated prevalence of 1 in 4000 live births.<sup>16</sup> Male and female children are equally affected.<sup>16</sup> There may also be associated genetic modifiers that vary in clinical presentation. In this disorder, the aplastic or hypoplastic thymus is unable to assist in the maturation of T cells. Therefore, T cells are deficient. B cells are normal.

**Clinical manifestations and treatment.** Because 22q11.2 deletion syndrome is a congenital disorder of fetal organ development, it is often associated with other congenital problems, such as developmental delay, cardiac and great vessel anomalies, hypoparathyroidism with hypocalcemia, hypothyroidism, esophageal atresia or reflux, urogenital anomalies, and unusual facial features, including mandibular hypoplasia, short forehead, and protuberant or low-set ears.<sup>15</sup> With partial loss of thymus function, the individual may not have trouble with infections. However, recurrent infections occur in up to 40% of patients and up to 1% of patients have severe immunodeficiency that resembles SCID with total loss of thymus function.<sup>16</sup> This increases the risk of fetal loss or infant death. For these children, thymic transplantation has been helpful in reestablishing T-cell populations. Specific treatments and therapies are needed for the management of these patients.

### Chronic Mucocutaneous Candidiasis

**Etiology and pathogenesis.** Chronic mucocutaneous candidiasis is a T-cell disorder caused by one of two genetic etiologies. The first is an autosomal recessive deficiency in a specific cytokine receptor: interleukin-17 receptor A (IL-17RA), which causes complete lack of cellular responsiveness to the inflammatory cytokines IL-17A and IL-17F.<sup>17</sup> The second etiology is an autosomal dominant deficiency of the cytokine IL-17F, which is partial and allows some cytokine activity.<sup>17</sup> As a result of these deficiencies, chronic mucocutaneous candidiasis is characterized by a selective deficiency of cell-mediated immunity against *Candida albicans* and, to a lesser extent, *Staphylococcus aureus*. In this case, T cells do not produce the correct cytokines needed for the cell-mediated immunity to *C. albicans*. This causes persistent or recurrent severe skin, nail, and mucous membrane infections with *C. albicans*. B-cell and T-cell functions are usually normal, except for the inability of the T cells to respond to *Candida* infections. Occasionally IgA or other antibody levels may be affected.

**Clinical manifestations and treatment.** The goal of treatment is to reduce the severity of skin and mucous membrane infection and to decrease the disfigurement from infection and scarring. Treatment involves antifungal therapy. This disorder is also associated with an autoimmune disorder called *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED).<sup>18</sup> The most common components of APECED are chronic mucocutaneous candidiasis, hypoparathyroidism, and Addison disease (see Chapter 40).

## B-Cell Disorders

### IgA Deficiency

**Etiology and pathogenesis.** The most common B-cell primary immunodeficiency disorder is selective IgA deficiency. This disorder affects 1 in 2000 persons.<sup>19</sup> It is a B-cell disorder characterized by failure of IgA-bearing lymphocytes to become plasma cells, with resulting lack of secretory IgA in the serum. Genetically, it can be an autosomal

recessive or autosomal dominant disease. The B-cell level is normal but there is a lack of B-cell response to interleukins (IL-4, IL-6, IL-7, or IL-10).<sup>19</sup>

**Clinical manifestations and treatment.** People with this disorder are prone to respiratory, gastrointestinal, and genitourinary tract infections. They tend to have many autoantibodies (including anti-IgA antibodies), with a high incidence of vascular, endocrine, and collagen autoimmune diseases.<sup>20</sup> They often react to cow's milk, and inflammatory bowel conditions such as celiac disease can develop. Because they have severe allergic reactions to blood or blood products containing IgA, exogenous IgA replacement is contraindicated. Treatment includes prevention of infection and management of infection with appropriate antibiotics.

### Bruton X-Linked Agammaglobulinemia

**Etiology and pathogenesis.** Bruton X-linked agammaglobulinemia (XLA), or congenital hypogammaglobulinemia, is a B-cell genetic disorder caused by a lack of normal B-cell development in the bone marrow. The disorder is linked to a mutation of the gene *btk* (Bruton tyrosine kinase) located on the long arm of the X chromosome at position Xq21.3 to Xq22. In 1952 it was the first genetic immunodeficiency disorder identified. This mutation occurs in a cytoplasmic signal-transducing molecule encoded by the *btk* gene, which results in B-cell deficiency. The B-cell deficiency causes decreased serum concentrations of IgG and no detectable IgA or IgM. The number of CD4<sup>+</sup> memory T cells is decreased.<sup>21</sup> The decreased number of CD4<sup>+</sup> T cells is believed to be due to the lack of B cells and supports the importance of B-cell and T-cell immune system interaction.<sup>21</sup> The thymus functions normally. Plasmacytes are absent and reticuloendothelial tissue and lymphoid organs (e.g., tonsils, spleen, Peyer patches, lymph nodes) are poorly developed.<sup>19</sup> The disease is characterized by recurrent bacterial infection and profound hypogammaglobulinemia resulting from decreased numbers of circulating B cells. Male infants are affected, but this disorder is typically diagnosed after the infant reaches 9 to 12 months of age because of passive maternal IgG protection. The frequency of the disease is 1:250,000 males.<sup>19</sup> Females are carriers.

**Clinical manifestations and treatment.** Frequent infections, most often attributable to *Haemophilus influenzae* and *Streptococcus pneumoniae*, occur in patients, causing pneumonia, otitis media, meningitis, sinusitis, and septicemia. The recurrent infections can lead to tissue destruction and injury.

Treatment of this disorder includes implementation of antibiotic therapy and prophylactic antibiotics as well as monthly administration of immunoglobulin infusions. However, passive immunotherapy is not always effective. Many children die before the age of 6. If the child survives to adulthood, life expectancy is decreased. Chronic lung disease and large joint arthritis are common in adults with XLA. Currently, curative hematopoietic stem cell–based gene therapy is advocated to correct B cell and myeloid deficiencies.<sup>22</sup> Children who have been diagnosed with XLA should not be immunized with live virus vaccine.<sup>19</sup>

### Transient Hypogammaglobulinemia

Transient hypogammaglobulinemia of infancy is a self-limiting condition in which the infant is slow to acquire normal immunoglobulin levels. The infant experiences a lengthened period of low IgG, IgM, and IgA levels after birth. Normal IgG production begins only after 2 months of life and increases slowly as maternal immunoglobulins are metabolized.<sup>19</sup> Affected infants can demonstrate normal immunoglobulin levels and immune system function by approximately age 3. During the period of low antibody levels, they are more susceptible to infections, particularly respiratory tract infections.

### Common Variable Immunodeficiency

Common variable immunodeficiency (CVI) is a B-cell disorder characterized by low titers of immunoglobulins, particularly IgG and IgA, with 50% of affected individuals also experiencing low titers of IgM.<sup>19</sup> The primary defect is the inability of B cells to differentiate into plasma cells. The exact genetic defect is unknown but there are mutations in genes that encode the production of antibody subclasses and interleukins.<sup>19</sup> This disease is usually not recognized until the second or third decade of life with an incidence of 1:10,000-50,000.<sup>19</sup> Males and females are equally affected.

**Clinical manifestations and treatment.** CVI is characterized by chronic infections, particularly respiratory tract disorders including sinusitis, otitis, laryngitis, and pneumonia. The most frequent pathogens involved are encapsulated bacteria such as *S. pneumoniae* and *H. influenzae*. Infections of the gastrointestinal tract also occur from *Giardia* and *Salmonella*. There is an increased incidence of gastric adenocarcinoma, lymphoma, and lymphoproliferative disease as well as autoimmune diseases including autoimmune thrombocytopenia purpura, arthritis, and thyroiditis. Treatment involves intravenous or subcutaneous administration of immunoglobulin every 2 to 4 weeks, use of corticosteroids, and prompt treatment with antibiotics as needed.

## SECONDARY IMMUNODEFICIENCY DISORDERS

A number of physical, psychosocial, nutritional, environmental, and pharmacologic factors can singly or in combination lead to the development of secondary immunodeficiency disorders. Many of these linkages are discussed in Chapter 8.

The direct and indirect linkages between the brain and the endocrine and immune systems are well known. As a result, excessive or defective neuroendocrine responses can lead to disease. For example, an excessive neuroendocrine response to stress with increased secretion of corticosteroids boosts a person's susceptibility to infectious agents and tumors but enhances resistance to autoimmune disease. On the other hand, a defective neuroendocrine response to stress with low corticosteroid levels enhances autoimmune disease and inhibits infections and tumors. Individuals experiencing physical and psychosocial stress, decreased social support, depression, and bereavement show decreased immune system functioning.

Morbidity and surgery also affect the function of the immune system. After surgery, T-cell and B-cell numbers decrease. This temporary deficiency can last up to 1 month and is most likely a result of the stress of surgery. Some types of surgery, such as splenic surgery, actually reduce the effectiveness of the immune system. Removal of the spleen reduces serum IgM and the antibody response to encapsulated bacteria (e.g., *S. pneumoniae*, *H. influenzae*, *S. aureus*). Disease states such as diabetes mellitus, drug- or alcohol-induced cirrhosis, severe burns, severe trauma, sickle cell anemia, malignancies, and severe infections are associated with secondary immune deficiencies. For example, when blood glucose level rises in patients with diabetes mellitus, white blood cell response to infection declines.

Pregnancy requires immune adaptation in order to be successful. Pregnancy's pro-inflammatory state requires careful control of the immune response and failure to adapt can lead to spontaneous abortion or preeclampsia.<sup>23</sup> During pregnancy, many factors are released from the placenta that influence the immune system, B-cell and T-cell function, and cytokine balance.<sup>22</sup> For example, syncytiotrophoblast microvesicles (STBMs) are shed from the placenta into the maternal circulation. These microvesicles bind to monocytes and B cells and induce cytokine release. Both proinflammatory and antiinflammatory cytokines are released, which prevents excessive inflammation.<sup>23</sup>

A number of pharmaceuticals affect the functioning of the immune system. Cytotoxins and other cancer pharmacotherapeutic drugs cause

a state of generalized immunosuppression. For example, methotrexate is a phase-specific cytotoxin in which cells are killed only if they are in the S, or DNA-synthetic, phase. Cyclophosphamide is toxic to cells in any mitotic phase, although it is better at killing active cells. Anesthetics (e.g., halothane, cyclopropane, nitrous oxide, ether), alcohol, antibiotics, antithyroids, anticonvulsants, antihistamines, and steroids decrease cellular or humoral immunity by various methods. For example, chronic nitrous oxide toxicity leads to cell-mediated immune deficits. Therapeutic radiation (x-rays) also affects the immune system by destroying rapidly proliferating cells. When T-cell and B-cell clones are needed, irradiation eliminates these cells, thus blunting or reducing the effectiveness of the body's response.

A number of studies have linked immune system competency and nutritional status. Malnutritional states can lead to protein depletion, as well as carbohydrate, lipid, vitamin, and mineral deficiencies. Protein and calorie depletion causes T-cell reductions and dysfunction. Antibodies are composed of proteins, levels of which are also low in a state of depletion. Low levels of zinc, an enzyme cofactor needed for lymphocyte function, as well as low levels of folic acid and vitamins B<sub>6</sub>, A, D, and E can result in T-cell and B-cell dysfunction. Overnutrition, especially hyperlipidemia, can lead to lymphocyte and granulocyte dysfunction. Nutritional balance is best for the development of all stem cells, the recognition and processing of antigens, and the attainment of optimal immune cell function.

In the elderly, immune system function is altered. The response to antigenic stimulation is variable. The elderly are less able to respond to "new" antigenic stimuli. The cells of the immune system in the elderly are not able to proliferate or reproduce as effectively as in younger persons. Although the total number of T cells remains the same, T-cell function is decreased. T cells are less capable of proliferating and have decreased cytotoxicity. Antibody production also decreases. A rise also is seen in autoantibody production, which may influence the increase in autoimmune disease in the elderly.

### KEY POINTS

- Primary deficiencies in immune function may be from congenital, genetic, or acquired defects that directly affect immune cell function.
- Secondary deficiencies are conditions that impair immune function as a result of other nonimmune system disorders, such as poor nutrition, pregnancy, stress, or drugs, that secondarily suppress immune function.
- Primary genetic immunodeficiency disorders are fairly common, with most causing moderate immune impairment that may not be diagnosed. Severe congenital immunodeficiency disorders are less common, but clinically significant. Impairment in T cells and B cells results in SCID. Functional B and T lymphocytes are lacking, and infants with SCID easily succumb to sepsis and opportunistic infections. Other types of primary immunodeficiency disorders affect a particular cell type: DiGeorge syndrome (now called 22q11.2 deletion syndrome) occurs with T-cell agenesis related to a lack of thymus function; chronic mucocutaneous candidiasis is caused by abnormal T cells that cannot respond to *Candida*; and selective IgA deficiency is caused by B-cell abnormality.
- Problems in neuroendocrine and immune system interactions are a cause of secondary immunodeficiencies. Excessive neuroendocrine response to stress with increased corticosteroid production increases susceptibility to infection.
- Medications such as cytotoxins and other cancer pharmacotherapeutic drugs cause generalized secondary immunosuppression. However, other medications, such as anesthetics, alcohol, antibiotics, and steroids, also affect the immune response and can lead to secondary immunosuppression.
- Malnutrition, a major cause of immune system dysfunction, leads to lymphocyte dysfunction and altered stem cell development.

## SUMMARY

Human beings live in internal and external environments teeming with antigens capable of producing immunologic responses. Contact with an antigen or antigens usually leads to induction of a normal protective immune response. However, some individuals experience disease caused by either excessive or deficient immune responses.

Both excessive and deficient immune reactions are damaging to tissue. The tissues that are affected depend on the type of antigen, the type of antigen exposure, and the degree of immune responsiveness. In children with immune system dysfunction caused by genetic or embryonic defects, the lack or dysfunction of T cells, B cells, and antibodies can lead to lethal or recurrent infections that severely limit the child's ability to interact with the environment. As a result of their immune disorder, some of these children may never reach maturity. In the elderly, malnutrition, medications, and decreased immune system function as a result of aging, surgery, stress, decreased social support, depression, and bereavement lead to increased infections and autoimmune disease. Autoimmune disease is a type of excessive immune reaction in which the immune system reacts against the body's own cells.

Excessive immune reactions are common and involve a complex interplay between antigen and components of the immune system. Hypersensitivity disorders are differentiated by the cell type involved

and the time course of the reaction. For example, type I hypersensitivity is a rapid response caused by a host of lethal chemicals generated by but involving only one antibody, IgE, and one effector cell, the mast cell. It is an antigen-antibody reaction causing the release of potent chemicals that can lead to extreme, even life-threatening reactions in susceptible individuals. Type II hypersensitivity is also immediate but is tissue specific involving IgG and IgM antibodies, a host of effector cells, and the complement system. It is a linkage between antigen on target cells and the Fab portion of IgG or IgM antibodies. Examples include blood transfusion reactions, hemolytic anemia, and myasthenia gravis.

Type III hypersensitivity reactions, which involve IgG as the major antibody and neutrophils and mast cells as the effector cells, take several hours to develop. These reactions involve the deposition of antigen-antibody immune complexes into tissue and activation of the complement system. This reaction is a deposition problem that depends on the solubility of the antigen-antibody complex and the vascular system. The tissues that have the antigen-antibody complex deposited into them become inflamed. SLE is the major example of type III hypersensitivity. Type IV hypersensitivity takes days to develop and involves cytotoxic T cells but no antibodies. Examples include poison ivy, contact dermatitis, and organ transplant rejection.

### KEY QUESTIONS

- How do the various types of leukemia, lymphoma, and plasma cell myelomas differ based on the type of malignant transformation?
- How do the clinical presentations, prognosis, and management of types of acute and chronic leukemia differ?
- Why are malignant disorders of white blood cells commonly associated with bone marrow depression?
- How is Hodgkin disease clinically and histologically differentiated from other types of lymphoma?
- What is the purpose and process of staging procedures for lymphomas?
- What clinical and laboratory findings would suggest a diagnosis of plasma cell myeloma?

*B-Cell, T-Cell, and NK-Cell Lymphoma (Non-Hodgkin), 229*

Leukemia, lymphoma, and plasma cell myeloma (multiple myeloma) are common neoplastic disorders of the bone marrow and lymphoid tissues. Depending on the location and specific types of white blood cells involved, these malignancies can be further divided into a number of specific subtypes. Leukemias can be conceptualized as circulating tumors that are disseminated from the beginning of the disease process and primarily involve the blood and bone marrow. Lymphoma tends to localize in lymph tissues but is often disseminated to other sites at the time of diagnosis. Plasma cell myeloma is a malignant transformation of B cell plasma cells and has a predilection to form localized tumors in bony structures.

Malignancies of the blood-forming tissues and lymphatic structures often present with nonspecific symptoms. Malaise, weakness, unexplained fever, night sweats, and recurrent infections should raise suspicion of malignancy. Enlarged, nontender lymph nodes (lymphadenopathy) are a common finding in lymphoma and some leukemias. Often, white blood cell malignancies are found by chance during routine assessment of the complete blood cell count (CBC). A very high total white blood cell count or the presence of abnormal cell types should precipitate an assessment for hematologic cell malignancy. In general, earlier detection of malignancy is associated with a better prognosis for cure.

**BOX 11-1 WHO CLASSIFICATION (2008) OF MYELOID NEOPLASMS****Myeloproliferative Diseases (MPD)**

Chronic myelogenous leukemia, Philadelphia chromosome (Ph1) (t(9;22)[q34;q11], bcr/abl)<sup>+</sup>  
 Chronic neutrophilic leukemia  
 Chronic eosinophilic leukemia/hypereosinophilic syndrome  
 Primary myelofibrosis  
 Polycythemia vera  
 Essential thrombocythemia  
 Myeloproliferative neoplasms, unclassifiable  
 Mastocytosis

**Myelodysplastic/Myeloproliferative Diseases**

Chronic myelomonocytic leukemia (CMML)  
 Atypical chronic myelogenous leukemia (aCML)  
 Juvenile myelomonocytic leukemia (JMML)  
 Myelodysplastic/myeloproliferative neoplasms, unclassifiable

**Myelodysplastic Syndromes**

Refractory cytopenia with unilineage dysplasia  
 Refractory neutropenia  
 Refractory thrombocytopenia  
 Refractory anemia (RA)  
   With ringed sideroblasts  
   Without ringed sideroblasts  
 Refractory cytopenia (myelodysplastic syndrome) with multilineage dysplasia (RCMD)  
 Refractory anemia (myelodysplastic syndrome) with excess blasts (RAEB)  
 Myelodysplastic syndromes associated with isolated del(5q)  
 Myelodysplastic syndrome, unclassifiable

**Acute Myeloid Leukemias (AML)**

Acute myeloid leukemias with recurrent cytogenetic translocations  
 AML with t(8;21)(q22;q22), AML1(CBF<sub>1</sub>)/ETO  
 Acute promyelocytic leukemia (AML with t(15;17)(q22;q11-12) and variants, PML/RAR<sub>α</sub>)  
 AML with abnormal bone marrow eosinophils (inv(16)(p13q22) or t(16;16)(p13;q11), CBF<sub>2</sub>/MYH1X)  
 AML with 11q23 (MLL) abnormalities  
 Acute myeloid leukemia with multilineage dysplasia  
   With prior myelodysplastic syndrome  
   Without prior myelodysplastic syndrome  
 Acute megakaryoblastic leukemia with t(1;22)(p13;q13), RBM 15-MKL1  
 Acute myeloid leukemia and myelodysplastic syndrome, therapy related  
 Other types

**Acute Myeloid Leukemia (AML) Not Otherwise Categorized**

AML minimally differentiated  
 AML without maturation  
 AML with maturation  
 Acute myelomonocytic leukemia  
 Acute monocytic leukemia  
 Acute erythroid leukemia  
 Acute megakaryocytic leukemia  
 Acute basophilic leukemia  
 Acute panmyelosis with myelofibrosis  
 AML associated with Down syndrome

**CLASSIFICATION OF HEMATOLOGIC NEOPLASMS**

Various classification schemes have been used to group hematologic neoplasms, with clinicians favoring schemes that use clinical findings and pathologists preferring morphologic criteria. With the advent of technologies to identify specific genetic alterations and molecular characteristics of neoplastic cells, the traditional classification systems have become less useful. However, many clinicians and organizations, such as the American Cancer Society, continue to use traditional groupings to collect statistics and to provide information to the public. The approach used in this chapter incorporates the most recent World Health Organization (WHO) classifications for hematologic neoplasms and also includes common clinical terminology. A major force behind the adoption of the WHO classification is the recognition that lymphoid leukemias and lymphomas are not separate disorders but represent different stages of the same biological disease. Thus, the major categories of the WHO system are based on the cell type of the neoplasm, rather than its location in the body.<sup>1</sup> Neoplasms involving cells of the myeloid lineage (Box 11-1) are separated from those of the lymphoid lineage (Box 11-2). The myeloid lineage includes red blood cells, platelets, monocytes, and granulocytes; the lymphoid lineage includes B cells, T cells, and natural killer (NK) cells (Figure 11-1). There are four major categories of myeloid neoplasms: myeloproliferative diseases; myelodysplastic/proliferative diseases; myelodysplastic syndromes; and acute myeloid leukemia (AML). There are three major categories of lymphoid neoplasms: B-cell neoplasm; T-cell and NK-cell neoplasm; and Hodgkin disease. The term non-Hodgkin

lymphoma is still in clinical usage and refers to lymphomas of B-cell, T-cell, and NK-cell origin. Non-Hodgkin lymphoma includes such a large and diverse group of malignancies that it has little relevance to prognosis or treatment. The WHO classification does not use this term. Other classification systems in current use include the FAB (French-American-British) system for subtypes of myeloid leukemia (Table 11-1). There are many etiologic, pathogenic, and treatment similarities among the hematologic malignancies, and these are addressed in a general way first, followed by sections concentrating on specific diseases.

**ETIOLOGY OF MYELOID AND LYMPHOID NEOPLASMS**

As in other malignant processes, the exact cause of hematologic neoplasms is unknown. The basic mechanism of malignant transformation involves mutation of cells, which disrupts growth control and differentiation pathways. These processes are thought to be similar to those described for solid tumors (see Chapter 7).

Viruses have long been suspected as mutagenic agents in some neoplasms, particularly retroviruses and herpesviruses. Close associations have been found between a small number of viruses and particular malignancies. For example, human T-cell leukemia virus (HTLV-1) is linked to the development of adult T cell lymphoma/leukemia and human immunodeficiency virus (HIV) is linked to B-cell lymphomas. Epstein-Barr virus (EBV) has been implicated in both Hodgkin disease and Burkitt lymphoma.<sup>2</sup> Effective immune surveillance is thought to

## BOX 11-2 WHO CLASSIFICATION OF LYMPHOID NEOPLASMS

### Precursor Lymphoid Neoplasms

Precursor B lymphoblastic leukemia/lymphomas (precursor B-cell ALL)  
Precursor T lymphoblastic leukemia/lymphoma

### Mature (Peripheral) B-Cell Neoplasms\*

B cell chronic lymphocytic leukemia/small lymphocytic lymphoma  
B cell prolymphocytic leukemia  
Lymphoplasmacytic lymphoma  
Splenic marginal zone B-cell lymphoma (6 villous lymphocytes)  
Hairy cell leukemia variant  
Plasma cell myeloma/plasmacytoma  
Waldenström macroglobulinemia  
Heavy-chain diseases  
Extranodal marginal zone B-cell lymphoma of MALT type  
Nodal marginal zone B-cell lymphoma (6 monocytoid B cells)  
Follicular lymphoma  
Mantle cell lymphoma  
Epstein-Barr virus positive DLBCL of the elderly  
Large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease  
Primary mediastinal (thymic) large B-cell lymphoma  
Primary effusion lymphoma  
Burkitt lymphoma/Burkitt cell leukemia

### Mature T-Cell and NK-Cell Neoplasms

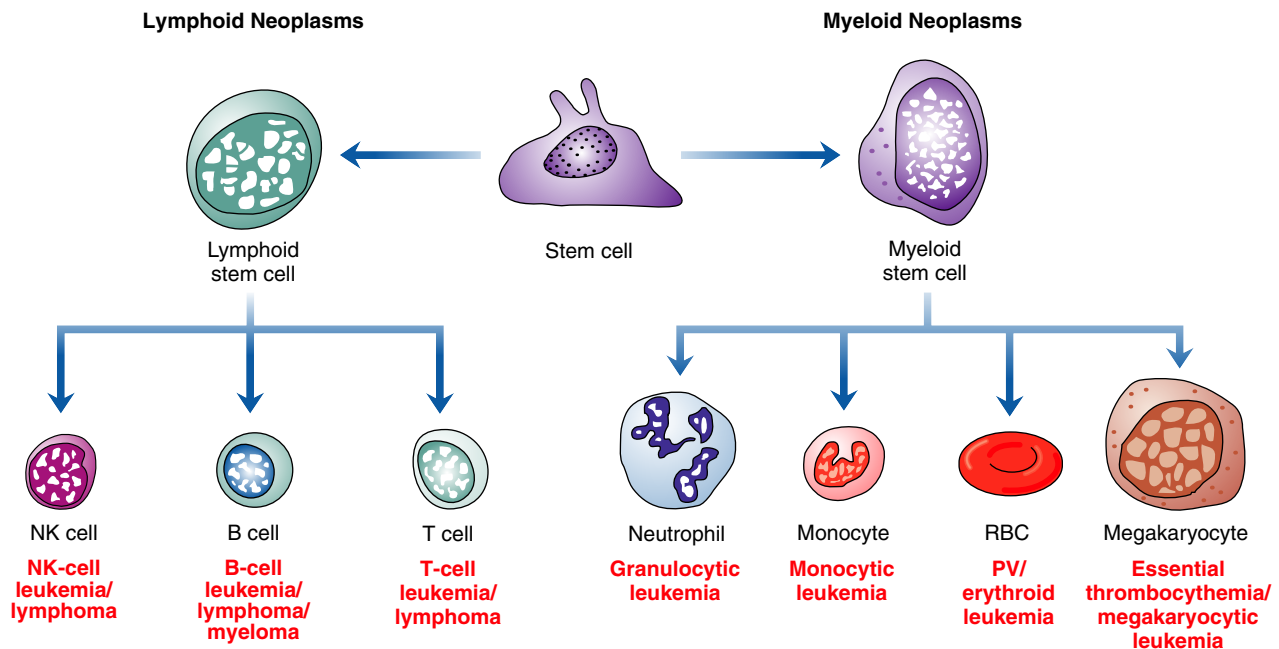

Mature (peripheral) T-cell neoplasms  
T-cell prolymphocytic leukemia  
T-cell granular lymphocytic leukemia  
Aggressive NK-cell leukemia  
Adult T-cell lymphoma/leukemia (HTLV1+)  
Extranodal NK/T-cell lymphoma, nasal type  
Enteropathy-type T-cell lymphoma  
Hepatosplenic  $\gamma\delta$  T-cell lymphoma  
Subcutaneous panniculitis-like T-cell lymphoma  
Mycosis fungoides  
Sézary syndrome  
Primary cutaneous anaplastic large cell lymphoma  
Peripheral T-cell lymphoma, not otherwise characterized  
Angioimmunoblastic T-cell lymphoma  
Anaplastic large cell lymphomas (ALK positive or ALK negative)

### Hodgkin Lymphoma (Hodgkin Disease)

Nodular lymphocyte predominance Hodgkin lymphoma  
Classical Hodgkin lymphoma  
Nodular sclerosis Hodgkin lymphoma (Grades 1 and 2)  
Lymphocyte-rich classical Hodgkin lymphoma  
Mixed cellularity Hodgkin lymphoma  
Lymphocyte depletion Hodgkin lymphoma

From Hoffbrand AV, Moss PAH: World Health Organization classification of tumours of the haematopoietic and lymphoid tissues, *Essential haematology*, ed 6, Oxford, England, 2011, Blackwell, pp 428-429.

\*B- and T/NK-cell neoplasms are grouped according to major clinical presentations (predominantly disseminated/leukemic, primary extranodal, predominantly nodal).

**FIGURE 11-1** Division of hematologic neoplasms into myeloid and lymphoid lineages. PV, Polycythemia vera.

keep proliferation in check and prevent progression in immunocompetent individuals.

Radiation exposure is an important etiologic factor for leukemia and lymphoma. Because of the relatively high turnover of hematologic cells, they are more susceptible to radiation-induced damage than

most other cell types. An acute whole-body dose of radiation like that which occurs with nuclear explosions is known to increase the risk of leukemia. In Japanese survivors of the atomic bomb, the estimated lifetime risk of leukemia is 0.85%, sixfold higher than the norm.<sup>3</sup> There are substantial uncertainties about the risk of low-level, long-term

TABLE 11-1 FAB CLASSIFICATION OF ACUTE MYELOBLASTIC (MYELOCYTIC) LEUKEMIAS

CLASS	MORPHOLOGY	COMMENTS
M0: Minimally differentiated AML	Blasts lack definitive cytologic and cytochemical markers of myeloblasts but express myeloid lineage antigens	2% to 3% of AML
M1: AML without differentiation	Very immature myeloblasts predominate; few granules or Auer rods	20% of AML; Ph chromosome present in 10% to 15% of cases, worsens prognosis
M2: AML with differentiation	Myeloblasts and promyelocytes predominate; Auer rods commonly present	30% of AML; presence of t(8;21) translocation associated with good prognosis
M3: Acute promyelocytic leukemia	Hypergranular promyelocytes, often with many Auer rods per cell; may have reniform or bilobed nuclei	5% to 10% of AML; disseminated intravascular coagulation common; presence of t(15;17) translocation is characteristic; responds to retinoic acid therapy
M4: Acute myelomonocytic leukemia	Myelocytic and monocytic differentiation evident; myeloid elements resemble M2; peripheral monocytosis	20% to 30% of AML; presence of inv16 or del16q associated with better prognosis
M5: Acute monocytic leukemia	Monoblasts (peroxidase negative, esterase positive) and promonocytes predominate	10% of AML; usually in children and young adults; gum infiltration common; associated with abnormalities of chromosome 11q23
M6: Acute erythroleukemia	Bizarre, multinucleated, megaloblastoid erythroblasts predominate; myeloblasts also present	5% of AML; high blood counts and organ infiltration are rare; affected persons are of advanced age
M7: Acute megakaryocytic leukemia	Blasts of megakaryocytic lineage predominate; react with antiplatelet antibodies; myelofibrosis or increased bone marrow reticulin	

From Kumar V, Cotran RS, Robbins SL, editors: *Basic pathology*, ed 7, Philadelphia, 2003, Saunders, p 437. AML, Acute myeloblastic (myelocytic) leukemia; FAB, French-American-British; Ph, Philadelphia.

exposure to radiation. The average annual exposure from usual sources including cosmic rays and medical procedures is very low and estimated to account for less than 5% of leukemia cases.

Despite intensive scrutiny only a small number of chemicals have been shown unequivocally to increase the risk of hematologic malignancies. Benzene has been implicated in numerous studies as has cigarette smoking. Other suggested carcinogens have failed to be confirmed, including exposure to hair dye, alcohol, and marijuana.<sup>4</sup> On the other hand, a study from the Children’s Cancer Group found a link between high maternal intake of products high in bioflavonoids (beans, fresh vegetables, and fruit) and an increased incidence of infant leukemia.<sup>5</sup> These bioflavonoids were enzyme inhibitors (topoisomerase II inhibitors) that caused DNA cleavage and chromosome translocations. Many of the anti-neoplastic drugs used to treat cancers, especially the alkylating agents, are significant factors in the development of posttreatment hematologic neoplasia. Any drugs that suppress the bone marrow or immune function are also believed to predispose to the emergence of malignancies.

A number of disease conditions have been linked to the development of leukemia, although the mechanisms are unclear. A reduction or alteration in normal hematopoiesis, as occurs in such disorders as Fanconi anemia and aplastic anemia (see Chapter 13), is associated with a higher incidence of leukemia. A higher risk also has been noted in some genetic diseases, including Down syndrome and Klinefelter syndrome (see Chapter 6).

## GENERAL PRINCIPLES OF MANAGEMENT

### Diagnosis of Hematologic Neoplasms

Manifestations of hematologic neoplasms vary somewhat, depending upon the cell type involved. Common manifestations are shown in Box 11-3. Clinical symptoms are related to bone marrow suppression and organ dysfunction secondary to leukemic infiltration. Bone marrow suppression results in varying degrees of **leukopenia**, **anemia**, and **thrombocytopenia**. These three deficiencies cause the most common clinical manifestations and may prompt the patient to seek care.

## BOX 11-3 COMMON MANIFESTATIONS OF HEMATOLOGIC MALIGNANCIES

### History

- Fever
- Weight loss
- Night sweats
- Itching (pruritus)
- Fatigue
- Bone pain (sternum, tibia, femur, back)
- Abdominal fullness
- Bleeding episodes (epistaxis, menorrhagia)
- Bruising, petechiae
- Frequent infections
- Headache, nausea, vomiting

### Physical

- Enlarged spleen
- Enlarged liver
- Enlarged lymph nodes
- Hyperplasia of gums

### Laboratory

- Anemia or polycythemia
- Thrombocytopenia or thrombocytopenia
- Leukopenia or leukocytosis
- Blasts on peripheral blood smear
- Elevated uric acid level
- Elevated alkaline phosphatase level
- Hypercalcemia

Anemia, with a hematocrit level of 25% to 30% or a hemoglobin level of 8 to 10 g/dl, may manifest with pallor, fatigue, malaise, shortness of breath, and decreased activity tolerance. The severity of symptoms is determined by the rate of red blood cell decrease as well as the absolute deficiency. Chronically low hemoglobin and hematocrit values may be better tolerated than a drastic drop in these measurements. Depending on symptoms, transfusion may be indicated when the hematocrit level falls below 30%.

Thrombocytopenia, with a platelet count less than 20,000 cells/ $\mu$ L, can manifest as petechiae, easy bruising, bleeding gums, occult hematuria, or retinal hemorrhages. Spontaneous intracranial bleeding can occur and may be fatal. In general, the risk of bleeding increases proportionately to the fall in platelet count. Platelet transfusion may be given when the risk of bleeding is high.

Insufficient numbers of functional leukocytes leaves the patient at high risk for development of infection and the complete blood count is routinely monitored. **Neutropenia** is an absolute neutrophil count less than 500 cells/ $\mu$ L, and an affected patient requires protective isolation (neutropenic precautions) to prevent infection. Infections may be caused by bacterial, viral, fungal, or protozoal organisms. Often, the microorganisms are of the opportunistic variety. That is, they are part of the patient's own flora, which normally do not cause disease unless the host's immune system becomes incompetent. It is very difficult to protect patients from their own flora, and infection is the most common cause of death in the immunocompromised leukemic patient. The presence of infection is suspected if fever develops. Infections are managed aggressively with antibiotic agents to prevent development of life-threatening sepsis.

Infiltrative manifestations include lymphadenopathy, joint swelling and pain, weight loss, anorexia, hepatomegaly, and splenomegaly. Sternal tenderness is frequently present in chronic myeloid leukemia (CML). Gingival hyperplasia occurs in acute myeloid leukemia (AML). Meningeal involvement is frequently encountered in children with acute lymphoid leukemia (ALL). Central nervous system (CNS) infiltration can occur with any type of leukemia and may be difficult to manage because of the poor ability of chemotherapeutic agents to cross the blood-brain barrier. CNS involvement can present with increased intracranial pressure, seizures, or changes in mental ability. Increased intracranial pressure should be suspected in the leukemia patient who complains of nausea, vomiting, headache, and visual changes.

A key aspect of diagnosis is the evaluation of a peripheral blood sample. Blood cell number and morphologic evaluation are indicative; however, definitive diagnosis is usually made after bone marrow aspiration or lymph node biopsy. Malignant cells can be subtyped according to genetic and molecular characteristics to better determine prognosis and choice of treatment.<sup>6</sup>

### Principles of Treatment

To make informed treatment decisions, patients and their families need information about the nature and prognosis of their disease as well as about the risks and benefits of various treatment options. Many treatment protocols are experimental, and the outcomes may be uncertain. Sometimes the side effects of treatment as well as its limited efficacy will weigh in favor of palliative care. Treatment decisions are complex and stressful for all concerned. A great deal of support must be available during the diagnostic, treatment, and monitoring phases.

The management of hematologic malignancies relies primarily on the use of combination chemotherapy to eradicate malignant cells and stem cell transplant to rescue and restore bone marrow function. In some cases radiation and tissue-specific drug therapy may be indicated. Unfortunately, the treatment regimen usually causes many serious side effects that must be monitored and treated.

The goal of chemotherapy is to induce long-term remission, that is, the absence of any detectable neoplastic cells in the body. A complete remission (CR) is defined as a return to normal hematopoiesis with normal red blood cell, neutrophil, and platelet counts and no detectable neoplastic cells. For leukemia, the bone marrow must have less than 5% blasts, which are the most immature bone marrow cells, and be maintained for at least 4 weeks.<sup>7</sup> CR is not synonymous with cure. Therefore, most treatment protocols include several cycles of chemotherapy to eradicate the undetected cells. The choice of antineoplastic agents varies with the type of neoplasia and the stage of clinical disease. Most chemotherapeutic agents work by disrupting some aspect of DNA synthesis or cell replication and induce **apoptosis** (cell suicide; see Chapter 4). In general, rapidly dividing cells are more susceptible to apoptosis because they have less time for repair. Neoplasms with genetic defects that impair apoptotic pathways may be more difficult to eradicate and require more intense therapy. Unfortunately, these high doses are toxic to normal stem cells as well and can produce fatal bone marrow failure. Therefore, to effect a cure, high-dose chemotherapy is often followed by bone marrow "rescue" with transplantation of functional stem cells.

Chemotherapy usually includes two or three treatment phases: (1) remission induction phase, (2) postremission or consolidation phase, and (3) remission maintenance phase. The aim of treatment during the remission induction phase is to eliminate all detectable neoplastic cells and achieve a CR. Postremission consolidation therapy begins after CR is attained in an attempt to eliminate the population of undetected cells that may have escaped initial induction phase treatment. Maintenance phase treatment is used in the management of some neoplasms to prolong the remission interval. Intermittent chemotherapy may be continued for 2 to 3 years after initial induction of remission. Drugs that target the neoplastic cells specifically, such as monoclonal antibodies or molecular therapies, are generally less toxic than other agents and may be used for long-term maintenance in patients with residual disease.

In children and adults, the CNS can act as a sanctuary for neoplastic cells in diseases such as acute lymphoblastic and acute myeloblastic leukemias. This makes conventional routes of chemotherapy unsuccessful, because they do not permit drugs to cross the blood-brain barrier efficiently. Chemotherapeutic agents administered into the cerebrospinal fluid (CSF) via lumbar puncture (intrathecal route) can effectively eliminate leukemic cells in the CNS. This therapy carries significant risk for temporary or permanent neurologic damage. A number of different chemotherapeutic agents can be administered safely by the intrathecal route, including methotrexate.<sup>8</sup>

### Prevention and Management of Complications

Maintenance of adequate nutrition in patients with hematologic malignancy is a major challenge. Anorexia, weight loss, nausea, vomiting, and **stomatitis** are common findings, especially during the treatment phase. Children and adolescents receiving chemotherapy may experience significant growth delay, and measures to maintain protein and caloric intake are necessary. Newer antiemetic agents have been helpful in reducing nausea, vomiting, and anorexia associated with chemotherapy and should be considered in patients experiencing these symptoms.

Infection is the most troublesome of complications for the patient who is immunosuppressed by either disease or treatments. Constant vigilance in prevention, early detection, and rapid management of infections can profoundly affect the outcome of chemotherapy. The length of time that a patient remains neutropenic can be shortened with the use of growth factors to stimulate bone marrow production of granulocytes.

Bone marrow transplantation (BMT) has been an important part of the management of certain leukemias for many years. The intense chemotherapy used to induce remission can lead to bone marrow failure. Stem cells can be reintroduced into the host's bone marrow by bone marrow transplantation. The transplanted cells are given intravenously; they find their way to the host's bone marrow, where they establish residence and begin to produce functional white blood cells, red blood cells, and platelets. A close match between donor and host is necessary for a successful transplantation. Otherwise, the transplanted cells can mount an immune attack on the host's tissues—a life-threatening problem called *graft-versus-host disease* (see Chapter 10). In past years, bone transplantation was obtained by aspiration from the marrow of a suitable donor and this is still appropriate in some cases. *Peripheral stem cell transplantation* allows stem cells to be harvested from the circulating bloodstream. This procedure can be used to collect stem cells from the patient's own blood to be stored and then reinfused after chemotherapy and irradiation. This type of transplant is called *autologous*, whereas a transplant from a closely matched relative is called *allogeneic* (Figure 11-2). Use of autologous transplants eliminates the problem of graft-versus-host disease and reduces transplant-related mortality, but the potential for disease recurrence is higher than with allogeneic transplants.

It has been noted that in AML and CML, transplantation with allogeneic cells is much more successful in curing leukemia than is autologous transplantation. Transplanted cells in the allograft are thought to detect and kill leukemic cells in a process termed *graft versus leukemia*. Autologous transplants are appropriate in some cases, especially when a matched donor is not available, because they may extend life even though cure is unlikely. Autologous transplants are well tolerated and cause fewer complications than allografts. Methods to purify a patient's collected peripheral blood by selectively removing neoplastic cells are available to reduce the risk of reintroducing malignant cells during autologous transplantation. Increased availability of stem cell transplants allows patients to undergo more intensive chemotherapy, aimed at cure rather than palliation, based on the knowledge that bone marrow rescue is possible.

Anemia is a common complication of leukemia and chemotherapy. Red blood cell production by the bone marrow is suppressed, but the size and shape of red blood cells present in the blood are normal. This is called *normocytic, normochromic anemia*. Administration of erythropoietin growth factors can enhance red blood cell production and moderate anemic episodes. However, patients frequently require red blood cell transfusion therapy to maintain adequate red blood cell counts. Patients with frequent or significant bleeding episodes are also

**FIGURE 11-2** Procedures for allogeneic and autologous stem cell transplantation. For nonmyeloblastic (reduced intensity) allogeneic stem cell transplantation, lower doses of chemotherapy with or without radiotherapy are used. (From Rodak B et al: *Hematology: clinical principles and application*, ed 4, Philadelphia, 2012, Saunders.)

predisposed to severe anemia, and efforts to prevent bleeding will help to minimize anemia.

Platelet deficiency (thrombocytopenia) with resultant hemorrhage can be a life-threatening complication of leukemia and chemotherapy. In patients at high risk of bleeding, fresh frozen plasma or pooled platelets may be given to inhibit bleeding. Patients must be protected from trauma and may be placed on activity restrictions.

Pain is a common complication of the diagnostic and treatment protocols used in the cancer patient as well as of the disease process itself. Pain most commonly involves the bones and joints, and is due to pressure caused by infiltration and accumulation of neoplastic cells in the bone marrow. *Hemarthrosis* (bleeding into joints) can cause acute episodes of joint pain. Chemotherapy may help reduce bone pain, as the number of neoplastic cells is reduced drastically. Patients are subjected to numerous painful procedures during diagnosis, treatment, and monitoring. Frequent collection of blood and bone marrow samples, placement of intravenous access lines for drug administration, and manifestation of unpleasant drug side effects all contribute to the pain experience. Nausea and mouth pain (stomatitis) are frequent complaints during chemotherapy. Pain management with a variety of strategies, including narcotic and nonnarcotic drugs, distraction, and biofeedback, is generally helpful. (See Chapter 47 for a discussion of pain and pain management.)

Epithelial cells, with normally high rates of turnover, are particularly susceptible to damage by radiation and chemotherapy. Sloughing of skin and mucous membranes and hair loss (alopecia) are common. Loss of skin and mucous membrane integrity increases the risk of infection and can contribute significantly to the pain and discomfort of treatment. Abnormalities in growth, development, and fertility are complications of particular concern in children undergoing radiation and chemotherapy.

### KEY POINTS

- Classification of the types of leukemia is based on cell type involved (lymphoid or myeloid) and degree of cell maturation. Common myeloid neoplasms include CML, polycythemia vera, essential thrombocythemia, and AML. Common lymphoid neoplasms include chronic lymphoid leukemia (CLL), acute lymphoblastic leukemia (ALL), plasma cell myeloma, Hodgkin disease, and various forms of non-Hodgkin lymphoma.
- Risk factors for the development of hematologic neoplasms include exposure to chemical, viral, and radiation mutagens; consequences of chemotherapy drugs; and effects of immunodeficiency disorders.
- Common manifestations of hematologic neoplasia are due to insufficient production of normal white blood cells, red blood cells, and platelets, as evidenced by leukopenia, anemia, and thrombocytopenia. Anemia manifests as pallor, fatigue, dyspnea, and decreased activity tolerance. Thrombocytopenia causes petechiae, bleeding gums, hematuria, and prolonged bleeding time. Leukopenia manifests as frequent, recurrent infections. Other manifestations may occur with infiltration of tissues and organs. These include weight loss, anorexia, lymphadenopathy, bone pain, and CNS dysfunction.
- Chemotherapy is the mainstay of management for most hematologic neoplasms. Several courses may be needed to kill neoplastic stem cells. Most chemotherapeutic agents interfere with some aspect of DNA replication and cell division to induce apoptosis (cell suicide).
- Treatment is associated with a number of potential complications including anemia, infection, and bleeding. Rapidly dividing hair cells and mucous membranes are also affected, leading to alopecia and stomatitis. Transfusion of blood products or stimulation of endogenous production with colony-stimulating factors and erythropoietin may be necessary. Bone marrow transplantation may be undertaken in some cases to restore stem cell function.

## MYELOID NEOPLASMS

Myeloid neoplasms result from transformation and proliferation of a precursor stem cell in the bone marrow (Figure 11-3). The progeny of the aberrant stem cell clone accumulate in the bone marrow and are released into the circulation. In many cases, the abnormal stem cell is multipotent and causes the overproduction of more than one cell type, resulting in myeloproliferative disease. The cells produced in myeloproliferative diseases are usually functional and have a normal morphologic appearance. The common myeloproliferative diseases are chronic myeloid leukemia (CML), polycythemia vera (PV), and essential thrombocythemia (ET), referring respectively to an excess of granulocytes, red blood cells, and platelets. These insidious and indolent disorders have few clinical symptoms and are commonly discovered on routine CBC analysis. Common features of CML, PV, and ET include involvement of a multipotent hematopoietic progenitor cell; hypercellularity of marrow; overproduction of one or more functional blood cells; chromosomal abnormalities involving chromosomes 1, 8, 9, 13, and 20; and eventual spontaneous conversion to AML or development of marrow fibrosis.<sup>9</sup>

In contrast to the myeloproliferative diseases, the myelodysplastic syndromes and AML are characterized by neoplastic cells that are morphologically and functionally abnormal. The prognosis for myelodysplastic syndromes and AML is poor, and intensive treatment is necessary to extend life. AML and CML are described next. A discussion of PV and ET can be found in Chapters 13 and 14, respectively.

### Chronic Myeloid Leukemia

**Pathogenesis and clinical manifestations.** CML represents approximately 15% of all cases of leukemia in the United States. The average age of onset is between 40 and 50 years, and CML occurs only

**FIGURE 11-3** Maturation pathways of myeloid cells showing the different types of leukemia associated with various stages of development. M1, M2, and M3 types result in granulocytic leukemia; M4 has characteristics of monocytic and granulocytic leukemia; M5 is monocytic; M6 is associated with erythroid leukemia; and M7 is associated with megakaryocytic leukemia. RBC, Red blood cell.

occasionally in childhood and adolescence.<sup>10</sup> The majority of CML cases are characterized by malignant granulocytes that carry a unique chromosomal abnormality, the Philadelphia chromosome (Ph<sup>+</sup>). The Philadelphia chromosome is formed because of a balanced translocation between chromosomes 9 and 22 (Figure 11-4). The translocation causes two genes to be juxtaposed, resulting in a new fusion gene called *bcr-abl*. This mutation is thought to be critical in the development of CML. Molecular studies have revealed that the protein product of the fusion gene is a functional enzyme that spurs cell proliferation and reduces apoptotic cell death. CML is unusual among human cancers because a single oncogene (*bcr/abl*) is capable of conferring a malignant state.<sup>11</sup> Numerous mutations are necessary for development of most other cancers (see Chapter 7). The cells in CML are more mature than those found in AML, as noted by the greater degree of nuclear segmentation (Figure 11-5).

The usual clinical presentation of CML includes a high granulocyte count on the CBC and splenomegaly. Symptoms, when present, may include fatigue, weight loss, diaphoresis, bleeding, and abdominal discomfort from the enlarged spleen.

**Prognosis and treatment.** CML does not respond well to chemotherapy. Although most patients will achieve a temporary remission, the overall survival time is poor. In untreated patients the median survival is about 2 years.<sup>12</sup> After discovery of the fusion protein (*bcr/abl*), drugs targeted to inhibit its action were developed (e.g., imatinib). The goal of anti-*bcr/abl* therapy is to reduce the number of leukemic cells with the *bcr/abl* phenotype to undetectable levels. It is not known whether imatinib can cure CML or what duration of treatment is necessary to permanently suppress the leukemic cell population. Some patients with CML have developed drug resistance against imatinib, and research is ongoing. The only known curative treatment is **allogeneic** bone marrow transplantation from a suitable donor. It is believed that the donor cells detect and kill the host's leukemic cells. Even with a human leukocyte antigen (HLA)-identical sibling donor, the probability of transplant-related mortality is about 25% and the likelihood of long-term disease-free survival is 50% to 60%.<sup>11,12</sup> Transplant-related mortality is about 50% if the HLA-matched donor is unrelated.<sup>11</sup> Bone marrow transplantation with cells harvested from the patient's own blood (autografting) during the early stages of CML may also be done, but it is less effective in curing the disease. For those not able to undergo stem cell transplantation, standard chemotherapy during the chronic phase may be instituted. Chemotherapy may include hydroxyurea, interferon- $\alpha$  (IFN- $\alpha$ ), cytosine arabinoside (cytarabine, Ara-C), and

imatinib. Once CML has progressed to the blast phase, essentially becoming AML, the prognosis is very poor regardless of treatment, with an expected median survival of 3 to 4 months.

### Acute Myeloid Leukemia

**Pathogenesis and clinical manifestations.** AML is primarily a disease of adults, comprising 80% of cases of acute leukemia in this population while accounting for only 20% of the cases of acute leukemia of childhood.<sup>10</sup> The median age at presentation is 64 years. Like CML, AML is a malignant disorder associated with transformation of a myeloid stem cell. The bone marrow aspirate must have more than 20% blasts to be classified as AML.<sup>13</sup> AML can present in a variety of ways because of the potential for myeloid stem cells to produce different cell types. Thus, AML has a number of subtypes. These are identified by the stage at which cell development stops (see Figure 11-3). The French, American, British (FAB) system for classifying AML as M0 through M7 is in common use (see Table 11-1). Acute granulocytic leukemia is the most common type of disorder, and the term is often used interchangeably with AML. Myeloblastic cells have a large, non-segmented nucleus and fine chromatin (Figure 11-6). AML is also subtyped according to genetic abnormalities. Worse outcomes are noted with loss of *TP53* or *RB* tumor suppressor gene function. The World Health Organization (WHO) classification of AML recognizes four common types of genetic abnormalities (and one other) (see Box 11-1). Most are chromosomal translocations or inversions. If cytogenetic class is not apparent, then AML is classified by morphologic characteristics, including myeloid cell of origin and degree of differentiation or maturation. Correct classification increases the accuracy of prognosis and may influence the choice of treatment.

AML presents in a manner very similar to that of ALL, and the two are difficult to distinguish by clinical findings alone. Acute leukemia causes bone pain, anemia, thrombocytopenia, and increased susceptibility to infection. The skin, the genitourinary and gastrointestinal systems, and the respiratory tract are common infection sites. The onset of symptoms is abrupt, with most patients seeking care within a few weeks of disease onset. The prognosis is much worse for AML than for ALL, with fewer than 50% of children and only about 30% of adults achieving long-term survival.<sup>6,14</sup> An exception is the promyelocytic

**FIGURE 11-4** Balanced translocation between chromosomes 9 and 22 results in the formation of a Philadelphia chromosome. The translocation causes two genes, *abl* and *bcr*, to become juxtaposed, resulting in a fusion gene. This fusion gene, *bcr-abl*, is thought to be essential for the development of chronic myeloid leukemia.

**FIGURE 11-5** Peripheral blood smear from a patient with chronic myeloid leukemia (CML). Note that a greater degree of neutrophil segmentation is found in CML than in acute myelogenous leukemia (see Figure 11-6), reflecting a more advanced stage of development. subtype of AML. Although it accounts for only 10% to 15% of AML cases, acute promyelocytic leukemia (APL) deserves special consideration because it is the most curable of all AML subtypes, with a 70% to 80% 5-year disease-free survival.<sup>6</sup> APL is characterized by a chromosomal translocation between chromosomes 8 and 21, which forms a fusion gene called *PML/RAR $\alpha$* . The *PML/RAR $\alpha$*  protein binds to a repressor complex in the cell nucleus and inhibits myeloid cell differentiation. *RAR $\alpha$*  is a retinoic acid receptor that can be induced to release its inhibitory hold on differentiation when *all-trans*-retinoic acid (ATRA) is administered. Addition of ATRA to the chemotherapy management of patients with APL significantly improves disease-free survival<sup>6</sup> (see Table 11-2 for a comparison of acute and chronic leukemias).

**Prognosis and treatment.** Treatment protocols for AML are increasingly incorporating the cytogenetic profile of the leukemic cells to individualize therapy and monitor response. Traditionally the management of AML has two phases: remission induction and consolidation/postremission. A CR is attempted in the remission induction phase, with an attempt to eliminate any undetected residual leukemic cells during the consolidation/postremission phase. Patients with AML who are able to complete only one or two cycles of their chemotherapy because of toxicity almost invariably have recurrence of leukemia even when CR was achieved. To induce remission, most protocols use two cycles of a combination of agents (e.g., idarubicin + Ara-C + etoposide, called the ICE protocol; or daunorubicin + Ara-C + 6-thioguanine,

called the DAT protocol). Postremission therapy commonly includes high-dose Ara-C in younger patients whereas the elderly require lower dose regimens. Drug treatment is constantly being evaluated and altered to obtain better outcomes. At present patients younger than 60 years have a 4-year survival of 30% to 40%, whereas elderly patients have a 2-year survival of 20%.<sup>6</sup> With the advent of allogeneic stem cell transplantation, the chances for cure may improve; however, procedure-related mortality is 10% to 25%. New therapies using monoclonal antibodies to detect and destroy leukemic cells have been used and show promise for improving outcomes in AML.

#### KEY POINTS

- CML is a myeloproliferative disorder that affects adults primarily, has an insidious onset, and responds poorly to chemotherapy. CML is characterized by the presence of a gene translocation (Philadelphia chromosome) that produces a fusion gene called *bcr-abl*. The product of this gene is thought to be responsible for producing the malignancy. This molecular abnormality is the target of new drug therapies to eliminate neoplastic cells. The prognosis of CML remains relatively poor but may be improved with allogeneic bone marrow transplantation in which transplanted cells destroy leukemic cells.
- AML affects adults primarily, has an acute onset, responds fairly well to treatment, and has a prognosis somewhat worse than that of ALL. AML is usually a malignancy of granulocytes, although other myeloid cell types may be affected. Several gene abnormalities have been identified in AML that may indicate better or worse prognosis. The median survival of patients younger than 60 years is 30% to 40% at 4 years.

## LYMPHOID NEOPLASMS

The lymphoid neoplasms include malignant transformations of B cells, T cells, and NK cells. When present in blood and bone marrow, lymphoid neoplasms are called *leukemias*, and when they are localized in lymphoid tissues they are called *lymphomas*. The location of lymphoid neoplasms is a consequence of the stage of the disease. The WHO classification uses cell type rather than stage to classify the lymphoid neoplasms, resulting in some difficulty with the traditional conceptualization of leukemias and lymphomas. The factors that determine whether a particular neoplastic cell will present as leukemia or as lymphoma are not presently known. Subcategories of the B-cell and T-cell/NK-groups are based on the maturity of the neoplastic cells (see Box 11-2). The *precursor cell* neoplasms are characterized by cells that have arrested development in the early blast stage, whereas the *mature cell* neoplasms are more differentiated and often located in peripheral sites (Figure 11-7).

### Chronic Lymphoid Leukemia

**Pathogenesis and clinical manifestations.** CLL accounts for about 30% of all cases of leukemia in the United States. In 95% of cases, a malignant B-cell precursor is at fault.<sup>15</sup> Only 5% of cases of CLL are associated with T-cell transformation, but this type is more aggressive.<sup>4</sup> In general, B-cell CLL follows an indolent course, which is usually asymptomatic. Often CLL is found by accident on routine blood count examinations. When CLL becomes symptomatic, patients may experience fatigue, weight loss, and anorexia. Because the leukemic B cells do not produce antibodies normally, an increased susceptibility to certain types of infection may occur. Malignant lymphocytes invade lymphoid tissues and bone marrow, disrupting function. Lymphoid invasion often presents as enlarged, painless lymph nodes (lymphadenopathy) or enlarged spleen (splenomegaly). Bone marrow

**FIGURE 11-7** Maturation pathways of T and B lymphocytes showing the stages at which lymphocyte development is typically arrested in leukemia. Different markers are present on the surface of B cells and T cells at progressive stages of development, which are helpful in identifying the neoplastic cell type and maturity.

**FIGURE 11-8** Bone marrow aspirate showing small lymphocytes with condensed nuclear chromatin typical of chronic lymphocytic leukemia, B-cell type. (From Henderson ES et al, editors: *Leukemia*, ed 7, Philadelphia, 2003, Saunders, color plate 11-28.)

infiltration reduces the production of other cells, including red blood cells and platelets. A typical slide of a bone marrow aspirate from a patient with CLL is shown in **Figure 11-8**. Note the preponderance of lymphoid cells. CLL cells are characterized by defective apoptosis and therefore have extended life spans. They are derived from mature peripheral B cells (see **Table 11-3** for a comparison of acute and chronic leukemias).

**Prognosis and treatment.** Certain genetic mutations confer better or worse prognosis. A mutation in the variable region of the immunoglobulin gene (IgV) is associated with a median survival of 24 years or more; those without this mutation have a median survival of less than 8 years.<sup>15</sup> CLL cell types demonstrating short telomere lengths and TP53 dysfunction have poor outcomes. Since the average age of patients with CLL is about 65 to 70 years, those with indolent disease may not be treated; they are more likely to die of another disorder

rather than CLL. Patients with cell types likely to progress rapidly may receive chemotherapy to induce remission. Those without complete response may consider stem cell transplantation to prolong the duration of remission.

### Acute Lymphoblastic Leukemia/Lymphoma

**Pathogenesis and clinical manifestations.** ALL is a malignant disorder of the lymphoid cell lineage. The great majority of cases are the result of malignant transformation of B cells (80%), with the remainder involving T cells.<sup>16</sup> The abnormal cells resemble immature lymphocytes, called *lymphoblasts* (**Figure 11-9**). Most lymphoblastic neoplasms present as leukemias, but lymphoblastic lymphomas are thought to be the same disease at a different stage. B cell leukemias are categorized into cytogenetic groups based on common chromosomal translocations. One of these transformations results in the *bcr/abl* fusion gene discussed previously in the context of CML. Three other types of translocations also form fusion genes that produce abnormal signaling components. These gene derangements have different prognoses and may respond differently to alternative treatment protocols.

Lymphoblasts do not mature and accumulate in large numbers in the blood and bone marrow. At least 20% of the bone marrow cells must be leukemic lymphoblasts to meet the diagnostic criteria for ALL.<sup>16</sup> The space occupied by the accumulation of leukemic cells in the bone marrow prohibits the production of normal red blood cells, platelets, and leukocytes. Circulating blasts are poorly functioning cells and do not provide effective immunocompetence (see **Table 11-3** for a comparison of acute lymphocytic leukemia [ALL] and acute nonlymphocytic leukemia [ANLL]).

ALL is primarily a disorder of children. It is the most common malignancy and the second leading cause of death in this population.<sup>17,18</sup> The peak incidence occurs between the ages of 3 and 7 years. A second peak occurs in middle age. The onset of symptoms is abrupt, with complaints of bone pain, bruising, fever, and infection being common. Children may refuse to walk and their parents may report

**FIGURE 11-9** Peripheral blood smear showing typical cells of acute lymphocytic leukemia. (From Kumar V et al, editors: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 448.)

**FIGURE 11-10** Peripheral blood smear showing cells typical of hairy cell leukemia. (From Henderson ES et al, editors: *Leukemia*, ed 7, Philadelphia, 2003, Saunders, color plate 11-29.)

**TABLE 11-3 COMPARISON OF ACUTE LYMPHOCYTIC (ALL) AND ACUTE NONLYMPHOCYTIC LEUKEMIA (ANLL)**

	ALL	ANLL
Age	Common in children	Common in adults
Hematology results	Anemia, neutropenia, thrombocytopenia	Anemia, neutropenia, thrombocytopenia
Cell morphology	Small to medium lymphoblasts, fine chromatin, indistinct nucleoli	Medium to large myeloblasts, distinct nucleoli, clear chromatin, Auer rods
Cytochemistry	PAS positive, peroxidase negative, Sudan black B negative	PAS negative, peroxidase positive, Sudan black B positive

PAS, Periodic acid–Schiff reaction.

loss of appetite, fatigue, and abdominal pain. The spleen, liver, and lymph nodes may be enlarged from leukemic infiltration. A small number of children (3%) may present with CNS signs from leukemic infiltration of brain tissues.<sup>19</sup>

**Prognosis and treatment.** ALL is highly curable in the pediatric population, but less so in adults. The 5-year survival rate is 85% in children and 30% to 50% in adults.<sup>19</sup> Certain forms of ALL are more responsive to therapy. For example, children with pre-B cell type have a 90% cure rate, whereas those with mature B-cell or immature T-cell leukemia have a poorer prognosis.

Chemotherapy is used for remission induction. Postremission chemotherapy with or without stem cell transplantation is indicated for most patients.<sup>20</sup> In general, adults with ALL require more intense therapy than children to achieve complete remission (CR). Monoclonal antibodies may be used in patients whose tumors express specific antigens.

### Hairy Cell Leukemia

**Pathogenesis and clinical manifestations.** Hairy cell leukemia is a rare, chronic type of leukemia. The disease represents about 2% of adult leukemias, but it is of interest because of its highly treatable nature. The median age at presentation is about 55 years and there is a 5-to-1 predominance of males.<sup>21</sup> Hairy cell leukemia has a B-cell phenotype and is characterized by the presence of peculiar cells with hair-like projections on their surface (Figure 11-10). At diagnosis, patients have hairy cells in the peripheral blood as well as reduced numbers of granulocytes, platelets, and red blood cells. Splenomegaly is a common finding, being present in 90% of patients.

**Prognosis and treatment.** Treatment may be instituted when a patient becomes symptomatic with an enlarged spleen, recurrent infection, bleeding disorder, or anemia. Appropriate chemotherapeutic protocol produces CR rates of 80%.<sup>22</sup>

### Plasma Cell Myeloma (Multiple Myeloma)

**Pathogenesis and clinical manifestations.** Plasma cell myeloma, also known as multiple myeloma, is a malignant disorder of mature, antibody-secreting B lymphocytes, called *plasma cells*. Malignant plasma cells have a predilection to invade bone and form multiple tumor sites. Other tissues may be targeted also, including lymph nodes, liver, spleen, and kidneys. Plasma cell myeloma occurs exclusively in the adult population, usually affecting individuals older than 40 years, with a median age at presentation of 65 years.<sup>23</sup> Men are affected more often than women.

As with other forms of neoplasia, the exact etiologic process of plasma cell myeloma is unknown, but abnormalities in chromosome structure and number are commonly found.<sup>23</sup> The malignant plasma cells all belong to a single clone, and the excessive antibodies they produce are identical monoclonal antibodies. These accumulate in the bloodstream and can be detected by serum protein electrophoresis. Normally, serum antibodies are of many forms (polyclonal) and show a varied distribution of size on the electrophoresis test. In plasma cell myeloma, there is a large amount of one type of antibody, which forms a characteristic spike (Figure 11-11). Excessive production of light-chain antibody fragments by malignant plasma cells results in their accumulation in blood and urine. When found in urine, these light-chain fragments are called **Bence Jones protein**. In addition to helping

**FIGURE 11-11** Serum protein electrophoresis comparing abnormal myeloma protein in the  $\gamma$  region typical of benign monoclonal gammopathy (**A**) with the large quantity of monoclonal antibody (spike)  $\gamma$  typical of plasma cell myeloma (**B**). (From Skarin AT: *Atlas of diagnostic oncology*, London, 2003, Gower Medical, pp 536-537.)

to confirm the diagnosis, Bence Jones protein is important to the pathogenesis of plasma cell myeloma because it can accumulate in the kidneys and cause kidney damage. Malignant plasma cells tend to accumulate in bone where they enhance osteoclastic activity and produce bone lesions.<sup>23</sup> Pathologic fractures, especially compression fractures of the vertebral column, are common. Bone destruction releases calcium into the bloodstream, with resultant hypercalcemia.

Most of the clinical manifestations of multiple myeloma are due to bone and renal damage. The diagnosis of plasma cell myeloma is suspected based on the monoclonal antibody peak, the presence of Bence Jones protein, hypercalcemia, and evidence of bone lesions. The diagnosis is confirmed by bone marrow biopsy. Normally, the plasma cell component of the marrow comprises about 5%. In multiple myeloma, plasma cells may occupy 30% to 95% of the bone marrow (Figure 11-12). A minimum of at least 10% to 15% bone marrow plasma cells is necessary for the diagnosis of plasma cell myeloma.<sup>23</sup> The likelihood of bone marrow dysfunction increases as the plasma cell component increases. Normal production of erythrocytes, platelets, and leukocytes can be impaired to varying degrees.

The onset of plasma cell myeloma is generally slow and insidious. A premalignant stage of plasma cell myeloma is apparent in some individuals who have excess production of monoclonal antibodies but no evidence of bone lesions or Bence Jones protein in the urine. This stage is called monoclonal gammopathy of undetermined significance (MGUS). Approximately 25% of patients with MGUS progress to malignant disease.<sup>17</sup> Affected individuals remain asymptomatic until the disease is fairly advanced. The asymptomatic stage often lasts for many years after malignant transformation. During this time the only complaint may be frequent infections. Diagnosis during the asymptomatic phase is usually made because protein in the urine or high serum calcium levels are found on routine examination. Bone pain is usually the first symptom. Sometimes the evaluation of a fracture or back pain leads to the identification of myeloma. Anemia, recurrent infections, and bleeding tendencies are suggestive of bone marrow depression.

**FIGURE 11-12** Bone marrow aspirate from a patient with multiple myeloma showing a large number of abnormal plasma cells with multiple nuclei and cytoplasmic droplets. (From Kumar V et al, editors: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 455.)

Renal insufficiency is a complication experienced by approximately 50% of patients with plasma cell myeloma.<sup>23</sup> Impairment of renal function is due to a combination of factors, including hyperproteinemia, high levels of Bence Jones protein, hypercalcemia, and hyperuricemia. Renal function may continue to decline over time, culminating in end-stage renal disease (chronic renal failure).

Bone involvement is a consistent feature of plasma cell myeloma. Radiologic studies of ribs, spine, skull, and pelvis show a characteristic “honeycomb” appearance, attributable to lucid areas of demineralized bone (Figure 11-13). Minimal trauma is likely to result in fractures. Sometimes fractures occur with no known trauma; these are called *pathologic fractures*.

**Prognosis and treatment.** Antineoplastic agents may be used to induce and maintain a remission in plasma cell proliferation. The best

**FIGURE 11-13** Vertebral body (A) and skull (B) radiographs showing the characteristic “honeycomb” appearance of demineralized bone associated with multiple myeloma. (Courtesy Marvin J. Stone, MD, Sammons Cancer Center, Baylor University Medical Center, Dallas, TX.)

chemotherapy regimen has not yet been determined. The remission induction rate with these agents is about 60%, with a median survival of about 3 years after initiation of therapy.<sup>23</sup> High-dose chemotherapy followed by allogeneic bone marrow transplantation is becoming more common and offers a better CR rate. However, the death rate associated with transplantation is high (approximately 40% to 50%).<sup>17</sup> Autologous stem cell transplantation is considered to be the optimal initial therapy for most patients. Pharmacologic management of renal dysfunction is often necessary.

Chronic bone pain is a common problem in the myeloma patient that may require use of multiple remedies. Narcotic and nonnarcotic pain relievers are often necessary. Localized application of radiation to bone lesions may reduce bone pain in some cases.

#### KEY POINTS

- CLL is a neoplastic transformation of a mature, peripheral B cell that affects adults primarily and has an insidious onset. CLL is usually asymptomatic. Disease in certain genotypes is associated with long survival times and does not require therapy; in other cases, disease is progressive and may be managed with stem cell transplantation or administration of monoclonal antibodies.
- ALL affects children primarily, has an acute onset, responds well to therapy, and has a good prognosis. ALL is associated with transformation of precursor “blasts” in the bone marrow. ALL often manifests with bone pain, infections, and a tendency to bleeding. A significant number of children with ALL have CNS involvement and intrathecal chemotherapy is necessary.
- Plasma cell myeloma is due to malignant transformation of antibody-secreting B lymphocytes. It primarily affects older adults. The onset of symptoms is insidious, with most patients experiencing a 4- to 10-year period of clinical latency. Some patients have a preneoplastic phase called monoclonal gammopathy of undetermined significance. When present, symptoms include bone pain, pathologic fractures, anemia, thrombocytopenia, leukopenia, and renal insufficiency. Malignant plasma cells all secrete the same monoclonal antibody, and detection of this antibody in the blood or urine (Bence Jones protein) aids in diagnosis.

#### Hodgkin Disease

Hodgkin disease represents about 30% of all cases of malignant lymphoma, accounting for approximately 7000 new cases annually in the United States.<sup>10</sup> It occurs across the age continuum, with half of cases occurring in persons between the ages of 20 and 40 years. The overall incidence of Hodgkin disease is higher in males, who have a worse prognosis. The overall 5-year survival rate for treated Hodgkin disease, including all stages, is about 85%.<sup>10</sup>

**Pathogenesis and clinical manifestations.** Hodgkin disease is a malignant disorder of the lymph nodes characterized by the presence of **Reed-Sternberg** cells on histologic examination. Reed-Sternberg cells originate from B cells in the germinal centers of lymph nodes.<sup>24</sup> Reed-Sternberg cells are malignant, but they tend to grow and spread in a very predictable manner. This predictability differentiates Hodgkin disease from other types of lymphoma. Hodgkin disease usually metastasizes along contiguous lymphatic pathways (Figure 11-14). Epstein-Barr virus is frequently found in the genome of transformed Reed-Sternberg cells and is thought to be important in the pathogenesis of Hodgkin disease. The malignant cells are clonal, originating from a single mutant precursor cell, and usually present in a single node or localized chain of nodes. In addition to malignant Reed-Sternberg cells, inflammatory cells accumulate within the node (Figure 11-15) such that Reed-Sternberg cells constitute only a small minority (2%) of the cells in the lymph node tumor.<sup>24</sup>

There are two types of Hodgkin disease: (1) the rare lymphocyte predominance type, which accounts for 5% of cases, and (2) the classical type (cHD) representing the other 95%. The classical type can be divided further into four subtypes according to the relative number of reactive cells in the tumor. The histologic pattern does not seem to predict the prognosis. The stage of Hodgkin disease is more relevant.<sup>24</sup>

Clinical manifestations of Hodgkin disease are dependent on the site of origin as well as on the stage of dissemination. Lymphomas often are asymptomatic in the early stages. The usual clinical presentation includes painless lymphadenopathy that may be accompanied by fever, night sweats, pruritus, weight loss, and malaise. Usually enlargement occurs in lymph nodes above the diaphragm, the cervical nodes being the most common site (Figure 11-16). Other supradiaphragmatic nodes are the supraclavicular, axillary, and mediastinal nodes. Less commonly,

**FIGURE 11-14** Schematic drawing showing the orderly, contiguous, and predictable spread of Hodgkin disease. (Redrawn and modified from Rosenberg SA: Hodgkin disease: no stage beyond cure, *Hosp Pract* 21[8]:97, 1986. After original illustrations by Bunji Tagawa.)

**FIGURE 11-15** Histologic sample showing the typical binucleate Reed-Sternberg cells found in Hodgkin disease. An eosinophil can be seen below the Reed-Sternberg cell. (From Kumar V et al, editors: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 457. Courtesy Dr. Robert W. McKenna, Department of Pathology, University of Texas Southwestern Medical School, Dallas, TX.)

nodes below the diaphragm are the primary site. The inguinal nodes are the most common subdiaphragmatic site. As the disease spreads from the site of origin, other lymph nodes and lymphatic tissues may become involved, including the spleen and bone marrow. Staging procedures are performed to determine the extent of metastasis at the time of diagnosis. Staging dictates the treatment modality best suited to provide the patient with the greatest chance for long-term survival.

**Prognosis and treatment.** The staging protocol commonly used today was first adopted in 1971 at the Ann Arbor symposium and modified later in 1989 at the Cotswold meeting (Box 11-4).<sup>25,26</sup> The same procedure is also used for staging non-Hodgkin lymphomas. This protocol uses the presence or absence of certain clinical symptoms as well as the locations of affected nodes to determine the clinical stage of disease. The four stages are shown in Figure 11-17. The letter A denotes the absence of clinical symptoms, whereas the letter B is used when symptoms are present at the time of staging. These symptoms

**FIGURE 11-16** Hodgkin disease (stage IIA). Marked enlargement of cervical lymph nodes is present in this patient. It is usually painless and may be confined to only one area or may affect two or more areas. (From Skarin AT: *Atlas of diagnostic oncology*, London, 2003, Gower Medical, p 482.)

include loss of more than 10% of body weight, unexplained fevers, and night sweats. The clinical stage (CS) is based on history, physical examination, and noninvasive procedures such as computed tomography (CT) scanning. The pathologic stage (PS) is determined by the results of invasive procedures such as laparotomy and tissue biopsy. The stage

Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring)

### Stage II

Involvement of two or more lymph node regions on the same side of the diaphragm. The number of anatomic regions is indicated by a subscript (e.g., II<sub>2</sub>).

### Stage III

Involvement of lymph node regions or structures on both sides of the diaphragm

- III<sub>1</sub>: with or without splenic, hilar, celiac, or portal nodes
- III<sub>2</sub>: with para-aortic, iliac, mesenteric nodes

### Stage IV

Involvement of extranodal site(s) beyond that designated "E"

The site is indicated by a letter code followed by a plus sign (+)

### Modifying Characteristics

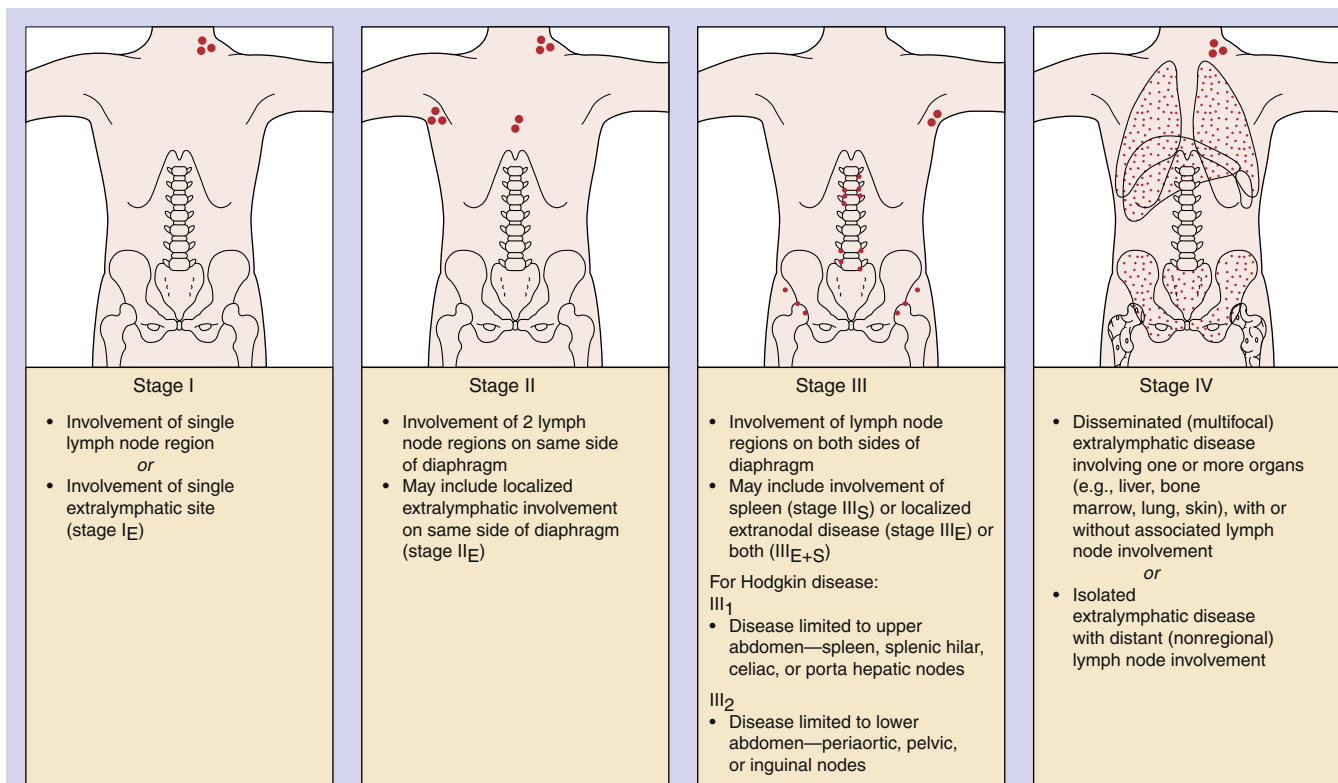

#### For Stages I to III

E: Involvement of a single, extranodal site contiguous or proximal to known nodal site

#### For All Stages

- A: No symptoms
- B: Fever (temperature >38° C), drenching sweats, weight loss (>10% body weight over 6 months)
- X: Bulky disease
  - >One third widening of mediastinum
  - >10 cm maximal dimension of nodal mass

\*Clinical stage (CS) is based on history, physical examination, laboratory studies, and CT scans. Pathologic stage (PS) is based on tissue sampling obtained through invasive procedures such as laparotomy and biopsy.

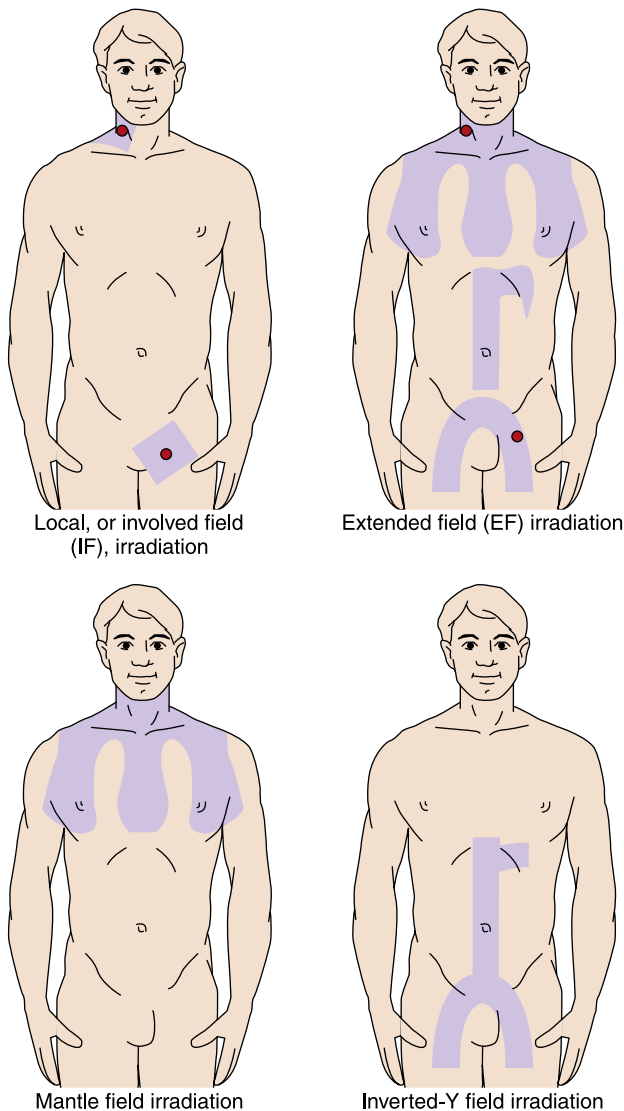

NOTE: Stage designation "B" indicates unexplained weight loss >10% of body weight in preceding 6 months and/or fevers of >38°C and/or night sweats. Stage designation "A" indicates the absence of the features characterizing "B."

**FIGURE 11-17** Depiction of the locations of malignant cells in the various stages of lymphoma using the Ann Arbor staging system. (From Skarin AT: *Atlas of diagnostic oncology*, London, 2003, Gower Medical, p 479.)

dictates the treatment modalities used. In general, localized tumors are more amenable to application of radiation therapy, whereas disseminated disease responds better to systemic chemotherapeutic agents. Since Hodgkin disease often is detected while localized, radiation therapy is commonly used, with good results (Figure 11-18).

Patients with nonbulky, stage IA or IIA disease may be candidates for radiation as sole therapy. However, a relatively high rate of relapse has been noted, and combined chemotherapy with limited field radiation is often used.<sup>27</sup> Patients with bulky disease, "B" symptoms, or stage III and IV disease require chemotherapy with or without

**FIGURE 11-18** Typical radiation fields for lymphoma. Different fields of radiation may be used depending on the location of disease.

radiation. In early stage disease appropriate treatment produces a 90% 10-year disease-free survival. More aggressive chemotherapy is indicated for patients with advanced Hodgkin disease.

**B-Cell, T-Cell, and NK-Cell Lymphoma (Non-Hodgkin)**

The malignancies included in the classification of non-Hodgkin lymphoma are those that do not have the characteristic Reed-Sternberg cells found in Hodgkin disease. The majority of cases of non-Hodgkin lymphoma arise from lymph nodes, but they can originate in any lymphoid tissue. With the exception of a few subtypes, most cases of non-Hodgkin lymphoma occur in older adults (95%), and males are at a slightly higher risk than females. The incidence of non-Hodgkin lymphoma is on the rise, particularly in areas with large AIDS populations. More than 50,000 new cases of non-Hodgkin lymphoma are diagnosed annually in the United States.<sup>9</sup> The lifetime risk of developing this disease is about 1 in 50.

Most cases of non-Hodgkin lymphoma arise from B cells, T cells, or NK cells. Some of the more common types of non-Hodgkin lymphoma are summarized in Table 11-4. The prognosis and recommended treatment protocols vary according to type. A general schema for grouping non-Hodgkin lymphoma according to indolent or aggressive types is

in common usage.<sup>28</sup> Generally, indolent disease is associated with longer survival times whereas aggressive lymphomas tend to be disseminated at presentation and carry a generally poorer prognosis. As a group, the non-Hodgkin types of lymphoma are more likely to spread early and unpredictably in comparison with Hodgkin disease.

**Pathogenesis and clinical manifestations.** The etiologic process of non-Hodgkin lymphoma is thought to be similar to that of other malignant transformations. The tumor cells are all derived from a single mutant precursor cell and are clonal. Viruses are suspected in the development of some types of lymphoma. In particular, Burkitt lymphoma is strongly associated with the presence of Epstein-Barr virus.<sup>2</sup> Adult T-cell lymphomas are associated with infection by human T cell leukemia virus, type 1 (HTLV-1).<sup>2</sup> The overall 5-year survival rate for all types of non-Hodgkin lymphomas combined is about 50%.<sup>10</sup>

Most patients with non-Hodgkin lymphoma present with advanced disease (stage III or IV). Clinical manifestations may include painless lymphadenopathy, fever, night sweats, weight loss, malaise, and pruritus (similar to Hodgkin disease). A comparison of the features of Hodgkin disease and non-Hodgkin lymphoma is shown in Table 11-5. Extranodal involvement occurs early in the course of non-Hodgkin lymphoma, and patients may present with infiltrative disease of the skin, gastrointestinal tract, bone, or bone marrow. Complications occur more frequently than in Hodgkin disease. Two of the most serious oncology emergencies are obstruction of the superior vena cava and spinal cord compression. Infection, bone metastasis, and joint effusions are also common. Staging of non-Hodgkin lymphoma is done in the same way as for Hodgkin disease, and the classification system is not different. Earlier clinical stages are associated with the best prognosis for survival.

**Prognosis and treatment.** The effectiveness of therapy for non-Hodgkin lymphoma is variable. Favorable outcomes are likely in stage I and II disease. However, non-Hodgkin lymphoma is likely to present as stage III or IV disease, which has a poor prognosis. Therapeutic management is determined by the clinical stage, histologic type, patient age, and bone marrow integrity at the time of diagnosis.<sup>29</sup> Radiation, chemotherapy, and tissue-specific therapies such as monoclonal antibodies and bone marrow transplants may all be applicable.

**KEY POINTS**

- Hodgkin disease is characterized by malignant transformation of B cells in lymph nodes, called *Reed-Sternberg cells*. The spread of malignant cells occurs along predictable, contiguous pathways. Most commonly, a single cervical lymph node is involved initially, with slow progression to nearby nodes.
- Non-Hodgkin lymphoma constitutes a diverse group of malignant diseases of lymphoid tissue. The characteristic Reed-Sternberg cell of Hodgkin disease is not present. Non-Hodgkin lymphoma is unpredictable in its spread and is often disseminated at diagnosis.
- Manifestations of Hodgkin disease and non-Hodgkin lymphoma are similar. These include painless lymph node enlargement, fever, night sweats, and weight loss. Early stage disease is often asymptomatic.
- Staging is done to determine the degree of dissemination of disease. When affected lymph nodes are localized to one area (stage I) or one side of the diaphragm (stage II), the prognosis for cure is very good. Dissemination to lymph nodes above and below the diaphragm (stage III) or to extralymphatic organs or tissues (stage IV) carries a poorer prognosis.
- Radiation of the involved field is commonly used for malignant lymphoma in early stages. More disseminated disease may be treated with chemotherapeutic protocols. Non-Hodgkin lymphoma is routinely treated with chemotherapy because the disease is often well advanced at the time of diagnosis. Treatment may lead to bone marrow suppression and may predispose the patient to anemia, thrombocytopenia, and leukopenia.

**TABLE 11-4 SUMMARY OF THE MORE COMMON LYMPHOID NEOPLASMS (NON-HODGKIN TYPE)**

ENTITY	FREQUENCY	SALIENT MORPHOLOGY	IMMUNOPHENOTYPE	COMMENTS
<b>B-Cell Lymphoma</b>				
Follicular lymphoma	40% of adult lymphomas	Germinal center cells arranged in a follicular pattern	CD10 <sup>+</sup> , BCL2 <sup>+</sup> mature B cells expressing surface immunoglobulin	Occurs in older patients; generalized lymphadenopathy; associated with t(14;18); leukemia less common than in small lymphocytic lymphoma; indolent course but difficult to cure
Mantle cell lymphoma	3% to 4% of adult lymphomas	Diffuse or vaguely nodular pattern with small cleaved cells	CD5 <sup>+</sup> mature B cells expressing surface immunoglobulin and cyclin D1	Occurs predominantly in older males; disseminated disease in nodes, spleen, marrow, and gastrointestinal tract common; t(11;14) is characteristic; aggressive and difficult to cure
Extranodal marginal zone lymphoma (MALT lymphoma)	About 5% of adult lymphomas; more common in parts of Europe (Italy)	Variable; small round to irregular lymphocytes predominate; 40% show plasmacytic differentiation; B cells invade epithelium in small nests (lymphoepithelial lesions)	Mature B cells expressing surface immunoglobulin CD5 <sup>-</sup> , CD10 <sup>-</sup>	Occurs at extranodal sites involved by chronic inflammation; very indolent; may be cured by local excision
Diffuse large B-cell lymphoma	40% to 50% of adult lymphomas	Various cell types; predominantly large germinal center-like cells; others with immunoblastic morphology	Mature B cells, ± surface immunoglobulin	Occurs in older patients as well as pediatric age group; greater frequency of extranodal, visceral disease; marrow involvement and leukemia very uncommon at diagnosis and poor prognostic sign; aggressive tumors, but up to 50% are curable
Burkitt lymphoma	<1% of lymphomas in United States	Cells intermediate in size between small lymphocytes and immunoblasts; prominent nucleoli; high mitotic rate; starry sky appearance caused by high rate of apoptosis	Mature B cells expressing CD10 and surface immunoglobulin	Endemic in Africa; sporadic elsewhere; increased frequency in immunosuppressed persons; predominantly affects children; extranodal visceral involvement presenting features; rapidly progressive but responsive to therapy
<b>T-Cell Lymphoma</b>				
Mycosis fungoides/Sézary syndrome	Most common type of cutaneous lymphoma	Variable; in most cases, small cells with markedly convoluted nuclei predominate; cells often infiltrate epidermis (Pautrier abscess)	CD4 <sup>+</sup> mature T cells (CD3 <sup>+</sup> )	Presents with local or more generalized skin involvement; very indolent course; Sézary syndrome associated with diffuse erythroderma and peripheral blood involvement
Peripheral T-cell lymphoma, not otherwise specified	Most common type of T-cell lymphoma in adults	Variable; usually a spectrum of small to large tumor cells with irregular nuclei	Mature T-cell phenotype (CD3 <sup>+</sup> )	Not clearly a specific entity; often presents as disseminated disease; generally poor prognosis

Modified from Kumar V et al, editors: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 448-449. MALT, Mucosa-associated lymphoid tissue.

**TABLE 11-5 CLINICAL DIFFERENCES IN HODGKIN DISEASE AND NON-HODGKIN LYMPHOMA**

CHARACTERISTIC	HODGKIN DISEASE	NON-HODGKIN LYMPHOMA
Pattern of spread	Contiguous spread	Noncontiguous spread
Extranodal disease	Uncommon	More common involvement of gastrointestinal tract, testes, bone marrow
Site of disease	Mediastinal involvement common Bone marrow involvement uncommon Liver involvement uncommon	Mediastinal involvement less common Bone marrow involvement common Liver involvement common
Extent of disease	Often localized	Rarely localized
B symptoms	Common	Uncommon

## SUMMARY

Malignant disorders of white blood cells are classified according to cell type and fall into two major categories: myeloid neoplasms and lymphoid neoplasms. Myeloid neoplasms commonly present as leukemia and usually involve transformation of granulocytes. Lymphoid neoplasms may present as leukemia, lymphoma, or plasma cell myeloma. Leukemia is a malignant neoplasm of immature stem cells that is characterized by diffuse replacement of the bone marrow by neoplastic blasts. In most cases the leukemic cells overflow into the bloodstream, where they may be seen in large numbers. These cells may also infiltrate the liver, spleen, lymph nodes, and other tissues throughout the body. Lymphoma is characterized by malignancy of cells found in lymphoid tissues and usually arises in the lymph nodes. Hodgkin disease is a special category of malignant lymphoma that is characterized by the presence of Reed-Sternberg cells. Hodgkin disease is more predictable in its spread than the non-Hodgkin types of lymphoma, and it is

generally curable in the early stages. Non-Hodgkin lymphoma types comprise a large number of different disorders that involve malignant transformation of B cells, T cells, or NK cells. As with Hodgkin disease, earlier stages are more easily cured. However, the non-Hodgkin lymphomas tend to be unpredictable in their dissemination, and the prognosis is less certain. Plasma cell myeloma is a malignant transformation of mature, antibody-secreting B cells. Malignant plasma cells are monoclonal and all produce identical antibodies, which accumulate in the blood. These cells have a predilection to settle in skeletal structures, where they cause bone demineralization and destruction. Hypercalcemia, bone fractures (pathologic fractures), and renal damage are common complications of plasma cell myeloma. Treatment for the various types of hematologic neoplasms continues to evolve, and excellent disease-free survival is commonly achieved when the disease is diagnosed in the early stages.

## KEY QUESTIONS

- What are the common modes of HIV transmission and how can infection be prevented?
- What is the scope of the HIV/AIDS epidemic in the United States and the world?
- How does infection with HIV lead to progressive immunodeficiency and AIDS?
- How has knowledge of the HIV life cycle led to the development of multidrug treatment strategies?
- How are CD4<sup>+</sup> cell counts and various clinical findings used to classify the stages of HIV disease and AIDS?
- What are the common systemic manifestations of AIDS and associated opportunistic infections?
- What are the current treatment recommendations for HIV disease and AIDS?

## CHAPTER OUTLINE

**Epidemiology, 233**

- History, 233
- Types of HIV, 233

- CCR5 Antagonists, 252
- Integrase Strand Transfer Inhibitors, 253
- Other Treatments and Vaccines, 253

This chapter focuses on HIV disease and AIDS—from epidemiology to pathogenesis and management. Human immunodeficiency virus (HIV), an infectious organism, is the prototypical public health infectious disease of the late twentieth century. Originally thought to be a rapid killer, it does not act like other infectious organisms that overwhelm the immune system. HIV infection triggers chronic widespread and diverse organ involvement with varying signs and symptoms. It encompasses all of the armamentarium of a viral infection that has completed the evolutionary progression from animal to human. HIV has done more than just confuse and captivate scientists and health professionals; it also has mobilized risk groups and placed medicine and society at a crossroads of opinion. In this epidemic, the lines between privacy and public health and between morality and compassion have been debated. HIV disease is complex, but in its complexity it has opened the door to better understanding of the immune system.

**Human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS)** are acquired immunodeficiency disorders resulting in defective immune functioning. The hallmark of HIV infection is defective cell-mediated immunity, especially the decrease in CD4<sup>+</sup> or T helper/inducer lymphocytes. CD4<sup>+</sup> T cells are necessary for appropriate immune responsiveness because they are the cells that mediate between the antigen-presenting cells and other immune cells, such as B cells and other T cells. CD4<sup>+</sup> lymphocytes are characterized by the presence of the CD4 receptor.

## EPIDEMIOLOGY

HIV infection is a primary immunodeficiency disease caused by the retroviruses HIV type 1 and HIV type 2. Despite research and public health surveillance and prevention activities, the virus has continued mutating and spreading globally. HIV infects people worldwide. However, HIV infection is increasingly becoming a disease of poor, uneducated, or undereducated people of color. Since its identification in the early 1980s, the HIV global epidemic continues with an estimated 33.3 million people living with HIV worldwide as of 2010 and a total of 1.8 million AIDS deaths worldwide in 2009.<sup>1</sup> Selected aspects of the global impact of HIV and AIDS are illustrated in Table 12-1.

The total adult prevalence is now 0.8% of the adult population of the world.<sup>1</sup> Of the 33.3 million people infected with HIV, women comprise 15.9 million and children <15 years old comprise 2.5 million.<sup>1</sup> According to the World Health Organization (WHO), the number of new HIV infections globally declined 19% over the past decade, attributable to expanded and improved HIV programs.<sup>1</sup> However, HIV infection rates continue to increase in sub-Saharan Africa as well as in eastern Europe and central Asia. In third world countries, those infected with HIV have more limited access to testing and medication for treatment, as well as limited information for prevention because of the effects of gender inequity and harmful social norms that drive transmission.<sup>1</sup> For example, only 37% of those infected in sub-Saharan Africa receive antiretroviral therapy compared to 50% in Latin America and the Caribbean.<sup>1</sup>

In the United States, more than 1 million people have been diagnosed with HIV/AIDS since the beginning of the epidemic.<sup>2</sup> It is estimated by the Centers for Disease Control and Prevention (CDC) that there are 663,084 persons living with HIV/AIDS in the United States, with 56,000 new HIV infections diagnosed yearly.<sup>2</sup> In the United States and other industrialized countries where access to medication, care, and prevention is greater, the number of patients diagnosed with and dying from AIDS is stable or declining (Figure 12-1). The proportion of people living 3 or more years after an AIDS diagnosis in the United States has increased. However, the CDC estimates that up to 25% of the people who are infected with HIV in the United States may be unaware that they are infected.

Current statistics show that of the people diagnosed with HIV/AIDS in the United States, racial and ethnic minorities, women of color, and men who have sex with men (MSM) are disproportionately affected.<sup>2</sup> Overall, there has been a decrease in the rates of new diagnoses between 1998 and 2007 by 20.7%—from 18.4 to 14.6 new cases per 100,000 population.<sup>3</sup> Among racial and ethnic groups, most of the new cases are in black non-Hispanics, followed by Hispanics.<sup>3-5</sup> Males had a higher rate of diagnoses (21.9 per 100,000 in 2007) than females (7.6 per 100,000 population).<sup>3</sup> According to the CDC, 75% of new HIV infections occur in men and of those 50% occur in men who have sex with men (MSM).<sup>4</sup> The highest rates of new diagnoses of HIV are in black men and women, with a lifetime risk of 1 in 16 for black males and 1 in 30 for black females compared to 1 in 104 for white males and 1 in 588 for white females.<sup>5</sup> The rate of diagnoses also varied by state, with the District of Columbia having 154.6 new cases per 100,000 population, which is the highest rate in the country.<sup>3</sup> It is thought that noninjection drugs (such as crack cocaine or methamphetamine) may also contribute to the spread of HIV/AIDS because of sex trading for drugs, shelter, or money. Ninety percent of children younger than age 13 are infected perinatally.<sup>6</sup> Ten to eleven percent of HIV cases are in people older than age 50 often as a result of a decreased perception of risk. As a result, older adults are often diagnosed later with a death rate that is higher than in other age groups.

## History

In 1981 the first descriptions of immunodeficiency disease in previously healthy persons appeared in the medical literature. At that time, previously healthy young homosexual men in increasing numbers contracted unusual diseases for their age group, such as *Pneumocystis jirovecii* (carinii) pneumonia (PCP) and Kaposi sarcoma, that researchers identified as HIV. The first evidence of alternative forms of transmission of the virus by blood and blood products appeared in 1982. All these early patients were shown to have a type of HIV virus called HIV-1. It was at this time that the term *acquired immunodeficiency syndrome (AIDS)* was first used. However, the specific retrovirus causing HIV infection and AIDS was not isolated until the early to mid-1980s. The timeline of HIV history is found in Table 12-2.

## Types of HIV

HIV is a type of retrovirus from the subfamily Lentivirinae, with *Lentivirus* being its only genus. This subfamily is so named from the Latin word *lentus*, meaning “slow,” because infection develops gradually. HIV-2, a related but distinct retrovirus, was later identified in 1986 and is most closely related to simian immunodeficiency virus. HIV-2 is differentiated from HIV-1 by a longer clinical latency period from the onset of infection to the development of symptoms. It is also characterized by having lower plasma HIV-2 viral loads and lower mortality rates and by generally being a milder form of the disease.<sup>6</sup> HIV-2 infection can progress to AIDS, even though it appears to be less virulent than HIV-1. It is also possible to be coinfecting with both HIV-1 and HIV-2.<sup>6</sup>

Both HIV-1 and HIV-2 are found worldwide. They are similar in structure and function but are differentiated from each other by their envelope glycoproteins, point of origin, and latency periods. The point of origin for HIV-1 is Central Africa and for HIV-2 it is West Africa. HIV-1 is the causative organism of most cases found in Central Africa, the United States, Europe, and Australia. HIV-2 is found primarily in West Africa or in countries with strong socioeconomic ties to West Africa (e.g., France, Spain, Portugal, and former Portuguese colonies).<sup>6</sup>

Many subspecies or strains of HIV also exist because of the rapid rate of HIV virion mutation. The subspecies may exist in different hosts, as well as within an individual host. Currently, at least 10 subtypes of HIV-1 have been identified: group N (YBF30), group O, and

TABLE 12-1 GLOBAL HEALTH CONSIDERATIONS FOR HIV/AIDS

COUNTRY/ REGION	PREVALENCE OF DISEASE	CULTURAL FACTORS	MOST COMMON MEANS OF TRANSMISSION	TREATMENT	ECONOMIC/SOCIAL IMPACT
Sub-Saharan Africa*	22.5 million people affected. This region carries 70% of the world's HIV/AIDS burden Adult prevalence % = 5.0% Adult and child deaths due to AIDS = 1.3 million	Gender inequalities: Males dominate sexual decision making and women are disproportionately infected	Heterosexual sex and mother-to-child transmission	Treatment available, but not affordable for most people Treatment coverage: 37% (3,911,000)	Life expectancy has decreased dramatically and population is beginning to bottleneck Reversing the progress in poverty reduction Stigma associated with disease causes people to lose property
East Asia/ China†	770,000 people affected Adult prevalence % = 0.1% Adult and child deaths due to AIDS = 36,000	Growing male demographic has led to a growing sex industry	Intravenous drug use, prostitution, and transmission through migrant workers	Medical coverage in rural areas is poor, so a large proportion of the population must pay out of pocket. Treatment coverage: 31%	Cost of therapy generally exceeds annual income Stigma is so great that many people do not disclose their HIV status to their families and thus do not seek treatment
North America	1.5 million people affected Adult prevalence % = 0.5%	Continued stigma	Men having sex with men (MSM), intravenous drug use, heterosexual transmission and prostitution	Treatment available to most people	Cost of therapy is high but programs are available for assistance
Western and Central Europe	820,000 people affected Adult prevalence % = 0.2% Adult and child deaths due to AIDS = 76,000	Continued stigma	MSM, intravenous drug use, heterosexual transmission and prostitution	Treatment available to most people	
South and Southeast Asia	4.1 million people affected Adult prevalence % = 0.3% Adult and child deaths due to AIDS = 260,000	Stigma Drug use and prostitution high in some areas such as Thailand	MSM, intravenous drug use, prostitution	Cambodia and Thailand have 50-80% antiretroviral coverage	
Central and South America	1.4 million people affected Adult prevalence % = 0.5% Adult and child deaths due to AIDS = 58,000	Men who have sex with men are highly stigmatized, so prevention efforts overlook this group. Drug use is commonplace	MSM, intravenous drug use, and prostitution	50-80% of infected people are receiving antiretroviral therapy. The government provides therapy for free.	Government has had a strong and positive response to the epidemic: Its efforts have reduced stigma, improved social reintegration, and reduced HIV prevalence among high risk populations.

group M with 8 subtypes (A, B, C, D, E, F, G, H). Research is currently focusing on the identification of HIV subtypes and strains in different populations and geographic areas. For example, in the United States, Europe, and Australia, most infected persons have HIV-1, subtype B, whereas in India, HIV-2 is found near Goa, and HIV-1 strains A, B, and C are also present.<sup>6</sup>

### Transmission

HIV-1 and HIV-2 are relatively weak viruses outside of the body. HIV viruses can infect people through three major types of transmission: sexual transmission via semen or vaginal and cervical secretions through homosexual, bisexual, or heterosexual intercourse; parenteral transmission via blood, blood products, or blood-contaminated needles or syringes; and perinatal transmission in utero, during delivery, or in breast milk. Of these forms of transmission, sexual transmission through unprotected vaginal or anal intercourse is the most common mode of

infection globally. In very low titers, HIV is known to be present but has not been shown to be transmitted via urine, saliva, tears, cerebrospinal fluid, amniotic fluid, and feces. HIV is not known to be transmitted via aerosol routes. In the United States, those at greatest risk of HIV infection include (1) men having sex with men (MSM); (2) intravenous drug users (IVDs) who share needles or syringes; (3) sexual partners of those in high-risk groups, particularly heterosexual women; and (4) infants born to infected mothers. Heterosexual intercourse with infected partners, contact with contaminated blood, and prenatal or perinatal exposure of the infant prenatally are the major routes of transmission of HIV in Africa, South and Southeast Asia, and developing countries.<sup>1</sup> In these countries, an equal proportion of males and females are infected.

Common modes of transmission include needle/syringe sharing between intravenous drug users, unprotected sex with infected partners, recipients of HIV-contaminated blood or blood products or infected semen during artificial insemination, unanticipated needle or scalpel

**FIGURE 12-1** Estimated AIDS incidence and deaths among persons with AIDS, by year of diagnosis or death and year-end prevalence, United States, 1981 to 2000. Data were adjusted for delays in reporting of cases and deaths. (From Update: AIDS—United States, 2000, *MMWR Morb Mortal Wkly Rep* 51[27]:592-595, 2002.)

**TABLE 12-2 HIV HISTORY TIMELINE**

1900	Retroviruses identified as cause of cancer in chickens
1930s	HIV-1 precursor virus crossed species from chimpanzees to humans during hunting from contact with infected chimpanzee blood
1950s	Positive tests on serum from man in Leopoldville (now Kinshasa) Congo
1960s	Virus reaches Haiti
1968	First case in U.S. in sexually active 15-year-old African-American male in St. Louis
1980	First retrovirus identified in humans affecting T cells (human T cell lymphocytic virus, HTLV-1)
1981	Syndrome of HIV first reported in healthy young homosexual men in LA and New York
1982	Identification of HIV transmission by blood/blood products with first use of term AIDS Syndrome also identified in women, infants, Haitians, and persons who had received blood or blood products
1983	CDC publishes first Blood and Body Fluid Precautions First WHO meeting on AIDS
1985	First HIV-1 antibody testing (ELISA and Western Blot) First international conference on AIDS
1987	HIV-2 identified in visitor to U.S. from West Africa First anti-HIV drug approved CDC revises guidelines with identification of mucocutaneous exposure – “Universal Blood and Body Fluid Precautions”
1988	World Health Organization (WHO) declares December 1 as World AIDS Day
1994	CDC announces that AIDS is leading cause of death among Americans 25 to 44 years old
1996	Combination antiretroviral therapy (HAART) is introduced
1999	Researchers discover origins of HIV-1 from chimpanzee species (see 1930s)
2006	WHO declares March 8 as National Women’s & Girls HIV/AIDS Awareness Day SMART trial found that episodic antiretroviral therapy more than doubles risk of AIDS or death in people with HIV infection

injury during care or surgical treatment of infected patients, and neonatal transmission from an infected mother to her infant. In both men and women, concomitant sexually transmitted diseases or genital lesions increase the risk of HIV infection. In women, high-risk heterosexual contact is influenced by lack of HIV knowledge, low socioeconomic status, low perception of risk, concomitant drug or alcohol use, relationship dynamics such as fear of abuse or loss of relationship, and the increased biological vulnerability of HIV contraction during vaginal

intercourse, especially in the presence of other sexually transmitted diseases or vaginal inflammation. In both men and women, the use of non-injection drugs (such as crack cocaine) contributes to HIV transmission by decreasing inhibition, allowing the person to engage in risky sexual behaviors or to trade sexual relations for drugs, money, or shelter.

Blood bank screening and testing procedures have nearly eliminated the transmission of HIV-contaminated blood in the United States. In the United States, all blood and blood products have been

tested by HIV-1, HIV-2, and HIV-1 p24 antigen tests since 1996. However, this route of transmission continues in third world countries, where there is a high number of HIV-infected persons and much of the blood and blood products are not screened before use.

Health care workers who are exposed to blood or infected body fluids or needles/sharp instruments are at risk of contracting HIV. The risk of developing HIV is greatest for those health care workers who have a deep injury with visible blood from a contaminated needle or sharp instrument or who have a direct puncture into an artery or vein. They also are at risk if they have prolonged blood-skin contact, especially if extensive. The risk of infection is much lower when both universal precautions and postexposure prophylaxis are employed.

Transmission from an infected mother to her infant may occur in the intrauterine period, in the intrapartum period at the time of delivery, or in the postpartum period via breast feeding; it may also be transmitted in some cultures from saliva attributable to premastication. Of these, intrapartum transmission at the time of delivery is thought to be the most common. HIV infection does not cause any specific congenital abnormalities, but there is an increased risk of spontaneous abortion. The overall risk to the fetus of HIV transmission is estimated to be between 15% and 40% for each pregnancy, with increasing risk in subsequent pregnancies for each HIV-positive fetus born. Increased risks of antepartum transmission include increased maternal viral load or high viremia during early infection, advanced maternal clinical disease as evidenced by low CD4<sup>+</sup> counts, and breaks in the placental barrier. Increased risks of intrapartum transmission include high maternal viral load at the time of delivery, prolonged ruptured membranes (more than 4 hours), infant exposure to blood/secretions, abruptio placentae, infant prematurity, and the presence of coinfections. The rate of HIV perinatal transmission is reduced with the use of antiretroviral therapy during pregnancy and during the first months of the infant's life.

Routine social contact with people who are HIV positive does not increase one's risk of HIV infection. The following examples are safe practices and will not cause exposure to HIV infection: using public restrooms, swimming in public swimming pools, touching or hugging someone who is HIV positive, and eating with community utensils or in restaurants. Insects such as mosquitoes cannot transmit the HIV virus to humans.

Exposure to HIV does not mean that one will contract HIV or AIDS, and it does not mean rapid progression. The interacting forces between viral and host factors influence whether a person will contract HIV infection, particularly the amount and virulence of the virus and the host's response by T cell-mediated cytotoxicity or by cytokines. For example, a woman's plasma viral load may predict the amount of her genital HIV viral shedding, which may influence the exposure to HIV virion by her sexual partner.<sup>7</sup> In studies of patients with hemophilia who received tainted blood products, 10% to 25% of the individuals evaded infection. Because of genetic differences that either increase or decrease susceptibility to the infection, the risk of acquiring HIV and the response to infection also vary within populations.<sup>8</sup> Despite infection for more than 10 years, some infected individuals remain symptom free; and some individuals, despite high-risk exposure, do not exhibit any signs of infection or immunodeficiency.<sup>8</sup>

Researchers have identified an HIV resistance mutation of the *CCR5* gene, called *CCR5-delta 32*, which is associated with natural resistance to HIV infection in certain people.<sup>8</sup> When inherited from both parents, the mutant *CCR5-delta 32* gene appears to protect individuals from infection even after multiple exposures. When only one gene is inherited, the progression to AIDS tends to be slower.<sup>8</sup> The *CCR5* gene is not equally distributed among people. Persons of Caucasian-American and Caucasian-European descent have the highest number of mutant allele

genes, approximately 10%, while Native American, African, and East Asian people have the lowest number of mutant alleles.<sup>8</sup> Researchers have also found that other mutations in the *CCR5* gene can delay progression of HIV infection, such as polymorphism-2459 (A/G).<sup>8</sup> There are other proteins that bind to *CCR5* and demonstrate antiviral activity, such as macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ) and MIP- $\beta$ , as well as chemokines and other factors such as stromal-derived factor (also known as pre-B cell growth-stimulating factor).<sup>9</sup> These factors can also effectively block HIV-1 infection in some people. People who have fewer genes encoding CCL3L1, a potent HIV-blocking protein that interacts with *CCR5*, are more susceptible to HIV infection and have more rapid progression to AIDS whereas individuals with natural killer (NK) cells that produce interferon- $\gamma$ , tumor necrosis factor- $\alpha$ , CCL3, CCL4, and CCL5 are less likely to develop HIV infection.<sup>8-10</sup>

### Prevention of Transmission

Prevention is essential, because effective management of HIV is expensive and a cure is not yet possible. However, one-time exposure to information or a single message is usually less successful than programs that teach prevention skills and reinforce positive behavior. The primary way to prevent transmission is to use safe sex practices. Safe sex practices include abstaining from sex, using a condom (barrier protection) during sexual intercourse, avoiding multiple sexual partners, and knowing the HIV status of all sexual partners. It is important that education regarding safe sex practices be tailored to appropriate age groups, ethnicity, culture, and sexual preference. Patient visits to health care providers are an excellent opportunity to encourage individual HIV protection.

Spermicides such as nonoxynol 9 or C31G do not inactivate HIV or other sexually transmitted microorganisms. No studies suggest any benefit from using progestins such as levonorgestrel (Norplant) or medroxyprogesterone (Depo-Provera), the diaphragm, or oral contraceptives to prevent HIV transmission. The early use of antepartum and intrapartum antiretroviral therapy and avoidance of breast feeding can prevent maternal-child HIV infection.

HIV infection in drug users can be prevented with the use of sterile needles via improved access to clean needles and avoidance of dirty or shared needles. Such intervention includes needle/syringe exchange programs for IVDs and cleaning of dirty needles with bleach before use. When using bleach, the user must rinse out all blood first; then fill the needle and syringe with full-strength bleach at least three times for 30 to 60 seconds.

Medical and health care personnel are at risk through occupational exposure to blood and body fluids. Self-protection through the use of standard precautions can decrease risk by reducing exposure. Health care providers should carefully wash their hands before and immediately after patient contact even when using gloves. It is essential to wear disposable gloves for any actual or potential contact with blood or body secretions, when handling items contaminated with blood or body fluids, when performing finger sticks or heel sticks, or when the health care provider has scratches or cuts on the hand.

Gowns or plastic aprons, masks, goggles, or face shields should be worn to protect the face and clothing when there is risk of splashes and airborne droplets of blood or body fluids. Protective gear should be changed between patients. Careful prevention of parenteral exposure when using needles or other equipment should be emphasized. Needles and sharp implements should be disposed in rigid, puncture-proof containers. Such implements should not be bent, broken, or recapped before disposal. In combative patients who must have blood drawn or injections given, careful use of humane and limited restraint devices may be necessary to prevent injury to the involved health care

workers. Resuscitation bags and masks should be readily available to minimize the need for mouth-to-mouth procedures.

Unfortunately, accidents necessitating the development of postexposure prevention protocols do occur. If a health care worker sustains an injury with significant exposure to HIV-infected blood or body fluids such as a needle stick, a workplace postexposure prevention protocol should be followed immediately. According to the U.S. Public Health Service and National Institutes of Health (NIH), the selection of a drug regimen for HIV postexposure prophylaxis must balance the risk for infection against potential toxicities and side effects of the medication(s). As such, consultation with an infectious disease provider is recommended. Treatment usually depends on knowledge of the viral status and/or viral load of the exposure source; this information will help determine the appropriate antiretroviral therapy regimen that should be implemented. Often postexposure protocols involve the administration of two or three medications. The length of administration of the agents depends on multiple factors and may be 4 weeks or longer. This same protocol has been advocated for use as post-sexual exposure prophylaxis.

### KEY POINTS

- HIV disease is a primary immunodeficiency disorder caused by viral infection of CD4<sup>+</sup> cells. It is a major health concern because it causes chronic, severe, long-term disease in industrialized countries with access to medication, care, and prevention. In third world countries where therapy is unavailable, the prognosis for HIV is very poor and death is more likely.
- HIV types 1 and 2 are retroviruses that primarily infect CD4<sup>+</sup> lymphocytes and macrophages. HIV-1 is the primary causative virus infecting persons in Central Africa, the United States, Europe, and Australia.
- HIV is acquired primarily through sexual transmission via semen and vaginal and cervical secretions; through parenteral transmission via blood, blood products, and contaminated needles/syringes; and through perinatal transmission from an infected mother to her infant antepartum, intrapartum, and postpartum via breast milk.
- HIV is known to be present in but is not believed to be transmitted via urine, saliva, tears, cerebrospinal fluid, amniotic fluid, feces, or aerosols.
- Those at greatest risk of HIV infection include homosexual and bisexual men, IVs who share needles or syringes, sexual partners of those in high-risk groups, and infants born to infected mothers.
- The use of safe sex practices (such as condoms) and safe parenteral practices (such as sterile needles/syringes) decreases the risk of infection.
- Exposure to blood and body fluids of infected individuals through skin, mucous membranes, and accidental needle sticks is the primary risk factor for health care workers. The universal use of standard precautions decreases the risk of infection.
- After significant accidental exposure to HIV-infected blood or body fluids, it is recommended that health care workers receive postexposure antiretroviral medication as soon as possible after exposure and as needed for 4 weeks following the incident.

## ETIOLOGY

### HIV Structure

HIV is an RNA retrovirus that causes a defect in cell-mediated immunity that may progress to AIDS. The viral RNA must be converted to DNA before the viral genes can be expressed to make copies of the RNA virus. Like other retroviruses, HIV differs from DNA viruses in that the RNA genome cannot replicate without undergoing conversion into DNA.

HIV consists of a core or nucleocapsid containing two strands or chains of RNA, protein, and enzymes surrounded and protected by a spherical lipid bilayer viral envelope that is 0.0001 mm in diameter. Between the envelope and core is a protein layer called p17. The nucleocapsid or core is composed of a protein called p24. Within the nucleocapsid, the two strands of RNA compose the HIV genome (Figure 12-2). The HIV genome consists of at least nine genes. The *gag* gene encodes the core antigen proteins. The *pol* gene encodes reverse transcriptase proteins. The *env* gene encodes the viral envelope protein glycoprotein gp160, which is split into two fragments, gp120 and gp41, by cellular protease.

Several other genes have been identified, including *tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*. These genes are primarily regulatory genes. The *tat* gene encodes proteins that regulate HIV replication and can accelerate HIV viral protein production. It is controlled by *tat*-binding protein. The *rev* gene encodes proteins that regulate viral messenger RNA expression. Rev proteins inhibit regulatory proteins, allowing the transport of HIV RNA from the nucleus. Rev proteins also enhance viral structural gene production. The *vif* (virion infectivity factor) gene appears to increase the ability of the virus to infect other cells. It suppresses the human protein (CEM 15) that inhibits HIV-1.

The HIV genome contains all the information regulating the virus's structural format and growth during its life cycle. The enzymes within the core also are very important because they facilitate the conversion of RNA to DNA. This conversion is the means of information transfer. The enzymes include reverse transcriptase, integrase, and protease. Reverse transcriptase is composed of two associated enzymes called polymerase and ribonuclease. It is the unique enzyme in HIV that allows the virus to copy RNA into DNA. Protease is a complex enzyme that works as a "molecular scissors." It splits the other viral components by a process known as autocatalysis. Immature, noninfectious virions containing inactive gag/pol, a long precursor protein, are released in the plasma, where they are cleaved by protease into smaller active units. Protease also clips p55, the core gag viral protein precursor, into smaller molecules and is needed to facilitate final mature viral assembly for HIV to be infectious.<sup>11</sup> In other words, HIV infection does not occur unless *protease* activates the virions.

The viral envelope consists of a membrane derived from the host cell. Viral glycoprotein studs protruding from the cell membrane make it look like a studded ball (Figure 12-3). Gp120 and gp41 are the two HIV envelope proteins that cover the viral particle surface. Gp120 is

**FIGURE 12-2** HIV particle showing the p24 capsid protein surrounding the two strands of viral RNA.

the most external and distal part of each “stud,” whereas gp41 is the bridge that holds it onto the virion surface. The surface envelope also contains other cell surface proteins derived from the host cell containing adhesion molecules. Although the viral particle (virion) is nearly spherical, great diversity is found in size and shape, such as comet-shaped virions and virions with tails.

### HIV Binding and Infection

Once inside the body, HIV particles are attracted to cells with receptors on their surface called CD4. The HIV envelope protein gp120 specifically binds to the CD4 receptor. The specific CD4<sup>+</sup> cells that are attracted to the virus change over time. The CD4 receptor is found on many types of cells, including T cells, microglial cells, monocyte-macrophages, follicular dendritic cells, immortalized B cells, retinal cells, Langerhans cells in the skin, bone marrow stem cells, cervical cells, bone marrow–derived circulating dendritic cells, and enterochromaffin cells in the colon, duodenum, and rectum. Of these cells, the CD4<sup>+</sup> T helper/inducer cells and macrophages are most often implicated and involved in the process of infection. Figure 12-4 illustrates a group of HIV-infected CD4<sup>+</sup> cells imaged by scanning electron microscopy. Initially the virus is attracted to macrophages and the virus is called “M tropic.” Later the virus either becomes dual tropic and affects both macrophages and T cells, or becomes “T tropic” and affects primarily T cells. During heterosexual transmission of HIV, the virus is attracted to Langerhans cells in the mucosal membranes mediated through the CD4/CCR5 pathway.<sup>12</sup> Later the virus becomes attracted to other cells in the body, primarily T cells, and is “T tropic.”

Usually T cells are infected before the onset of symptoms. CD4<sup>+</sup> T cells are composed of two subsets: T helper-1 (T<sub>H1</sub>) and T helper-2

(T<sub>H2</sub>). The T<sub>H1</sub> subset produces interferon- $\gamma$  and interleukin-2 (IL-2). The T<sub>H2</sub> subset produces IL-4, IL-6, and IL-10. Of these two subsets, the one that is markedly decreased in advanced disease is T<sub>H1</sub>.

However, CD4 alone is not sufficient for fusion of the virion and host cell. A number of important coreceptors on the target cells called chemokines are necessary for the virus to gain entry into cells.<sup>13</sup> These important chemokine coreceptors must be present for the virion to fuse with the host cell. The chemokine called CCR5 must be present for the HIV particles to bind to the CD4<sup>+</sup> cells in early infection during the M-tropic phase, and another chemokine receptor named CXCR4 must be present in later infection during the T-tropic phase.<sup>13</sup> Since 1996 when the coreceptors were first discovered, a number of other coreceptors have been identified, including APJ, CCR2b, CCR3, CCR8, CCR9, CX3CR1, CXCR4, GPR1, GPR15, STRL33, US28, and V28. The function of most of these coreceptors is unknown. It is hypothesized that some of the coreceptors may be needed for various strains of HIV, for HIV infection in infants and children, or for infection of the brain and nervous system.

The gp120 portion of the virion envelope must combine with the first receptor, CD4, and then change shape by refolding. In the second shape, it combines with the second receptor, either CCR5 or CXCR4, to fuse with the cell. Once the HIV particle is bound to both the CD4 receptor and the chemokine receptor on the host cell, gp41 implants itself in the cell membrane (Figure 12-5). This sequence of events causes the viral particle and the cell to fuse. The core of the virus is then injected into the cytoplasm of the host cell and infection is produced. The gp120 portion of the virion envelope is “hyper-variable in

**FIGURE 12-3** Schematic view of a retrovirus particle. The core is surrounded by an envelope that is derived from host membranes enriched with viral glycoproteins (gp120, gp41). Interaction of the envelope glycoproteins with a host-encoded cell surface receptor (CD4) is shown.

**FIGURE 12-4** Scanning electron micrograph (low magnification) of a population of HIV-infected lymphocytes. (Courtesy Centers for Disease Control and Prevention, Atlanta.)

**FIGURE 12-5** Early HIV infection, M tropic. In HIV infection, the virus must bind both a CD4 receptor and a coreceptor to fuse with the host cell. In the M-tropic phase, the key coreceptor is CCR5.

**FIGURE 12-6** HIV life cycle. A schematic representation from the time of initial HIV fusion with a host cell, to integration into the host cell's DNA, and ending with the replication of a new virion.

sequence,” which allows for the flexibility of the protein loops that permits the virion to escape neutralizing antibodies.<sup>13</sup>

Once in the cytoplasm, a single-stranded DNA copy is made by reverse transcriptase from the viral RNA. Using the single-stranded DNA as a template, DNA polymerase copies it to make a second DNA strand and destroys the original RNA strands. The accuracy of DNA transcription is poor, with mutations occurring frequently. This tendency to mutate makes HIV highly resistant to antiviral medications.

Once formed, the new viral DNA, called viral provirus or preintegration complexes (PICs), migrates to the cell nucleus and is actively transported in the nuclear compartment.<sup>14</sup> Inside the nucleus, integrase splices the viral DNA, or **provirus**, into the host cell's DNA. Once in the host cell's DNA, the viral DNA is replicated together with the host cell's DNA during every cell division. Now the viral DNA is permanently part of the host cell's DNA (Figure 12-6).

The process of building new virus particles begins within the host cell's DNA. Segments at the end of the viral genome instruct the host cell to make RNA copies of the viral DNA. Some of the genes direct the host cell to manufacture viral envelope proteins (gene name: *env*) and enzymes (gene name: *pol*), whereas other RNA strands become future genetic material (gene name: *gag*). The HIV DNA then hijacks cellular protein pathways to produce the proteins needed for replication of HIV.<sup>14</sup> In the nucleus of the cell, there is an interaction between the host cellular kinases and the HIV DNA that affects the HIV replication cycle.<sup>14-15</sup> Sometimes the host cell produces kinases or factors that aid viral integration and sometimes there are kinases or factors that inhibit viral integration by recognizing and neutralizing infecting retroviral DNA.<sup>15</sup> New studies are also demonstrating that not all proviral DNA is integrated into the cell's DNA and yet the proviral DNA can still synthesize viral gene products and replicate within the cell assisted by the expression of *tat* and *nef*.<sup>15</sup>

To cause further infection, the viral RNA must be produced, leave the nucleus, and migrate to the cell surface. Rev proteins along with a human protein called CRM1 aid in the process of transporting the viral RNA proteins from the cell nucleus. A human RNA helicase enzyme, DDX3, helps to straighten HIV's twisted strand of RNA before threading it through a small pore in the nucleus. The assembly of new virus particles, called **virions**, occurs at the cell membrane. Three proteins are produced and migrate to the cell periphery, attach to the cell membrane,

and cause the viral material to bud out from the membrane. The protein-cutting enzyme protease separates the envelope proteins from enzymes and RNA genetic material and binds the viral core (Figure 12-7). Therefore, the completed virion has a host cell membrane from which the envelope proteins gp120 and gp41 protrude like spikes.

When CD4<sup>+</sup> cells decline, the diversity of CD4<sup>+</sup> cells is affected. With antiretroviral therapy, the naive T cells that can respond to new infections persist in low numbers despite an increase in memory T cells. Therefore, persons with HIV who are receiving antiretroviral therapy can respond to old but not new infections. This phase is indicative of deterioration in immune system function despite any temporary increase in CD4<sup>+</sup> cell counts and decreased viral load from antiretroviral therapy.

Exposure to HIV-1 in epithelial cells (genital and gastrointestinal) and subsequent transmission and infection following exposure are incompletely understood. These processes involve multiple and complex interactions between HIV, cytokines, and CD4 cells. With HIV exposure, proinflammatory cytokines are produced by epithelial cells. Among the proinflammatory cytokines, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is produced, which impairs the tight epithelial junctional barrier and allows migration of HIV and bacteria to move or translocate across the epithelium.<sup>15</sup> Infection in the presence of inflammation is also influenced by the presence of CD4<sup>+</sup> macrophages or Langerhans cells that lie directly under the epithelial cells. Macrophages may also release tumor necrosis factor or other cytokines stimulating other antigen-presenting cells, or T cells.<sup>16</sup>

#### KEY POINTS

- HIV is an RNA virus known as a retrovirus. It must undergo reverse transcription within infected cells to form viral DNA.
- HIV consists of a nucleocapsid containing two strands of RNA, protein, and enzymes surrounded by a spherical lipid bilayer viral envelope. At least nine genes comprise the HIV genome.
- The HIV genome contains all the information regulating the virus's structural format and growth, including the conversion of RNA to DNA.
- The enzymes needed to convert HIV RNA to DNA include reverse transcriptase, integrase, and protease.
- HIV gains access to CD4<sup>+</sup> cells by attaching to the CD4 receptor on the cell surface. Viral envelope protein gp120 and coreceptor chemokines such as CCR5 or CXCR4 mediate attachment.

**FIGURE 12-7** HIV-1/lymphadenopathy virus found in a hemophiliac patient with AIDS. Virus particles range in size from 90 to 120 nm. Viral budding and the production of new virions are facilitated by protease. (Courtesy Centers for Disease Control and Prevention, Atlanta.)

## PATHOGENESIS

### Effect of HIV on Immune Cells at the Cellular Level

The hallmark of HIV infection is the decrease in the number of CD4<sup>+</sup> T helper/inducer lymphocytes. T helper/inducer cells are necessary for appropriate immune responsiveness because they are the cells that mediate between the antigen-presenting cells, other immune cells such as B cells, and other T cells. During acute and chronic untreated HIV infection, the immune system is in a hyperactive state with high T-cell death, nonspecific T cell activation, polyclonal activation of B cells, and elevated levels of proinflammatory cytokines.<sup>17</sup>

Macrophages have CD4 receptors and act as both targets and reservoirs for HIV. As the infection progresses, they become more functionally impaired with defective phagocytosis and chemotaxis, abnormal antigen presentation, and abnormal cytokine production. They also contribute to the T-cell decline by increasing CD4<sup>+</sup> cell death.

Humoral immune system dysfunction is also present, although the effect of HIV on antibody-producing B cells is more poorly understood. There are changes in B cell structure and function. B cell numbers usually remain normal but they are progressively dysfunctional with overproduction of nonessential antibodies, as well as failure to respond appropriately to normal immune system signals.<sup>18</sup>

**FIGURE 12-8** Scanning electron micrograph of HIV-1–infected CD4<sup>+</sup> lymphocytes showing virus budding from the plasma membrane of the lymphocytes. (Courtesy Centers for Disease Control and Prevention, Atlanta.)

Immunoglobulin G1 (IgG1) and IgG3 levels are usually elevated, causing hypergammaglobulinemia. IgM levels are elevated in early infection, whereas IgA levels are elevated in late infection. Despite these elevations, the responsiveness to bacterial cell wall (polysaccharide) antigens that require CD4<sup>+</sup> cell activation of B cells is decreased. Immune complexes are increased, and B-cell differentiation and response to antigens are decreased. Autoantibodies, especially against erythrocytes, platelets, lymphocytes, neutrophils, nuclear proteins, myelin, and spermatozoa, occur either in association with disease processes (e.g., HIV-associated thrombocytopenia) or spontaneously. HIV antibodies are produced, but they are ineffective against the disease. Also B cells have an increased risk of cell death through apoptosis.<sup>16</sup>

The envelope glycoproteins (gp120 and gp41) on the surface of HIV virions are the reason for successful HIV infection. The immunogenic portions of the viral envelope glycoproteins are well disguised and variable—most likely because of the large amount of carbohydrate on the surface of gp120.<sup>13</sup> Within the human body, high-carbohydrate substances look like “self” to the immune system. Therefore, the virus “hides” under the cover of the glycosylation. Another factor that allows HIV envelope proteins to escape the early antibodies is the way that gp120 and gp41 are bound together. Although the interface between gp120 and gp41 is an area that is highly immunogenic, the gp120 and gp41 molecules are noncovalently bonded together. Early antibodies cannot bind the assembled, functional envelope glycoprotein complex. Later, neutralizing antibodies are effective against the complex, but by that time the infection is well established.

### Viral Production and Cell Death

A key element in the success of HIV infection is that HIV replicates prolifically from the onset of infection. It generates so many virions that it overwhelms the body’s defenses. Because HIV is primarily a mucosal disease, the gastrointestinal (GI) tract is the major site of HIV replication.<sup>17</sup> Within the first 3 to 6 weeks and continuing throughout the infection, HIV replication is high in the lamina propria CD4 T cells of the GI tract.<sup>17</sup> HIV infection is characterized by a high level of virion turnover (HIV replication) and a high level of CD4<sup>+</sup> cell turnover (host cell death). HIV-infected CD4<sup>+</sup> cells undergo viral budding to generate and produce new virions (Figure 12-8). At least 10 billion HIV particles are produced and destroyed each day, with a plasma virus half-life of 6 hours and an acutely infected T-cell half-life of 1.1 days. Total T-cell

numbers in acute HIV infection decline sharply, but with continuing infection blood T-cell numbers rebound slightly as a result of antiviral immune responses whereas GI T cell numbers remain low. In children infected with HIV, the virus is more aggressive and leads more rapidly to immune system dysfunction.

The production of new virus is variable between individuals and dependent on the host's cellular activity, as well as the interaction between HIV regulatory genes (*tat*, *nef*, *rev*, *vif*). In some cells, such as T cells, HIV can lie dormant until activated. In other cells, such as macrophages and monocytes, RNA copies of HIV are consistently being made and released, initially without destruction of the host cell. Other host cellular factors that influence viral production of HIV include inhibition by other proteins or low concentrations of initiation factors.

There are other proteins in the body that can repress or inhibit HIV-1 if present in the cell. One of these is the delta 32 mutation in the *CCR5* gene, which involves the chemokine coreceptor needed for HIV to infect cells.<sup>18</sup> Other inflammatory proteins from macrophages decrease the probability of becoming infected with HIV-1 and promote recovery of the CD4 cells after starting therapy, including macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ /CCL3) and macrophage inflammatory protein-1 $\beta$  (MIP-1 $\beta$ /CCL4).<sup>18</sup> HLA-B57 and HLA-B27, part of the major histocompatibility complex alleles, have been found to target several gag epitopes inducing cytolytic destruction of infected cells.<sup>18</sup> Natural killer (NK) cells and macrophages secrete soluble factors that can inhibit HIV infection including TNF- $\alpha$ , interferon, and chemokines CCL3, CCL4, and CCL5. The chemokines tend to compete with the virus for cell adhesion because of their attraction to *CCR5*.<sup>18</sup> Interferon type 1 also inhibits HIV cell adhesion and induces apoptosis of HIV-1-infected CD4 T cells.<sup>18</sup> These factors have been associated with lower viral loads and improved survival.

Long-term survivors with HIV often have a lower viral load and strong CD8<sup>+</sup> killer T-cell activity. The CD8<sup>+</sup> killer T-cell activity suppresses viral replication and thus slows progression of the disease, especially in the early stages of the disease. It is also thought that a strong immunologic defense preserves the manufacture of CD4<sup>+</sup> T cells that especially recognize and react to HIV. If this ability is lost, these cells may not regenerate, even with treatment. The presence of a weaker strain of HIV, particularly during the M-tropic phase, may also lead to longer survival.

Once viral production starts or restarts in activated cells, death of the infected cells may occur by a variety of mechanisms. Cells may die from the accumulation of intracellular viral DNA or from the loss of normal cellular protein synthesis because of the infection. Some cell death may occur due to the action of natural killer T cells. Most methods of host cell death involve the envelope protein gp120 or immune processes. Cross-linking of CD4 and gp120 can trigger automatic preprogrammed T-cell death (**apoptosis**). *Apoptosis is the major mechanism of CD4 T cell depletion.*<sup>19</sup> CD4 and gp120 cross-linking can also cause the cell to stop dividing and decreases the cell's ability to fight new infections—a condition called **anergy**. Profuse viral production with multiple CD4 receptors in close proximity can rip holes in the cell membrane and cause host cell death (Figure 12-9). Multiple virion buds with gp120 on their surfaces attach to the surrounding host cell membrane CD4 receptors. This attachment causes tearing of the host cell membrane with subsequent cellular edema and death.<sup>17</sup> Viral proteins, such as *nef*, *vpr*, or *tat*, also contribute to the causes of cell death in HIV. Microvesicles containing *nef* protein released into the blood can cause *nef*-induced apoptosis associated with death receptors on a cell surface or by triggering the intrinsic pathway.<sup>17</sup> *Tat* protein can disrupt mitochondrial function, and trigger extrinsic and intrinsic

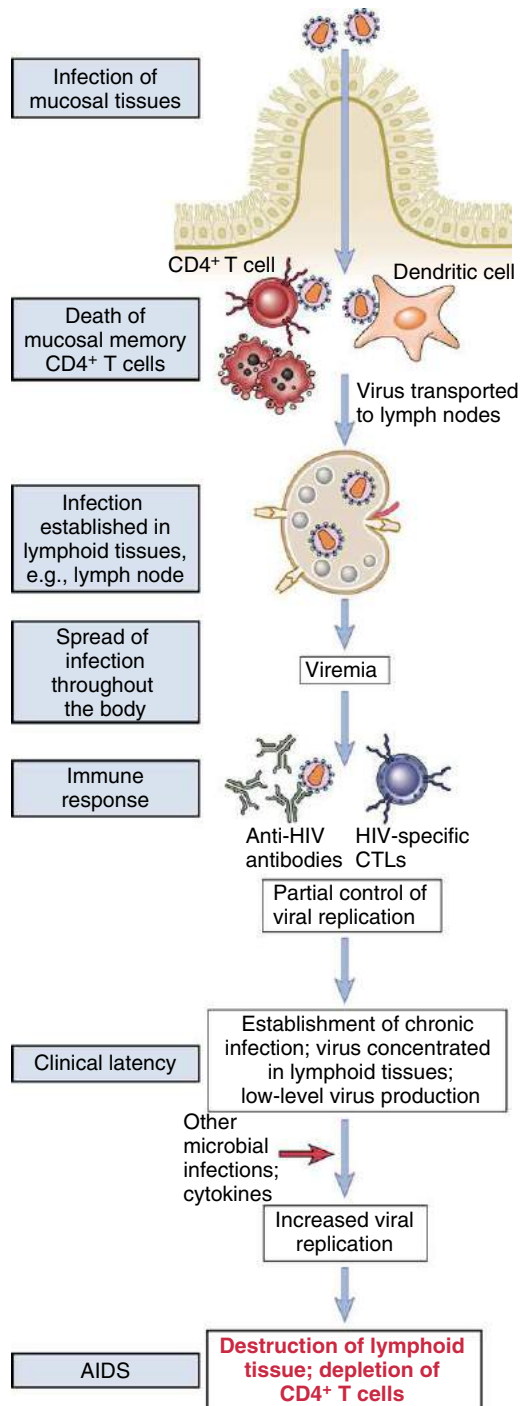

**FIGURE 12-9** High magnification of a CD4<sup>+</sup> lymphocyte infected with HIV-1. Note the large number of budding HIV virions, which can lead to host cell death by membrane tearing or syncytium formation. (Courtesy Centers for Disease Control and Prevention, Atlanta.)

apoptosis pathways.<sup>17</sup> *Vpr* either directly or indirectly causes induction of apoptosis because it causes cell cycle arrest and/or the intrinsic pathway.<sup>17</sup>

Another process of cell death occurs when multiple uninfected cells become fused together with infected cells by the virus. This mass of cells, called a **syncytium**, can lead to a large number of cell deaths from a single event. During the T-tropic phase, there is a greater tendency to produce syncytia, causing even faster depletion of T cells. Myeloid-derived dendritic cells (MDDCs) aid in the formation of syncytia when they patrol the body, engulfing the virus and presenting the virus to T cells. During this presentation, virus, receptors, and coreceptors are in close proximity, facilitating infection as well as the development of a syncytium.

Cell death can occur when the immune system makes antibodies to the viral envelope protein. When gp120 is shed, it can bind to uninfected CD4 receptors. The immune system then attacks the uninfected but antibody-coated cells via the complement system (antibody-dependent cellular cytotoxicity) or killer T cells. Cell death can also be secondary to a type III hypersensitivity reaction. As discussed earlier, gp120 and gp41 hide from the immune system because of the large amount of carbohydrate on the surface of gp120 and gp 41. The binding and glycosylation of gp120 and gp41 cause them to have characteristics

**FIGURE 12-10** Progression of HIV infection. The clinical stages of HIV disease correlate with a progressive spread of HIV from the initial site of infection to lymphoid tissues throughout the body. The immune response of the host temporarily controls acute infection but does not prevent the establishment of chronic infection of cells in the lymphoid tissues. Cytokine stimuli induced by other microbes serve to enhance HIV production and progression to AIDS. CTLs, Cytotoxic T lymphocytes. (From Abbas AK et al: *Cellular and molecular immunology*, ed 6, Philadelphia, 2007, Saunders, p 481.)

similar to those of major histocompatibility class (MHC) antigens. In this case, immune system cells may fail to recognize the difference between gp120 and “self MHC markers” causing them to attack normal cells as “nonself.” This phenomenon causes immune cells to attack and destroy large numbers of T cells. Cells also may be affected by T cell–mediated cytotoxicity or by cytokines and inflammation resulting from infection.

### Progression of HIV Infection from Seroconversion to AIDS

HIV disease infection progresses over time to AIDS with many manifestations. AIDS is a syndrome, not a disease, which means that the virus can express itself in many ways. No one symptom typifies either HIV infection or AIDS. However, groups of signs and symptoms are useful in staging progress of the infection. HIV is characterized by two major phases: acute and chronic.

Once the HIV virion enters the body, it rapidly replicates (Figure 12-10). HIV is present in the blood and cerebrospinal fluid but is not detected by usual laboratory tests because no antibodies have formed yet. Usually no symptoms are present. It is a time of rapid virus replication with widespread attack of CD4<sup>+</sup> T cells in mucosal membranes, especially in the gastrointestinal (GI) system. The person is infectious but does not know it.

Seroconversion occurs when sufficient antibodies are detected in the blood, usually between 3 weeks and 6 months after exposure (range: 3 weeks to 14 months). At the time of seroconversion, the person experiences signs and symptoms of acute retroviral syndrome or primary HIV infection. Up to 80% of people newly infected with HIV have flu-like symptoms that can mimic other viral illnesses. At this time, the symptoms of primary HIV infection include flulike or mononucleosis-like symptoms, such as fever, chills, headaches, nausea, vomiting, fatigue, weakness, arthralgias, sore throat, stiff neck, photophobia, irritability, and rash. The rash is not the same in everyone and may be maculopapular, vesicular, or urticarial. Encephalopathy may even develop. The CD4<sup>+</sup> T-cell count is greater than 400 cells/ $\mu$ L. The number of white blood cells, including lymphocytes, is decreased except for an increased number of CD8<sup>+</sup> T cells. The number of platelets is also decreased. The person has an elevated erythrocyte sedimentation rate. During this period, the HIV count in the blood and genital fluids is high and the individual is very infectious. Then, after 1 to 4 weeks, the symptoms disappear. However, HIV is still present and the person continues to be infectious throughout the rest of the course of the infection.

After this period of seroconversion, the patient experiences the clinical latency period, which may last for longer than 10 years (range: 3 to 12 years). During this period, seeded HIV replicates in the lymph nodes and gradually destroys lymph tissue over time. Antiviral immune activity is ongoing. Production of virus is maintained or stabilized at a set level. The person feels well but may experience chronic lymphadenopathy (enlargement of lymph nodes for more than 3 months) or mild general symptoms, including lack of energy, weight loss, frequent fevers, and sweats. The CD4<sup>+</sup> T-cell count is greater than 400 cells/ $\mu$ L. Stabilization of the serum level of virus at a certain point is attributable to the antiviral response, the number of CD4<sup>+</sup> cells, and the virulence of the HIV strain. During this period of asymptomatic or mild infection, large numbers of virions are produced, destroying the body’s immune system. Up to 2 million viral particles can be produced daily. The lymphadenopathy is caused by a vigorous immune response against HIV infection. The key point is that although the infection is clinically asymptomatic or mildly symptomatic, the virus is active, not latent.

Immediately after the latency period of infection, a period of rapid virus production occurs for up to 18 months. It is hypothesized that the

TABLE 12-3 CDC HIV/AIDS CLASSIFICATION MATRIX

CD4 <sup>+</sup> T CELL CATEGORIES	CLINICAL CATEGORIES		
	A ASYMPTOMATIC ACUTE HIV	B SYMPTOMATIC, NOT A OR C	C AIDS INDICATOR
≥500/μL	A1	B1	C1
200-499/μL	A2	B2	C2
<200/μL AIDS indicator T-cell count	A3	B3	C3

From Centers for Disease Control and Prevention: 1993 Revised Classification System for HIV Infection and Expanded Surveillance Case Definition for AIDS Among Adolescents and Adults, *MMWR Morb Mortal Wkly Rep* 41(RR-17):1-6, 1993.

destroyed lymph nodes are no longer capable of removing or holding virus, thus allowing viral escape into the bloodstream (viremia). During this time, a persistent and continuous drop in the CD4<sup>+</sup> T cell count to less than 400/μL is taking place. The antiviral innate immune activity is less effective as the viral load (level of virus in the blood) increases. Also during this time, HIV can persist for years in pools of resting, memory CD4<sup>+</sup> T cells. This pool of CD4<sup>+</sup> T cells carries only provirus DNA and lacks HIV surface antigens, so they are not detected or destroyed by the immune system.

As the viral loads increase and the immune system declines, the patient enters the stage of symptomatic, chronic HIV infection. At this time, the patient progresses from partially responding to skin testing (partial anergy) to complete anergy with no response to skin testing. Severe viral or fungal infections of the skin and mucous membranes develop. Oral and genital herpes simplex infections, including shingles or candidiasis (yeast) infections, usually develop, as well as oral hairy leukoplakia. The patient also may have persistent skin rashes or flaky skin, short-term memory loss, or pelvic inflammatory disease that does not respond to treatment. Children tend to have growth delays and frequent illnesses. The person may develop cytomegalovirus (CMV) infection, Epstein-Barr virus infection, or both, as well as other opportunistic infections.

An HIV-infected person is not diagnosed with AIDS until the CD4<sup>+</sup> T-cell count is less than 200/μL. At that time, the person typically has one or more opportunistic infections, including *Pneumocystis carinii* pneumonia (PCP), *Toxoplasma gondii*-associated neural toxoplasmosis, cryptosporidiosis (gastroenteritis), and *Mycobacterium tuberculosis*. The person usually has one or more tumors or cancers, including Kaposi sarcoma (a connective tissue skin cancer), lymphomas, or cancer of the rectum or tongue. General symptoms of opportunistic infections include coughing or shortness of breath; difficult or painful swallowing (dysphagia); cognitive symptoms such as confusion, forgetfulness, or lack of coordination; seizures; fever; vision loss; severe headaches; and gastrointestinal symptoms such as abdominal cramps, nausea and vomiting, severe and persistent diarrhea, and weight loss, causing extreme fatigue.

Disease progression in infants and children is determined by the timing of the child's infection, the viral load, the child's immune response, and the viral virulence. In general, children with HIV progress more rapidly than adults. Most children fall into two distinct groups: rapid disease progression or slower disease progression. In those with rapidly progressing disease, symptoms develop within the first 6 months of life, sustained decreases in CD4<sup>+</sup> T-cell counts are noted, and AIDS develops within the first 2 years of life. Early aggressive treatment in perinatally infected infants may slow disease progression and prolong immune function. Children with AIDS generally manifest the same opportunistic infections as adults and also may have severe forms of common childhood diseases, such as conjunctivitis, otitis media, and tonsillitis.

### CDC HIV Classification System

The CDC HIV classification system is a simple matrix classification system for adults and children and is the preferred method of staging. In this system, CD4<sup>+</sup> T-cell counts are linked with clinical symptomatology. The CDC has defined three CD4<sup>+</sup> T-cell categories and three clinical categories that are mutually exclusive. The CD4<sup>+</sup> T-cell categories define three T-cell ranges. In category 1, the CD4<sup>+</sup> T-cell count is greater than or equal to 500/μL; in category 2, the CD4<sup>+</sup> T-cell counts range from 200 to 499/μL; and in category 3, the CD4<sup>+</sup> T-cell count is less than 200/μL.<sup>20</sup>

In adults, the clinical categories are labeled A through C. Category A includes a variety of clinical conditions, such as asymptomatic, persistent generalized lymphadenopathy and a history of or current acute HIV infection with accompanying illness. Category B includes conditions that are secondary to impaired cell-mediated immunity, such as candidiasis (oral or vaginal), fever, persistent diarrhea, oral hairy leukoplakia, shingles, idiopathic thrombocytopenic purpura, pelvic inflammatory disease, listeriosis, and peripheral neuropathy. Category C includes conditions that are listed in the AIDS surveillance case definition. An individual in category C will remain in this category. The CDC classification matrix is shown in Table 12-3. An HIV-positive person with a CD4<sup>+</sup> count less than 200/μL or a category C AIDS indicator condition is diagnosed with AIDS. A list of AIDS indicator conditions is shown in Box 12-1.

In children, category N is an asymptomatic phase with no signs or symptoms of disease. Category A is a mildly symptomatic phase with two or more of the following conditions: lymphadenopathy, hepatomegaly, splenomegaly, dermatitis, parotitis, or recurrent/persistent upper respiratory tract infection, sinusitis, or otitis media. Category B is a moderately symptomatic phase in which the child exhibits some opportunistic infections as a result of impaired cell-mediated immunity or impaired bone marrow function. These conditions include anemia, thrombocytopenia, bacterial meningitis, pneumonia or sepsis, candidiasis, thrush, CMV, diarrhea, hepatitis, herpes simplex infection, herpes zoster infection, leiomyosarcoma, nephropathy, persistent fever, toxoplasmosis, and varicella. The category C phase is severely symptomatic with AIDS. The revised pediatric HIV classification system based on age-specific CD4<sup>+</sup> T-cell counts and percentage is shown in Table 12-4.

### DIAGNOSTIC TESTING

To diagnose HIV infection, laboratory tests such as the enzyme-linked immunosorbent assay (ELISA) and the Western blot are used to detect the presence of HIV antibodies. The ELISA test result is positive for HIV antibodies if the blood or oral mucosal transudate of an infected person reacts with the surface antigen of a killed HIV virus. The ELISA test uses purified viral proteins placed on plastic beads or in multiwell trays. When

### BOX 12-1 CONDITIONS INDICATIVE OF AIDS IN HIV-INFECTED PERSONS

- Candidiasis of bronchi, trachea, or lungs
- Candidiasis, esophageal
- Cervical cancer, invasive\*
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (greater than 1 month's duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes)
- Cytomegalovirus retinitis (with loss of vision)
- Encephalopathy, HIV-related
- Herpes simplex: chronic ulcer(s) (greater than 1 month's duration); or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (greater than 1 month's duration)
- Kaposi sarcoma
- Lymphoma, Burkitt (or equivalent term)
- Lymphoma, immunoblastic (or equivalent term)
- Lymphoma, primary, of brain
- *Mycobacterium avium complex* or *M. kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, any site (pulmonary\* or extrapulmonary)
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii* pneumonia
- Pneumonia, recurrent\*
- Progressive multifocal leukoencephalopathy
- Salmonella septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome attributable to HIV

\*Based on age-specific CD4<sup>+</sup> count per microliter and percentage.

the test serum or oral mucosal transudate from a patient is contacted by the purified viral proteins, an antigen-antibody reaction occurs. Antihuman antibody added to the reaction can be detected colorimetrically and indicates whether any antigen-antibody compounds have formed. This test is highly sensitive (more than 99%) and specific (more than 99%) in high-risk populations. For the test to be specific, however, it must be performed with both HIV-1 and HIV-2 viral antigens.

When the ELISA test result is positive, a second test, the Western blot, is used to confirm the presence of HIV antibodies. The Western blot test uses an expensive process called *electrophoresis*, so usually it is used only as a confirmatory test. This test identifies specific antibodies against the HIV protein antigens. The specificity of this test in combination with the ELISA is greater than 99.9%. The problem with this additional testing is that the patient must wait up to 1 to 2 weeks for confirmation.

A rapid, fingerstick-based HIV assay is being used as well: OraQuick Rapid HIV-1. Antibody test results can be obtained in about 20 minutes. However, positive results must be confirmed by a Western blot. It is also important to remember that false-negative tests can occur during the initial period of HIV infection before seroconversion.

Testing neonates for HIV is difficult because of maternal transmission of IgG antibodies against HIV. These passive maternal antibodies cross the placenta and can last as long as 15 months. Therefore, the best method to determine whether a neonate has HIV is to culture the virus from blood and peripheral tissue.

### MONITORING THE PROGRESSION OF HIV

After initial diagnosis of HIV, other laboratory tests need to be performed to stage the disease and assist in the selection and monitoring of appropriate drug treatments. One of the most important of these tests is the CD4<sup>+</sup> T-cell count, which monitors HIV disease status.<sup>6</sup> The CD4<sup>+</sup> count is a specific indicator of disease progression of HIV to AIDS. As the CD4<sup>+</sup> T-cell count declines, the risk of progression to AIDS and development of opportunistic infections and malignancies increases. Highly virulent communicable diseases can still occur when the CD4<sup>+</sup> count is high. However, when the CD4<sup>+</sup> T-cell count drops below 200 cells/ $\mu$ L, the number and severity of low-virulence diseases and opportunistic infections increase. It is at this level that many patients begin taking prophylactic medications to prevent opportunistic and other infections. Also used is the CD4<sup>+</sup> lymphocyte percentage, which is more stable and has less variation over time. When the CD4<sup>+</sup> lymphocyte percentage is less than 20%, the risk of developing AIDS is higher.

Another useful test is the plasma HIV RNA or viral load. This test indicates the amount of viral replication, and helps predict disease progression. The level of HIV RNA in plasma is the strongest predictor of outcome over time. When the plasma HIV RNA content is low, the risk of disease progression declines. The plasma viral load helps the clinician to assess the effectiveness of various therapies and is the basis for initiating more aggressive therapies to decrease the viral load. Usually, HIV RNA levels should drop after the onset of therapy and by 6 months should be undetectable in the plasma. The viral load assay counts copies of HIV RNA in 1 ml of plasma and is either a reverse transcriptase polymerase chain reaction (RT-PCR) or a branched DNA (bDNA) assay. Because each virion contains two strands of RNA, the actual virion level is half the HIV RNA counted. Tests are currently sensitive to 50 copies per milliliter.

Genotypic resistance testing is now part of routine management of HIV infection and is usually part of the initial evaluation of HIV.<sup>6</sup> Genotypic testing identifies viral mutations, whereas phenotypic testing identifies the concentration of antiretroviral drug needed to inhibit viral replication in culture medium. Ideally this testing can help to determine the best drugs to be given to the patient. Genotypic resistance tests specifically examine protease and reverse transcriptase and are now used even when the viral loads are less than 1000 copies/ml.<sup>21</sup> These tests are expensive, which can limit their use in some populations.

Another common test is an anergy test or a delayed hypersensitivity (type IV) test for such organisms as *M. tuberculosis* or mumps or measles virus. In early HIV infection, these skin test results are normal. However, in advanced cases, the patient will have no response to testing because of the loss of macrophage and CD4<sup>+</sup> T-cell functioning.

**BOX 12-2 TESTS USED TO EVALUATE PROGRESSION OF HIV INFECTION****Complete Blood Cell Count with Differential****At entry into care and every 3-6 months**

White blood cell count normal to decreased  
Lymphopenia (<30% of normal number of WBCs)  
Thrombocytopenia (decreased platelet count)

**CD4<sup>+</sup> Count****At entry into care and every 3-6 months**

Reduced CD4<sup>+</sup>/CD8<sup>+</sup> T cell ratio  
CD4<sup>+</sup> (helper) lymphocytes decreased  
CD8<sup>+</sup> lymphocytes increased

**Resistance Testing****At entry into care, and before initiation of or any modification in HAART**

Determines viral resistance to HAART

**Quantitative Immunoglobulin****As needed depending on immune function**

IgG increased  
IgA frequently increased

**Chemistry Panel****At entry into care and every 6-12 months**

Lactate dehydrogenase increased (all fractions)  
Serum albumin decreased  
Total protein increased  
Cholesterol decreased  
AST and ALT elevated  
Total bilirubin elevated  
Serum glucose elevated

**Lipid Panel****At entry into care and, if abnormal, every 6-12 months**

Total cholesterol increased  
Triglycerides increased  
LDL cholesterol increased

**Anergy Panel****As needed**

Nonreactive (anergic) or poorly reactive to infectious agents or environmental materials (e.g., pokeweed, phytohemagglutinin mitogens and antigens, mumps, *Candida*)

**Urinalysis****At entry into care and as needed**

To detect urinary tract infections or hematuria

**Hepatitis B Serology****At entry into care and as needed**

To detect the presence of hepatitis B

**Blood Cultures****As needed**

To detect septicemia

**Chest Radiograph****At entry into care and as needed**

**HLA-B5701 Testing****If considering use of abacavir****Tropism Testing****If considering use of CCR5 antagonist****Pregnancy Testing****If female at entry into care and as needed**

To detect early pregnancy

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; HAART, highly active antiretroviral therapy.

Data from DHHS Panel on Antiretroviral Guidelines for Adults and Adolescents: *Adult and adolescent treatment guidelines*, Office of AIDS Research Advisory Council, Department of Health and Human Services, p 6, October 14, 2011.

Two other tests may be used:  $\beta_2$ -microglobulin and p24 antigen.  $\beta_2$ -Microglobulin is a cell surface protein that indicates macrophage stimulation. Levels greater than 3.5 mg/L are associated with rapid progression of the disease. P24 antigen is indicative of active HIV replication and confirms the diagnosis of HIV infection. It is positive before seroconversion and may be used before confirmation of the disease by ELISA. It is also elevated in later stages of the disease, a period when antibody testing may be unreliable.

Other laboratory and diagnostic tests can assist in the identification, monitoring, and treatment of persons infected with HIV, including a complete blood cell count (CBC), a chemistry panel or screen, and chest radiographs. These tests are routinely used to detect infections and changes in a patient's physiologic status (Box 12-2). The CBC detects the development of anemia (as a result of infection, chronic illness, or secondary to therapy) and neutropenia and thrombocytopenia, which may occur in advanced stages of the disease. In addition to the aforementioned tests, it is important to measure serologic values for hepatitis A, B, and C viruses as well as to obtain screening tests for sexually transmitted infections in light of the risk of coinfection.<sup>6</sup>

**KEY POINTS**

- HIV virions are attracted to cells with CD4 receptors such as T cells, microglial cells, monocyte-macrophages, follicular dendritic cells, immortalized B cells, retinal cells, Langerhans cells in the skin, bone marrow stem cells, cervical cells, bone marrow-derived circulating dendritic cells, and enterochromaffin cells in the colon, duodenum, and rectum.
- The hallmark of AIDS is a decrease in the number of CD4<sup>+</sup> cells, including T helper lymphocytes and macrophages, especially in mucosal membranes. B cell responsiveness is decreased because of dependence on T helper cell cytokines.
- The key element in HIV infection is the high level of virion production and the high level of CD4<sup>+</sup> cell death.
- CD4<sup>+</sup> cell death occurs via several mechanisms. Cross-linking of CD4 receptors by viruses may result in T-cell death, apoptosis, or anergy. Virions may cause the linkage of infected and uninfected cells, followed by cell fusion and death. B cells may form antibodies against infected T cells. Viral budding may cause excessive loss of cell membranes.

- Laboratory testing for HIV is accomplished by using either the ELISA or the Western blot test. Usually the ELISA test is performed first. If it is positive, the Western blot test is performed to confirm the presence of specific antibodies against HIV protein antigens.
- HIV is an infectious disease that progresses to AIDS and is characterized by different clinical manifestations at each stage. Individuals move through the stages at different rates.
- Flulike symptoms and the formation of anti-HIV antibodies (seroconversion) characterize the early stage of viral seeding. Next, symptoms of early immune dysfunction are present, including lymphadenopathy, fever, and night sweats. A surge in viral production and a drop in the CD4<sup>+</sup> lymphocyte count follow this stage.
- In the later stages, CD4<sup>+</sup> counts continue to fall and the person is subject to a number of opportunistic infections and tumor formation. An HIV-positive individual is diagnosed with AIDS when the CD4<sup>+</sup> T-cell count is less than 200/μL or when a category C AIDS indicator condition is present.
- Children often have rapidly progressive disease, with onset of AIDS between ages 4 and 8 years.

## CLINICAL MANIFESTATIONS

HIV affects all body systems, particularly the integumentary, pulmonary, gastrointestinal (GI), neurologic, and ocular systems. GI manifestations develop in nearly all persons with HIV because of the major effect of HIV infection on the GI system. Pulmonary and cutaneous symptoms develop in approximately 50% to 75% of all persons with HIV, and neurologic symptoms develop in 50% to 60%. **Box 12-3** outlines the common agents of infection in patients with AIDS.

### Systemic Manifestations

As implied in the classification systems presented earlier, the course of HIV infection parallels the functioning of the immune system. As immune function declines, the number of opportunistic infections and malignancies increases and the normal functioning of organ systems declines.

One of the most significant systemic symptoms is malnutrition or wasting syndrome. In Africa, HIV is known as “slim disease” because of the wasting. Malnutrition is defined as unintended, involuntary loss of greater than 10% body weight. The systemic symptoms attributable to HIV infection malnutrition include major muscle wasting, weight loss, and loss of vitamins, minerals, and other nutrients. HIV malnutrition is the result of a combination of factors, including an elevated metabolic rate with increased resting energy expenditure (REE), chronic inflammation, malabsorption, anorexia, decreased intake of food, and the effect of multiple opportunistic insults.<sup>22,23</sup> There is a 10% to 30% increase in resting metabolic rate attributable to secondary infections or elevated plasma viral load.<sup>23</sup> In addition, levels of tumor necrosis factor, interleukin-1, interleukin-6, and other pro-inflammatory cytokines are elevated in HIV infection, causing anorexia as well as increased metabolism of fat.<sup>23</sup> Malabsorption is affected by the loss of GI-associated lymphoid tissue (especially during the initial phase of HIV infection) impairing the integrity of the epithelial mucosal barrier and predisposing to secondary infections of the GI tract.<sup>23</sup> Low basal metabolic index (BMI), failure to regain weight after weight loss, and continued weight loss after the start of medication hasten disease progression and are risk factors for increased mortality.<sup>22,23</sup> In children, growth failure is indicative of poor outcomes and mortality.<sup>23</sup> Malnutrition is a leading cause of death among AIDS patients worldwide. Prevention is key—involving assessment of nutritional parameters as well as nutritional education/counseling and exercise. A patient’s body mass index, weight, waist-to-hip ratio, mid-arm circumference, calorie and protein intake, and prealbumin, serum albumin, and triglyceride levels are frequently measured.

## BOX 12-3 COMMON AGENTS OF INFECTION IN PATIENTS WITH AIDS

### Viruses

Herpes simplex 1 and 2  
Herpes zoster  
JC virus  
Epstein-Barr virus  
Human papillomavirus  
Varicella  
Adenovirus

### Bacteria

*Campylobacter* spp.  
*Shigella* spp.  
*Neisseria* spp.  
*Salmonella* spp.  
*Chlamydia* spp.  
*Staphylococcus* spp.  
*Haemophilus influenzae* spp.  
*Legionella* spp.

*Treponema* spp.

*Mycobacterium* spp.

### Fungi

*Candida albicans*  
*Cryptococcus neoformans*  
*Histoplasma capsulatum*  
*Coccidioides immitis*  
*Nocardia*

### Protozoa

*Pneumocystis jiroveci* (*carinii*)  
*Toxoplasma gondii*  
*Isospora belli*  
*Cryptosporidium*  
*Giardia lamblia*  
*Entamoeba histolytica*

Data from Stites DP, Terr AI: *Basic and clinical immunology*, ed 7, Los Altos, CA, 1991, Appleton & Lange; Ungvarski PJ, Schmidt J: AIDS patients under attack, *RN* 55(11):35-44, 1992; Anastasi JK, Rivera JL: Identify the skin manifestations of H.I.V., *Nursing* 92(11):58-61, 1992.

To prevent or delay the wasting process, some medications have been used, including anabolic steroids, growth hormone treatments, cytokine inhibitors, and appetite stimulants.<sup>23</sup> Ketotifen is a tumor necrosis factor inhibitor and antihistamine that is used because its side effects are appetite stimulation and weight gain. Thalidomide, which is also a tumor necrosis factor inhibitor, appears to be effective against wasting syndrome and increases fat-free mass. Oxandrolone is an anabolic steroid designed specifically to promote weight gain, particularly lean body mass. Megestrol acetate (Megace), a progestational agent, and dronabinol, an antiemetic, are often used to decrease nausea and increase appetite. Use of human growth hormone (somatropin, Serostim) may also be given to increase lean body mass.

Vitamins A, C, D, and E; the B vitamins; zinc; selenium; sulfur-containing amino acids; and other antioxidants are also prescribed. The use of these nutrients can prevent the up-regulation of inflammatory cytokines and thereby decrease inflammation. High-protein, high-calorie meals and snacks are recommended, along with nutritional supplements to meet the required amounts of energy, protein, and micronutrients needed as a result of increased metabolic rates (REE). High-fat foods should be avoided because they increase diarrhea, as can lactose-containing foods. Nutritional supplements (Ensure, Nitrofuel, Sustacal Plus, Advera, Lipisorb), which provide both protein and calories, are full of nutrients and can be formulated either with or without lactose and with or without medium-chain triglyceride oil (a more easily digested fat). Implementation of total parenteral nutrition (TPN), including gastrostomy or jejunostomy tube feedings, is reserved for those with severe malnutrition and GI manifestations.<sup>27</sup>

### Gastrointestinal Manifestations

GI manifestations are nearly universal in persons with HIV. In fact, the GI tract is the major target organ in HIV infection. HIV may be a significant direct pathogen in the GI tract. The major HIV GI complication is chronic diarrhea, which increases with decreasing CD4<sup>+</sup> counts.<sup>24</sup> The diarrhea, often watery or bloody, causes malabsorption and consequently severe weight loss. This complication of HIV-related malnutrition causes

muscle loss leading to increased morbidity and risk of death. Antiemetics and anti-diarrheals are often useful in controlling symptoms.

Whenever chronic diarrhea or other GI symptoms develop in a patient with HIV, it is important to determine the cause. GI symptoms can be the result of multiple opportunistic infectious agents and are rarely the result of tumors occurring in the GI tract. Some of the most significant infectious agents are viruses such as CMV and herpes simplex; fungi such as *Candida*; bacteria such as *Salmonella*, *Shigella*, *Clostridium difficile*, *Chlamydia trachomatis*, and *Campylobacter*; and parasites such as *Giardia*, *Isospora*, *Entamoeba histolytica*, and *Cryptosporidium*. GI symptoms include chronic diarrhea, oral candidiasis, anorexia, nausea, vomiting, mucous membrane ulcers, retrosternal pain on swallowing, abdominal pain, and low levels of serum vitamin B<sub>12</sub>. Ulcerations occur as a primary manifestation or secondary to the inflammation. Treatment involves the use of disease-appropriate antimicrobials, depending on the offending organism.

A common cause of diarrhea is the protozoa *Cryptosporidium*, which infects the intestinal epithelial lining. This organism is transmitted via water, food, animals, and other humans. The onset is generally acute and associated with explosive diarrhea within 4 to 14 days after infection. In nonimmunocompromised persons, the symptoms last up to 2 weeks, but in immunocompromised persons, the diarrhea and symptoms can persist indefinitely. Cryptosporidiosis causes nausea, vomiting, severe watery nonbloody diarrhea (more than 15 to 20 L), abdominal pain, cramping, electrolyte disturbances, and dehydration.

Diagnosis is made by stool examination for ova and parasites and by bacterial culture and sensitivity. Antibiotic treatment is not always effective, but antimicrobials such as the macrolides have been used. In the acute phase, some patients must be given intravenous hydration for support. Thereafter, increased oral intake along with low-residue, high-protein, high-calorie diets and loperamide (Imodium) 2 mg tablets, up to 16 to 18 tablets or 36 mg per day, are used to help control the diarrhea.

Prevention of *Cryptosporidium* infection is most important. Preventive activities include routine testing of well water, using water filters at home, avoiding ice or unfiltered tap water both at home and in restaurants, and avoiding fresh fruits or vegetables rinsed with unfiltered water. Fruits and vegetables can be washed in bottled water, filtered water, or water with 20 drops of 2% iodine per gallon.

Oropharyngeal and esophageal *Candida albicans* infections occur in most patients with HIV during the course of their disease. Most often, oral candidiasis is pseudomembranous in type, with white plaques that bleed when removed and leave an erythematous surface. *Candida* oropharyngeal lesions produce pain and discomfort during eating, loss of taste, and xerostomia (dry mouth). *Candida* esophageal lesions cause pain with swallowing, dysphagia, and a feeling of “throat swelling.” These lesions lead to worsening wasting syndrome. Management of oropharyngeal candidiasis includes the use of topical antifungal agents (such as clotrimazole or nystatin) in a suspension or lozenges, whereas management of esophageal candidiasis includes antifungal agents by oral or intravenous routes of administration. Side effects include an unpleasant taste and GI side effects, with inconvenient dosing regimens (up to six times per day).

### Pulmonary Manifestations

Pulmonary manifestations are a major source of morbidity and mortality in AIDS patients. Pulmonary diseases include opportunistic pneumonias, such as those associated with *P. jiroveci* (*carinii*), CMV, *M. tuberculosis*, *Histoplasma*, or *Staphylococcus*, as well as parenchymal lung diseases including Kaposi sarcoma, lymphoma, nonspecific pneumonitis, and adult respiratory distress syndrome. Infection with *M. tuberculosis* occurs in 4% of patients with HIV and is particularly problematic in third world countries where the tuberculosis comorbidity

**FIGURE 12-11** *Pneumocystis jiroveci* (*carinii*). A chest radiograph shows bilateral lower lobe interstitial infiltrates. (Courtesy Dr. Paula Karvalho, Veterans Administration Medical Center, Boise, Idaho.)

rates are up to 50%. Patients with HIV have an increased risk of being infected with a multidrug-resistant type of tuberculosis organism.

PCP is a common initial opportunistic infection in HIV and is an AIDS-defining diagnosis in the United States and Europe. However, the incidence of *P. carinii* has decreased with the use of prophylaxis. *P. carinii* is a fungus (renamed *P. jiroveci*). This organism prefers alveolar environments and infects most people during early childhood. Children usually have *Pneumocystis* antibodies by 2 to 3 years of age, but the organism does not cause disease in immunocompetent persons. With immunodeficiency and CD4<sup>+</sup> T-cell counts below 200/μL, *Pneumocystis* becomes activated and causes PCP. The nonspecific symptoms of PCP include flu-like fever, fatigue, and weight loss. The major pulmonary feature of PCP is severe hypoxemia with a PaO<sub>2</sub> less than 60 mm Hg. The most severe pulmonary symptoms are similar to those of adult respiratory distress syndrome (Figure 12-11). These symptoms include decreased phospholipid (surfactant) production, early dry cough, dyspnea, tachypnea, chest discomfort, and marked pallor and cyanosis.

Diagnosis of PCP is by chest radiography, and organisms are identified in sputum with Wright-Giemsa stain. *Pneumocystis* cannot be cultured.<sup>25</sup> Sputum is induced by using 3% saline via nebulizer, and patients must avoid brushing their teeth, using mouthwash, or eating for 8 hours before expectoration of a sputum sample. Other tests that can be performed include bronchoalveolar lavage or biopsy and gallium scanning. Treatment usually includes the use of intravenous or oral trimethoprim-sulfamethoxazole (Bactrim, Septra) and parenteral and aerosolized pentamidine (NebuPent, Pentam 300).

To prevent PCP infections by prophylaxis, patients with CD4<sup>+</sup> counts of less than 200 cells/μL are given trimethoprim-sulfamethoxazole tablets either daily or three times per week to prevent the recurrence of infection. This is a very effective suppressive therapy that prevents life-threatening

**FIGURE 12-12** Herpes zoster in an HIV-infected individual. (From Callen JP: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 382.)

PCP. However, there is growing concern about trimethoprim-sulfamethoxazole drug resistance. If patients cannot tolerate it, substitutes include aerosolized pentamidine, dapsone, or dapsone with pyrimethamine and leucovorin.

### Mucocutaneous Manifestations

Mucocutaneous manifestations occur both early and late in the course of HIV infection. The early viral exanthem of HIV infection, associated with seroconversion, is an erythematous, fine maculopapular rash found on the face, trunk, and arms. It is a self-limited manifestation that occurs in 40% to 60% of all HIV-infected persons. It is generally seen within 2 to 6 weeks of exposure and lasts up to 1 to 2 weeks. It is associated with mild pruritus, fever, malaise, night sweats, fatigue, pharyngitis, weight loss, diarrhea, headache, and lymphadenopathy.

Other mucocutaneous manifestations may be allergic, infectious, or neoplastic in origin. Cutaneous symptoms depend on the cause and location. Allergic causes may be the result of drug reactions or the development of seborrheic dermatitis, psoriasis, or skin-colored papular eruptions.

Viral causes include herpes simplex virus, varicella-zoster virus, Epstein-Barr virus, and human papillomavirus (Figure 12-12). The development of genital warts (condylomata acuminata) from human papillomavirus is an early symptom of HIV disease in women. For mucocutaneous viral infections, acyclovir (Zovirax) or vidarabine is the recommended antiviral agent.

Oral hairy leukoplakia is an example of an oral mucous membrane infection first described in 1984. It occurs only in immunosuppressed individuals and is associated with Epstein-Barr virus. It occurs in up to 50% of patients with untreated HIV, especially when the CD4<sup>+</sup> count declines. Oral hairy leukoplakia is characterized by white to gray thickened, raised lesions with vertical folds, corrugations, or “hairs” that form on the tongue and buccal mucosa. Usually they form on the sides of the tongue (Figure 12-13). These lesions cannot be removed with a tongue blade, which differentiates this infection from oral candidiasis or thrush. They are not usually painful. There is no specific treatment for oral hairy leukoplakia. It will often resolve with treatment of the HIV infection with improvement in the CD4<sup>+</sup> cell count.<sup>26</sup>

In HIV-infected persons, herpes simplex viruses 1 and 2 cause the formation of large groups of painful vesicles on an erythematous base. The HSV-1/-2 vesicles then rupture, crust, and become large, ulcerative, and occasionally necrotic. They are chronic and painfully persistent, and usually occur on the genitalia, digits, and perianal or perioral areas. Herpes simplex virus may produce protein that enhances the replication of HIV.

**FIGURE 12-13** Oral hairy leukoplakia, a manifestation of Epstein-Barr virus infection in HIV-infected individuals. (From Callen JP: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 377.)

**FIGURE 12-14** *Candida albicans* in an HIV-infected person. (From Callen JP: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 386.)

Bacterial infectious causes of mucocutaneous manifestations include *Mycobacterium avium* or *Staphylococcus aureus*. *Staphylococcus* is a common bacterial skin infection in patients with HIV associated with folliculitis, furuncles (boils), or bullous impetigo. Occasionally sepsis may occur. Treatment includes application of topical antibiotics, use of an antibacterial soap, and administration of systemic antibiotics, either oral or intravenous, as needed. Abscesses usually are surgically opened and drained.

Fungal skin infectious agents include *Candida*, *Cryptococcus*, or *Histoplasma* (Figure 12-14). Vaginal candidiasis is the most common early skin symptom in HIV-positive women. Other infectious agents include parasites such as the mites that cause scabies. Treatment is with topical, oral, or intravenous antifungal or antiparasitic agents, depending on the severity of the infection.

Neoplasms can also occur, including Kaposi sarcoma, squamous cell carcinoma, basal cell carcinoma, or cutaneous lymphomas. Kaposi sarcoma is an AIDS-related malignancy that affects the skin and mucous membranes, lymphatics, and other internal organs. It is one of the few neoplasms indicative of immune system dysfunction. Since 1981, Kaposi sarcoma is the most common tumor found in HIV-infected homosexual men. It rarely occurs in other high-risk groups or in women in the United States. The skin lesions of Kaposi sarcoma are individual tumors that begin as flat or macular subcutaneous patches.

**FIGURE 12-15** HIV-associated Kaposi sarcoma in the macular stage. (From Callen JP: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 55.)

**FIGURE 12-17** Cervical dysplasia. Women with AIDS require more frequent monitoring because cervical dysplasia commonly occurs and progresses rapidly.

**FIGURE 12-16** HIV-associated Kaposi sarcoma in the nodular stage. (From Callen JP: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 379.)

The patches initially range from light pink to deep purple and are painless, nonblanching, and nonpruritic (Figure 12-15). The lesions evolve from patches into thickened plaques or large nodules that may change to brown over time, especially in darkly pigmented persons. They may occur anywhere on the body, and usually begin on the head—face, eyelids, conjunctivae, pinnae, scalp, or buccal membranes (Figure 12-16). Lesions range in size from a few millimeters to coalesced patches covering large areas of the body. The lesions are highly vascular but do not bleed excessively. The lesions also may occur internally in either the lungs or the intestines in approximately 40% of patients.

Kaposi sarcoma is managed with radiation therapy and medications, including chemotherapy. Surgery is rarely indicated except to remove large, uncomfortable lesions. Radiation therapy is used primarily for oral or cutaneous lesions. Mitotic inhibitors (e.g., vinblastine, vincristine) or immunomodulators (e.g., interferon- $\alpha$ ) have been useful chemotherapeutic agents in the management of Kaposi sarcoma. Smaller lesions may be managed with intralesional injections of a mitotic inhibitor. Those with the best prognosis tend to have limited disease, no other opportunistic infections, and no weight loss, fevers, or night sweats.

### Gynecologic Manifestations

The primary genital barrier to HIV virus is the genital epithelial cell (GEC). When pro-inflammatory cytokines are produced in response

to HIV virus, the usually tight epithelial junction barrier becomes impaired allowing HIV virus to move across the epithelium.<sup>16</sup> The gynecologic manifestations of HIV disease are marked by persistent monilial vaginitis secondary to *C. albicans*, cervical dysplasia, and neoplasia, as well as pelvic inflammatory disease. Cervical dysplasia affects 40% of HIV-infected women (Figure 12-17). Cervical dysplasia has no symptoms, but the cell changes can lead to neoplasia (cancer). Therefore, either Papanicolaou smears or colposcopic examinations should be performed every 6 months to detect cervical cancer early in HIV-positive women. Cervical cancer is particularly aggressive in women with HIV. Pelvic inflammatory disease (PID) is common in HIV-positive women. PID is caused by a variety of organisms, including *C. trachomatis*, and is managed with antibiotics.

### Neurologic Manifestations

Neurologic manifestations are often the reason that people with HIV seek treatment. HIV invades the neurologic system early in the course of its infection, infecting glial cells, endothelial cells, and brain macrophages—particularly microglial cells, which are the main cellular targets of HIV in the brain. Microglial HIV infection results in elevated levels of the enzyme *glutaminase*, which produces increased extracellular glutamate concentrations leading to increased neurotoxicity.<sup>27</sup> Central and peripheral nervous system manifestations are caused by HIV infection directly, as a result of infectious agents causing meningitis, or secondary to neoplasms causing space-occupying lesions. Opportunistic infectious agents affecting the neurologic system include *Toxoplasma* and *Cryptococcus*. A variety of peripheral neuropathies can result from HIV infection directly, although some may be caused by herpes zoster infection.

HIV encephalopathy (AIDS dementia complex, subacute, or AIDS encephalopathy) is the most common neurologic manifestation. HIV encephalopathy is caused directly or indirectly by HIV infection or viral products, by cytokine-related cellular damage, and by the competition or interference between gp120 and neuroleukin, a nerve growth factor. This disorder can affect both adults and children. It occurs when other opportunistic infections begin to appear later in the disease process. HIV encephalopathy is a syndrome characterized by progressive cognitive impairment or subcortical dementia. In other words, the patient is alert but demented and confused. Computed tomography shows diffuse atrophy in the cerebral cortex, widened sulci, ventricular enlargement, and shrinking of the basal ganglia. Cerebrospinal fluid analysis shows elevated protein and abnormal IgG levels.

The cognitive neurologic symptoms associated with HIV encephalopathy include inattentiveness, confusion, forgetfulness, loss of concentration, slower verbal response, headache, apathy, and inability to complete or perform complex tasks. Symptoms may wax and wane over the course of a day, with intermittent periods of lucidity and confusion. Symptoms can progress to global dementia associated with marked memory impairment and disorientation. Before motor strength declines, the patient may forget time, place, person, and activities, leading to safety issues such as wandering, leaving appliances on, and forgetting to take medications. The associated focal motor deficits include slower motor responses, clumsiness, weakness, loss of balance, handwriting changes, and slurred speech. With progression, motor strength declines with subsequent large muscle weakness causing difficulty walking and moving. Associated generalized symptoms consist of fever and mild metabolic acidosis. Behavioral symptoms include personality changes, social withdrawal, depression, poor hygiene and grooming, lack of insight, apathy, agitation, and, less commonly, anxiety and hyperactivity. In children, head circumference does not increase with age. As the disorder progresses, the neurologic symptoms become more severe. Ataxia, hypertonia, tremors, and incontinence appear. The person may be alert but cognitively impaired, mute, and paraplegic. Hemianopia (partial blindness), myoclonus, and seizures also may develop. The person may become comatose and lethargic with other systemic dysfunctions. Management of HIV encephalopathy includes treatment with antiretroviral agents and neuroleptics (to control agitation) as well as coordination of home and environmental safety plans and patient/family support.

### Ocular Manifestations

Ocular manifestations of HIV infection may be of infectious or noninfectious origin. Noninfectious causes of ocular problems include HIV retinopathy and malignancy. Infectious causes include bacteria such as *Treponema pallidum* (syphilis) and *Staphylococcus*; fungi including *Candida*, *Cryptococcus*, and *Histoplasma*; protozoa such as *Pneumocystis* and *Toxoplasma*; and viruses such as herpes simplex and CMV.

The most severe type of ocular infection is CMV retinitis. After an insidious onset, ocular CMV causes perivascular hemorrhages, fluffy exudates, and vasculitis in the retina, leading to destruction and necrosis of the retina with resulting blindness. Treatment of CMV retinitis involves the use of anti-CMV agents (e.g., ganciclovir) intravenously and the use of oral anti-CMV agents for prophylaxis. An intraocular sustained-release anti-CMV implant is also available for the management of acute and chronic CMV retinitis.

HIV-associated retinopathy causes the development of cotton-wool spots and microvascular retinal changes. Cotton-wool spots are small, indistinct white spots with associated hemorrhage. These changes are not as severe as CMV retinitis and may remit spontaneously.

### Cardiovascular Manifestations

Cardiovascular disease is the second most frequent cause of death after cancer in persons with HIV.<sup>28</sup> Increased cardiovascular risk is an important treatment consideration in an aging HIV-positive population with either untreated or treated HIV infection. The 2006 Strategies for Management of Antiretroviral Therapy (SMART) study found that cardiovascular events, hypertriglyceridemia, and lipidemia were the result of HIV infection and not just caused by medications for HIV. This study determined that cardiovascular and renal diseases were higher in those not treated effectively with antiretroviral medications. Therefore, lipid abnormalities and cardiovascular disease are due either to HIV immunosuppression and HIV viremia or to highly active antiretroviral therapy (HAART), or both. Hypertriglyceridemia and lipogenesis are the result of inflammatory responses to HIV infection secondary to elevated

serum interferon- $\alpha$  (IFN- $\alpha$ ) level as well as decreased triglyceride clearance from the blood in HIV infection.<sup>29</sup> Antiretroviral therapies also cause dyslipidemias primarily because of the effects on hepatocytes.<sup>29</sup>

The treatment of HIV-associated dyslipidemia includes education/counseling on heart-healthy diet, exercise, and smoking cessation; management of hypertension and diabetes if present; treatment of dyslipidemia with medications as needed; and use of antiplatelet agents.<sup>29</sup> The treatment of dyslipidemia includes the use of fish oils, fibrates, statins, niacin, and ezetimibe.<sup>29</sup> Of the statins, atorvastatin and pravastatin (Pravachol) are less likely to cause adverse interactions with HAART medications. Fibrates, such as gemfibrozil, are generally well tolerated and do not interact adversely with most HAART medications. Ezetimibe, in combination with Pravachol, appears to benefit most patients. However, ezetimibe, which blocks cholesterol absorption in the intestine, does not appear to lower lipid levels alone.<sup>29</sup>

### Manifestations in Other Systems

Renal impairment can also occur with HIV infection. HIV can affect the kidneys and cause AIDS-associated nephropathy (AIDS-related glomerulopathy or HIV-associated nephropathy [HIVAN]), drug-induced ischemia, and renal failure. Hematologically, individuals with HIV have anemia, thrombocytopenia, and granulocytopenia. Liver dysfunction is also a problem in persons with HIV because there is an increased risk of concomitant hepatitis C or B (HCV/HBV) infection. This comorbidity of HIV/HCV or HIV/HBV causes increased mortality from end-stage liver disease. Also compounding liver dysfunction in patients with HIV is the effect of multiple medications on the liver itself.

HIV-related endocrine dysfunction is usually associated with inflammation; changes in hormone secretion secondary to the stress response; destruction of endocrine tissue from infection, cancer, or inflammation; use of pharmacologic agents; or the effect of severe illness on hormonal function and metabolic homeostasis.<sup>30</sup> Insulin resistance is a major metabolic complication of antiretroviral therapy. Insulin resistance can be either direct (from insulin signal interference at the cellular level) or indirect (from antiretroviral therapy and lipid dysfunction).<sup>31</sup> It leads to abnormal glucose metabolism and the development of diabetes mellitus. The adrenal gland is another organ affected by HIV infection because of increased adrenal secretion of cortisol with stress. Injury to the adrenal gland rarely leads to frank cortisol deficiencies. Levels of thyroid hormones (e.g., triiodothyronine [T<sub>3</sub>], thyroxine [T<sub>4</sub>], and thyroid-stimulating hormone [TSH]) may be elevated or decreased. Hypogonadism can be primary in HIV infection or secondary to antiretroviral therapy.

Adipose tissue endocrine function is also affected by HIV infection and antiretroviral therapy. This dysfunction may cause the development of HIV-1 HAART-associated lipodystrophy syndrome (HALS) in some persons. It is characterized by subcutaneous adipose tissue atrophy, dorsocervical fat ("buffalo hump") accumulation, and visceral adipose tissue hypertrophy.<sup>32</sup> The cause of this dysfunction is multifactorial due to the effects on systemic metabolism, as well as enhanced production of proinflammatory cytokines and excessive free fatty acid release.<sup>32</sup> Not all people treated with antiretroviral therapy develop lipodystrophy. It is suspected that there may be a genetic component or predisposition to development.<sup>33</sup> At this time, the treatment and causes of adipose tissue dysfunction are still being researched.

Rheumatologic manifestations of HIV infection are varied, encompassing osteoporosis, osteopenia, and musculoskeletal infections (infectious arthritis and osteomyelitis). Musculoskeletal infections are caused by a decrease in the number of T cells. The most common infectious organisms include *S. aureus*, *Streptococcus pneumoniae*, *C. albicans*, *Mycobacterium kansasii*, and *Mycobacterium avium-intracellulare*. Other manifestations are caused by immune-mediated arthritis (such as Reiter

disease, psoriatic arthritis, and undifferentiated spondyloarthropathy syndromes) or occur as a direct result of the immune response to HIV (including polymyositis, vasculitis, and immune complex diseases related to the production of autoantibodies). The increasing incidence of osteopenia, osteoporosis, and osteonecrosis in the HIV population is significant and may be due either to HIV infection or to antiretroviral therapy. Treatment includes using bisphosphonate medications and selective estrogen receptor modulators as well as risk factor modification.

### Manifestations in Children

Children with HIV become symptomatic much faster than adults—usually within their first year of life. Because of the invasion of virus, children's growth and development are markedly affected, including physical growth retardation with failure to thrive, impaired intellectual development, and impaired motor functioning with decreased coordination. The infant develops normally until the virus begins its nervous system invasion. After that time, neurologic impairment is characterized by development of weakness, loss of previously accomplished developmental milestones, hypotonia, or hypertonia. Extensive candidiasis without any relationship to antibiotic therapy may be an early symptom. Respiratory problems, including the development of PCP, are common.

More serious bacterial and viral infections also develop in children who undergo repeated bouts of communicable diseases such as chickenpox or measles. As a result, it is recommended that children obtain vaccinations. In a recent meta-analysis of the safety of measles vaccination, the vaccination using live virus appears to be safe in HIV-infected children as early as 6 months of age.<sup>34</sup>

Because lactose intolerance is common in HIV-infected children, soy formulas are often used. Dairy products may be introduced into the diet gradually, as tolerated. Children need particular attention to their diet; increased intake of calories and protein, as well as nutrient-rich snacks such as raisins and peanuts for growth and development, is advisable.

#### KEY POINTS

- All body systems are affected by HIV.
- Early HIV infection is characterized by fever, chills, headaches, nausea, vomiting, diarrhea, fatigue, weakness, arthralgia, sore throat, stiff neck, photophobia, irritability, and rash.
- The most significant systemic symptom is malnutrition or wasting, which is due to a combination of factors, including an elevated metabolic rate, chronic inflammation, malabsorption, anorexia, and the effect of multiple opportunistic insults.
- GI symptoms occur frequently in patients with HIV. Symptoms include diarrhea caused by *Cryptosporidium* or other agents, ulceration, and candidiasis, as well as multiple opportunistic infections.
- Pulmonary symptoms include opportunistic pneumonias (particularly PCP), tuberculosis, and adult respiratory distress syndrome.
- Mucocutaneous symptoms occur both early and late in the course of HIV infection. One of the first symptoms is the viral exanthem that occurs during the primary infection. Other manifestations may be allergic; infectious, such as candidiasis or herpes, human papillomavirus, and Epstein-Barr virus infections; or neoplastic, such as Kaposi sarcoma.
- Neurologic manifestations include peripheral neuropathy, encephalopathy with dementia, headache, apathy, and focal deficits.
- Gynecologic manifestations include persistent monilial vaginitis, cervical dysplasia, and pelvic inflammatory disease.
- Ocular manifestations include HIV-associated retinopathy, CMV retinitis, malignancy, and a variety of infectious causes.
- Children with HIV have growth and development problems, including impaired physical growth, intellectual development, and motor functioning.

## TREATMENT

### Antiretroviral Therapy Recommendations

The goal of medication and therapeutic management of HIV/AIDS is to delay disease progression, restore or preserve immunologic function, suppress plasma HIV viral load, minimize clinical manifestations, reduce morbidity, prolong survival, and prevent HIV transmission.<sup>6</sup> Drug management of HIV infection has evolved from monotherapy, or therapy with one agent, to the use of multiple medications, called antiretroviral therapy (ART) or highly active antiretroviral therapy (HAART). This polydrug therapy approach involves the administration of multiple antiretroviral agents. It provides better viral suppression, thereby decreasing viral load, increasing CD4<sup>+</sup> counts, and decreasing resistance for a longer period. The objective of HAART is to provide the greatest viral suppression for the longest time to prevent viral mutations. This approach makes good sense. If one drug blocks 90% of viral replication, the others may eliminate the rest of the resistant virions. However, even with HAART, complete viral eradication is not possible with current treatment strategies. It has also been found that continuous HIV therapy is more beneficial than treatment interruption with prolonged drug treatment holidays.

Antiretroviral therapy in HIV infection is more successful in some patients than others, depending on both internal and external factors. Some important factors include prescribing the appropriate polydrug therapy and ensuring maximal convenience of therapy, aiding patient adherence to the treatment regimen. Other factors include early identification of HIV infection with low baseline viremia and higher baseline CD4<sup>+</sup> count, usually >200 cells/mm<sup>3</sup>.<sup>6</sup> However, there are also unknown factors involving the response of individual patients to the therapy, including the rate of reduction of viremia in response to treatment.<sup>6</sup> People who present for treatment later in HIV infection with higher viremia and lower CD4<sup>+</sup> counts tend to have increased morbidity, increased progression, and decreased immune system responses, as well as poor adherence to therapy.

HIV drug treatment failures are the result of HIV resistance, which is a widespread problem and concern. Failure of HIV drug treatment is usually caused by poor adherence to HAART, poor toleration of the drugs, prior exposure to single or multiple antiretroviral drug therapy, or counteracting interactions among the drugs used. It is easy to see why persons taking the multidrug regimen may fail to comply with nutritional and drug therapy because of the sheer volume of drugs to be taken in a day. A person infected with HIV may take up to 13 to 30 pills per day; he or she must also remember which medications should be taken with food or on an empty stomach and which medications cannot be taken together simultaneously. In addition, some persons with HIV/AIDS may be demented because of the disease or may be homeless or addicted to intravenous drugs, any of which limits the person's ability to adhere to the strict treatment regimens. Finally, some of the treatments for opportunistic infection or cancer involve many other drugs: intravenous, oral, and intracavitary. Multidrug therapy retails at approximately \$900 to \$1400 per month. Patient compliance with complicated drug therapy that has many side effects and high cost is often variable. Virus resistance increases with treatment protocol noncompliance. Therefore, the key appears to be encouraging patient compliance by tailoring medication regimens that improve tolerability and convenience.

Current recommendations for antiretroviral therapy for HIV per U.S. Department of Health and Human Services (USDHHS) guidelines (October 14, 2011) include initiation of therapy for all persons

**FIGURE 12-18** Antiretroviral therapy. The stages in the life cycle of HIV in which antiretroviral therapy is effective are shown.

with AIDS-defining illness or severe symptoms at any  $CD4^+$  count or viral load, for all asymptomatic HIV-infected persons with a  $CD4^+$  cell count  $<350$  cells/ $mm^3$ , and for all persons with HIV-associated nephropathy or hepatitis B virus (HBV) coinfection.<sup>11</sup> Antiretroviral therapy is recommended but not mandated for patients with  $CD4^+$  cell counts between 350 and 500 cells/ $mm^3$ . In asymptomatic HIV-infected persons who have a  $CD4^+$  cell count greater than 500/ $\mu L$  some clinicians may delay treatment until after patient consultation. The USDHHS panel was evenly divided, with 50% favoring early treatment and the other 50% viewing treatment as optional. Early antiretroviral treatment seems to be better tolerated by patients and helps to prolong life, but it is imperative that patients starting antiretroviral therapy be committed to life-long treatment and adherence to therapy with knowledge of the risks and benefits of therapy.

Some of the current medications available to adults with HIV have not been recommended for children younger than 13 years. In the past, treatment for infants and children was often delayed weeks or months; this is because virion levels are usually not detectable for up to 2 weeks after birth. Some clinicians recommend intensive therapy for all infants born to HIV-positive women even though the infant may not have infection. This controversial method is not universal but does take into consideration the rapid progression of infection in infants.

The major classes of antiretroviral medications are nucleoside reverse transcriptase inhibitors (NRTIs) (nucleoside analogues), nonnucleoside reverse transcriptase inhibitors (NNRTIs) (nonnucleoside analogues), protease inhibitors (PIs), fusion inhibitors, integrase strand transfer inhibitors (INSTIs), and CCR5 antagonists. The current optimal combination of medications is multi-drug therapy with two nucleoside analogues (NRTIs) and one active drug from one of the following classes: protease inhibitors (PIs) boosted with ritonavir (RTV), a nonnucleoside reverse transcriptase inhibitor (NNRTI, which is called protease-sparing regimen), an integrase strand transfer inhibitor (INSTI), or a CCR5 antagonist. Viral resistance to treatment is reduced by the complete suppression of the virus with multiple drugs (Figure 12-18). In general, there are now a variety of antiretroviral medication choices available to meet patient needs, tolerance, and cost concerns (Table 12-5).

### Nucleoside Reverse Transcriptase Inhibitors

NRTIs resemble the natural substances used by the virus to build HIV DNA. NRTIs prevent HIV replication by preventing HIV DNA synthesis and have been found to slow progression of the disease. Nucleoside analogues include zidovudine, didanosine, zalcitabine, stavudine, lamivudine, and abacavir. All must be converted to an active state intracellularly.

### Nonnucleoside Reverse Transcriptase Inhibitors

NNRTIs also inhibit reverse transcriptase, but by a different mechanism. Drugs in this class include efavirenz (Sustiva), nevirapine (Viramune), and delavirdine (Rescriptor). These medications need not be converted intracellularly to be activated. The greatest benefit is that they are potent antiretrovirals. The biggest problem is that they affect the cytochrome P-450 system, which increases drug interactions and must be given cautiously. They can only be administered in combination with other antiretrovirals.

### Protease Inhibitors

PIs attack at another phase in the viral life cycle. These medications inhibit the enzyme protease, whose action is to clip the viral protein precursors to the appropriate size. These precursors are essential for HIV maturation, infection, and replication. Protease inhibitor therapy is extremely expensive, with a retail price of approximately \$6000 to \$8000 per year. Protease inhibitors are never used as single agents because of the potential for a patient to develop resistance. PIs have poor central nervous system (CNS) penetration.

### Fusion Inhibitors

Fusion inhibitors (e.g., enfuvirtide [Fuzeon, ENF]) work extracellularly by blocking fusion between viral and target cell membranes. They are always used with other treatment regimens to decrease viral load, never as monotherapy. They increase the effects of protease inhibitors. They are given only by subcutaneous injection. The pediatric dosage is weight-based and given twice daily. The adult dose is usually 90 mg twice daily.

### CCR5 Antagonists

CCR5 antagonists are best suited for earlier infection when the CCR5 tropic virus (M-tropic phase) predominates (see Figure 12-5).

TABLE 12-5 ANTIRETROVIRAL THERAPY

CLASS	GENERIC NAME (TRADE NAME)	USE IN PREGNANCY OR CHILDREN	SIDE EFFECTS	MONITORING
Nucleoside reverse transcriptase inhibitors	Zidovudine (AZT, Retrovir) Lamivudine (3TC, Epivir) Didanosine (ddI, Videx)	Pregnancy Class B or C: approved and used in pregnancy as early as 10 weeks' gestation Can be given to infants and children	Pancreatitis, bone marrow toxicity, anemia/neutropenia, peripheral neuropathy, dyslipidemia, insulin resistance, hepatic toxicity, headache, nausea, vomiting, diarrhea, insomnia, malaise, myalgia, hypersensitivity, lactic acidosis, osteopenia, confusion	Liver function studies, CBC, metabolic panel studies (chem 14)
Nonnucleoside reverse transcriptase inhibitors	Efavirenz (Sustiva) Nevirapine (Viramune) Delavirdine (Rescriptor)	Pregnancy Class D: not approved d/t teratogenic and CNS defects Avoid during lactation Approved in children over 3 yr	CNS effects, dizziness, drowsiness, concentration problems, insomnia, vivid dreams, depression, headache, maculopapular rash, nausea, vomiting, diarrhea, myalgia, hyperlipidemia, hyperglycemia, liver enzyme elevations, Stevens-Johnson syndrome, hepatitis	Liver function studies, CBC, chem 14, lipid function; take between 6 and 9 PM to sleep through side effects
Protease inhibitors	Ritonavir (Norvir) Atazanavir (Reyataz) Nelfinavir (Viracept)	Pregnancy Class B or C: approved in pregnancy and in children Avoid during lactation	Hyperlipidemia, lipid abnormalities, lipodystrophy, elevated LFTs/uric acid, dizziness, anxiety, bleeding, pancreatitis, MI, stroke, weakness, asthenia, headache, nausea, diarrhea, vomiting, anorexia, abdominal pain, taste perversion, paresthesias	Liver function studies, CBC, chem 14, lipid function, uric acid levels; must take with food
Fusion inhibitor	Enfuvirtide (ENF, Fuzeon)	Pregnancy Class B: approved Approved in children older than 6 yr	Fatigue, insomnia, diarrhea, nausea, abdominal pain, anorexia, elevated CPK, myalgia, cough, bacterial pneumonia, flu-like syndrome, thrombocytopenia, hyperlipidemia, elevated LFTs	Liver function studies, chem 14, lipid function
CCR5 antagonist	Maraviroc (Selzentry)	Pregnancy Class B: approved Approved in adolescents 16 yr and older	Hepatotoxicity, hypersensitivity reactions, fever, cough, vascular hypertensive disorder, dizziness, insomnia, pruritus, lipodystrophy, elevated LFTs, peripheral neuropathy, myalgia	Liver function studies, CBC, chem 14, lipid function
Integrase transfer inhibitor	Raltegravir (Isentress)	Pregnancy Class C: not approved Approved in adolescents 16 yr and older	Myopathy, rhabdomyolysis, hyperlipidemia, hypertension, fatigue, dizziness, elevated glucose/lipase/LFTs/creatinine, anemia, thrombocytopenia	Liver function studies, CBC, chem 14, lipid function, uric acid levels

CBC, Complete blood cell count; CNS, central nervous system; CPK, creatine phosphokinase; d/t, due to; LFTs, liver function tests; MI, myocardial infarction; yr, year.

This medication acts to prevent infection by blocking the coreceptor CCR5 and preventing HIV binding to the cell membrane. Tropism testing is necessary before treatment with this medication. It is always given with other antiretroviral medications.

### Integrase Strand Transfer Inhibitors

INSTIs are the newest class of antiretroviral medications. These medications target and inhibit *integrase* encoded by the viral *pol* gene. The first INSTI approved by the U.S. Food and Drug Administration (FDA) was raltegravir (Isentress).

### Other Treatments and Vaccines

Antibiotics, antivirals, antifungals, antiparasitics, and antimycobacterial medications are administered as needed to treat the many opportunistic infections that are secondary to HIV infection. Human granulocyte colony-stimulating factor (filgrastim [Neupogen]) may be used to improve nonspecific immunity by increasing the number of neutrophils in persons with neutropenia. This agent is particularly

helpful in decreasing medication-induced neutropenia. It is given daily in a subcutaneous dose calculated according to the patient's weight (usually 5 µg/kg). However, it is of questionable value because it may act as a growth factor for cancers. Epoetin alfa (erythropoietin) is used to manage medication-induced anemia. The starting dosage is 8000 units subcutaneously per week and may be increased to 48,000 units/week until the hematocrit is 35% to 40%. An associated side effect is hypertension. Intravenous immunoglobulin can sometimes be used in HIV-infected children with T-cell counts greater than 200/µL. It helps to decrease the incidence of serious bacterial, minor bacterial, viral, and opportunistic infections. Interferon alfa-2b (Intron A) is used to treat AIDS-related Kaposi sarcoma in adults. The usual dosage is 30 million units/m<sup>2</sup> three times per week. Other studies are being conducted in an effort to find ways to rebuild the immune system. Researchers want to make sure that the T cells cloned after initiation of antiretroviral therapy will respond to both new and old infections.

Prevention of HIV infection by vaccine-conferred active immunity is the ultimate goal of current research. This task is extremely

difficult because of HIV strain variability and HIV mutation frequency. To date, none of the vaccine trials have been successful and several have been stopped in phase II. In September 2007, Merck stopped the AIDS vaccine trial (STEP study) that focused on killer T cells, because 24 of 741 patients became infected with HIV as a result of the vaccine. Ongoing research is being carried out in an effort to quantify the effectiveness of other vaccines in stimulating both cellular and humoral responses to HIV. The most recent trial (RV144 Thai) in September 2009 focused on neutralizing antibodies.<sup>35</sup> This regimen provided some modest protection to HIV-1 infection but neutralizing antibodies were not induced.<sup>35</sup> At this time, there is no effective or efficacious vaccine available for prevention of HIV.

### KEY POINTS

- Management of HIV and AIDS includes the use of antiretroviral medications, including NRTIs, NNRTIs, PIs, fusion inhibitors, INSTIs, and CCR5 antagonists.
- The current optimal combination of medications is multidrug therapy with two nucleoside analogues (NRTIs) and one active drug from one of the following classes: protease inhibitors (PIs) boosted with ritonavir (RTV), a non-nucleoside reverse transcriptase inhibitor (NNRTI), an integrase strand transfer inhibitor (INSTI), or a CCR5 antagonist.
- Efforts to stimulate immune function with peptide growth factors and the development of vaccines are under investigation.
- Aggressive treatment of opportunistic infections with appropriate antibiotics and antivirals is a large part of the treatment regimen.

### SUMMARY

HIV is an RNA virus that primarily infects and destroys the immune system. In so doing, it destroys one of the basic foundations of human regulation and protection. HIV decreases the body's ability to fight organisms, opens the door to opportunistic infections, and allows

neoplasms to emerge. HIV can infect anyone of any age. The ultimate intracellular pathogen, it slowly destroys the host while manufacturing billions of copies of itself. Study of this virus has improved our understanding of the immune system as well as of cellular function.

## KEY QUESTIONS

- What factors are necessary for normal red blood cell production?
- How are oxygen and carbon dioxide transported in the circulation?
- How are laboratory tests used to detect anemia and polycythemia?
- What are the general effects of anemia on body systems?
- How are history, clinical manifestations, and laboratory studies used to differentiate the various forms of anemia?
- How are history, clinical manifestations, and laboratory studies used to differentiate the various forms of polycythemia?
- What are the appropriate treatment measures for each of the common types of anemia and polycythemia?

Blood is a critical body fluid composed of formed elements and cells suspended in plasma that circulates through the cardiovascular system. As the primary transport system of the body, blood is involved in the physiologic and pathologic activities of all organs. The **red blood cell (RBC)**, or **erythrocyte**, is essential to oxygen transport within the circulatory system. Red blood cells contain large numbers of hemoglobin molecules, which are designed to move oxygen efficiently from the lungs to other body tissues. Hemoglobin also aids in acid-base balance.

In addition, RBCs carry carbon dioxide wastes away from the cells and back to the lungs for expiration.

### COMPOSITION OF BLOOD

The total blood volume averages 75.5 ml/kg in men and 66.5 ml/kg in women, which is 5 to 6 L or 7% to 8% of body weight. The blood cells comprise approximately 45% and the blood plasma 55% of the blood

**FIGURE 13-1** Composition of blood in the normal adult.

## CHAPTER 13 Alterations in Oxygen Transport

volume. Blood **plasma** is composed of about 92% water and 7% plasma proteins (Figure 13-1). The arterial pH of normal blood is 7.35 to 7.45.

### Organic and Inorganic Components

The plasma proteins are formed mainly in the liver. They are unable to leave the vascular space under normal circumstances and assist in regulating blood volume and the body's fluid balance. Plasma proteins contribute to colloid osmotic pressure, which is important in maintaining blood pressure. There are three general types of plasma proteins. The first is serum albumin, which is an essential factor in maintaining blood volume and pressure. The second is serum globulin, which is composed of three general fractions: the  $\alpha$  fraction is associated with the transport of bilirubin, lipids, and steroids; the  $\beta$  fraction is associated with the transport of iron and copper in plasma; and the  $\gamma$  fraction contains the antibody molecules. Fibrinogen is the third major type of plasma protein. It is the inactive precursor of

fibrin, which forms the framework of blood clots. Regulatory proteins, such as hormones and enzymes, are also present in the plasma. Diffusible nonorganic substances, such as sodium chloride, calcium, potassium, iodine, and iron, are used by body cells and constitute 0.9% of plasma. Diffusible organic constituents, such as urea, uric acid, xanthine, creatine, creatinine, and ammonia, are products of tissue metabolism that are transported from the tissues to the kidneys and skin for excretion. Also included in this category are nutritive organic materials, such as amino acids, glucose, fats, and cholesterol, which are foodstuffs in solution absorbed from the gastrointestinal (GI) tract. They are transported to other body tissues for utilization and storage (Table 13-1).<sup>1</sup>

### Cellular Components

The amounts of the different cellular components in the blood vary with age. Table 13-2 gives normal values from birth to 21 years.<sup>2</sup>

**TABLE 13-1 ORGANIC AND INORGANIC COMPONENTS OF BLOOD**

CONSTITUENT	AMOUNT/CONCENTRATION	MAJOR FUNCTIONS
Water	92% of plasma weight	Medium for carrying all other constituents
Electrolytes	Total <1% of plasma weight	Keep H <sub>2</sub> O in extracellular compartment; act as buffers; function in membrane excitability
Na <sup>+</sup>	136-145 mEq/L (142 mM)	
K <sup>+</sup>	3.5-5 mEq/L (4 mM)	
Ca <sup>2+</sup>	4.5-5.5 mEq/L (2.5 mM)	
Mg <sup>2+</sup>	1.5-2.5 mEq/L (1.5 mM)	
Cl <sup>-</sup>	100-106 mEq/L (103 mM)	
HCO <sub>3</sub> <sup>-</sup>	27 mEq/L (27 mM)	
Phosphate (mostly HPO <sub>4</sub> <sup>2-</sup> )	3-4.5 mEq/L (1 mM)	
SO <sub>4</sub> <sup>2-</sup>	0.5-1.5 mEq/L (0.5 mM)	
Proteins	6-8 g/dl (2.5 mM)	
Albumin	3.5-5.5 g/dl	Provides colloid osmotic pressure of plasma; acts as buffers; bind other plasma constituents (e.g., lipids, hormones, vitamins, metals)
Globulins	1.5-0.3 g/dl	Enzymes; enzyme precursors; antibodies (immune globulins); hormones
Fibrinogen	0.2-0.4 g/dl	Clotting factor
Gases, arterial plasma		
CO <sub>2</sub> content	22-30 mmol/L of plasma	By-product of metabolism; most CO <sub>2</sub> content is from HCO <sub>3</sub> <sup>-</sup> and acts as buffer
O <sub>2</sub>	PaO <sub>2</sub> , 80 mm Hg or greater (arterial); PvO <sub>2</sub> , 30-40 mm Hg (venous)	Oxygenation
N <sub>2</sub>	0.9 ml/dl	By-product of protein catabolism
Nutrients		Provide nutrition and substances for tissue repair
Glucose and other carbohydrates	70-105 mg/dl (5.6 mM)	
Total amino acids	40 mg/dl (2 mM)	
Total lipids	450 mg/dl (7.5 mM)	
Cholesterol	150-250 mg/dl (4-7 mM)	
Individual vitamins	0.0001-2.5 mg/dl	
Individual trace elements	0.001-0.3 mg/dl	
Waste products		
Urea (BUN)	10-20 mg/dl (5.7 mM)	End product of protein catabolism
Creatinine	0.7-1.5 mg/dl (0.09 mM)	End product of energy metabolism
Uric acid	2.5-8 mg/dl (0.3 mM)	End product of protein metabolism
Bilirubin	0.3-1.1 mg/dl	End product of red blood cell destruction
Direct conjugated	0.1-0.5 mg/dl	
Indirect unconjugated	0.1-0.7 mg/dl	
Individual hormones	0.000001-0.05 mg/dl	Functions specific to target tissue

TABLE 13-3 CHARACTERISTICS OF BLOOD CELLS

CELL	STRUCTURAL CHARACTERISTICS	NORMAL AMOUNTS IN CIRCULATING BLOOD*	FUNCTION	LIFE SPAN
Erythrocyte (red blood cell) 	Nonnucleated biconcave disk containing hemoglobin	Males: $4.7-6.1 \times 10^{12}/L$ Females: $4.2-5.4 \times 10^{12}/L$	Gas transport to and from tissue cells and lungs	80-120 days
Leukocyte (white blood cell) Lymphocyte 	Nucleated cell Mononuclear immunocyte	$4.8-10.8 \times 10^9/L$ $1.2-3.4 \times 10^9/L$ ; 20-44% leukocyte differential	Body defense mechanisms Humoral and cell-mediated immunity	See below Days or years, depending on type
Neutrophil 	Segmented polymorphonuclear granulocyte with neutrophilic granules	$1.4-6.5 \times 10^9/L$ ; 50-70% leukocyte differential	Phagocytosis, particularly during early phase of inflammation	5 days
Eosinophil 	Segmented polymorphonuclear granulocyte with eosinophilic granules	$0-0.7 \times 10^9/L$ ; 0-4% leukocyte differential	Phagocytosis, antibody-mediated defense against parasites; participates in mucosal immune response	Unknown
Basophil 	Segmented polymorphonuclear granulocyte with basophilic granules	$0-0.2 \times 10^9/L$ ; 0-2% leukocyte differential	Transport and release of heparin and histamine; involved in immune and inflammatory responses	Unknown
Monocyte-macrophage 	Large mononuclear phagocyte	$0.11-0.59 \times 10^9/L$ ; 2%-9% leukocyte differential	Phagocytosis; process and present antigens	Months to years

WBC COUNT (cells/mm <sup>3</sup> )	PMN COUNT, ADULT	BAND FORMS (%)	EOSINOPHILS (%)	BASOPHILS (%)	LYMPHOCYTES (%)	MONOCYTES (%)
9000-30,000 (avg., 18,000)	9400 (52%)	9.1	2.2	0.6	31	5.8
9400-34,000 (avg., 19,045)	9800 (52%)	9.2	2.4	0.5	31	5.8
5000-21,000 (avg., 12,279)	4700 (39%)	6.8	4.1	0.4	41	9.1
5500-18,000 (avg., 11,000)	3300 (30%)	4.4	2.7	0.5	57	5.9
6000-17,500 (avg., 11,900)	3300 (28%)	3.8	2.5	0.4	61	4.8
6000-17,000 (avg., 10,680)	3200 (30%)	3.0	2.6	0.5	59	5.0
5000-14,500 (avg., 8500)	4000 (48%)	3.0	2.7	0.6	42	4.7
4500-13,000 (avg., 7900)	4200 (53%)	3.0	2.5	0.5	37	4.7
4500-11,000 (avg., 7400)	4200 (56%)	3.0	2.7	0.5	34	4.0

TABLE 13-3 CHARACTERISTICS OF BLOOD CELLS—cont'd

CELL	STRUCTURAL CHARACTERISTICS	NORMAL AMOUNTS IN CIRCULATING BLOOD*	FUNCTION	LIFE SPAN
 Platelet	Discoid cytoplasmic fragment derived from megakaryocytes	130-400 × 10 <sup>9</sup> /L	Hemostasis following vascular injury; forms hemostatic plug, provides cofactors, maintains vascular endothelium	9.5 days

\*Given in SI units.

### Erythrocytes

Of the cellular elements of blood (Table 13-3), RBCs, or erythrocytes, are the most numerous, with normal concentrations ranging from 4.2 to 6.2 million cells/mm<sup>3</sup>. RBCs are responsible for transporting oxygen to the tissues, and participate in both removing carbon dioxide from the tissues and buffering blood pH. They have no cytoplasmic organelles, nucleus, mitochondria, or ribosomes. Therefore, RBCs cannot synthesize protein or carry out oxidative reactions. Instead the erythrocyte's cytoplasm consists of a solution containing proteins, hemoglobin, and electrolytes that regulates diffusion through the cellular membrane. RBCs live for 80 to 120 days in the circulation; then they die and are replaced. Hemoglobin is the main functional constituent of the red cell. It is a protein that enables the blood to transport 100 times more oxygen than could be transported in plasma alone. An enzyme inside RBCs, carbonic anhydrase, is responsible for the buffering mechanism of red cells.<sup>3</sup>

The erythrocyte's size and shape also contribute to its function as a gas carrier (Figure 13-2). It is a small, biconcave disk (about 7.2 μm in diameter) that must circulate through splenic sinusoids and capillaries, which are only 2 μm in diameter. This remarkable feat is accomplished through a property called *reversible deformability*, which allows the RBC to assume a torpedo-like conformation and then return to a biconcave disk shape.<sup>3</sup>

### Leukocytes

**White blood cells (WBCs), or leukocytes,** protect the body by phagocytosis of microorganisms and other debris and participate in immune antibody formation. Leukocytes act primarily in the tissues but are also transported in the circulatory and lymphatic systems. The average adult has approximately 5000 to 10,000 leukocytes per cubic millimeter of blood. Monocytes and granulocytes are WBCs that share a common lineage with RBCs and platelets. Because of the interrelationship of RBCs, WBCs, and

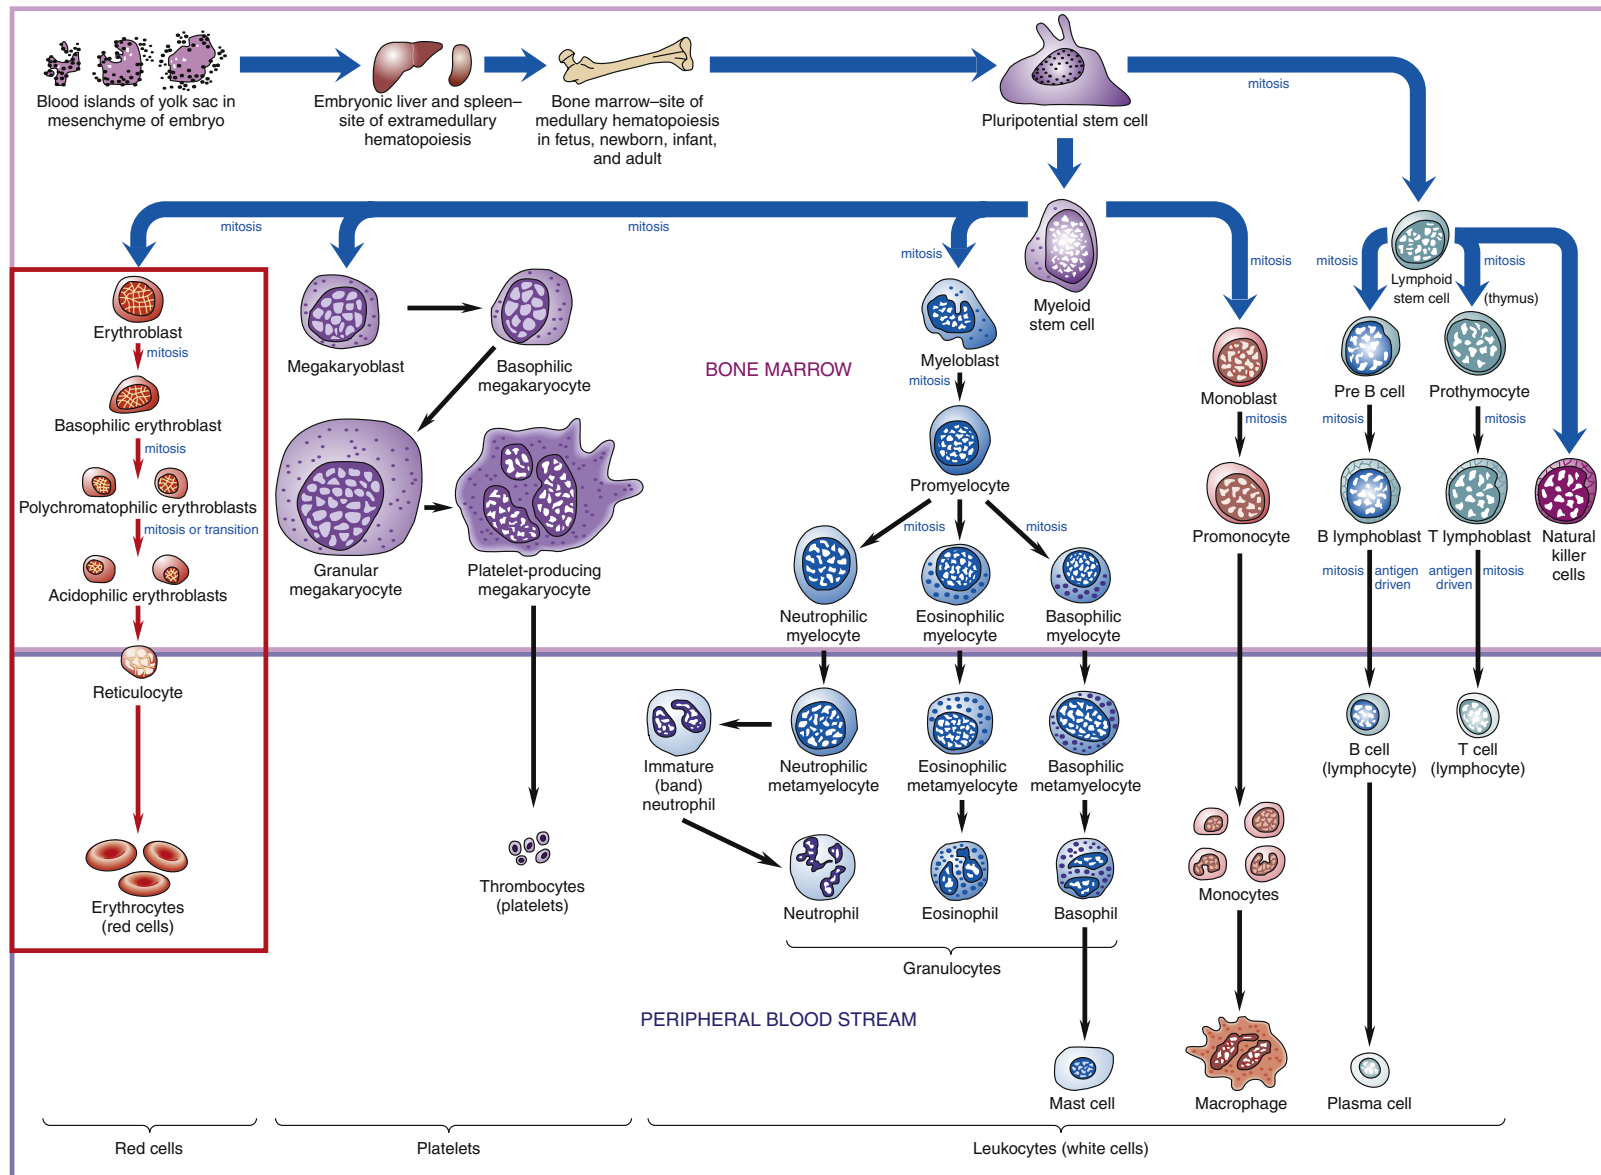

FIGURE 13-2 Mature erythrocytes. A mature neutrophil is also shown. (Courtesy Beth Payne, Sacred Heart Medical Center, Spokane, WA.)

platelets, which are all derived from the myeloid stem cell (Figure 13-3), abnormalities in these cells are seen in some red cell diseases.<sup>4</sup> Leukocyte structure and function are discussed in detail in Chapter 9.

### Platelets

**Platelets** are essential in the formation of blood clots and in the control of bleeding. They are not cells but are circulating cytoplasmic fragments of megakaryocytes and are incapable of mitotic division. They contain cytoplasmic granules that release biochemical mediators involved in the hemostatic process. Normally, 150,000 to 400,000 platelets/mm<sup>3</sup> circulate freely in the blood. An additional one third of the body's platelets are in a reserve pool in the spleen. The average life span of platelets in the peripheral blood is approximately 4 to 5 days.<sup>5</sup>

**FIGURE 13-3** Maturation of human blood cells. Probable pathways of blood cell differentiation from the pluripotent stem cell to mature leukocytes, erythrocytes, and platelets. Production of cells begins in embryo blood islands of the yolk sac. As the embryo matures, production shifts to the liver and spleen (extramedullary hematopoiesis) and progresses to bone marrow (medullary hematopoiesis). In an adult, all production is in the bone marrow. Current thinking is that all cell production begins with a pluripotent stem cell, which differentiates into either a myeloid stem cell or a lymphoid stem cell, which then differentiates into a specific blast cell. For example, red cell differentiation begins with the proerythroblast, which matures into a basophilic erythroblast, to a polychromatophilic erythroblast, and to an acidophilic erythroblast, all of which are found in the bone marrow. Red cell differentiation concludes with production of reticulocytes and mature red cells (erythrocytes), which normally are found only in the peripheral blood.

**KEY POINTS**

- Of the 4 to 6 L of blood in the circulatory system, approximately 45% is blood cells and 55% is plasma. The plasma fraction contains dissolved substances, including nutrients, ions, plasma proteins, metabolic wastes, hormones, and enzymes.
- Red cells function to carry oxygen and carbon dioxide in the blood. They have a limited life span of 80 to 120 days because they contain no cytoplasmic organelles and thus are incapable of replacing lost or damaged cellular components. The normal red cell concentration is 4.2 to 6.2 million cells/mm<sup>3</sup>.
- Leukocytes, or WBCs, are the other cell type present in blood. Leukocytes circulate in much lower numbers than RBCs (5000 to 10,000/mm<sup>3</sup>). Leukocytes are important mediators of immunity.
- Platelets are not cells but are small fragments of megakaryocytes. The normal platelet count is 150,000 to 400,000 cells/mm<sup>3</sup>.

**STRUCTURE AND FUNCTION OF RED BLOOD CELLS**

The cellular components of blood originate in the yolk sac mesenchyme, move to the liver and spleen during fetal life, and finally are limited to the marrow of the body skeleton (Figure 13-4). Bone marrow provides a special environment for hematopoietic cell proliferation and maturation. Developing cells are held in a fine reticular meshwork, which provides free access to plasma nutrients but retains developing cells until their maturity allows penetration of the endothelial barrier. In times of need, immature cells (reticulocytes and nucleated red blood cells, or NRBCs) are released early into the circulation; their presence in increased numbers is a sign that the hematopoietic system is stressed or is experiencing disease.<sup>2</sup>

**Hematopoiesis**

**Hematopoiesis** is the developmental process leading from pluripotential stem cells to mature, differentiated red cells, neutrophils, eosinophils, basophils, monocytes, and platelets. **Lymphopoiesis** describes this process for lymphocytes. Both hematopoietic and lymphopoietic stem cells probably derive from a single totipotent stem cell pool in fetal development, but it is uncertain if this is the functioning stem cell after birth (Figure 13-5). Research suggests that a pluripotential stem cell that is stimulated by erythropoietin and other poietins to cause further differentiation into separate cell lines may be the primary stem cell in adults.<sup>6</sup>

Hematopoiesis is a two-stage process that involves mitotic division (proliferation) and maturation (differentiation). Each type of blood cell has stem cells that undergo mitosis when stimulated by a specific biochemical signal, indicating that the number of circulating cells has decreased. Medullary or bone marrow hematopoiesis continues throughout life and can be accelerated by several mechanisms, including (1) an increase in differentiation of daughter cells, (2) an increase in number of stem cells, and (3) conversion of yellow (fatty) bone marrow (which does not produce cells) to red marrow (which does produce cells). Marrow conversion is stimulated by erythropoietin, which is the hormone from the kidney that stimulates erythrocyte production. In adults, extramedullary hematopoiesis, or production of blood cells in tissue other than bone, is usually due to disease.<sup>7</sup>

Erythrocyte development is shown in detail in Figure 13-3. During this process, the cell changes from a large nucleated cell, rich in ribosomes, to a reticulocyte, which is a small disk that has lost its nucleus. The reticulocyte (Figure 13-6) leaves the marrow, enters the bloodstream, and matures into an erythrocyte in 24 to 48 hours. During this period, mitochondria and ribosomes disappear; the cell can no longer synthesize hemoglobin, and it relies on glycolysis for adenosine triphosphate (ATP) production. The normal reticulocyte count is 1% of the total RBC count.

This makes it a useful test to determine effective erythropoietic activity<sup>7</sup> because erythropoietin stimulates uncommitted stem cells to differentiate into proerythroblasts.

**Hemoglobin Synthesis**

The immature red cell can be viewed as a factory for hemoglobin synthesis. In a mature red cell, **hemoglobin**, the oxygen-carrying protein, composes about 90% of the cell's dry weight in the form of approximately 300 hemoglobin molecules.<sup>3</sup> Hemoglobin that is carrying oxygen is called oxyhemoglobin. Hemoglobin is composed of two pairs of polypeptide chains—the globins. Each globin has an attached heme molecule that is composed of iron plus a protoporphyrin molecule (Figure 13-7).<sup>8</sup>

After dietary iron is absorbed in the duodenum and proximal jejunum, it is transported through the plasma by the protein transferrin to transferrin iron receptors on the RBC membrane. The transferrin-receptor complex is engulfed by the cell into an invagination of the cell surface. The invagination becomes sealed off and forms an intracytoplasmic vacuole. Iron is then released and either stored as ferritin or used to synthesize heme (Figure 13-8).<sup>2</sup> About 67% of total body iron is bound to heme in erythrocytes and muscle cells, and 30% is stored bound to ferritin or hemosiderin-containing macrophages and hepatic parenchymal cells. The remaining 3% is lost daily in urine, sweat, bile, and epithelial cells that are shed in the intestines. The mitochondria are responsible for the synthesis of protoporphyrin. The final heme molecule consists of four porphyrin moieties assembled in a ring structure around a central iron molecule.<sup>2</sup>

**Hemoglobin Synthesis in Infants**

When an infant is born many mechanisms occur to decrease the infant's hemoglobin level. At birth, erythropoietin, a hormone that stimulates red blood cell production, disappears from blood plasma; there is an increase in arterial oxygen saturation and the infant is born with immature bone marrow. These mechanisms cause a slow rate of red blood cell production at birth. In addition, infants primarily have fetal hemoglobin, accounting for about 70% of their total hemoglobin. Although fetal hemoglobin is a more efficient oxygen carrier, it has a shorter life span than adult hemoglobin. This causes red blood cells to be turned over every 70 to 90 days, instead of 120 days for adult red blood cells. Fetal hemoglobin may suppress production of erythropoietin.

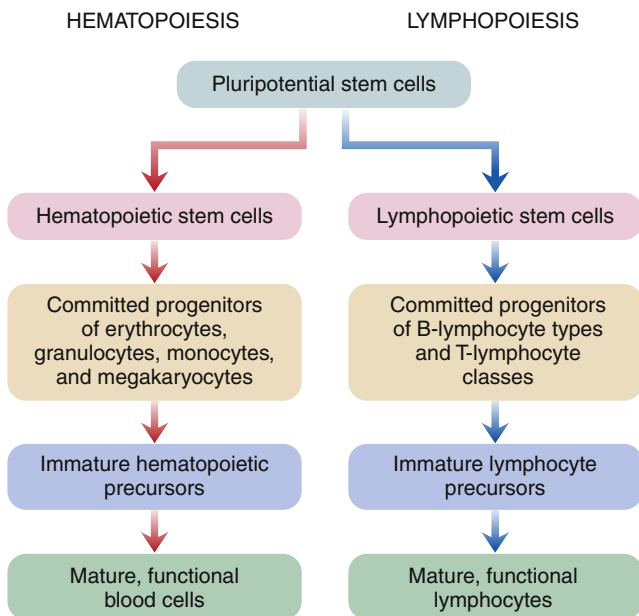

Hemoglobin levels gradually decrease in the infant over the first 2 to 3 months because of the rapid destruction of fetal hemoglobin, decreased red blood cell production and depressed erythropoietin production. Additionally, the infant experiences rapid growth during this time, which creates quick expansion of blood volume that further dilutes the supply of hemoglobin. Maternal iron stores are rapidly depleting at this time and the baby's iron stores will gradually diminish by 6 months.

As fetal hemoglobin is metabolized, the iron is released and stored. The body has enough iron to synthesize hemoglobin, but there is no stimulation to create hemoglobin at this time. Hemoglobin levels will continue to decrease until the oxygen needs of the tissues in the body are depleted enough to stimulate erythropoietin production. Release of erythropoietin causes erythropoiesis to resume. Adult hemoglobin is made at this time with the iron stored in the body. Hemoglobin levels will steadily increase in the infant starting about 6 months of age as fetal hemoglobin is replaced by adult hemoglobin.<sup>9</sup>

Globin is assembled from two pairs of polypeptide chains produced on specific ribosomes. The protein chain produced in fetal life is altered after birth by sequential gene suppression and activation. At birth, red cells contain mainly fetal hemoglobin (hemoglobin F), which is composed of two  $\alpha$  chains and two  $\gamma$  chains. Hemoglobin F is a more efficient gas carrier under decreased oxygen tension than hemoglobin A and releases CO<sub>2</sub> more readily. Within 120 days, fetal hemoglobin disappears

**FIGURE 13-4** Location of active marrow growth in the fetus and adult. During fetal development, hematopoiesis is first established in the yolk sac mesenchyme, later moves to the liver and spleen, and finally is limited to the bony skeleton. From infancy to adulthood, there is progressive restriction of productive marrow to the axial skeleton and proximal ends of the long bones, which appear as shaded areas on the drawing of the skeleton.

**FIGURE 13-5** Stem cells and normal hematopoiesis.

and is replaced by adult hemoglobin (hemoglobin A) (Figure 13-9). This switch is the result of globin genes and is not well understood. Hemoglobin A is composed of two  $\alpha$  chains and two  $\beta$  chains and constitutes 97% of the hemoglobin found in adults. Hemoglobin A<sub>2</sub> comprises 2% to 3% of hemoglobin found in adults and is composed of  $\alpha_2\delta_2$ .<sup>8,9</sup>

Several hundred hemoglobinopathies have been described that have changes in the two  $\alpha$  chains and two  $\beta$  chains. Most are characterized by the substitution of only one amino acid and are classified by the polypeptide chain in which the substitution occurs.<sup>8</sup>

### Nutritional Requirements for Erythropoiesis

In addition to iron, which is required for hemoglobin synthesis, the normal development of erythrocytes requires adequate supplies of

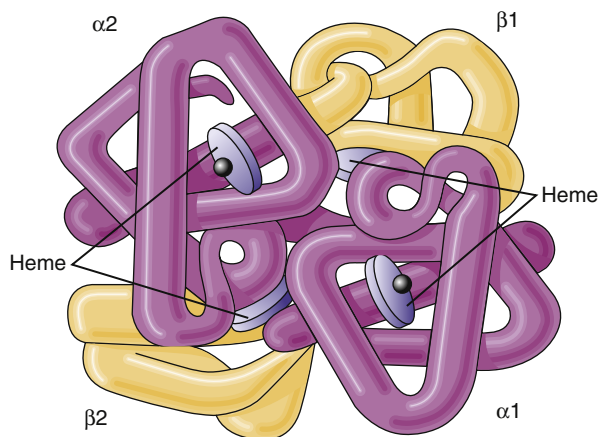

**FIGURE 13-6** Reticulocytes seen on peripheral blood smear. The two reticulocytes in the center still contain remnants of intracellular organelles. (Courtesy Beth Payne, Sacred Heart Medical Center, Spokane, WA.)

protein, vitamins, and minerals. Erythropoiesis cannot proceed in the absence of vitamins, especially B<sub>12</sub>, folate, B<sub>6</sub>, riboflavin, pantothenic acid, niacin, ascorbic acid, and vitamin E. Folate and vitamin B<sub>12</sub> (cobalamin) are absorbed from food by the ileal mucosa. Folate deficiencies or vitamin B<sub>12</sub> deficiencies lead to impaired DNA synthesis in erythroid cells because the vitamins are coenzymes in a large number of key reactions in cellular metabolism. Absorption of vitamin B<sub>12</sub> requires intrinsic factor in the gastric juice. Intrinsic factor is secreted by the stomach parietal cells and binds to vitamin B<sub>12</sub>. The complex then moves down the gastrointestinal tract to the ileum, where it attaches to specific receptor sites on the ileum mucosal cell. It is absorbed into the cell, released, and transported in the blood to the tissues and liver.<sup>10,11</sup>

### Energy and Maintenance of Erythrocytes

For the RBC to perform efficiently and survive in the circulation for the full 120-day life span, it must have a source of energy. Without an energy source, ion pumps fail and the RBC becomes sodium logged

**FIGURE 13-7** Molecular structure of hemoglobin. The molecule is a spherical tetramer weighing approximately 64,500 daltons. It contains two  $\alpha$ - and two  $\beta$ -polypeptide chains and four heme groups.

**FIGURE 13-8** Intracellular pathways for iron uptake and incorporation into hemoglobin in erythroblasts in the bone marrow. The iron-transferrin complex is picked up by a membrane-associated receptor and brought into the cell by invagination and formation of an intracytoplasmic vacuole. The iron is then released and stored as intracytoplasmic ferritin or used to synthesize heme, the precursor of hemoglobin. The transferrin-receptor complex is returned to the cell membrane, where the apotransferrin is expelled back into the circulation. (Redrawn from Hillman RS, Finch CA, editors: *Red cell manual*, ed 6, Philadelphia, 1992, FA Davis, p 8.)

and potassium depleted. The shape changes from a biconcave disk to a sphere, and it is quickly removed from the circulation by the filtering action of the spleen and the mononuclear phagocyte system. The metabolism of the RBC is limited because of the absence of a nucleus, mitochondria, and other subcellular organelles. Although the binding, transport, and release of  $O_2$  and  $CO_2$  is a passive process that does not require energy, other energy-dependent metabolic processes occur that are essential to RBC viability. The chief metabolic pathway, accounting for about 90% of the glucose used, is the anaerobic or Embden-Meyerhof pathway. The Embden-Meyerhof pathway provides ATP for regulation of intracellular  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ , and  $Mg^{2+}$  concentrations via cation pumps. About 10% of the glucose undergoes aerobic glycolysis in the hexose monophosphate shunt. The hexose monophosphate shunt provides nicotinamide adenine dinucleotide

#### KEY

- $\xi$  (embryonic)

**FIGURE 13-9** Changes in hemoglobin with development. Sequential suppression and activation of individual globin genes in the immediate postnatal period result in a switch from fetal hemoglobin (hemoglobin F: two  $\alpha$  chains and two  $\gamma$  chains) to adult hemoglobin (hemoglobin A: two  $\alpha$  chains and two  $\beta$  chains). A small amount of hemoglobin A<sub>2</sub> (two  $\alpha$  chains and two  $\delta$  chains) is also present in the adult. (From Young NS et al, editors: *Clinical hematology*, Philadelphia, 2006, Mosby, p 24.)

phosphate (NADPH) and glutathione (GSH) to reduce cellular oxidants. This protects the cell from permanent oxidant injury. The methemoglobin reductase pathway protects hemoglobin from oxidation via NADH and methemoglobin reductase. Last, the Rapoport-Luebering pathway forms 2,3-diphosphoglycerate (2,3-DPG), which facilitates oxygen release to the tissues. These pathways contribute energy for maintaining (1) high intracellular  $K^+$ , low intracellular  $Na^+$ , and very low intracellular  $Ca^{2+}$  levels (cation pumps); (2) reduced hemoglobin concentration; (3) high levels of reduced GSH; and (4) membrane integrity and deformability.<sup>2</sup> Deficiencies of enzymes that regulate these pathways can be due to natural causes, such as the normal aging process, or to an inherited deficiency of an enzyme.<sup>3,12</sup>

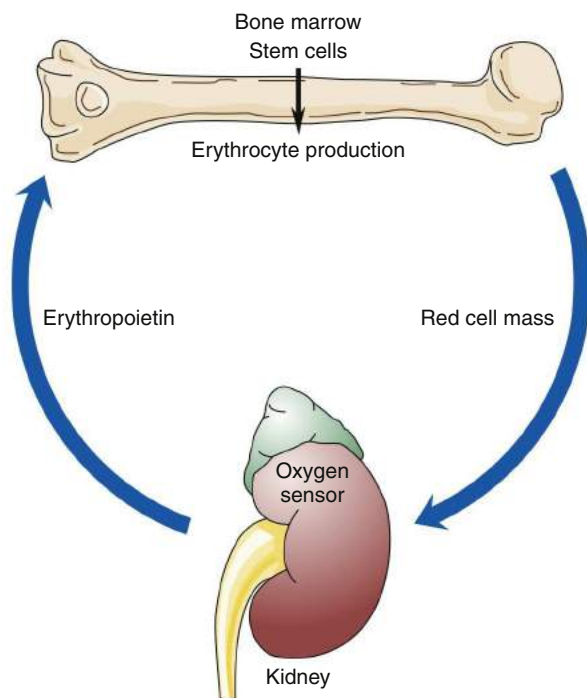

Red cell membrane structures are matrices formed from a double layer of phospholipids. In the red cell membrane, the globular proteins floating on the “sea of lipids” form a protein network on the cytoplasmic surface of the membrane. Half of the mass of the membrane is lipid, which is partially responsible for many of its physical characteristics. Both passive cation permeability and mechanical flexibility can be significantly influenced by changing the lipid composition of the membrane. Maintenance and renewal of membrane lipids in well-developed RBCs is important, and problems in these pathways result in premature cell death.<sup>13</sup>

### Red Cell Production

When blood is described as a single body system, it is called the **erythron** (Figure 13-10). The erythron includes the blood cells and their bone marrow precursors. The size of the erythron increases or decreases based on the erythropoietic process and the pathologic changes in red cells seen in anemia.<sup>14</sup> **Erythropoiesis** is controlled by a system sensitive to alterations in the concentration of hemoglobin in the blood. A decrease in hemoglobin level decreases the tissue oxygen tension in the kidney. In response to this hypoxia, the kidney secretes a hormone, **erythropoietin**, that stimulates primitive stem cells in the bone marrow to differentiate into proerythroblasts or pronormoblasts, thereby increasing the

**FIGURE 13-10** Scale model of the erythron, showing the relative proportions of each component. The numbers below each box indicate the average number of cells per kilogram of body weight. (Redrawn from Wintrobe M et al, editors: *Clinical hematology*, ed 8, Philadelphia, 1981, Lea & Febiger, p 109.)

**FIGURE 13-11** Feedback circuit illustrating the role of erythropoietin in the regulation of red cell mass.

erythron (Figure 13-11).<sup>3,15</sup> Hypoxia from a low hemoglobin level and other causes, such as high altitudes, can also initiate this response.

### Red Cell Destruction

While the red cell ages, the various enzyme activities decrease, amounts of membrane lipids decrease, levels of hemoglobin A<sub>2</sub> and methemoglobin increase, and changes in cell size occur. **Methemoglobin** is formed when the iron of the hemoglobin molecule is oxidized to the ferric state (Fe<sup>3+</sup>). The cell loses its ability to deform and becomes increasingly fragile. These aging red cells are then removed by the mononuclear phagocytic system. The red cells are digested by proteolytic and lipolytic enzymes in phagolysosomes of macrophages. Almost 80% to 90% of this process occurs in macrophages of the spleen and liver. Only 10% to 20% of normal destruction occurs intravascularly.<sup>3,16</sup>

Globin is broken down into amino acids, and the iron is recycled. Porphyrin is reduced to **bilirubin**, which is transported to the liver and conjugated by the enzyme glucuronyl transferase. Finally, conjugated bilirubin is excreted in the bile as glucuronide. Bacteria in the intestine convert conjugated bilirubin into urobilinogen, which is excreted primarily in the stool but also in the urine (Figure 13-12). Any condition causing increased red cell destruction increases the load of bilirubin to be cleared, which leads to increased serum levels of unconjugated bilirubin and increased excretion of urobilinogen. Increased levels of circulating bilirubin give the skin a yellowish tone, which is called *jaundice*. In newborns, the albumin levels for bilirubin transport are low and the amount of liver glucuronidase available for bilirubin conjugation is low, which may cause an accumulation of toxic unconjugated bilirubin. Unconjugated bilirubin is toxic because in this form it is lipid soluble and can easily cross cell membranes. This form of bilirubin has a high affinity for basal ganglia of the central nervous system. The conjugated form of bilirubin is water soluble but lipid insoluble so it cannot cross cell membranes.<sup>3,16</sup>

### KEY POINTS

- Red cell development from pluripotential stem cells in the bone marrow is stimulated by a hormone growth factor called *erythropoietin*. Erythropoietin is secreted into the bloodstream by kidney cells in response to low oxygen tension in the blood.
- During development, red cells lose their nuclei and other cytoplasmic organelles. A reticulocyte is an immature red cell that still retains some cellular organelles. An increased blood reticulocyte count is a useful indicator of increased red cell production.
- Hemoglobin is the major component of red cells. It is composed of two pairs of polypeptide chains, each of which has a heme molecule attached. Oxygen can bind reversibly to an iron molecule at the center of each heme. When fully saturated, a hemoglobin molecule carries four oxygen molecules, and is referred to as *oxyhemoglobin*.
- Red cell production requires adequate amounts of several nutrients, particularly iron, vitamin B<sub>12</sub>, and folate. Lack of intrinsic factor inhibits absorption of B<sub>12</sub> from the small intestine and is a risk factor for anemia.
- Red cells rely on glycolysis for energy production because they do not contain mitochondria. As energy production declines because of red cell aging and loss of essential glycolytic enzymes, the cell swells, is trapped in the spleen, and is removed from the circulation. Red cell degradation releases bilirubin, a toxic substance that is conjugated in the liver and excreted in urine and bile.

**FIGURE 13-12** Most hemoglobin degradation occurs in the macrophages of the spleen. The globin and iron portions are conserved and reused. Heme is reduced to bilirubin, eventually degraded to urobilinogen, and excreted in the feces. Thus, indirect indicators of erythrocyte or erythrocyte destruction include the blood bilirubin level and urobilinogen concentration in the feces. (From Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 6, St Louis, 2007, Mosby, p 654.)

## GAS TRANSPORT AND ACID-BASE BALANCE

RBCs have many important functions in the body related to gas transport and acid-base balance.<sup>3,16,17</sup> RBCs contain hemoglobin, which is responsible for oxygen transport to the body tissues.<sup>3,16</sup> Oxygen combines with the heme portion of hemoglobin to form oxyhemoglobin in a loose and reversible bond in the pulmonary capillary attributable to a high partial pressure of oxygen ( $PO_2$ ) and is carried to the tissues with a low  $PO_2$ , where it is released.<sup>17</sup> Large quantities of carbonic anhydrase in RBCs catalyze the reaction between  $CO_2$  produced by cellular metabolism in the tissues and water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions for elimination by the lungs and kidneys. Approximately 90% of the  $CO_2$  in the arterial blood and 60% of the  $CO_2$  in the venous blood are transported as bicarbonate. Finally, the hemoglobin protein directly binds with the remaining  $CO_2$  to form carbaminohemoglobin for  $CO_2$  transport. Carbamino compounds are acid-base buffers responsible for as much as 50% of the whole blood-buffering power.<sup>3,16</sup>

### Oxygen Transport

Transport of oxygen to the body tissues and removal of carbon dioxide is a complex process involving interdependent function of the lungs, heart, and blood (Figure 13-13). Approximately 97% of oxygen in the blood is transported on red cells loosely and reversibly combined with hemoglobin (oxyhemoglobin), and 3% is dissolved in plasma. Each hemoglobin molecule can bind four atoms of oxygen. Despite a combining potential of 1.39 ml of oxygen per gram of hemoglobin in pure hemoglobin, a maximum of about 1.34 ml of oxygen per gram of hemoglobin is available, owing to a reduction of about 4% by impurities such as methemoglobin. The blood of an average person contains

approximately 15 g of hemoglobin per 100 ml of blood. Therefore, in the average person, the hemoglobin in 100 ml of blood can combine with approximately 20 ml of oxygen if the hemoglobin is 100% saturated. This value is expressed as 20 vol%.<sup>17,18</sup>

The partial pressure of oxygen ( $PO_2$ ) reflects the pressure or tension that oxygen exerts when it is dissolved in blood. Partial pressure is measured in millimeters of mercury (mm Hg). In the pulmonary capillaries, where  $PO_2$  is high, oxygen binds efficiently with hemoglobin, but in the tissue capillaries, where  $PO_2$  is low, oxygen is released from hemoglobin. The partial pressure affects the tendency of oxygen to bind with hemoglobin.<sup>19</sup> The partial pressure of oxygen in arterial blood ( $PaO_2$ ) is usually 80 to 100 mm Hg, whereas the partial pressure of oxygen in venous blood ( $P\bar{v}O_2$ ) is usually 35 to 40 mm Hg. The amount of hemoglobin bound to oxygen relative to the total amount of hemoglobin is expressed as the oxygen saturation, in a percentage.<sup>19,20</sup> Saturation of arterial blood with oxygen ( $S\bar{a}O_2$ ) is normally 95% to 100%, whereas that of venous blood ( $S\bar{v}O_2$ ) is 60% to 80%.<sup>17-20</sup>

The oxygen-hemoglobin dissociation curve (Figure 13-14) describes the relationship between  $PO_2$  and  $SO_2$ . The upper part of the curve represents oxygen uptake in the lungs and demonstrates that significant changes in  $PO_2$  result in only small changes in  $SO_2$  to help ensure adequate oxygen delivery to the tissues.<sup>18,19</sup> On the steep lower portion of the curve, reflecting the venous blood, small changes in venous  $PO_2$  result in large changes in  $S\bar{v}O_2$ .<sup>19</sup> Therefore, the tissues are protected with an available oxygen reserve as large quantities of oxygen are released from the blood for relatively small decreases in  $PO_2$ . Normally, tissue  $PO_2$  does not rise above 40 mm Hg to enhance diffusion of oxygen from the blood to the tissues. The strength of the bond between hemoglobin and oxygen is called the *oxygen-hemoglobin affinity*. For

**FIGURE 13-13** Oxygen transport. Diffusion of oxygen into the pulmonary capillaries occurs when alveolar  $PO_2$  exceeds capillary  $PO_2$ . Maintenance of this gradient is dependent on adequate alveolar ventilation and perfusion. Delivery of oxygenated blood to the tissues ( $\dot{D}O_2$ ) is determined by the content of oxygen in the blood ( $CaO_2$ ) and the cardiac output ( $CO$ ). The difference between arterial and venous oxygen is a reflection of oxygen consumption by tissues ( $\dot{V}O_2$ ). *Hb*, Hemoglobin; *HR*, heart rate; *SV*, stroke volume.

any given  $PO_2$ , hemoglobin saturation will be higher when affinity is increased and saturation will be lower when affinity is decreased. Changes in hemoglobin affinity are represented by shifts in the oxyhemoglobin dissociation curve (see Figure 13-14). Shifts in the oxyhemoglobin curve affect the ability of hemoglobin to bind  $O_2$  in the lungs and release it in the tissues. The ability of hemoglobin to release oxygen to the tissues is commonly assessed at point  $P_{50}$  on the oxygen-hemoglobin dissociation curve. The  $P_{50}$  is the  $PO_2$  at which 50% of the hemoglobin is saturated. A decrease in oxygen affinity (shift to the right on the oxyhemoglobin dissociation curve) or an increase in oxygen affinity (shift to the left) can be caused by the conditions listed in Figure 13-14.<sup>18</sup>

A shift of the oxyhemoglobin dissociation curve attributable to changes in the blood levels of  $PCO_2$  and the  $H^+$  concentration is important to enhance oxygen uptake by the blood in the lungs and the release of oxygen from the hemoglobin to the body tissues. This is called the *Bohr effect*.<sup>17</sup>

A shift of the oxyhemoglobin dissociation curve to the right enhances oxygen release to the cell. The shift provides the increase in oxygen delivery that is needed during exercise and other types of stress, as well as in chronic disease states. A shift of the oxyhemoglobin dissociation curve to the left is seen with a decrease in  $H^+$  ion concentration, with a decrease in  $PCO_2$ , with an increase in pH, with a decrease in temperature, with a decrease in 2,3-DPG concentration, in some congenital hemoglobinopathies, and with increased carboxyhemoglobin concentration.

Another important factor affecting  $O_2$  delivery to tissues is the arterial oxygen content ( $CaO_2$ ).<sup>17,18,20</sup> Arterial blood oxygen content ( $CaO_2$ ) and venous blood oxygen content ( $CvO_2$ ) can be calculated by adding the amount of oxygen combined with hemoglobin, and the amount of oxygen dissolved in plasma (Table 13-4).

Oxygen delivery, or ( $\dot{D}O_2$ ), is the amount of oxygen (in milliliters) delivered per minute to the tissues.<sup>18</sup> It is calculated by multiplying the arterial oxygen content ( $CaO_2$ ) by the cardiac output (CO). Cardiac output is usually between 4 and 8 L/min. Therefore, oxygen delivery is approximately 1000 ml/min.

Oxygen consumption ( $\dot{V}O_2$ ) is the amount of oxygen consumed by the tissues and is measured in milliliters of oxygen per minute. Once the oxygen reaches the tissues, oxygen consumption is controlled by the rate of energy expenditure within the cells or the rate at which adenosine diphosphate (ADP) is formed from ATP to provide energy. The increasing concentration of ADP enhances the metabolic utilization of oxygen.<sup>17</sup> Oxygen consumption can be determined by subtracting the oxygen remaining in the venous blood ( $CvO_2$ ) from the oxygen delivered to the tissues by the arteries ( $CaO_2$ ), and is known as the *Fick equation*.<sup>20</sup>

Gas values (pressure and content) relative to the oxygenation of blood are summarized in Table 13-4.

## Carbon Dioxide Transport

RBCs are also important in the transport of carbon dioxide in the blood. Carbon dioxide, a by-product of cellular metabolism, is transported in three forms in the blood: (1) as dissolved gas, (2) as bicarbonate ion ( $HCO_3^-$ ), and (3) in association with hemoglobin (Figure 13-15).<sup>17</sup> The partial pressure of carbon dioxide ( $PCO_2$ ) reflects the pressure or tension that carbon dioxide exerts when it is dissolved in the blood. Partial pressure is measured in millimeters of mercury (mm Hg). In the pulmonary capillaries, carbon dioxide easily dissociates from hemoglobin and then diffuses across the alveolar membrane into the alveolar sacs. In the body tissues, the carbon dioxide inside the cells diffuses into the blood and attaches to the hemoglobin as oxygen is released to the tissues. The partial pressure of carbon dioxide in the arterial blood ( $PaCO_2$ ) is usually 40 mm Hg and in the venous blood ( $PvCO_2$ ) it is usually 45 mm Hg.<sup>17</sup> These differences are much smaller than those of oxygen, but carbon dioxide diffuses much more readily. Dissolved carbon dioxide combines slowly with water in the plasma to form carbonic

acid ( $H_2CO_3$ ), but in the red cell the presence of carbonic anhydrase acting as a catalyst significantly accelerates this reaction.<sup>17,20</sup> Carbonic acid rapidly dissociates into hydrogen ions ( $H^+$ ) and bicarbonate ions ( $HCO_3^-$ ).<sup>17,20</sup> As the concentration of  $HCO_3^-$  in the red cell increases, it diffuses into the plasma, whereas the  $H^+$  remains. This increase in intracellular cation concentration causes the anion chloride to diffuse from the plasma into the red cell to maintain electrical neutrality. This is referred to as the **chloride shift**.<sup>18</sup>

Hemoglobin provides an excellent acid-base buffer by reacting with the free hydrogen ions and directly with carbon dioxide to form carbaminohemoglobin ( $HbCO_2$ ), which is easily dissociated in the lungs to yield free carbon dioxide for exhalation.<sup>17</sup> Unloading of oxygen in the tissue facilitates the loading of carbon dioxide and is referred to as the *Haldane effect*.<sup>17,18</sup>

## Alterations in Oxygen Transport

There must be sufficient circulating hemoglobin mass to meet the metabolic needs of the body. A feedback mechanism ensures that when the amount of oxygen reaching the tissues decreases, a compensatory increase occurs in the production of red cells.<sup>3</sup> The feedback mechanism regulating RBC production is under the control of erythropoietin. As stem cells differentiate into the erythroid committed line, the most primitive stem cell is referred to as the erythroid burst-forming unit (BFU-E), which is controlled by growth factors derived from T lymphocytes and macrophages and, to a lesser degree, by erythropoietin.<sup>2,4</sup> The BFU-E further differentiates into erythroid colony-forming units (CFU-E) more responsive to erythropoietin, and subsequently into normoblasts and mature RBCs.<sup>2-4</sup> The majority of erythropoietin is actively secreted by the kidney. Another 10% of erythropoietin is formed elsewhere in the body.<sup>2-4</sup>

### KEY POINTS

- Nearly all (97%) of the oxygen transported in blood is bound to hemoglobin within the red cells. Only 3% is dissolved in plasma. It is this 3% that is measured as  $PaO_2$ . At a normal  $PaO_2$ , hemoglobin is 95% to 100% saturated with oxygen. About 25% of the bound oxygen is unloaded to the tissues, resulting in a venous hemoglobin saturation of about 75%.
- The oxyhemoglobin dissociation curve describes the relationship between the partial pressure of oxygen and hemoglobin saturation. In the lung, where  $PO_2$  is high (100 mm Hg), oxygen is loaded onto hemoglobin. In the tissues, where  $PO_2$  is low (40 mm Hg), oxygen is unloaded from hemoglobin to tissues.
- The affinity of hemoglobin for oxygen is affected by temperature, acid-base status, 2,3-DPG levels, and carbon dioxide concentration. Affinity decreases at the tissue level because of increased levels of acid, 2,3-DPG, and carbon dioxide. This shift to the right of the oxyhemoglobin dissociation curve enhances unloading of oxygen to the tissue. A shift to the left occurs in the lungs, where blood is more alkalotic and carbon dioxide levels are lower. The increased affinity of hemoglobin for oxygen at the lung facilitates oxygen binding.
- The oxygen content of arterial blood is calculated by adding the amount bound to hemoglobin (Hb) plus the amount dissolved in plasma:  $CaO_2 = (Hb \times 1.34 \times SaO_2) + (PaO_2 \times 0.003)$ . Oxygen delivery to the body tissues is calculated by multiplying  $CaO_2$  by cardiac output (CO):  $\dot{D}O_2 = CaO_2 \times CO \times 10$ .
- The consumption of oxygen by tissues can be estimated using the Fick equation:  $\dot{V}O_2 = CO \times (CaO_2 - CvO_2) \times 10$ . Oxygen consumption increases with increased tissue metabolism.
- Hemoglobin is an important factor in carbon dioxide transport in the blood. In the tissues, hemoglobin binds carbon dioxide to form carbaminohemoglobin, which then releases carbon dioxide in the lungs. RBCs contain the enzyme carbonic anhydrase, which greatly increases conversion of carbon dioxide and water into  $HCO_3^-$  and  $H^+$  at the tissue level. In the lungs, the reaction proceeds in reverse, producing carbon dioxide, which is eliminated by the lungs.

TABLE 13-4 GAS VALUES SIGNIFICANT TO THE OXYGENATION OF BLOOD

GAS VALUES	DESCRIPTION	MEASUREMENT/ REFLECTION	CALCULATION/FORMULA	NORMAL VALUE/ FORMULA
CaO <sub>2</sub>	Arterial blood oxygen content is amount of oxygen carried in arterial blood	Measured in milliliters of oxygen per deciliter of blood (ml/dl), or vol%	Sum of oxyhemoglobin (15 Hb g/100 ml × 1.34 ml O <sub>2</sub> /g Hb × 97.5% arterial saturation = 19.6 vol%) + amount of oxygen dissolved in plasma (PaO <sub>2</sub> = 100 mm Hg × 0.003 vol%/mm Hg = 0.3 vol%)	~20 vol% Formula: 19.6 vol% oxyhemoglobin + 0.3 vol% dissolved in plasma = 19.9 vol%
Cv̄O <sub>2</sub>	Venous blood oxygen content is amount of oxygen carried in venous blood	Measured in milliliters of oxygen per deciliter of blood (ml/dl), or vol%	Sum of oxyhemoglobin (15 Hb/100 ml × 1.34 ml O <sub>2</sub> /g Hb × 75% venous saturation = 15.0 vol%) + amount of oxygen dissolved in plasma (Cv̄O <sub>2</sub> = 40 mm Hg × 0.003 vol%/mm Hg = 0.12 vol%)	~15 vol% Formula: 15 vol% oxyhemoglobin + 0.12 vol% dissolved in plasma = approximately 15 vol%
ĐO <sub>2</sub>	Oxygen delivery or transport is amount of oxygen delivered to tissues	Measured in milliliters of oxygen per minute (ml/min)	<i>Normal arterial:</i> ĐO <sub>2</sub> = cardiac output (L / min) × CaO <sub>2</sub> × 10 <i>Normal venous:</i> ĐO <sub>2</sub> = cardiac output (L / min) × Cv̄O <sub>2</sub> × 10	<i>Normal arterial:</i> ~1000 ml of O <sub>2</sub> /min <i>Normal venous:</i> ~750 ml of O <sub>2</sub> /min
PaO <sub>2</sub>	Partial pressure of oxygen in arterial blood	Measured in millimeters of mercury (mm Hg) Reflects tension or pressure that is exerted by oxygen when it is dissolved in plasma		Normal PaO <sub>2</sub> is 80-100 mm Hg
PaCO <sub>2</sub>	Partial pressure of carbon dioxide in arterial blood	Measured in millimeters of mercury (mm Hg) Reflects tension or pressure that is exerted by carbon dioxide when it is dissolved in plasma		Normal PaCO <sub>2</sub> is 35-45 mm Hg
Pv̄O <sub>2</sub>	Partial pressure of oxygen in venous blood	Measured in millimeters of mercury (mm Hg) Reflects tension or pressure that is exerted by oxygen when it is dissolved in plasma		Normal Pv̄O <sub>2</sub> is 35-40 mm Hg
Pv̄CO <sub>2</sub>	Partial pressure of carbon dioxide in venous blood	Measured in millimeters of mercury (mm Hg) Reflects tension or pressure that is exerted by carbon dioxide when it is dissolved in plasma		Normal Pv̄CO <sub>2</sub> is 41-51 mm Hg
SaO <sub>2</sub>	Amount of hemoglobin bound to oxygen relative to total amount of hemoglobin, both reduced and bound, in arterial blood	Expressed as percentage		Normal SaO <sub>2</sub> is 95-100%
Sv̄O <sub>2</sub>	Amount of hemoglobin bound to oxygen relative to total amount of hemoglobin, both reduced and bound, in venous blood	Expressed as percentage		Normal Sv̄O <sub>2</sub> is 60-80%
ṂO <sub>2</sub>	Oxygen consumption is amount of oxygen consumed by tissues	Measured in milliliters of oxygen per minute (ml/min) Oxygen consumption is derived from difference between arterial oxygen transport and venous oxygen transport	ṂO <sub>2</sub> = cardiac output × (CaO <sub>2</sub> - Cv̄O <sub>2</sub> ) × 10	Normal ṂO <sub>2</sub> is 200-250 ml of O <sub>2</sub> /min

**FIGURE 13-15** Carbon dioxide is transported in three forms in the blood. Transportation of CO<sub>2</sub> (1) as dissolved gas, (2) as bicarbonate ion (HCO<sub>3</sub><sup>-</sup>), and (3) in association with hemoglobin (Hb).

Factors that decrease hemoglobin mass (such as anemia) or decrease arterial saturation (such as hypoxia from either cardiac or pulmonary conditions) impair oxygen delivery to the body tissues. This stimulates an increased release of erythropoietin and the production of RBCs.<sup>3</sup> Figure 13-16 illustrates the compensatory regulation of erythropoiesis that is seen in hypoxia, anemia, and polycythemia.

### ANEMIA

Erythrocyte disorders are divided into two groups: (1) **anemia**, defined as a deficit of red cells, and (2) **polycythemia**, defined as an excess of red cells (Box 13-1).<sup>21,22</sup> An anemic patient has tissue hypoxia attributable to the low oxygen-carrying capacity of the blood. In contrast, a patient with polycythemia has increased blood viscosity and volume attributable to the increase in the number of RBCs.<sup>22</sup> (Polycythemia is discussed in greater detail later in this chapter.) Table 13-5 presents the laboratory findings for erythrocyte disorders in terms of relative anemia, absolute anemia caused by decreased RBC production, and absolute anemia caused by increased RBC destruction.

**Relative anemia** is characterized by normal total red cell mass with disturbances in the regulation of plasma volume. For example, in pregnant women the average plasma volume is 43% greater than in non-pregnant women, which causes a “dilutional anemia.”<sup>21</sup>

**Absolute anemia** includes those types of anemia with an actual decrease in numbers of red cells. This can be caused by decreased production of red cells or increased destruction of red cells.<sup>21</sup>

**FIGURE 13-16** Alterations in the erythropoietin feedback circuit. Any factor decreasing oxygen delivery to the oxygen sensor cells results in increased secretion of erythropoietin and a compensatory increase in erythrocyte production as illustrated in (A) for anemia, with a decrease in erythrocyte mass; and in (B) for hypoxia, with a decrease in arterial oxygen saturation. An increase in erythrocyte mass, as occurs with polycythemia vera (C), decreases erythropoietin production.

## BOX 13-1 CLASSIFICATION OF ANEMIA AND POLYCYTHEMIA

## I. Anemia

## A. Absolute

1. Decreased red cell production
  - (a) Acquired
    - 1) Pluripotent stem cell failure
      - a) Aplastic anemia
        - {1} Radiation induced
        - {2} Drugs and chemicals
        - {3} Viruses
        - {4} Idiopathic
      - b) Anemia of leukemia and myelodysplastic syndrome
      - c) Anemia associated with marrow infiltration
      - d) Anemia associated with chemotherapy
    - 2) Erythroid progenitor cell failure
      - a) Pure red cell aplasia
      - b) Endocrine disorders
      - c) Acquired sideroblastic anemia
    - 3) Functional impairment of erythroid progenitors
      - {1} Megaloblastic anemias
        - a) B<sub>12</sub> deficiency
        - b) Folate deficiency
        - c) Acute megaloblastic anemia due to nitrous oxide
        - d) Drug-induced megaloblastic anemia
          - {2} Iron deficiency anemia
          - {3} Anemia from other nutritional deficiencies
          - {4} Anemia of chronic disease
          - {5} Anemia of renal failure
          - {6} Anemia caused by chemical agents
          - {7} Anemia caused by thalassemias
          - {8} Erythropoietin antibodies
    - (b) Hereditary
      - 1) Pluripotent stem cell failure
        - {1} Fanconi anemia
        - {2} Shwachman syndrome
        - {3} Dyskeratosis congenita
      - 2) Erythroid progenitor cell failure
        - {1} Diamond-Blackfan syndrome
        - {2} Congenital dyserythropoietic syndrome
      - 3) Hereditary sideroblastic anemia
      - 4) Thalassemias

2. Increased red cell destruction or loss
  - (a) Acquired
    - 1) Mechanical
      - a) Macroangiopathic (artificial heart valves)
      - b) Microangiopathic (DIC)
      - c) Parasites and microorganisms
    - 2) Antibody mediated
    - 3) Hypersplenism
    - 4) Chemical and physical injury
    - 5) Acute blood loss
  - (b) Hereditary
    - 1) Hemoglobinopathies (sickle cell)
    - 2) Red cell membrane disorders
    - 3) Red cell enzyme defects
    - 4) Porphyrrias
- B. Relative (increased plasma volume)
  1. Macroglobulinemia
  2. Pregnancy
  3. Athletes
  4. Postflight astronauts

## II. Polycythemia (Erythrocytosis)

## A. Relative (decreased plasma volume)

1. Dehydration
2. Diuretics
3. Stress or smoker's erythrocytosis

## B. Absolute (increased red cell volume)

1. Primary polycythemia
  - (a) Acquired (polycythemia vera)
  - (b) Hereditary congenital polycythemia
2. Secondary polycythemia
  - (a) Appropriate
    - 1) Altitude
    - 2) Cardiopulmonary disorders
    - 3) Increased hemoglobin affinity for oxygen
  - (b) Inappropriate
    - 1) Renal cysts and tumors
    - 2) Hepatoma
    - 3) Cerebellar hemangioblastoma
    - 4) Essential

## GENERAL EFFECTS OF ANEMIA

The clinical manifestations of anemia include a reduction in oxygen-carrying capacity, tissue hypoxia, and compensatory mechanisms to restore tissue oxygenation.<sup>21,22</sup> Increased pulmonary and cardiac function increases the oxygen supply, and an increase in oxygen extraction occurs to protect tissues. Specific adaptations to anemia to increase oxygenated blood flow include an increase in the heart rate, cardiac output, circulatory rate, and preferential increase in blood flow to vital organs. Specific adaptations to anemia to increase oxygen utilization by tissues include an increase in 2,3-DPG concentration in erythrocytes and a decreased oxygen affinity of hemoglobin in tissues. Selective tissue perfusion provides shunting to vital organs in short-term compensation, and increased erythropoietic activity is stimulated to provide long-term compensation.<sup>6</sup> The extent of the physiologic

adaptations is influenced by (1) the severity of the anemia; (2) the competency of the pulmonary and cardiac systems; (3) the oxygen requirements of the individual, which are dependent on physical and metabolic activity; (4) the duration of the anemia; (5) the underlying disease or condition; and (6) the presence and severity of coexisting disease.<sup>21</sup> Mild anemia is usually associated with no clinical symptoms; however, early symptoms in patients with mild to moderate anemia include fatigue, generalized weakness, and loss of stamina, followed by tachycardia and exertional dyspnea. Healthy young patients may present with very few symptoms at hemoglobin levels of 7 to 8 g/dl; however, elderly patients and patients with cardiovascular or pulmonary disease may have symptoms with even modest degrees of anemia and hemoglobin levels of 9 to 11 g/dl. Specific symptoms related to moderate to severe anemia are orthostatic and nonorthostatic hypotension, vasoconstriction, pallor, tachypnea, dyspnea, tachycardia, transient

**TABLE 13-5 LABORATORY FINDINGS FOR ERYTHROCYTE DISORDERS**

DISEASE	HCT	HB	MCV	MCH	MCHC	RETIC	RBC	WBC	PLT	BLOOD SMEAR	OTHER LABORATORY TESTS	OTHER DIAGNOSTIC CHARACTERISTICS
Relative anemia	Low	Low	Normal	Low	Low	Normal	Low	Low	Low	Normal	Plasma volume increased, causing relative decrease in number of cells	Increased volume can be caused by pregnancy, splenomegaly, IV infusions
<b>Absolute Anemia Caused by Decreased Production</b>												
Aplastic anemia	Low	Low	Normal	Low	Low	Low	Low	Low	Low	Normocytic, hypochromic RBCs; lack of neutrophils; increased lymphocytes	HbF may be increased; erythropoietin increased; bone marrow aplastic	Specific cause should be identified and removed from environment
Chronic renal failure	Low	Low	Normal	Normal	Normal	Low	Low	Normal	Normal	Normocytic, normochromic RBCs; RBCs often have spicules	Erythropoietin decreased; bone marrow production suppressed	Kidney tests abnormal
Pernicious anemia	Low	Low	High	High	Normal	Low	Low	Low	Low	Oval macrocytes; hypersegmented segs	Decreased B <sub>12</sub> level; positive Schilling test	Neurologic symptoms; increased bilirubin
Folate deficiency	Low	Low	High	High	Normal	Low	Low	Low	Low	Oval macrocytes; hypersegmented segs	Decreased folic acid level; negative Schilling test	No neurologic symptoms
Iron deficiency	Low	Low	Low	Low	Low	Normal or high	Low	Normal	Normal	Microcytic, hypochromic RBCs	Serum iron decreased; iron-binding	Bone marrow iron decreased
Thalassemia	Low	Low	Low	Low	Low	High	Low	Normal	Normal	Microcytic, hypochromic RBCs	Decreased osmotic fragility; hemoglobin electrophoresis diagnostic; serum iron, TIBC, and ferritin normal	Hereditary disease
<b>Absolute Anemia Caused by Increased Destruction</b>												
<b>Intrinsic Abnormality</b>												
Sickle cell	Low	Low	Normal	Normal	Normal	High	Low	Normal	Normal	Normocytic, normochromic RBC target cells; sickle cells; NRBCs	HbS present on electrophoresis	Hereditary disease
Hereditary spherocytosis	Low	Low	Normal	Normal	Normal to high	High	Low	Normal	Normal	Spherocytes present	Bilirubin elevated; haptoglobins reduced; abnormal RBC fragility	Hereditary disease

## ANEMIA RELATED TO DECREASED RED CELL PRODUCTION

### Aplastic Anemia

**Etiology and pathogenesis.** Aplastic anemia is a stem cell disorder that is characterized by a reduction of hematopoietic tissue in the bone marrow, fatty marrow replacement, and pancytopenia. The decrease in functional bone marrow mass is usually caused by toxic, radiant, or immunologic injury to the bone marrow stem cells, which causes a decrease in the levels of red cells, white cells, and platelets, or **pancytopenia**.<sup>23</sup>

Aplastic anemia can be classified as acquired or familial. Acquired aplastic anemia can be caused by chemical and physical agents, such as those listed in Table 13-6. Other causes include certain viral infections (e.g., hepatitis, Epstein-Barr virus, human immunodeficiency virus [HIV], dengue), some mycobacterial infections, diffuse eosinophilic

fasciitis, pregnancy, Simmonds disease, and sclerosis of the thyroid. Familial aplastic anemia is associated with Fanconi constitutional pancytopenia, pancreatic deficiency in children, and putative hereditary defect in cellular uptake of folate.<sup>24</sup>

**Laboratory features.** Pancytopenia is characterized by low red cell, white cell, and platelet counts. The magnitude of the **granulocytopenia** is very important for the immediate prognosis. An absolute granulocyte count of less than 200/mm<sup>3</sup> results in immediate susceptibility to infectious complications. Coagulation tests are generally normal except for the bleeding time, which reflects the low platelet count.<sup>24</sup> The ultimate diagnosis of aplastic anemia rests on the interpretation of an adequate bone marrow biopsy specimen, although important clues to the cause of pancytopenia can be obtained from the history, physical examination, and laboratory data. Pancytopenia that is not primarily hematologic in origin but secondary to other disease processes is usually an obvious diagnosis.<sup>25</sup>

**Clinical manifestations.** Aplastic anemia is a disease of the young with most patients presenting between 15 and 25 years of age. Another age group likely to present with aplastic anemia are those ≥60 years old. The most common form of aplastic anemia is iatrogenic—resulting from

TABLE 13-6 DRUGS ASSOCIATED WITH APLASTIC ANEMIA\*

CATEGORY	HIGH RISK	MODERATE RISK	LOW RISK
Analgesic			Phenacetin, aspirin, salicylamide
Antidysrhythmic			Quinidine, tocainide
Antiarthritic		Gold salts	Colchicine
Anticonvulsant		Carbamazepine, hydantoin, felbamate	Ethosuximide, phenacemide, primidone, trimethadione, sodium valproate
Antihistamine			Chlorpheniramine, pyrilamine, tripelemnamine
Antihypertensive			Captopril, methyldopa
Anti-inflammatory		Penicillamine, phenylbutazone, oxyphenbutazone	Diclofenac, ibuprofen, indomethacin, naproxen, sulindac
Antimicrobial			
Antibacterial		Chloramphenicol	Dapsone, methicillin, penicillin, streptomycin, β-lactam antibiotics
Antifungal			Amphotericin, flucytosine
Antiprotozoal		Quinacrine	Chloroquine, mepacrine, pyrimethamine
Antineoplastic			
Alkylating agents	Busulfan, cyclophosphamide, melphalan, nitrogen mustard		
Antimetabolites	Fluorouracil, mercaptopurine, methotrexate		
Cytotoxic antibiotics	Daunorubicin, doxorubicin, mitoxantrone		
Antiplatelet			Ticlopidine
Antithyroid			Carbimazole, methimazole, methylthiouracil, potassium perchlorate, propylthiouracil, sodium thiocyanate
Sedative and tranquilizer			Chlordiazepoxide, chlorpromazine (and other phenothiazines), lithium, meprobamate, methypylon
Sulfonamides and derivatives			
Antibacterial			Numerous sulfonamides
Diuretic		Acetazolamide	Chlorothiazide, furosemide
Hypoglycemic			Chlorpropamide, tolbutamide
Miscellaneous			Allopurinol, interferon, pentoxifylline

From Segel GB: Aplastic anemia. In Lichtman MA et al, editors: *Williams hematology*, ed 7, New York, 2006, McGraw-Hill, p 421. This list was compiled from the AMA Registry, Publications of the International Agranulocytosis and Aplastic Anemia Study, other reviews and studies, previous compilations of offending agents, and selected reports.

\*Drugs that invariably cause marrow aplasia with high doses are termed high risk; drugs with 30 or more reported cases are listed as moderate risk; others are less often associated with aplastic anemia (low risk).

a transient marrow failure following treatment with cytotoxic chemotherapeutic drugs or irradiation. Certain chemical or physical agents directly injure proliferating and quiescent hematopoietic cells.<sup>25</sup> The onset is usually insidious, and patients often present only after the late manifestations of pancytopenia are evident. The symptoms attributable to the gradual decrease in the number of RBCs include weakness, fatigue, lethargy, pallor, dyspnea, palpitations, onset of transient murmurs, and tachycardia of anemia. Fever, chills, and bacterial infections (particularly in the mouth or perirectal area) are seen secondary to neutropenia. Petechiae, bruising, nosebleeds, retinal hemorrhage, and increased menstrual flow are manifestations of thrombocytopenia.<sup>23</sup>

**Treatment.** Treatment for aplastic anemia is multifaceted and dependent on the etiology and severity of the disease. Treatment includes (1) identification and avoidance of further toxin exposure; (2) human leukocyte antigen (HLA) and ABO typing of family members to identify serologically defined loci and potential bone marrow transplant donors; (3) maintenance of minimally essential levels of hemoglobin and platelets; (4) prevention and management of infection; (5) determination of efficacy of bone marrow transplantation; and (6) implementation of other forms of therapy, such as immunosuppressive therapy or stimulation of hematopoiesis and bone marrow regeneration in patients not suited for transplantation.<sup>23-26</sup> In patients with severe disease, the major curative approach is allogeneic bone marrow transplantation; however, only one third of all patients have compatible donors.<sup>23-26</sup> Preparative regimens using cyclophosphamide and anti-thymocyte globulin followed by post-transplant immunosuppression with cyclosporine and methyltrexate as prophylaxis against graft-versus-host disease (GVHD) have resulted in a 90% disease-free survival rate at 2 years for patients with bone marrow transplants derived from an HLA-matched sibling donor.<sup>27</sup>

**Course and prognosis.** Bone marrow transplantation is highly successful and curative for 80% to 85% of untransfused patients and 55% to 60% of patients with multiple previous transfusions.<sup>27</sup> Approximately 20% to 30% of transplantation survivors with multiple previous transfusions experience severe GVHD, which can be significantly improved by immunosuppressive therapy in 50% to 70% of patients.<sup>22</sup> The risk of graft failure in patients who have not been transfused is less than 5%. Prognosis is related to the absolute neutrophil count and the platelet count. Children respond better than adults with both bone marrow transplantation and immunosuppression therapy, especially in patients with mild to moderate disease. Aplastic anemia is usually fatal unless managed with bone marrow transplantation.<sup>23-27</sup>

### Anemia of Chronic Renal Failure

**Etiology and pathogenesis.** The anemia of chronic renal failure occurs primarily from failure of the renal endocrine function, which causes impaired erythropoietin production and bone marrow compensation, and secondarily from failure of the renal excretory function, leading to hemolysis, bone marrow cell depression, and blood loss.<sup>28</sup>

**Laboratory features.** This anemia is characterized by a decreased red cell count and low hemoglobin and hematocrit values. Some red cells appear grossly deformed with a few large spicules (Figure 13-17). The total leukocyte differential cell count, leukocyte counts, and platelet count are usually normal. The red cell indices—mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC)—are also normal.<sup>28,29</sup>

**Clinical manifestations.** Any of the clinical manifestations described earlier (see General Effects of Anemia) may be evident in chronic renal failure. The hematocrit falls in proportion to the degree of renal insufficiency, and uremia occurs as the glomerular filtration rate drops below 40 ml/min. Signs and symptoms of anemia usually manifest when the hematocrit decreases to  $\leq 20\%$ .<sup>29</sup>

**FIGURE 13-17** Burr cells found in acute kidney disease. (Courtesy Beth Payne, Sacred Heart Medical Center, Spokane, WA.)

**Treatment.** Therapy consists of dialysis when the glomerular filtration rate is less than 15 ml/min, and erythropoietin is administered to achieve the target hematocrit concentration of 33% to 36% and hemoglobin level of 11 to 12 g/dl. However, excessive correction of the hemoglobin level to greater than 12 g/dl may be associated with an increased incidence of cardiovascular and thromboembolic events. Therefore, the use of erythropoiesis-stimulating agents to increase hemoglobin values to greater than 12 g/dl is not routinely recommended.<sup>30</sup> The hematocrit and hemoglobin values are monitored at least every 2 weeks to ensure adequate oxygen-carrying capacity and minimize an increased respiratory rate and heart rate. When the target hematocrit is achieved, adult patients can be maintained by administering 50 to 100 units per kilogram per week in divided doses. Pediatric patients younger than 5 years usually require higher initial and maintenance doses.<sup>28-33</sup> Patients with chronic renal failure are also prone to nutritional anemias (lack of iron, folate, and B<sub>12</sub>) because of dietary restrictions and anorexia. Patient replacement of iron, folate, and B<sub>12</sub> to adequate levels should be considered a treatment goal. Some patients may fail to respond or may be resistant to the effects of erythropoietin. The most common cause for a failure in response is iron deficiency anemia.<sup>30</sup>

**Course and prognosis.** More than 95% of patients respond to erythropoietin therapy. Patients who do not respond or first respond when larger doses are given should be evaluated for an adequate iron supply, infection, or excessive splenic hemolysis.<sup>28-33</sup>

### Anemia Related to Vitamin B<sub>12</sub> (Cobalamin) or Folate Deficiency

**Etiology and pathogenesis.** The anemia resulting from a deficiency of either vitamin B<sub>12</sub> (cobalamin) or folate is caused by a disruption in DNA synthesis of the blast cells in the bone marrow. This disruption produces very large abnormal bone marrow cells called **megaloblasts**. In the peripheral blood, the red cells are larger than normal (**macrocytic**), the granulocytes are hypersegmented, and the numbers of red cells, white cells, and platelets are decreased.<sup>34,35</sup> All of these signs can be seen on the peripheral blood smear.

The classic anemia in this classification is pernicious anemia. The fundamental defect causing pernicious anemia is the lack of intrinsic factor. Without it, vitamin B<sub>12</sub> cannot be absorbed, thus leading to vitamin B<sub>12</sub> deficiency. This deficiency results in disordered nucleic acid metabolism, which causes **megaloblastic dysplasia**, a condition involving abnormal production and maturation of red cell, white cell, and platelet systems. There is strong evidence that pernicious anemia develops as a result of genetically determined autoimmune disease, which is manifested by serum and gastric juice antibodies against

intrinsic factor and parietal cells.<sup>34</sup> The biochemical basis of the neurologic lesions in pernicious anemia is not known. There can be peripheral nerve degeneration, degeneration of the posterior columns of the spinal cord, or both. There is some evidence of abnormal fatty acid metabolism in the peripheral nerves and degeneration of the white matter in the spinal cord in animals.<sup>34,35</sup>

Folate deficiencies resemble vitamin B<sub>12</sub> deficiencies except for the neurologic disease, which is more characteristic of vitamin B<sub>12</sub> deficiency. Folate deficiencies are usually the result of dietary deficiencies, alcoholism and cirrhosis, pregnancy, or infancy.

**Laboratory features.** The peripheral blood shows low RBC counts of 500,000 to 750,000 cells/mm<sup>3</sup>, low WBC counts of 4000 to 5000 cells/mm<sup>3</sup>, and low platelet counts of 50,000 cells/mm<sup>3</sup>. These counts are usually not as low as those seen in aplastic anemia. The bone marrow shows megaloblastic dysplasia, which results in a peripheral blood picture of macrocytosis and hypersegmented neutrophils. The red cell indices reveal normal MCH and MCHC and increased MCV. The Schilling test, which measures excretion of radioactive vitamin B<sub>12</sub>, indicates low levels, and the serum level of vitamin B<sub>12</sub> is low. Gastric analysis indicates a lack of free hydrochloric acid in the gastric juice (achlorhydria).<sup>34,35</sup>

**Clinical manifestations.** The clinical features of vitamin B<sub>12</sub> deficiency include paranoid ideation, dementia, cognitive dysfunction, delusions, and hallucinations, often referred to as “megaloblastic madness.”<sup>34</sup> The neurologic abnormalities include symmetric paresthesias of the feet and hands with vibratory sense and proprioception disturbances. The paresthesias progress to spastic ataxia as a result of degenerative changes of the dorsal and lateral columns of the spinal cord. Cerebral signs include irritability, somnolence, memory impairment, and perversion of taste, smell, and vision.<sup>34,35</sup> Manifestations of pure folate deficiency include a blunted affect in general demeanor with evidence of depression, sleep deprivation, and irritability. History of circumstances likely to result in folic acid deficiency includes poor or fad diet, frank malabsorption, or alcoholism. In folate deficiency, cerebral symptoms, such as irritability, memory loss, and personality changes, are seen.<sup>34,35</sup> Clinical manifestations that are seen in both vitamin B<sub>12</sub> and folate deficiencies include pedal edema, nocturia, tachypnea, dyspnea, and tachycardia associated with heart congestion; glossitis, weight loss, malabsorption, and episodic or chronic diarrhea with steatorrhea are gastrointestinal manifestations. Musculoskeletal symptoms of arthralgia and frank arthritis are seen in autoimmune diseases; nocturnal pain and upper and/or lower extremity cramps often indicate spinothalamic tract involvement. Dermatologic symptoms include blotchy brown skin pigmentation, especially in nail beds and skin creases. When this is associated with vitiligo, autoimmune processes should be suspected.<sup>34,35</sup>

Recent research has reported an association between low folate levels and the risk of neural tube defects and abnormalities of the heart, urinary tract, and limbs in neonates. These data support the routine supplementation before pregnancy of all women who might become pregnant with 1.0 mg/day of folic acid.<sup>34,35</sup> This is the largest dose that will not mask vitamin B<sub>12</sub> deficiency.

**Treatment.** Routine treatment with full doses of parenteral vitamin B<sub>12</sub> (1 mg/day) and oral folate (1 to 5 mg/day) before the cause of the deficiency is identified should only be used in critically ill patients. In managing the anemia related to vitamin B<sub>12</sub> or folate deficiency, it is important to (1) recognize that megaloblastic anemia is present; (2) ascertain if vitamin B<sub>12</sub>, folate, or a combined deficiency is the cause; and (3) diagnose the underlying disease and mechanism responsible for the deficiency. In vitamin B<sub>12</sub> and folic acid deficiency anemia, replacement therapy for vitamin B<sub>12</sub> is oral cobalamin and folic acid. Transfusion therapy may be indicated in elderly or critically ill patients. Hypokalemia should be managed with potassium supplements to

prevent sudden death, reportedly associated with a sharp drop in serum potassium level seen in vitamin B<sub>12</sub> therapy.<sup>34,35</sup>

**Course and prognosis.** The majority of patients respond well to replacement therapy; however, continued assessment and monitoring of these patients is essential to prevent hematologic or neurologic relapse secondary to inadequate therapy.<sup>34,35</sup> In patients with neurologic signs and symptoms, the reversibility of the neurologic damage is slow, with a maximal response requiring up to 6 months. Further substantial increases in recovery are unlikely after 12 months. In 90% of patients with subacute combined degeneration, major improvement is seen.<sup>34</sup> The degree of functional recovery is inversely related to the extent of the disease and duration of the signs and symptoms. Patients with signs and symptoms of less than 3 months' duration may have complete reversal.<sup>34,35</sup>

### Iron Deficiency Anemia

**Etiology and pathogenesis.** Iron deficiency, the most common nutritional deficiency in the world, is the most common cause of anemia. Iron deficiency results in the unavailability of iron for hemoglobin synthesis. This may be due to low intake, diminished absorption (such as from chronic disease), physiologic increase in requirements (such as during pregnancy), excessive iron loss (such as from acute or chronic hemorrhage), or chronic renal failure, hemodialysis, and idiopathic iron loss. The most common cause in men is occult gastrointestinal bleeding and in women is menorrhagia. Iron is one of the most carefully conserved body substances, and under normal conditions very little is lost except as a result of bleeding. Normal dietary requirements, if 10% is absorbed, are as follows: adult men, 12 mg/day; adult women ages 14 to 30 years, 15 mg/day; and adult women ages 60 years or more, 10 mg/day. Pregnant women require up to 30 mg/day, and children require 10 mg/day. A normal diet supplies the adult with about 10 to 15 mg/day.<sup>36-40</sup>

**Laboratory features.** In latent iron deficiency there may be no anemia; however, after patients receive iron, they respond with a significant increase in blood hemoglobin level. In a typical case caused by chronic bleeding, the reduction in hemoglobin concentration is proportionately greater than the reduction in the red cell count. The red cells are smaller and paler than normal RBCs because of the decreased amount of hemoglobin and are described as **hypochromic, microcytic red cells**. Therefore, the red cell indices MCV, MCH, and MCHC are decreased. The white cell counts are usually normal. The platelet count varies, depending on the cause of the deficiency. In severely anemic children and infants, thrombocytopenia may be present. In patients who are bleeding, thrombocytosis may be present. The serum ferritin level is decreased to less than 10 ng/ml, the serum iron level is decreased, total iron binding capacity (TIBC) is increased, and tissue iron stores are decreased.<sup>36-40</sup>

**Clinical manifestations.** Patients with iron deficiency may present with (a) no signs or symptoms, only seeking medical attention because of abnormalities noted on laboratory tests; (b) features of the underlying disorder responsible for the development of iron deficiency; or (c) manifestations common to all anemias, such as pallor, weakness, fatigue, dyspnea, palpitations, new and transient heart murmurs, irritability, headaches, or lightheadedness. Patients may also present with (d) one or more of the few signs and symptoms considered highly specific for iron deficiency, including pagophagia or pica (craving for nonfood substances such as dirt, clay, ice, laundry starch, cardboard, or hair), koilonychia (spoon-shaped nails), and blue sclerae. In addition, a high prevalence of iron deficiency with or without anemia has been reported among patients with restless legs syndrome (Ekbohm syndrome), especially in the elderly.<sup>39</sup> In severe cases, gastrointestinal symptoms are seen, such as glossitis, dysphagia, erosions at the corners of the mouth, esophageal webbing, and atrophic gastritis, as well as changes in the fingernails, conjunctival pallor, and splenomegaly.<sup>36-40</sup>

**Treatment.** To maintain a normal iron balance in the body, men need to absorb 1.0 to 1.5 mg/day and women need to absorb 2 to 3 mg/day because of iron losses with menstruation. The goal of therapy for iron deficiency anemia is to supply sufficient iron to repair the hemoglobin deficit and to replenish iron stores. Oral iron is the treatment of choice for almost all patients because of its effectiveness, safety, and economy and should always be given preference over parenteral iron for initial treatment.<sup>39</sup> Iron deficiency anemia is managed with oral administration of ferrous sulfate taken separately from meals in three or four divided doses and supplying a daily total of 150 to 200 mg of elemental iron in adults or 3 mg of iron per kilogram of body weight in children until hematologic normality is reached.<sup>39</sup> Infants may be given 50 to 100 mg daily in divided doses. Thereafter it is important to continue the treatment for 4 to 6 months to build iron stores. Urgent treatment may be accomplished with the administration to intravenous ferric gluconate following a test dose to determine possible hypersensitivity. Patients undergoing dialysis should have a serum ferritin level greater than 100  $\mu\text{g/L}$  to optimize their response to erythropoietin administration. Although iron therapy remedies the iron deficiency anemia, the underlying cause must be determined and corrected.<sup>36-40</sup>

**Course and prognosis.** The symptoms may be alleviated in the first few days of treatment. The reticulocyte count is an index of erythropoiesis. The reticulocyte count increases as the RBC production increases and usually reaches maximal levels in 7 to 12 days, and the hemoglobin level is usually normal by 2 months after initiation of therapy.<sup>36-40</sup> Failure to obtain a complete and characteristic response to iron therapy should cause the clinician to review the findings and reevaluate the patient. One possible problem is an incorrect diagnosis, when the anemia of chronic disease is mistaken for the anemia of iron deficiency.<sup>39</sup> The prognosis is excellent if the underlying cause is benign; however, even in patients with incurable disease states, management of iron deficiency anemia with iron therapy can increase the comfort level.<sup>36-40</sup>

## ANEMIA RELATED TO INHERITED DISORDERS OF THE RED CELL

### Thalassemia

Anemia can also be caused by increased RBC destruction, or **hemolysis**. Hemolytic anemias are characterized by decreased red cell survival rates. The thalassemias are examples of a type of anemia caused by decreased red cell survival rates. The red cells produced are abnormal and prone to destruction. This destruction is based on an intrinsic defect in the red cells.<sup>41-44</sup>

**Etiology and pathogenesis.** The thalassemias are a group of diseases associated with the presence of mutant genes that suppress the

rate of synthesis of globin chains. Thalassemias are classified according to the polypeptide chain or chains with deficient synthesis, such as  $\alpha$ -thalassemia or  $\beta$ -thalassemia.<sup>41-44</sup> There are two main classes of thalassemia,  $\alpha$  and  $\beta$ , in which the  $\alpha$ - and  $\beta$ -globin genes are involved, and rarer forms caused by abnormalities of other globin genes. These conditions all have in common an imbalanced rate of production of the globin chains of adult hemoglobin—excess  $\alpha$  chains in  $\beta$ -thalassemia and excess  $\beta$  chains in  $\alpha$ -thalassemia. Several hundred different mutations at the  $\alpha$ - and  $\beta$ -globin loci have been defined as the cause of the reduced or absent output of  $\alpha$  or  $\beta$  chains. The high frequency and genetic diversity of the thalassemias are related to past or present heterozygote resistance to malaria.<sup>41</sup> A deficiency in one or more polypeptide chains causes decreased hemoglobin synthesis and an imbalance between  $\alpha$ -chain and non- $\alpha$ -chain production. Because of the lack of hemoglobin, the anemia is severe, and the peripheral cells are microcytic and hypochromic. The disruption of the globin balance causes the normal chains to accumulate and precipitate within the cytoplasm. This damages the cell membranes, which leads to premature cell destruction. The most clinically severe form of the thalassemias is *thalassemia major*, which occurs in homozygous patients. *Thalassemia minor* is the term used to describe the heterozygous carrier state. For example, in homozygous  $\beta$ -thalassemia, the deficiency of  $\beta$ -chain synthesis results in the accumulation of  $\alpha$  chains, which aggregate to form insoluble inclusions in bone marrow erythroid precursors (Figure 13-18). These inclusions cause early destruction of 70% to 85% of marrow erythroblasts. In response to this massive destruction, erythroid cell proliferation in homozygous  $\beta$ -thalassemia is significant.<sup>41-44</sup>

Patients who are significantly anemic have an increased intestinal iron absorption that is related to the degree of expansion of the RBC precursor population. This can be decreased with blood transfusions. The iron accumulates in the Kupffer cells of the liver, the macrophages in the spleen, and the parenchymal cells of the liver.<sup>41</sup>

**Laboratory features.** Laboratory values vary, depending on the severity of the imbalance, which is determined by the genetic pattern. Because of the decrease in hemoglobin level, the red cells are hypochromic and microcytic, and red cell indices—MCV, MCH, and MCHC—are decreased. Many target cells are present. In homozygous or major syndromes, the hemoglobin concentration is often less than 7 g/dl, and there are nucleated red cells in the peripheral blood. The leukocyte number is usually increased but the platelet number is normal. The bone marrow is hypercellular, with profound erythroblastic hyperplasia. There is evidence of hemolysis with increased unconjugated bilirubin levels and increased excretion of urobilin and urobilinogen. Hemoglobin electrophoresis is performed to determine the type of abnormal hemoglobin. An increased level of fetal hemoglobin ranging from 10%

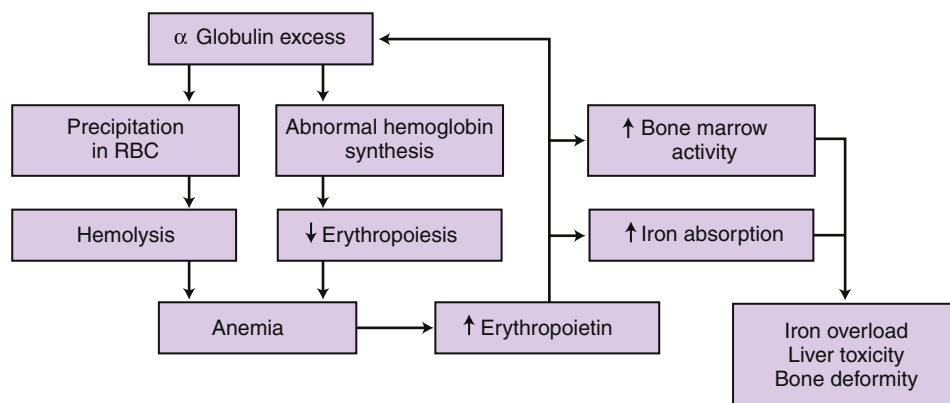

FIGURE 13-18 Pathophysiology of  $\beta$ -thalassemia.

to 90% is characteristic of homozygous  $\alpha$ -thalassemia. No hemoglobin  $\alpha$  is produced. Excess  $\gamma$  chains form  $\gamma_4$  homotetramers or Bart's hemoglobin. Excess  $\beta$  chains form  $\beta_4$  homotetramers or hemoglobin H.<sup>41-44</sup>

**Clinical manifestations.** Patients may have any of the clinical manifestations described earlier (see General Effects of Anemia). The clinical findings are the result of deficient  $\alpha$ -globin production in  $\alpha$ -thalassemia or  $\alpha$ -globin chain excess and persistent hemoglobin F production in  $\beta$ -thalassemia.<sup>41-44</sup>

$\alpha$ -Thalassemia is found primarily in Asian individuals; however, it has also been documented in increasing numbers in individuals of Mediterranean or African descent. Usually patients with  $\alpha$ -thalassemia minor are silent carriers or present with mild to moderate anemia. They are recognized during familial studies following the identification of a family member with Bart's hemoglobin hydrops fetalis or hemoglobin H disease ( $\alpha$ -thalassemia major). Infants with Bart's hemoglobin hydrops fetalis are pale and edematous and have hepatomegaly, splenomegaly, and ascites. Individuals with hemoglobin H disease have typical facies and bone changes seen in  $\beta$ -thalassemia, splenomegaly, and hepatomegaly.<sup>41-43</sup>

$\beta$ -Thalassemia occurs mainly in individuals of Mediterranean descent and presents as thalassemia major, intermedia, or minor. It is also seen in the Middle East, parts of India and Pakistan, and throughout Southeast Asia. Untreated patients with thalassemia major have skull bone deformities from intramedullary and extramedullary bone marrow expansion, mongoloid facies, bowing and **rarefaction** of long bones, extension of bone marrow into paraspinal or intraabdominal tumors, **icterus**, hepatomegaly, splenomegaly, and cardiac failure or endocrinopathies, such as diabetes mellitus and hypogonadism from excessive intestinal iron absorption. Patients with thalassemia intermedia show fewer effects of iron overload, growth retardation, marrow expansion, and splenomegaly; however, deforming bone and joint disease, chronic leg ulceration, and infection are common in this form of thalassemia. Thalassemia minor is usually relatively asymptomatic.<sup>41-44</sup>

**Treatment.** Because the carrier states for the thalassemias can be identified and affected fetuses can be diagnosed by DNA analysis after the ninth to tenth week of gestation, these conditions are widely amenable to prenatal diagnosis. Currently, bone marrow transplantation is the only way in which they can be cured. Symptomatic management is based on regular blood transfusions, iron chelation therapy, and the judicious use of splenectomy.<sup>41</sup> Children with thalassemia are treated with blood transfusion therapy to maintain a hemoglobin level of 11 to 13 g/dl to ensure normal growth and development and to avoid skeletal deformities. Patients should be tested for the presence of hepatitis B antibodies and immunized if they test negative. Splenectomy is recommended in children 6 to 7 years of age or in adolescents when their transfusion requirements exceed 1.5 times normal (>200 ml/kg/yr). Before splenectomy, children should be immunized with polyvalent pneumococcal vaccine, *Haemophilus influenzae*, and *Neisseria meningitidis*. Iron supplements are avoided, and chelation therapy is started when the serum ferritin levels reach 1000  $\mu$ g/dl. Vitamin C is required for management of iron overload. Bone marrow transplantation has been used with success in severe  $\beta$ -thalassemia. The best candidates are younger children, because older children have high rejection and mortality rates.<sup>41-44</sup> Two experimental approaches are currently being pursued in the search for more effective therapy of the thalassemias: (1) reactivation or augmentation of fetal hemoglobin production and (2) somatic gene therapy.<sup>41</sup>

**Course and prognosis.** Infants with Bart's hemoglobin hydrops fetalis inherit an  $\alpha$ -thalassemia gene from both parents who only have the  $\alpha$ -thalassemia trait. These infants are usually stillborn or die within hours to days of birth. Some patients with hemoglobin H disease live a full life. Patients with  $\beta$ -thalassemia intermedia can expect to live until middle age; however, iron loading and crippling bone disease occur in the third and fourth decades. Children with adequate treatment with

iron chelation before bone marrow transplantation have disease-free survival rates up to 95%, whereas older patients and those exhibiting more than one risk factor have a rejection-free survival rate of less than 75%. Treatments under investigation include manipulation of globin gene expression with drugs such as 5-azacytidine, hydroxyurea, erythropoietin, or butyrate analogues and gene therapy directed at replacing or compensating for the defective  $\beta$ -globin alleles. Because this is a genetically transmitted disease, it is important for patients and parents to receive appropriate genetic counseling.<sup>41-44</sup>

### Sickle Cell Anemia

**Etiology and pathogenesis.** Sickle cell anemia is a genetically determined defect of hemoglobin synthesis. Sickle cell disease is a disorder in which patients inherit specific mutated variants of the  $\beta$ -globin gene that lead to hemoglobin polymerization. The sickle mutation of the  $\beta$ -globin gene results in the production of an abnormal hemoglobin called sickle hemoglobin S (HbS). In hemoglobin S, valine is substituted for glutamic acid in the sixth position of the  $\beta$  chain, rather than the normal configuration. This apparently minor change in the molecular structure causes profound changes in hemoglobin stability and solubility. Under decreased oxygen tension, hemoglobin S undergoes polymerization, which causes the red cell to assume a sickled shape (Figure 13-19). Patients who are homozygous produce only hemoglobin S. No hemoglobin A is synthesized because all the  $\beta$  chains are S chains, which

**FIGURE 13-19** Sickle cell anemia: effects of sickling. *HbS*, Hemoglobin S; *RBC*, red blood cell. (From Gould BE: *Pathophysiology for the health professions*, ed 2, Philadelphia, 2002, Saunders, p 247.)

combine with normal  $\alpha$  chains to form hemoglobin S. In heterozygous patients with sickle cell trait, both normal and S chains are formed. Because fewer abnormal chains are produced than normal ones, the amount of hemoglobin A usually exceeds that of hemoglobin S. The sickle mutation has undergone positive selection during human evolution because individuals with one copy of the sickle gene and one normal  $\beta$ -globin gene (sickle cell trait) have a survival advantage in malaria-endemic regions. The preferential sickling of cells with malarial parasites reduces the number of parasites and allows children with sickle cell trait who are infected with these parasites to reach reproductive age. This has provided a selective advantage to the hemoglobin S trait, thereby preventing S from being genetically eliminated.<sup>45-48</sup>

The pathogenetic signs and symptoms of sickle cell disease all relate to the red cell sickling. Sickled red cells have a decreased survival time, which causes anemia, and sickled cells cause vascular occlusion, which results in capillary stasis, venous thrombosis, and arterial emboli. The

most dangerous feature of sickle cell anemia is the occurrence of acute episodes of "crisis," which can be hemolytic or vascular (Box 13-2).<sup>45-48</sup>

**Laboratory features.** The laboratory features in sickle cell anemia are distinctive. The anemia is usually severe, with red cells of different shapes and sizes. Target red cells are present, and occasionally sickled cells can be seen on smears (Figure 13-20). Red cell breakdown products are increased, which increases serum bilirubin, urobilinogen, and urobilin levels. Acute hemolytic crisis is characterized by hemoglobinuria, leukocytosis, and normoblastosis; diffuse intravascular coagulation may develop.<sup>45-48</sup>

**Clinical manifestations.** Chronic hemolytic anemia, recurrent painful episodes, and acute and chronic organ dysfunction particularly of the spleen, bones, brain, kidneys, lungs, skin, and heart are the cardinal features of sickle cell anemia. Sickle cell anemia and sickle cell trait are found almost entirely in the black race.<sup>45-48</sup> Hemolysis of the sickle cells occurs in the spleen or vascular space, and vaso-occlusive

### BOX 13-2 COMPLICATIONS OF SICKLE CELL ANEMIA

#### Decreased RBC Survival

Anemia  
Reticulocytosis  
Hyperbilirubinemia  
Increased pigment excretion  
Cholelithiasis  
Hyperplastic bone marrow  
Osteoporosis  
Osteosclerosis  
Siderosis

#### Acute Hemolytic Crisis

Leukocytosis  
Reticulocytosis  
Hyperbilirubinemia  
Hemoglobinuria  
Normoblastosis  
Diffuse intravascular coagulation (consumption coagulopathy)

#### Vascular Occlusion (Capillary Stasis, Venous Thrombosis, Arterial Emboli)

Splenomegaly  
Splenic infarction  
Splenic atrophy  
Hepatomegaly  
Cirrhosis  
Hematuria  
Sickle cell dactylitis  
Aseptic necrosis of bones  
Infarction of bone marrow  
Infarction of various organs (brain)  
Priapism  
Skin ulcers  
Pulmonary embolism

#### Painful Crisis (Occlusive Vascular Crisis)

Fever  
Pain  
Sudden death

Data from Miale J, editor: *Laboratory medicine hematology*, ed 6, St Louis, 1982, Mosby, p 637.

**FIGURE 13-20** A, Blood smear showing sickle cells in sickle cell anemia. B, Scanning electron micrograph of deoxygenated sickled red cells. (A, Courtesy Beth Payne, Sacred Heart Medical Center, Spokane, WA. B, From Young NS et al, editors: *Clinical hematology*, Philadelphia, 2006, Mosby, p 39.)

events occur in the small capillaries and venules caused by sickle cells.<sup>45</sup> The red cell life span is already shortened by the sickling and may precipitate a hemolytic crisis with jaundice. Sudden massive pooling of red cells, particularly in the spleen, can create a sequestration crisis, which is thought to result in the deaths that occur in the first years of life.<sup>45-48</sup> Infarctive crises or painful episodes are a result of obstruction of blood vessels, tissue hypoxia, and tissue death, and may occur throughout the body. Vaso-occlusive events are described in Table 13-7. Children with sickle cell anemia are shorter and experience delayed puberty, but they attain normal height with late adolescent growth. Bony abnormalities, “hand-foot” syndrome with periostitis of the metacarpal and metatarsal bones, splenomegaly, inability to concentrate urine, priapism with subsequent impotence, underdeveloped genitalia and hypogonadism, hepatomegaly, jaundice, gallstones, tachycardia, acute chest syndrome (fever, chest pain, increasing WBC count, and pulmonary infiltrates), retinal vessel obstruction, cerebrovascular accidents, leg ulcers, and infections are all seen in sickle cell disease patients. Pregnant women may exhibit signs of pyelonephritis, pulmonary infarction, pneumonia, antepartum hemorrhage, premature fetal delivery, and fetal death.<sup>45-48</sup>

**Treatment.** Stem cell transplantation is curative and the treatment of choice. Currently there are no safe, effective antisickling agents, and treatment is primarily supportive. To avoid precipitation of a vaso-occlusive crisis, it is important to prevent dehydration, infection, fever, acidosis, hypoxemia, and cold exposure.<sup>45-48</sup> Because salicylates impose an acid load, acetaminophen is the preferred antipyretic.<sup>46</sup> Vaccination for pneumococcal pneumonia should be done before 2 years of age in patients with sickle cell anemia and booster vaccinations given 3 to 5 years later. Penicillin prophylaxis is important to prevent streptococcal pneumonia and pneumococcal septicemia. Other vaccinations include *Haemophilus influenzae* type B and hepatitis B. Transfusions are used to restore normal hematocrit levels, and splenectomy is performed in children with sequestration syndrome. Treatment with oral hydroxyurea reduces leukocyte, polymorphonuclear (PMN), reticulocyte, and sickle cell counts while increasing the hemoglobin and hematocrit levels and resulting in fewer acute painful episodes. Appropriate treatment of pain is important. During pregnancy, folic acid should be given to prevent neural tube defects. If iron deficiency is present, iron supplements should also be administered. Transfusion should be used only when clinical and hematologic indicators are present.<sup>45-48</sup>

**Course and prognosis.** Successful bone marrow stem cell transplantation cures sickle cell anemia. Bone marrow transplantation from a sibling-matched donor has a 94% survival rate and an 84% event-free survival rate. Sickle cell anemia is a serious disorder, and without stem cell transplantation many patients die in childhood, especially in sequestration crisis. In young children with sickle cell anemia, there is a 30% incidence of splenic sequestration crisis with a 15% death rate. Functional hyposplenism predisposes individuals to infections, such as pneumonia and chronic pyelonephritis with renal failure. Heart failure, bone marrow and fat emboli, shock, and organ failure are common causes of death. In developed countries, patients who have not undergone stem cell transplantation may survive into the third and fourth decades, whereas survival past childhood in underdeveloped countries is unusual.<sup>45-48</sup> The survival rates have increased dramatically because of stem cell transplantation, newborn screening, early diagnosis, preventive measures to avoid sequestration crisis, and patient education.<sup>45-48</sup>

**Hereditary Spherocytosis**

**Etiology and pathogenesis.** In hereditary spherocytosis, the red cells have defective red cell membrane skeletons, altered membrane properties, and altered cell metabolism. This causes them to have a decreased survival time in patients with an intact spleen. The disease is inherited as an autosomal dominant trait and is characterized by red cells that are fragile microspherocytes. In addition, there is increased destruction of **spherocytes** (abnormal spherical erythrocytes) in the spleen. Patients have anemia, intermittent jaundice, splenomegaly, and uniform responsiveness to splenectomy. The principal cellular defect is a loss of membrane surface area attributable to defects of several membrane proteins, including ankyrin, band 3,  $\alpha$ -spectrin, and  $\beta$ -spectrin.<sup>49-52</sup>

**Laboratory features.** The concentration of hemoglobin within the red cells is increased. Reticulocytosis is present, and microspherocytes are seen on the blood smear. Osmotic fragility is increased, and serum unconjugated bilirubin level is increased. Following splenectomy, the hemoglobin level is in the high-normal range.<sup>49-52</sup>

**Clinical manifestations.** Hereditary spherocytosis is the most common hereditary hemolytic anemia and is most common in people with a northern European background. The major clinical manifestations are anemia, jaundice, splenomegaly, bile pigment gallstones, and

TABLE 13-7 VASO-OCCLUSIVE CONSEQUENCES OF SICKLE CELL DISEASE

EVENT	INCIDENCE	FEATURES
<b>Acute</b>		
Painful episodes	>50% of patients with HbSS and HbS $\beta$ -thalassemia	Mild to severe pain; one or several areas
Chest syndrome	10-20% of adults	Difficult to distinguish from pneumonia; may involve entire lung
Priapism	10-40% of males	Can have a more chronic form; causes impotence
Cerebrovascular accidents	1-10% of children	Usually subarachnoid bleeding in adults
Hepatopathy	<2% of adults	Bilirubin may reach >80 mg/dl
<b>Chronic</b>		
Aseptic bone necrosis	10-25% of adults	Hips and shoulders, common in HbSC
Proliferative retinopathy	50% of adults with HbSC; <5% HbSS 10%	Can lead to retinal detachment
Leg ulcers		Can be severe and disabling
Functional asplenia and autosplenectomy	Starts in infancy; >90% of adults with HbSS	Predispose to sepsis
Nephropathy	Renal failure in older patients	Nephritic syndrome, renal failure

Adapted from Sternberg MH: Hemoglobinopathies and thalassemias. In Stein JH et al, editors: *Internal medicine*, ed 5, St Louis, 1998, Mosby, p 658. HbS, Hemoglobin S (sickle hemoglobin); HbSC, hemoglobin SC disease; HbSS, hemoglobin SS (sickle cell anemia).

chronic leg ulcers. The anemia is usually mild because of compensation by the erythropoietic bone marrow cells. Aplastic crisis precipitated by an infection may be seen with associated fever, abdominal discomfort, nausea, vomiting, rapidly increasing weakness, pallor, tachycardia, low blood pressure, and shock.<sup>49-52</sup>

**Treatment.** Treatment usually consists of splenectomy in children with severe cases (hemoglobin concentration <8 g/dl and reticulocyte count >10%) and children with moderate disease reflected (hemoglobin concentration 8 to 11 g/dl and reticulocyte count of 8% to 10%) when the anemia compromises physical activity. All children undergoing splenectomy should be immunized with polyvalent pneumococcal vaccine, *Haemophilus influenzae*, and *Neisseria meningitidis*. Oral penicillin should be given for several years after splenectomy to prevent pneumococcal sepsis. Folic acid therapy to prevent folate deficiency is necessary as well. Transfusion is usually indicated only in aplastic crisis.<sup>49-52</sup>

**Course and prognosis.** Most patients have no or mild anemia, fluctuating degrees of jaundice, and episodes of aplastic or hemolytic anemia. Splenectomy is usually curative; however, the subsequent risk of acquiring a serious infection is significant.<sup>49-52</sup>

### Glucose-6-Phosphate Dehydrogenase Deficiency

**Etiology and pathogenesis.** An example of an RBC intracellular defect caused by an enzyme deficiency is glucose-6-phosphate dehydrogenase (G6PD) deficiency. The energy required for RBC membrane function and cellular integrity is derived from the anaerobic metabolism of glucose. Traditionally, hemolytic anemias caused by enzyme deficiencies have been called nonspherocytic to distinguish them from classic hereditary spherocytosis. When black soldiers receiving the antimalarial drug primaquine began suffering hemolytic episodes, a type of hemolytic anemia caused by a deficiency of G6PD (an enzyme in the red cell glycolytic pathway) was discovered. When G6PD-deficient RBCs are challenged by one of several drugs, glutathione is depleted and glucose utilization is inhibited. These events cause RBC membrane damage, which results in removal of the damaged cells by mononuclear phagocytes. Except in rare instances, G6PD-deficient persons do not have hemolytic anemia unless challenged by drugs.<sup>53-58</sup> G6PD deficiency is the most common metabolic disease of the RBC, affecting hundreds of millions of people worldwide. This gene is found in 11% of African-American males and in Sephardic Jews. Because the responsible gene is an X-linked recessive gene, close relatives of affected individuals should be screened. Because G6PD deficiency is found in areas where malaria was once endemic, G6PD deficiency is thought to have conferred selective advantage against *Plasmodium falciparum* malaria infection.<sup>58</sup>

**Laboratory features.** Usually this anemia is first recognized during or after an infectious illness or following exposure to a suspect drug or chemical. The hematologic tests reflect the severity of the hemolytic episode. The diagnosis of G6PD deficiency is based on the generation of NADPH from NADP as detected either by quantitative spectrophotometric analysis or by a rapid fluorescent screening test.<sup>53-58</sup>

**Clinical manifestations.** Most individuals have no clinical manifestations of this disease. When such manifestations occur, hemolytic anemia is triggered by drug administration, infection, diabetic acidosis, the newborn period, and, in one subset, exposure to fava beans.<sup>53-58</sup>

**Treatment.** Treatment is usually preventive and consists of avoidance of drugs that trigger hemolytic episodes and aggressive infection management. Some patients may require transfusion therapy or exchange transfusion in the case of life-threatening hemolysis.<sup>53-58</sup>

**Course and prognosis.** The prognosis is generally good since the episodes of hemolytic crisis are usually self-limiting, except in fava bean-susceptible individuals, in whom shock may develop in a short time.<sup>55</sup>

## ANEMIA RELATED TO EXTRINSIC RED CELL DESTRUCTION OR LOSS

The final category of types of absolute anemia includes those caused by extrinsic abnormalities. The most important of these category types is immune hemolytic anemia caused by antibodies to red cells. Immune hemolytic anemias are further subdivided into those caused by isoantibodies, which may be the result of accidental immunization of individuals (e.g., hemolytic disease of the newborn), and those caused by autoantibodies (in individuals whose bodies create antibodies against their own red cells).<sup>59-64</sup>

### Hemolytic Disease of the Newborn

**Etiology and pathogenesis.** When fetal red cells cross the placenta, they may stimulate the production of maternal antibodies against antigens on the fetal red cell not inherited from the mother. These maternal antibodies cross into the fetal circulation and cause destruction of fetal cells. In severe cases, hydrops fetalis may result. Fetal-maternal ABO incompatibility is the most common cause of hemolytic disease of the newborn (HDNB), but Rh incompatibility is clinically more important because of the severity of the hemolytic disease in the fetus. With the introduction of Rh treatment, the total incidence of HDNB in Rh-negative women has been greatly reduced.<sup>60,63</sup>

**Laboratory features.** Anemia, **reticulocytosis** (an increased number of circulating reticulocytes), and nucleated red cells are seen in the peripheral blood of the infant. There is a rough correlation between the hemoglobin levels and the severity of the disease. Untreated infants may experience a rapid drop in hemoglobin levels after birth. Leukocytosis is present, but platelet counts are usually normal. Infants with severe disease may have thrombocytopenia. Serum bilirubin, a hemolytic breakdown product, is readily transferred across the placenta. At birth, the infant's total bilirubin level reflects both the severity of the hemolytic process and the ability of the infant's liver enzyme system to conjugate and excrete bilirubin. Cord blood red cells show a characteristic positive direct antiglobulin test (**Coombs test**), reflecting the maternal antibodies attached to the infant's red cells.<sup>60,63</sup>

During pregnancy, laboratory tests of amniotic fluid for bilirubin and antibodies and tests of the mother's peripheral blood for maternal sensitization are useful in predicting whether infants will be affected by HDNB.<sup>60,63</sup>

**Clinical manifestations.** The clinical manifestations of HDNB are hemolytic anemia, extramedullary erythropoiesis, and hyperbilirubinemia. Jaundice, petechial hemorrhages, hepatomegaly, splenomegaly, heart failure (with pulmonary edema, pleural effusions, ascites, and edema), kernicterus (a condition in the newborn marked by severe neural symptoms, associated with high levels of bilirubin in the blood), and diffuse intravascular coagulation are seen in these infants. Many infants die in utero.<sup>60,63</sup>

**Treatment.** A standard dose of anti-Rh immunoglobulin (RhoGAM) is given to the mother before or after delivery. This immunoglobulin destroys the infant's RBCs before they can sensitize the mother. This dose protects the mother against 30 ml of Rh-positive blood. Amniocentesis and fetal blood sampling are used to evaluate the severity of the disease. In severe cases, in utero transfusion and early delivery have been performed on fetuses with severe **erythroblastosis**. Exchange transfusion lowers the serum bilirubin level and the antibody content of the neonatal blood and removes cells susceptible to hemolysis. Phototherapy and phenobarbital are used to lower the bilirubin level.<sup>60,63</sup>

**Course and prognosis.** The consequences of HDNB range from death, to possible retardation, to a barely perceptible hemolytic process. Severe anemia correlates with equally severe hyperbilirubinemia and

**TABLE 13-8 MECHANISMS OF DRUG-INDUCED HEMOLYSIS OR POSITIVE DIRECT ANTIGLOBULIN TEST**

	DRUG ABSORPTION	NEOANTIGEN	AUTOIMMUNE	NONIMMUNE ABSORPTION
Prototype drug	Penicillin	Quinidine/stibophen	$\alpha$ -Methyldopa	First-generation cephalosporins
Role of drug	Cell-bound hapten	Antibody binds drug + RBC	Induces drug-independent RBC antibody	Modifies RBC membrane; absorbs proteins nonantibody-specifically
Typical DAT	IgG	C3	IgG	Nonimmunoglobulin
Antibody reactions	Reacts only with drug-coated cells	Reacts only with drug present	Drug independent; panagglutinin	No antibody present
Typical clinical presentation	Subacute onset; mild to severe hemolysis	Acute onset; severe hemolysis	Insidious onset; chronic mild hemolysis	No hemolysis

From Greer JP et al, editors: *Wintrube's clinical hematology*, ed 11, Philadelphia, 2004, Lippincott Williams & Wilkins, p 1176. C3, Complement third component; DAT, direct antiglobulin test; IgG, immunoglobulin G; RBC, red blood cell.

high risk of central nervous system complications.<sup>60,63</sup> Many infants appear normal at birth, only to develop jaundice within 2 to 3 hours. Petechial hemorrhages develop soon after birth, and kernicterus is usually seen late in the second day of significant jaundice. Successful Rh-GAM administration prevention programs have reduced the perinatal death rate to about 1% to 2%.<sup>60,63</sup>

### Antibody-Mediated Drug Reactions

**Etiology and pathogenesis.** Drug-induced immune hemolytic anemia is an example of a disease in which exposure to a drug causes destruction and lysis of the sensitized person's own red cells. Drugs can lead to red cell hemolysis by four different immune mechanisms (Table 13-8).<sup>53,59,61,62,64</sup>

**Hapten mechanisms.** In the hapten mechanism, which is seen with penicillin, cephalosporins, and tetracycline, the drug combines with a component of the RBC membrane. An antibody is developed against the drug. When the drug is given again, it coats the red cells, and the antibody attaches to the drug–red cell complex. The antigen-antibody complex then causes hemolysis.<sup>53,59,61,62,64</sup>

**Neoantigen formation.** The old terminology for neoantigen formation is *immune complex formation*. In this situation, the drug combines with the RBC membrane and the antibody reacts with the new antigenic sites created by the combination of the drug and membrane. The RBC is hemolyzed. The immune complex can also bind to platelet and leukocyte membranes, causing anemia, leukopenia, and thrombocytopenia. Quinidine, hydrochlorothiazide, sulfonamides, isoniazid, tetracycline, and cephalosporin are common drugs that cause this type of reaction.<sup>53,59,61,62,64</sup>

**Membrane modification.** In membrane modification, seen in cephalosporin sensitivity, the drug alters the RBC membrane protein. Plasma proteins attach to the altered RBC protein and cause a positive serologic test but no cell hemolysis.<sup>61</sup>

**Autoantibody induction.** This mechanism was first studied in cases of hemolytic anemia with patients who were taking the antihypertensive agent methyldopa (Aldomet). The drug appears to induce antibody formation to red cell membrane Rh antigens. About 29% of the patients receiving this drug develop a positive antiglobulin test response.<sup>53,59,61,62,64</sup>

**Laboratory features.** The laboratory features for all mechanisms show increased red cell turnover and anemia if hemolysis exceeds the rate of RBC production. Serologic tests, such as the direct antiglobulin test, will be positive. In hapten antibody-mediated drug reactions and

**FIGURE 13-21** Schistocytes are fragments of red blood cells produced by hemolytic pathologies. (Courtesy Beth Payne, Sacred Heart Medical Center, Spokane, WA.)

in immune complex formation, the antiglobulin reaction is positive for immunoglobulins. In autoantibody induction, the antiglobulin reaction is positive for complement. Fragmented RBCs may be seen on the peripheral blood smear. These fragments are called *schistocytes* (Figure 13-21). Leukopenia and thrombocytopenia are sometimes seen with drug-induced platelet or leukocyte destruction.<sup>53,59,61,62,64</sup>

**Clinical manifestations.** Types of immune drug-induced hemolytic anemia vary in symptoms and severity, depending on the mechanism involved. Hapten (e.g., penicillin) and autoimmune (e.g., methyldopa) drug-induced hemolytic anemias have an insidious onset of symptoms over a period of weeks. The neoantigen formation (e.g., quinine or quinidine) may present with sudden, severe hemolysis with hemoglobinuria and result in acute renal failure. Other clinical manifestations include acute respiratory distress syndrome and respiratory arrest.<sup>53,59,61,62,64</sup>

**Treatment.** Recognition and discontinuation of the responsible drug are usually the only treatment necessary. Steroid therapy and transfusions may be required in cases of severe hemolysis.<sup>53,59,61,62,64</sup>

**Course and prognosis.** Immune hemolytic anemia attributable to drugs is usually mild and the prognosis is good; however, with severe hemolysis, death can occur.<sup>53,59,61,62,64</sup> Laboratory findings for erythrocyte disorders are summarized in Table 13-5.

### Acute Blood Loss

**Etiology and pathogenesis.** Acute blood loss anemia may present after trauma or secondary to a disease process. Acute blood loss anemia rapidly decreases the overall blood volume and impairs oxygen delivery.<sup>65,66</sup>

**Laboratory features.** A decrease occurs in both hematocrit level and hemoglobin concentration attributable to blood loss. The hematocrit level is less than 40% in men and less than 37% in women. The hemoglobin concentration is less than 14 g/dl in men and less than 12 g/dl in women.<sup>65</sup> Anemia may not be apparent in the early stages because the cells and plasma are diminishing simultaneously. As replacement fluids move into the intravascular space, the anemia becomes apparent in later laboratory tests. The cells have normal MCV, MCH, and MCHC values.

**Clinical manifestations.** In a normal 70-kg person with a 5000-ml total blood volume, 10% loss of blood (500 ml) rarely causes any clinical signs except occasional vasovagal syncope. A 20% loss (1000 ml) usually causes no clinical symptoms at rest, but tachycardia is seen with exercise, and a slight postural drop in blood pressure occurs.<sup>65,66</sup> A person with a 30% loss (1500 ml) usually presents with flat neck veins when supine, postural hypotension, and exercise tachycardia. A 40% loss (2000 ml) causes the central venous pressure, cardiac output, and arterial blood pressure to fall below normal while the patient is supine and at rest, with associated air hunger, tachycardia, and cold, clammy skin. A 50% loss of total blood volume (2500 ml) often causes shock and death.<sup>65,66</sup>

**Treatment.** Blood volume replacement therapy with crystalloid solutions, colloid solutions (plasma protein, albumin, or dextran), and fresh whole blood is essential in the early management of acute hemorrhage to restore blood volume and to prevent shock. Complete reliance on fresh whole blood for managing acute blood loss is contraindicated and should be reserved for patients with a low red cell mass, in whom tissue hypoxia is a threat. Replacement of red cell mass by increased red cell production is a gradual process, which occurs over 2 to 5 days as the marrow stem cells proliferate and mature. Maximal red cell production is seen by the tenth day after hemorrhage.<sup>65,66</sup>

**Course and prognosis.** With adequate replacement therapy, the prognosis is excellent; however, the underlying cause must be identified and managed.

### Other Extrinsic Abnormalities

Other *mechanisms*, such as mechanical heart valves or cardiopulmonary bypass machines, may cause physical damage to the red cells, resulting in hemolysis. Drugs and chemicals, physical agents (e.g., burns), or infectious diseases (e.g., malaria) may result in anemia. Venom from bee and wasp stings, spider and scorpion bites, and snake bites has been associated with hemolytic anemia. Finally, hypersplenism and splenomegaly can cause anemia, leukopenia, or **thrombocytopenia** severe enough to require splenectomy.<sup>67</sup>

#### KEY POINTS

- The general effects of anemia are due to tissue hypoxia and efforts to compensate for low oxygen-carrying capacity. Vasoconstriction, pallor, tachypnea, dyspnea, tachycardia, ischemic pain, lethargy, and lightheadedness may be present. In addition, signs and symptoms relating to the specific cause of the anemia may be present. These accompanying manifestations are helpful in determining the cause of the anemia.
- Anemia may be due to abnormally low production of red cells and/or excessive loss or destruction. Decreased production of red cells may be due to stem cell failure (aplastic anemia), lack of erythropoietin (renal disease), or nutritional deficiencies of iron, vitamin B<sub>12</sub>, or folate. Excessive red cell loss may be due to hemolysis (e.g., ABO and Rh incompatibility, drugs) or bleeding (e.g., surgery, trauma). Inherited disorders of red cells often impair production and increase destruction of red cells.

- Determination of the cause of anemia is based on the history, differential signs and symptoms, and results of laboratory studies. The important differentiating features of the major types of anemia are as follows:
  - **Aplastic anemia:** History of toxic or radiation injury to bone marrow. Accompanying leukopenia and thrombocytopenia. Red cells are normocytic and normochromic.
  - **Chronic renal failure:** History of renal disease. Decreased erythropoietin level and erythropoietin responsiveness. Red cells are normocytic and normochromic.
  - **Vitamin B<sub>12</sub> and folate deficiency:** History of poor nutrient intake or gastrointestinal disease. Accompanying neurologic dysfunction. Red cells are megaloblastic (macrocytic).
  - **Iron deficiency:** History of poor nutrient intake or chronic blood loss. Decreased serum ferritin and iron levels. Red cells are microcytic and hypochromic.
  - **Hemolytic:** History of ABO or Rh incompatibility or drug exposure. Increased bilirubin level, jaundice, positive direct antiglobulin test. Red cells are normocytic and normochromic.
  - **Acute blood loss:** History of trauma, surgery, or known bleeding. Accompanying manifestations of volume depletion. Red cells are normal. Anemia may not be apparent until fluid loss is replaced.
- Inherited disorders of the red cell (thalassemia, sickle cell anemia, spherocytosis, G6PD deficiency) predispose red cells to early destruction because of abnormalities in hemoglobin structure, cell shape, membrane structure, or energy production. Manifestations of hemolysis (e.g., bilirubin, jaundice) are often present.
- The general management of anemia is aimed at removing the cause, if possible; restoring oxygen-carrying capacity with blood transfusion when necessary; and preventing the complications of ischemia (e.g., with rest, oxygen therapy) and hemolysis (e.g., increased fluid intake, management of high bilirubin levels).

## TRANSFUSION THERAPY

Medical indications for transfusion therapy are restoration or maintenance of oxygen-carrying capacity, blood volume, hemostasis, and leukocyte function. Red cell transfusions are administered to improve tissue oxygenation in the context of anemia or acute blood loss. Adaptive responses to a declining hemoglobin concentration include increased cardiac output, augmented oxygen extraction, blood flow redistribution to the heart and brain, a right shift in the oxyhemoglobin dissociation curve, and increased red cell production by the marrow. These compensatory mechanisms help to ensure continued oxygen delivery.<sup>17-20</sup> A summary of blood components, indications, actions, contraindications, precautions, and hazards is presented in Table 13-9.<sup>66,68</sup> Before transfusion therapy can occur, various donor tests are performed on the blood unit sample. These include ABO and Rh(D); syphilis; HIV antigen and antibodies; hepatitis B and C antigens; and human T-cell lymphotropic virus. Blood centers, which are producing plasma for fractionation, also test for alanine aminotransferase.<sup>68</sup> Specific pretransfusion testing using blood samples from the recipient and the donor unit must be done to ensure that the blood component will not harm the recipient and that the blood component will have an acceptable survival time when transfused. ABO and Rh typing and RBC antibody detection tests are performed, and then a cross-match between the donor unit and the recipient is performed.<sup>68</sup> Types of transfusion reactions, signs and symptoms, usual causes, treatment, and precautions are summarized in Table 13-10. Two serious complications of transfusion therapy include transfusion-related acute lung injury (TRALI) and transfusion-related circulatory overload (TACO). TRALI is a syndrome of acute hypoxia as a result of

noncardiogenic pulmonary edema that follows transfusion. All blood components have been implicated in TRALI, but plasma-containing products are more prevalent. Supportive care is the mainstay of therapy in TRALI with (1) oxygen supplementation, (2) aggressive respiratory support, and (3) intravenous administration of fluids as well as vasopressors, which are essential for blood pressure support. Corticosteroids can be beneficial and diuretics should be avoided in TRALI. TACO is defined as an expansion in the intravascular volume when the infused blood components and/or other fluids exceed the cardiovascular ability to handle the additional workload, and results in congestive heart failure. Diuretics are given in TACO along with the supportive care noted previously.<sup>66,68</sup>

## POLYCYTHEMIA

In polycythemia, red cells are present in excess, increasing blood viscosity, which in turn causes clinical manifestations such as hypertension. The three types of polycythemia are classified according to cause. *Polycythemia vera* is associated with neoplastic transformation of bone marrow stem cells. *Secondary polycythemia* is due to chronic hypoxemia, with a resultant increase in erythropoietin production. *Relative polycythemia* is due to dehydration, which causes a spurious increase in the RBC count.<sup>69,73</sup>

### Polycythemia Vera

**Etiology and pathogenesis.** Polycythemia vera or primary polycythemia is a type of chronic **panmyelosis** (see Chapter 11) and is part of the spectrum of myeloproliferative disorders. Polycythemia vera arises from the transformation of a single stem cell into a cell with a selective growth advantage that gradually becomes the predominant source of marrow precursors. There is an overproduction of normal red cells, white cells, and platelets. As with many malignancies, the cause is unknown. Possible mechanisms for the proliferation include (1) unregulated neoplastic proliferation of stem cells, (2) presence of abnormal myeloproliferative factor acting on normal stem cells, and (3) increase of stem cell sensitivity to erythropoietin and other hematopoietins.<sup>69-73</sup> Some researchers have postulated that it is damage to the undifferentiated stem cell by a virus, radiation, drugs, or other agents that causes mutation and subsequent neoplastic transformation.<sup>69-73</sup>

**Laboratory features.** The diagnosis depends primarily on results of laboratory studies, which show an absolute increase in red cell mass and leukocytosis and thrombocytosis. The bone marrow shows **hyperplasia** of red cells, white cells, and platelets and extension of active hematopoietic marrow into bones of the extremities. Uric acid concentration is increased because of excessive cell proliferation, which results in the destruction of an increased number of cells. Arterial oxygen saturation is normal, which differentiates polycythemia vera from the more common secondary (hypoxemic) polycythemia. Additional findings include elevated serum vitamin B<sub>12</sub> and elevated leukocyte alkaline phosphatase levels (Figure 13-22).<sup>69-73</sup>

**Clinical manifestations.** Symptoms include headache, backache, weakness, fatigue on exertion, pruritus, dizziness, sweating, visual disturbances, weight loss, paresthesias, dyspnea, joint complaints, and epigastric distress and pressure.<sup>69-73</sup> Common clinical manifestations include hypertension, thrombosis, and mucosal hemorrhage attributable to engorgement of retinal and sublingual veins, but each phase of the disease presents somewhat differently. Most of the clinical symptoms of polycythemia vera are related to the increased red cell mass, which gives rise to an increased blood viscosity. The liver and spleen become congested, which increases the risk of clots, acidosis, and organ infarction. The onset is insidious, with variable manifestations in virtually any organ system. Clinical symptoms appear

between 60 and 80 years of age, and they appear more often in men and Caucasians. The disorder is rarely seen in children. In the pre-erythrocytic or developmental phase, hepatosplenomegaly, night sweats, and postbathing pruritus are common. Other patients experience mild thrombohemorrhagic symptoms or **erythromelalgia** (painful erythematous palms and soles from an increased number of circulating platelets).<sup>69-73</sup>

The evolution of polycythemia vera is shown in Figure 13-23. The phases include an asymptomatic phase, a plethoric or erythrocytic phase, an inactive phase, and a spent phase when anemia develops. The final evolutionary phase of polycythemia vera is that of acute myeloid leukemia.<sup>69-73</sup>

In the erythrocytic phase, occlusive vascular lesions, such as transient ischemic attacks, cerebrovascular accidents (strokes), myocardial ischemia or infarctions, portal venous obstruction, or superficial venous thrombosis, occur and may be the first indication of the presence of the disease. The hyperviscosity produces symptoms of reduced cerebral blood flow, such as headaches, dizziness, and visual disturbances. Walking may induce leg pain and spasm, called *intermittent claudication*.<sup>69-73</sup>

Mucosal hemorrhagic manifestations include epistaxis, ecchymosis, and gastrointestinal and genitourinary bleeding. Progressive splenomegaly, intermittent claudication, peptic ulcer, hyperuricemia, and gout are often seen. The most striking feature is a ruddy or florid face, telangiectasis (chronic dilation of capillaries and small arterial branches, producing small, reddish tumors of the skin) of the cheeks and nose, and purplish cyanosis of the lips and ears. Hypertension is seen in about half of patients. Distention of the retinal veins with a dark purple coloration is another important clinical finding. As the disease develops into the spent or postpolycythemia myeloid metaplasia phase, many patients complain only of **asthenia**; however, progressive hepatosplenomegaly, severe anemia, hemorrhage (particularly cutaneous), weight loss, and wasting often occur. The final phase is the development of acute myeloid leukemia.<sup>69-73</sup>

**Treatment.** There is no cure. Treatment is directed at reducing the increased blood volume, blood viscosity, red cell mass, and platelet counts by use of phlebotomy and myelosuppressive therapy with radioactive phosphorus and chemotherapeutic agents. Phlebotomy of 450 to 500 ml every 2 to 4 days until a normal hematocrit level is reached alleviates many symptoms for most patients. Phlebotomy of only 200 to 300 ml should be considered for elderly patients or those with cardiovascular disease. In the past, a hematocrit of 50% was used as the upper limit of hematocrit tolerated before phlebotomy was used. Studies have found that increased vascular complications, decreased cerebral blood flow, and decreased mental alertness occurred when hematocrit levels exceeded 45%. Hematocrit levels should be maintained at 42% for females and 45% for males. Phlebotomy is effective in controlling red cell mass, but myelosuppressive therapy is needed when the platelet count increases to more than 800,000-1,000,000/ $\mu$ L to control hepatosplenomegaly and thrombocytosis. The agent of choice for myelosuppressive therapy is hydroxyurea, but radioactive phosphorus is also used. Hyperuricemia is treated with allopurinol (100 to 300 mg/day), pegylated interferon (90 to 180  $\mu$ g/week), or interferon- $\alpha$  ( $3 \times 10^6$  units three times a week; alter dose depending on response and toxicity). Pegylated interferon, which can be administered once weekly, should be considered. As the disease progresses, thrombosis or hemorrhage, systemic symptoms, severe pruritus refractory to histamine antagonists, and painful splenomegaly occur and a splenectomy is indicated.<sup>69-73</sup>

**Course and prognosis.** Unmanaged polycythemia vera has a poor prognosis, with a survival of less than 2 years. The prognosis depends on the nature and severity of the complications, the duration of the

**TABLE 13-9 SUMMARY OF BLOOD COMPONENTS**

COMPONENT*	MAJOR INDICATIONS	ACTION	NOT INDICATED FOR THESE CONDITIONS	SPECIAL PRECAUTIONS	HAZARDS	RATE OF INFUSION
Whole blood	Symptomatic anemia with large volume deficit	Increases oxygen-carrying capacity Increases blood volume	Condition responsive to specific component Treatment of coagulopathy	Must be ABO identical; labile coagulation factors deteriorate within 24 hr after collection	Infectious diseases Hemolytic, septic/toxic, allergic, febrile reactions TACO TRALI TA-GVHD	For massive loss, as fast as patient can tolerate
Whole blood irradiated	See <i>Whole blood</i> Increased risk for TA-GVHD	See <i>Whole blood</i> Donor lymphocytes are inactivated, reducing risk of TA-GVHD	See <i>Whole blood</i>	See <i>Whole blood</i>	See <i>Whole blood</i>	See <i>Whole blood</i>
RBCs; RBCs (adenine-saline added) <sup>†</sup>	Symptomatic anemia	Increases oxygen-carrying capacity	Pharmacologically treatable anemia Coagulation deficiency Volume expansion	Must be ABO-compatible	Infectious diseases Hemolytic, septic/toxic, allergic, febrile reactions TACO TRALI TA-GVHD	As patient can tolerate, but <4 hr
RBCs, deglycerolized	See <i>RBCs</i> IgA deficiency with anaphylactoid reactions	See <i>RBCs</i> Deglycerolization removes plasma proteins Risk of allergic and febrile reactions reduced	See <i>RBCs</i>	See <i>RBCs</i>	See <i>RBCs</i> Hemolysis due to incomplete deglycerolization can occur	See <i>RBCs</i>
RBCs, irradiated	See <i>RBCs</i> Increased risk for TA-GVHD	See <i>RBCs</i> Donor lymphocytes are inactivated, reducing risk of TA-GVHD	See <i>RBCs</i>	See <i>RBCs</i>	See <i>RBCs</i>	See <i>RBCs</i>
RBCs, leukocytes reduced; apheresis red blood cells, leukocytes reduced	Symptomatic anemia Reduces risk of febrile reactions	Increases oxygen-carrying capacity Reduces risk of febrile reactions from leukocyte antibodies, HLA alloimmunization, and CMV infection	Pharmacologically treatable anemia; coagulation deficiency Leukocyte reduction should not be used to prevent TA-GVHD	Must be ABO-compatible Hypotensive reaction may occur if bedside leukocyte reduction filter is used	Infectious diseases Hemolytic, septic/toxic, allergic reactions (unless plasma also removed [e.g., by washing]) TACO TRALI TA-GVHD	As patient can tolerate, but <4 hr
RBCs washed	See <i>RBCs</i> IgA deficiency with anaphylactoid reactions Recurrent severe allergic reactions to unwashed red cell products	See <i>RBCs</i> Washing reduces plasma proteins Risk of allergic reactions may be reduced	See <i>RBCs</i>	See <i>RBCs</i>	See <i>RBCs</i>	See <i>RBCs</i>
Fresh-frozen plasma (FFP)	Clinically significant deficit of labile and stable plasma protein coagulation factors and TTP	Source of labile and nonlabile plasma proteins, including all coagulation factors	Volume expansion Coagulopathy can be more effectively treated with specific therapy	Must be ABO-compatible	Infectious diseases Hemolytic, septic/toxic, allergic, febrile reactions TACO TRALI TA-GVHD	<4 hr

Liquid plasma, plasma, and thawed plasma	Bleeding patients with deficit of stable coagulation factors	Source of plasma proteins and nonlabile factors	Deficit of labile coagulation factors or volume replacement	Must be ABO-compatible	Infectious diseases Allergic reactions TACO TRALI	<4 hr
Plasma, cryoprecipitate reduced	TTP	See <i>FFP</i> Deficient in fibrinogen; factors I, VIII, vWF, and XIII Deficient in high molecular weight vWF multimers as compared to FFP	Volume expansion Deficiency of coagulation factors known to be depleted in this product, fibrinogen, and factors I, VIII, vWF, and XIII	Must be ABO-compatible	See <i>FFP</i>	<4 hr
Cryoprecipitated AHF; pooled cryoprecipitated AHF	Provides fibrinogen, vWF, factor XIII, and factor VIII	Provides fibrinogen, vWF, factor XIII <sup>‡</sup>	Deficit of any plasma protein other than those enriched in cryoprecipitated AHF	Frequent repeat doses may be necessary	Infectious diseases Allergic reactions	<4 hr
Platelets; platelets pooled	Bleeding from thrombocytopenia or platelet function abnormality Prevention of bleeding from marrow hypoplasia	Improves hemostasis	Plasma coagulation deficits Some conditions with rapid platelet destruction (e.g., ITP, TTP) unless life-threatening hemorrhage	Must be ABO-compatible with plasma Should not use some filters (check manufacturer's instructions)	Infectious diseases Hemolytic, septic/toxic, allergic, febrile reactions TACO TRALI TA-GVHD	<4 hr
Platelets, apheresis <sup>‡</sup>	See <i>Platelets</i>	See <i>Platelets</i> May be HLA or other antigen selected	See <i>Platelets</i>	See <i>Platelets</i>	See <i>Platelets</i>	See <i>Platelets</i>

TABLE 13-10 TRANSFUSION REACTIONS

TYPE	SIGNS AND SYMPTOMS	USUAL CAUSE	TREATMENT	PRECAUTIONS
Acute intravascular hemolytic (immune)	Hemoglobinemia and hemoglobinuria, fever, chills, anxiety, shock, disseminated intravascular coagulation (DIC), dyspnea, chest pain, flank pain, nausea/vomiting, headache, pain at needle site and along venous tract	Incompatibility because of clerical errors; involves ABO (primarily) or other erythrocyte antigen-antibody incompatibility	Stop transfusion; hydrate; support blood pressure and respiration; induce diuresis; treat shock and DIC	Positively identify donor and recipient blood types and groups before transfusion is begun; verify with one other nurse or physician. Transfuse blood slowly for first 15-20 min and/or initial one-fifth volume of blood; remain with patient. In event of signs or symptoms, stop transfusion immediately, maintain patent IV line, and notify physician. Save donor blood to re-cross-match with patient's blood. Monitor blood pressure for shock. Insert urinary catheter and monitor hourly outputs. Send sample of patient's blood and urine to laboratory to determine presence of hemoglobin (indicates intravascular hemolysis). Observe for signs of hemorrhage resulting from DIC. Support medical therapies to reverse shock.
Delayed extravascular hemolytic (immune)	Fever, malaise, indirect hyperbilirubinemia, increased urine urobilinogen, falling hematocrit and hemoglobin	Occurs in previously RBC-alloimmunized patients in whom antigen on transfused red cells provokes anamnestic production of antibody; destruction of RBCs; usually involves non-ABO antigen-antibody incompatibility occurring 2-14 days post-transfusion	Monitor hematocrit, renal function, coagulation profile; no acute treatment generally required	Observe for post-transfusion anemia and decreasing benefit from successive transfusion.
Graft versus host disease (GVHD) or TA-GVHD		Viable T lymphocytes react against tissue antigens in recipient Immunocompromised recipients most at risk		Use $\gamma$ -irradiated components to prevent TA-GVHD.
Febrile	Fever, chills, rarely hypotension	Antibodies to leukocytes or plasma proteins	Stop transfusion; give antipyretics, acetaminophen (or aspirin if patient not thrombocytopenic)	Use of leukocyte-poor RBCs is less likely to cause reaction.
Allergic	Urticaria (hives), flushing, wheezing, laryngeal edema, rarely hypotension or anaphylaxis	Antibodies to plasma proteins	Stop transfusion; give antihistamine; if severe, give epinephrine and/or steroids	Administer pretransfusion antihistamine; use washed RBC components.
Hypervolemic or TACO	Dyspnea, rales, hypertension, pulmonary edema, cardiac dysrhythmias, precordial pain, cyanosis, dry cough, distended neck veins	Transfusion-associated circulatory overload from too rapid or excessive blood transfusion	Induce diuresis; phlebotomy; support cardiorespiratory system as needed	Transfuse blood slowly. Prevent overload by using packed RBCs or administering divided amounts of blood. Use infusion pump to regulate and maintain flow rate. If signs of overload, stop transfusion immediately. Place patient in semi-Fowler position to increase venous resistance.

TRALI	Acute onset of hypoxemia within 6 hr of a blood or blood component transfusion; dyspnea, pulmonary edema, normal cardiac pressures	Anti-HLA or antileukocyte antibodies	Support blood pressure and aggressive respiratory support that may require intubation and mechanical ventilation	Use washed RBCs; avoid unnecessary transfusion.
Hypothermia	Chills, low temperature, irregular heart rate, possible cardiac arrest	Rapid infusion of cold blood products	Monitor temperature; if markedly subnormal, stop transfusion	Allow blood to warm at room temperature (<1 hr). Use an electric warming coil to rapidly warm blood.
Electrolyte disturbances, hyperkalemia	Nausea, diarrhea, muscular weakness, flaccid paralysis, paresthesia of extremities, bradycardia, apprehension, cardiac arrest	Massive transfusions or in patients with renal problems	Kayexalate enemas if potassium >5.0 mEq/L	Use washed RBCs or fresh blood if patient at risk.
Citrate intoxication (hypocalcemia)	Tingling in fingers, tetany, muscular cramps, carpopedal spasm, hyperactive reflexes, convulsions	Massive transfusion of blood	Stop transfusion; administer IV calcium if severe	Infuse blood slowly (citrate reaction less likely to occur). If signs of tetany occur, clamp tubing immediately, maintain patent intravenous line, and notify physician.
Air emboli	Sudden difficulty in breathing, sharp pain in chest, apprehension, respiratory or cardiac arrest	Air emboli from blood administered under pressure	Stop transfusion; turn patient on left side; aspirate right atrial/ventricular air emboli	When infusing blood under pressure before container is empty: if air is observed in tubing, clamp tubing immediately below air bubble, clear tubing of air by aspirating air with syringe or disconnecting tubing and allowing blood to flow until air has escaped.
Bacterial sepsis	Shock, chills, high fever	Bacterial contamination of blood component or endotoxin reaction seen more commonly with platelet components stored at room temperature	Stop transfusion; support blood pressure; give antibiotics	Use care in blood collection and storage.
Delayed reactions, transmission of infection	Signs of infection after transfusion (e.g., jaundice from hepatitis; bacterial or toxin contamination—high fever, severe headache or substernal pain, hypotension, intense flushing, vomiting/diarrhea)	Hepatitis, AIDS, malaria, syphilis, bacteria, viruses, other	Stop transfusion; do culture and sensitivity tests; treat specific infection	Blood is tested for HBsAg (hepatitis B), syphilis, and, in most centers, HIV (AIDS); positive units are destroyed. Individuals at risk for carrying certain viruses are deferred from donation. Observe for signs of infection.

**Diagnostic Algorithm for Polycythemia Based on Serum Epo Level**

**FIGURE 13-22** Algorithm showing differentiating features of different forms of polycythemia. *BFU-E*, Burst-forming unit-erythroid; *2,3-BPG*, 2,3-bisphosphoglycerate; *Epo*, erythropoietin; *EPOR*, erythropoietin receptor gene; *VHL*, von Hippel-Landau gene. (From Lichtman MA et al, editors: *Williams hematology*, ed 7, New York, 2006, McGraw-Hill, p 791.)

erythrocytotic phase, and the duration of the acute myeloid leukemia phase. Treatment in the erythrocytotic phase is essential, or the patient is at extremely high risk for thromboses. The development of thrombosis, hemorrhage, and myeloproliferative syndromes is common. Treated patients have a median survival of 10 to 15 years, with the most common causes of death being thrombosis, hemorrhage, leukemia, and other myeloproliferative conditions.<sup>69-73</sup>

### Secondary Polycythemia

**Etiology and pathogenesis.** Secondary polycythemia is absolute erythrocytosis caused by increased stimulation of RBC production, usually in response to tissue hypoxia caused by, for example, high altitude or lung disease. There are other less common types of secondary polycythemia that are caused by renal or other organ tumors, which cause an increase in erythropoietin production.<sup>69-70,74</sup>

Because this type of polycythemia demonstrates an increase in red cell mass with no involvement of other marrow elements, it is most commonly seen in association with a known hypoxic stimulus, increased erythropoietin concentration, or excess levels of adrenocortical steroids or androgens.<sup>69-70,74</sup>

**Laboratory features.** The laboratory findings confirm increased red cell production with no increase in white cells or platelets. Erythropoietin levels are increased.<sup>69-70,74</sup>

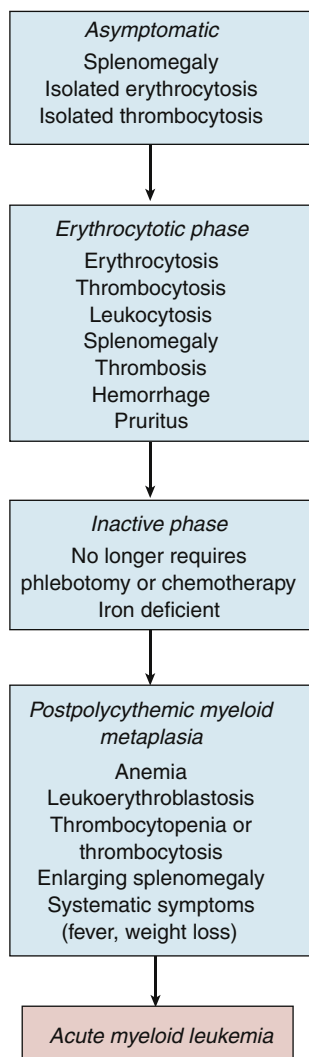

**Clinical manifestations.** The symptoms are those of the underlying disease state, such as cardiovascular disease with right-to-left shunt, chronic lung disease or alveolar hypoventilation, low barometric pressure and/or high altitude, or abnormal hemoglobin concentration.<sup>69-70,74</sup>

**Treatment.** Because this condition is a physiologic compensation, the clinical treatment is directed at identifying and managing the underlying cause. Phlebotomy has been used to reduce cardiovascular work and appears to be helpful in both cardiovascular and chronic obstructive pulmonary disease. Oxygen administration is helpful in chronic lung diseases.<sup>69-70,74</sup>

**Course and prognosis.** The course and prognosis are influenced by the underlying disease process.

### Relative Polycythemia

**Etiology and pathogenesis.** Relative (spurious) polycythemia is characterized by an increased hematocrit level in the presence of normal or decreased total RBC mass. Two types of patients manifest this characteristic. In the first group, the laboratory finding is secondary to an obvious disturbance in fluid balance such as is seen in severe dehydration or endocrinologic disorders. Patients in the other group, often described as having stress polycythemia, present with hypertension, increased hematocrit levels, and no increase in total RBC mass or obvious fluid loss. Research is continuing on the etiologic process and pathogenesis.<sup>69,74,75</sup>

**Evolution of Polycythemia Vera**

**FIGURE 13-23** Clinical evolution of polycythemia vera. (From Hoffman R et al, editors: *Hematology: basic principles and practice*, ed 4, New York, 2005, Churchill Livingstone, p 1216.)

**Laboratory features.** All hematologic tests are normal except for elevated hematocrit and hemoglobin levels and RBC count. The size and color of the red cell are normal. Increased levels of cholesterol and uric acid are common.<sup>70,74,75</sup>

**Clinical manifestations.** The manifestations are contingent on the underlying cause. In dehydration, the patient will have flat neck veins, decreased skin turgor, thirst, tachycardia, and, in severe cases, low cardiac output and blood pressure. If the underlying condition is stress related, the symptoms are those of a catecholamine stress response. Patients are usually Caucasian middle-aged men. In patients with spurious polycythemia caused by smoking, the problem is usually chronic, and the symptoms attributable to the hyperviscosity described for polycythemia vera are often found.<sup>70,74,75</sup>

**Treatment.** Because this is a spurious form of polycythemia, it is important to recognize and manage the underlying cause. Fluid administration and management will resolve dehydration; however, spurious polycythemia is likely to be associated with a long-term condition that will require concurrent medical management. When the condition is a result of stress, identification of the stressors and stress management are indicated, with long-term follow-up. In spurious polycythemia attributable to smoking, the patient must stop smoking in order for the condition to resolve.<sup>70,74,75</sup>

**Course and prognosis.** The long-term prognosis is excellent if the underlying condition is identified and resolved, but patients with chronic anxiety or an inability to quit smoking may experience the same complications related to erythrocytosis as are seen in polycythemia vera.<sup>70,74,75</sup>

**KEY POINTS**

- Three types of polycythemia have been identified, according to cause. Polycythemia vera is associated with neoplastic transformation of bone marrow stem cells. Secondary polycythemia is due to chronic hypoxemia, with a resultant increase in erythropoietin production. Relative polycythemia is due to dehydration, which causes a spurious increase in RBC count.
- Differential diagnosis of the type of polycythemia is based on the history and accompanying manifestations:
  - *Polycythemia vera*: Absence of hypoxemia and dehydration, accompanied by leukocytosis and thrombocytosis.
  - *Secondary polycythemia*: History of lung disease or living at high altitude. Hypoxemia evident on blood gas evaluation. Erythropoietin level is elevated.
  - *Relative polycythemia*: History of fluid loss or poor intake. Accompanying manifestations of dehydration.
- Treatment of polycythemia is aimed at removing the cause, if possible. Phlebotomy and bone marrow-suppressing agents may be used for polycythemia vera. Major complications of polycythemia are increased blood viscosity and the risk of thrombi.

## PEDIATRIC CONSIDERATIONS

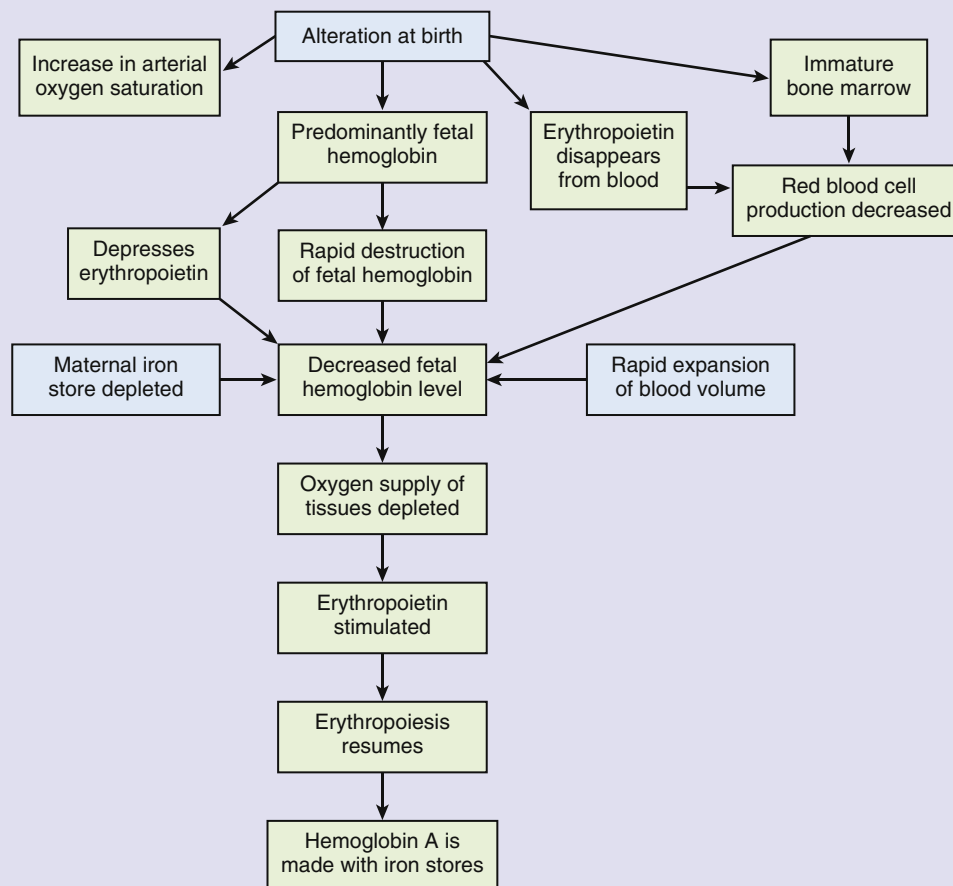

### Hemoglobin Synthesis in Infants

When an infant is born many mechanisms occur to decrease the infant's hemoglobin level. At birth, erythropoietin, a hormone that stimulates red blood cell production, disappears from blood plasma; there is an increase in arterial oxygen saturation and the infant is born with immature bone marrow. These mechanisms cause a slow rate of red blood cell production at birth. In addition, infants primarily have fetal hemoglobin, accounting for about 70% of their total hemoglobin. Although fetal hemoglobin is a more efficient oxygen carrier, it has a shorter life span than adult hemoglobin. This causes red blood cells to be turned over every 70 to 90 days, instead of 120 days for adult red blood cells. Also, fetal hemoglobin is thought to suppress production of erythropoietin.

Hemoglobin levels gradually decrease in the infant over the first 2 to 3 months because of the rapid destruction of fetal hemoglobin, decreased red blood cell

production, and depressed erythropoietin production. Additionally, the infant experiences rapid growth during this time, which creates quick expansion of blood volume that further dilutes the supply of hemoglobin. Maternal iron stores are rapidly depleting at this time and will gradually diminish by 6 months.

As fetal hemoglobin is metabolized, the iron is released and stored. The body has enough iron to synthesize hemoglobin, but it is not stimulated to create hemoglobin at this time. Hemoglobin levels will continue to decrease until the oxygen needs of the tissues in the body are sufficiently depleted enough to stimulate erythropoietin production. Release of erythropoietin causes erythropoiesis to resume. Adult hemoglobin is made at this time with the iron stored in the body. Hemoglobin level will increase steadily in the infant starting around 6 months of age and fetal hemoglobin is replaced by adult hemoglobin.

## SUMMARY

The purpose of the erythron is to ensure adequate oxygen delivery with respect to oxygen demand. This is enhanced by the unique ability of hemoglobin in RBCs to carry and release oxygen at a suitable tension to support energy-generating systems in the body tissues. Anemia, a deficit in RBCs, poses a serious threat to oxygen transport

and to the ability of the body to receive adequate oxygenation. Intense research in RBC physiology and pathophysiology continually yields new information for a better understanding of erythrocyte disorders, improved treatment modalities, and improved prognoses.

### KEY QUESTIONS

- How do platelets and factors of the clotting cascade contribute to hemostasis?
- What findings from the patient history, physical examination, or laboratory studies would indicate a potential bleeding disorder?
- How are laboratory tests used to differentiate the various coagulation disorders?
- What vascular alterations result in abnormalities of hemostasis?
- What are the common causes of platelet deficiencies, excesses, and dysfunction?
- What are the common causes of inherited and acquired disorders of coagulation?

The term **hemostasis** means arrest of bleeding or prevention of blood loss after a blood vessel is injured. Hemostasis is accomplished via a complex interaction involving the vessel wall, circulating platelets, and plasma coagulation proteins. If hemostasis is inadequate, bleeding results; if hemostasis is excessive, inappropriate clotting or thrombosis results.

This chapter reviews the process of hemostasis and describes how that process is evaluated by means of clinical assessment and laboratory tests. The focus of this chapter is disorders of hemostasis and coagulation that result in bleeding. Disorders that result in thrombosis are discussed in Chapter 15.

### THE PROCESS OF HEMOSTASIS

#### Stages of Hemostasis

Primary hemostasis, the initial response to vascular injury, involves the interaction between platelets and the endothelium of the injured blood vessel. The immediate response of the vessel to trauma is vasoconstriction to reduce blood loss. Although nervous reflex may play a part, this vasoconstriction results primarily from local myogenic spasm that may last from minutes to hours. The more trauma to the vessel, the greater the degree of vascular spasm.<sup>1</sup>

**FIGURE 14-1** Platelets are complex cell fragments containing numerous chemical mediators that are released when platelets are activated. Platelets display a variety of cell surface receptors that mediate both adhesion to exposed subendothelium and aggregation with other platelets. *ADP*, Adenosine diphosphate; *Epi*, epinephrine; *TxA<sub>2</sub>*, thromboxane A<sub>2</sub>; *vWF*, von Willebrand factor.

The second component of primary hemostasis is formation of a platelet plug. Platelets not only adhere to endothelial collagen exposed by injury but also aggregate (clump together) at the site of vessel injury. The formation of this platelet plug is usually completed within 3 to 7 minutes.

Secondary hemostasis involves the formation of a fibrin clot, or **coagulation**, at the site of injury to maintain the hemostasis already initiated. Clotting factors are activated via the **intrinsic pathway** or **extrinsic pathway**, and participate in a series of events that catalyze or facilitate the conversion of fibrinogen to fibrin.<sup>1</sup> This process takes an average of 3 to 10 minutes.

Clot retraction, the final stage of clot formation, occurs when the components of the fibrin clot—the platelet plug, fibrin strands, and trapped red blood cells—are compressed or contracted to form a firm clot. This stage takes approximately 1 hour.

### Platelets

Platelets have an integral role in hemostasis; thus, it is important to review their nature and function (Figure 14-1). A normal platelet count is between 150,000 and 400,000 platelets/mm<sup>3</sup> of blood. Platelets, also known as *thrombocytes*, are the smallest of the formed elements in the blood. They are produced in the bone marrow from megakaryocytes, which are derived from the pluripotent stem cell. Most of the platelets are found in the circulation and about 25% are sequestered in the liver and spleen.<sup>3</sup> Factors such as the stress response, epinephrine, and exercise may stimulate platelet production. The average life span of a platelet is 7 to 12 days. On completion of its life span, a platelet is eliminated from the circulation by the tissue macrophage system.<sup>1-3</sup>

Platelets play a complex role in the process of hemostasis. Initially, platelets adhere to subendothelial collagen exposed by trauma (Figure 14-2). After adhesion, the platelets become activated and initiate degranulation, the release of  $\alpha$  granules and dense bodies.  $\alpha$  granules release platelet thrombospondin, fibrinogen, fibronectin, von Willebrand factor (VWF), and coagulation factors V and VIII. The dense

granules release adenosine diphosphate (ADP), adenosine triphosphate (ATP), and serotonin. The presence of ADP and collagen encourages arachidonic acid formation, which leads to formation of thromboxane A<sub>2</sub> (TxA<sub>2</sub>, a potent platelet aggregation agonist). Aspirin and other cyclooxygenase enzyme inhibitors can be used to block this cascade. Thromboxane A<sub>2</sub> stimulates the glycoprotein IIb/IIIa (GpIIb/IIIa) receptors on platelets to be expressed and further promotes platelet adhesion. The glycoprotein IIb/IIIa blockers (e.g., eptifibatid) are useful antiplatelet agents.<sup>2-5</sup>

In addition to the major role platelets play in primary hemostasis, they are also involved in secondary hemostasis and clot retraction. Platelets catalyze interactions between activated coagulation factors, accelerating the conversion of prothrombin to thrombin. Platelets also have a role in clot retraction.

### Blood Coagulation Factors

With the exception of tissue factor (factor III; tissue thromboplastin) and calcium, blood coagulation factors are plasma proteins that circulate in the bloodstream in an inactive state. These factors are listed in Table 14-1 according to the internationally standardized nomenclature. The factors are numbered in the order of their discovery, not the order in which they participate in the clotting cascade. Factors with both active and inactive forms are differentiated with the letter “a” after the Roman numeral to designate the active form.

The liver is responsible for the synthesis of coagulation factors, with the exception of part of factor VIII. Factors II, VII, IX, and X; protein C; and protein S are dependent on vitamin K for synthesis and normal activity. Some of the coagulation proteins also can be synthesized by other cells, such as megakaryocytes and endothelial cells.<sup>4,5</sup> Antithrombin III (ATIII) and protein C are protein complexes that promote anticoagulation. Antithrombin is a potent anticoagulant that binds to and inactivates free thrombin, preventing its binding and cleaving of fibrinogen. Protein C, a plasma protein that inactivates factors V and VIII, prevents clot formation. Protein S assists protein C in binding to phospholipase and stimulates release of tissue plasminogen activator,

**FIGURE 14-2** **A**, Endothelial cells normally prevent platelet adhesion by releasing nitric oxide (NO) and prostaglandin I<sub>2</sub> (PGI<sub>2</sub>), which increases platelet cGMP and cAMP levels, reducing the likelihood of their being activated. **B**, Injury to the vessel wall exposes collagen and von Willebrand factor (vWF), which are bound by specific receptors on platelets, causing them to adhere and become activated. **C**, Activated platelets release numerous chemical mediators that bind to and stimulate other nearby platelets. Groups of platelets aggregate together by binding to fibrinogen molecules through their GpIIb/IIIa receptors. ADP, Adenosine diphosphate; TxA<sub>2</sub>, thromboxane A<sub>2</sub>.

**TABLE 14-1 THE CLOTTING FACTORS**

FACTOR	ACTION
I: Fibrinogen	Factor I is converted to fibrin by the enzyme thrombin. Individual fibrin molecules form fibrin threads, which are the scaffold for clot formation and wound healing.
II: Prothrombin	Factor II is the inactive precursor of thrombin. Prothrombin is activated to thrombin by coagulation factor X (Stuart-Prower factor). After it is activated, thrombin converts fibrinogen (coagulation factor I) into fibrin and activates factors V and VIII. Synthesis is vitamin K-dependent.
III: Tissue thromboplastin	Factor III interacts with factor VII to initiate the extrinsic clotting cascade.
IV: Calcium	Calcium (Ca <sup>2+</sup> ), a divalent cation, is a cofactor for most of the enzyme-activated processes required in blood coagulation. Calcium also enhances platelet aggregation and makes red blood cells clump together.
V: Proaccelerin	Factor V is a cofactor for activated factor X, which is essential for converting prothrombin to thrombin.
VI: Discovered to be an artifact	No factor VI is involved in blood coagulation.
VII: Proconvertin	Factor VII activates factors IX and X, which are essential in converting prothrombin to thrombin. Synthesis is vitamin K-dependent.
VIII: Antihemophilic factor	Factor VIII together with activated factor IX enzymatically activates factor X. In addition, factor VIII combines with another protein (von Willebrand factor) to help platelets adhere to capillary walls in areas of tissue injury.
IX: Plasma thromboplastin component (Christmas factor)	Factor IX, when activated, activates factor X to convert prothrombin to thrombin. This factor is essential in the common pathway between the intrinsic and extrinsic clotting cascades. A lack of factor IX is the basis for hemophilia B. Synthesis is vitamin K-dependent.
X: Stuart-Prower factor	Factor X, when activated, converts prothrombin into thrombin. Synthesis is vitamin K-dependent.
XI: Plasma thromboplastin antecedent	Factor XI, when activated, assists in the activation of factor IX. However, a similar factor must exist in tissues. People who are deficient in factor XI have mild bleeding problems after surgery but do not bleed excessively as a result of trauma.
XII: Hageman factor	Factor XII is critically important in the intrinsic pathway for the activation of factor XI.
XIII: Fibrin-stabilizing factor	Factor XIII assists in forming cross-links among the fibrin threads to form a strong fibrin clot.

From Ignatavicius DD, Workman ML: *Medical surgical nursing: patient-centered collaborative care*, ed 7, Philadelphia, 2013, Saunders, p 860.

initiating fibrinolysis.<sup>4,5</sup> Low-molecular-weight heparins and heparin work by enhancing the activity of antithrombin III (Figure 14-3).

### Fibrin Clot

In normal hemostasis, the fibrin clot is produced through activation of the intrinsic or extrinsic pathway and, in turn, the common final

pathway. Effective hemostasis is the result of interactions between all of these pathways and is commonly referred to as the *coagulation cascade*.

Figure 14-4 illustrates the coagulation cascade. The intrinsic pathway of coagulation begins when blood comes into contact with altered vascular endothelium or another negatively charged surface, such as

**FIGURE 14-3** Antithrombin III (ATIII) can bind and neutralize the activity of thrombin. Heparin is a catalyst that increases the activity of ATIII, making it more effective. Thrombin is a potent inducer of clot formation; thus, ATIII and heparin have significant anticoagulant properties.

glass. This contact phase of coagulation involves four factors: (1) factor XII, (2) high-molecular-weight kininogen (HMWK), (3) prekallikrein, and (4) factor XI. Factor XII is activated to factor XIIa, which in turn activates XI to XIa and prekallikrein to its active form, kallikrein (KAL). Kallikrein liberates bradykinin from HMWK. The release of bradykinin produces an initial vasodilation followed by release of angiotensin II and vasoconstriction. The major role of factor XIa is activation of factor IX to factor IXa in the presence of calcium. Factor IXa then activates factor X to factor Xa in the presence of factor VIII, calcium, and phospholipid. This activation usually takes place on the membrane of stimulated platelets. The common final pathway is initiated by factor Xa.

The extrinsic pathway of coagulation begins when the vascular wall is traumatized, as in a crush injury. Tissue factor (factor III) from injured tissue activates factor VII. Factor VIIa activates factor X to Xa, which in turn initiates the common final pathway. Factor VIIa also activates factor IX in the intrinsic system.

The common final pathway of coagulation is initiated by factor X, which is activated by both the intrinsic and extrinsic pathways. Factor Xa, in the presence of factor V, calcium, and phospholipid, converts prothrombin (factor II) to thrombin. This conversion is facilitated by the presence of activated platelets. Thrombin then cleaves fibrinogen to form an insoluble fibrin clot. Thrombin also activates factor XIII, which promotes fibrin stabilization. The clot is further stabilized by clot retraction. Thrombin also helps to perpetuate the clotting cascade by continuing to activate factors V and VIII.

### Fibrinolysis

At the same time the fibrin clot is forming, the process of **fibrinolysis** or clot dissolution is initiated (Figure 14-5). Factor XII, HMWK, kallikrein, and thrombin are involved in the release of plasminogen activators. The plasminogen activators cleave plasminogen, a plasma protein that has been incorporated into the fibrin clot, to its active form, plasmin. Plasmin digests fibrinogen and fibrin and inactivates blood coagulation factors V and VIII. Fibrin split products, or fibrin degradation products, result from the dissolution of the fibrin clot.

The control of fibrinolysis is complex. The Kupffer cells of the liver and macrophages located in the spleen and bone marrow clear the circulation of activated clotting factors and fibrin degradation products. Antiplasmins that inhibit plasmin exist to prevent inappropriate fibrinolysis. All these factors and mechanisms are present to create a balance between clot production and clot dissolution.

### KEY POINTS

- Hemostasis involves several critical steps. These include vasospasm, formation of a platelet plug, and activation of the clotting cascade to form a fibrin clot.
- Factors released from platelets contribute to hemostasis by enhancing vasoconstriction, platelet aggregation, and vessel repair.
- Fibrin clot formation can be initiated by the intrinsic or extrinsic pathway. Each pathway requires the sequential activation of specific clotting factors, ultimately resulting in enzymatic cleavage of fibrinogen to form an insoluble fibrin clot.
- Initiation of fibrinolysis occurs simultaneously with clot formation to prevent excessive clotting and vessel occlusion.

## EVALUATION OF HEMOSTASIS AND COAGULATION

Data obtained from clinical assessment and laboratory tests facilitate the identification and evaluation of a hemostatic abnormality. Evaluation of a patient for a bleeding tendency is indicated in the following circumstances: when there is a personal or family history of bleeding; during active bleeding that is unresponsive to standard interventions; as part of screening before surgery; and for ongoing evaluation of anticoagulation therapy. A bleeding tendency may be inherited or acquired, and may result from defects in blood vessels, platelets, or coagulation factors. The purpose of the evaluation process is to determine if a problem exists and to ascertain the underlying cause so that appropriate management can be initiated.

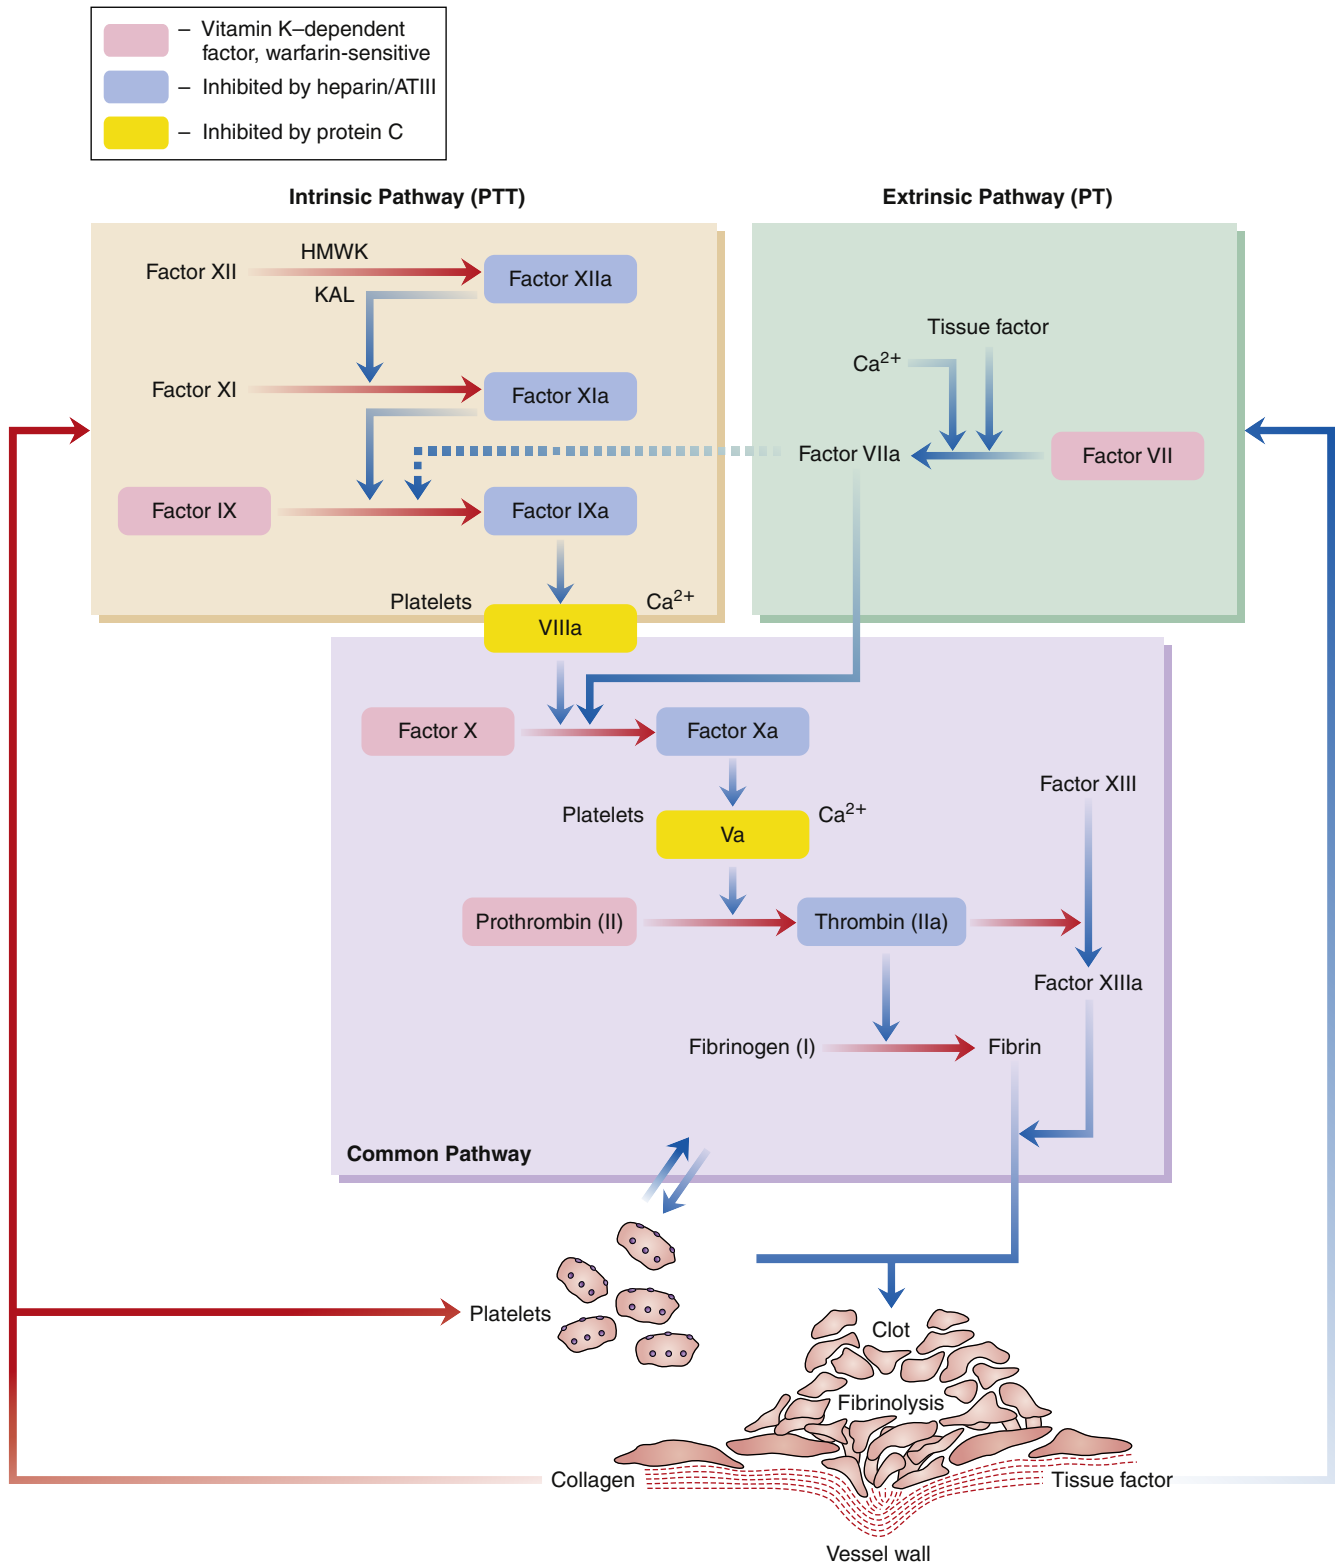

### Clinical Assessment

Both the family history and the personal history are important in the evaluation of a bleeding problem (Table 14-2). A family history of bleeding in males is often linked to one of the types of hemophilia, which accounts for the majority of serious inherited coagulation problems.<sup>4,5</sup> The location, severity, duration, and setting in which bleeding occurs are also important clues to the type of defect that is present. Bleeding associated with vascular or platelet defects usually occurs immediately after trauma (e.g., dental extraction), involves skin or mucous membranes, and is brief. Delayed bleeding or bleeding into muscles or joints is more typical of a coagulation defect.<sup>5-8</sup>

Systemic diseases, such as renal failure, liver disease, systemic lupus erythematosus, and malignancies, may be associated with a bleeding problem. Medication history, including use of over-the-counter medications, is another important aspect in the evaluation of a hemostatic defect. A common cause of acquired bleeding problems is drug ingestion. Specific drugs that alter hemostasis include aspirin and aspirin-containing preparations, nonsteroidal antiinflammatory agents, some antibiotics, anticoagulants, alcohol, and chemotherapeutic and thrombolytic agents.

Many of the physical findings of bleeding are manifested in the skin and mucous membranes. The individual may appear pale or jaundiced. Pallor is associated with a marked decrease in hemoglobin level; jaundice is associated with liver or gallbladder disease, possible coagulation disorders, and excessive red blood cell destruction.

**Petechiae** are flat, pinpoint, nonblanching red or purple spots caused by capillary hemorrhages in the skin and mucous membranes (Figure 14-6). Petechiae are commonly seen with vascular and platelet disorders. They are usually present on dependent areas of the body, such as the legs, or on areas constricted by tight clothing. Not all petechiae indicate a bleeding problem. Petechiae found on other body areas not constricted by tight clothing, such as the abdomen or thorax, may be associated with infectious disease or other pathophysiologic sources. Petechiae may be seen in the newborn as a result of the trauma of delivery, not as a result of a bleeding problem.

**FIGURE 14-4** Coagulation cascade. *PT*, Prothrombin time; *PTT*, partial thromboplastin time.

When petechiae occur in groups or patches, the term **purpura** is used (Figure 14-7). Purpuric lesions are often pruritic (itchy). Fever and malaise may be present, as may effusions into joints or viscera, manifested by joint or abdominal pain.

**Ecchymosis** occurs when blood escapes into the tissues, producing a bruise (Figure 14-8). If the area is raised, it is called a **hematoma**.

**Hemarthrosis**, manifested by swelling and pain, is bleeding into a joint. Large ecchymoses, hematomas, and hemarthroses are seen in coagulation disorders.

**Telangiectasia** is a lesion created by dilation of capillaries and small arteries, typically on the lips, tongue, tips of the fingers and toes, and sometimes in visceral vessels (Figure 14-9). These thin, dilated, tortuous

**FIGURE 14-5** Fibrinolysis. Plasmin, activated from plasminogen, enzymatically cleaves fibrin proteins in the clot. This results in fibrin split products, which can be measured.

**FIGURE 14-6** Petechiae. (From Dockery GL: *Cutaneous disorders of the lower extremity*, Philadelphia, 1997, Saunders.)

**TABLE 14-2 CLUES FROM PATIENT HISTORY REGARDING BLEEDING DISORDERS**

CLUE FROM PATIENT HISTORY	POSSIBLE CAUSE
Family history of bleeding in both males and females	von Willebrand disease
Family history of bleeding in males	Hemophilia A or B
Newly acquired bruising	Drugs (especially aspirin and NSAIDs, anticoagulant therapy), thrombocytopenia
Excessive bleeding/bruising during/after surgery	Mild-severe deficiency of coagulation factors, von Willebrand disease; thrombocytopenia, drug ingestion
Bleeding following initial hemostasis	Factor XIII deficiency

NSAIDs, Nonsteroidal antiinflammatory drugs.

vessels are red to violet in color, blanch with pressure, and tend to bleed with minimal trauma. Spider telangiectasia branch into the subcutaneous and dermal layers of the skin and are often associated with liver disease.

Other significant findings indicative of a bleeding disorder include blood (bright red, rusty, or black) in drainage or excreta, such as feces (**hematochezia** or **melena**), urine (**hematuria**), vomitus (**hematemesis**), nasal drainage (**epistaxis**), gastric drainage, or sputum (**hemoptysis**). Excessive menstrual bleeding may occur (**menorrhagia**). Acute abdominal or flank pain may indicate internal bleeding. Hypovolemia from bleeding may produce a shock state and present as hypotension, tachycardia, pallor, altered mentation, and decreased urine output. The two sites at which bleeding is most life threatening are the oropharynx

**FIGURE 14-7** Purpura. (From Hurwitz S: *Clinical pediatric dermatology: a textbook of skin disorders of childhood and adolescence*, ed 2, Philadelphia, 1993, Saunders, p 269.)

(resulting in airway compromise) and within the brain tissue. One of the leading causes of death in patients experiencing severe disorders of coagulation is intracerebral hemorrhage.<sup>5</sup>

### Laboratory Tests

Many laboratory tests are available to aid in the diagnosis of hemostasis problems (Table 14-3). Basic screening includes a complete blood

**FIGURE 14-8** Ecchymosis. A large patch of capillary bleeding into tissues. Color in a light-skinned person is first red-blue or purple (1) immediately after or within 24 hours of trauma and generally progresses to blue to purple (2), blue-green (3), yellow (4), and brown to disappearing (5). (From Jarvis C: *Physical examination and health assessment*, ed 6, Philadelphia, 2012, Saunders.)

**FIGURE 14-9** Telangiectasia (spider or star angioma). A fiery red, star-shaped marking with a solid circular center. Capillary radiations extend from the central arterial body. With pressure, note a central pulsating body and blanching of extended legs. Develops on face, neck, or chest; may be associated with pregnancy, chronic liver disease, or estrogen therapy, or may be normal. (From Hurwitz S: *Clinical pediatric dermatology: a textbook of skin disorders in childhood and adolescence*, ed 2, Philadelphia, 1993, Saunders, p 266.)

**TABLE 14-3 SELECT LABORATORY TESTS USED TO ASSESS BLEEDING**

TEST	NORMAL VALUE*	PURPOSE OR SIGNIFICANCE
Platelet count	150,000-400,000/mm <sup>3</sup>	Determines number of platelets; decreased in ITP, anemias, DIC, infection, chemotherapy; increased in leukemia, cancer, splenectomy
Bleeding time	3-10 min	Assesses platelet and vascular response; increased in thrombocytopenia, vascular defects, severe liver disease, DIC, von Willebrand disease, aspirin ingestion
Prothrombin time	10-14 sec; 100%	Evaluates extrinsic pathway of coagulation; increased in vitamin K deficiency, hemorrhagic disease of the newborn, liver disease, DIC, anticoagulant therapy. Evaluates all coagulation factors except VIII and XII.
International normalized ratio	1.5 (low-level anticoagulation for atrial fibrillation) 2.0-3.0 (medium-level anticoagulation for DVT, pulmonary embolism, MI, stroke prophylaxis) 2.5-3.5 (high-level anticoagulation for mechanical heart valve)	Evaluates extrinsic pathway of coagulation (as prothrombin time); provides uniformity worldwide, independent of reagents
Activated partial thromboplastin time	33-45 sec	Evaluates intrinsic pathway of coagulation; increased in hemophilia, vitamin K deficiency, liver disease, DIC, circulating anticoagulants, heparin therapy
Thrombin time	15 sec, or control + 5 sec	Measures conversion of fibrinogen to fibrin; increased in DIC, liver disease, low fibrinogen <100 mg/dl, multiple myeloma
Fibrinogen	200-400 mg/dl	Measures fibrinogen level; decreased in liver disease, DIC
Fibrin split products or fibrin degradation products <sup>†</sup>	<3 µg/ml	Measures by-products from breakdown of fibrin clot; increased in DIC, hypoxia, leukemia, thromboembolic disorders
Clot retraction <sup>†</sup>	1hr: evidence of shrinking and increased firmness 24hr: 50% of volume is clot, 50% is serum	Approximate measure of platelet function; decreased in thrombocytopenia, von Willebrand disease
Platelet aggregation <sup>†</sup>	Visible aggregates form in <5 min	Measures rate and percentage of aggregation; decreased in mononucleosis, ITP, von Willebrand disease, leukemia, aspirin ingestion, thrombasthenia, Bernard-Soulier syndrome
Tourniquet test (Rumpel-Leede test, capillary fragility test) <sup>†</sup>	No petechiae or occasional petechiae	Evaluates vascular fragility and platelet function; positive test in thrombocytopenia, vascular purpuras, thrombasthenia
Euglobulin lysis time <sup>†</sup>	No lysis of fibrin clot at 37° C for 3 hr; clot is observed for 24 hr	Assesses fibrinolysis; increased lysis in DIC, incompatible blood transfusion, cirrhosis, cancer, obstetric complications
Plasma D-dimer assay	<200 ng/ml	Assesses fibrinolysis; increased in DVT, pulmonary embolism (highly nonspecific), DIC (high negative predictive value)

\*Value may vary, depending on source.

<sup>†</sup>Tests not included in a routine coagulation screen.

DIC, Disseminated intravascular coagulation; DVT, deep vein thrombosis; ITP, immune thrombocytopenic purpura; MI, myocardial infarction.

**TABLE 14-4 ALTERATIONS IN LABORATORY VALUES SEEN WITH MAJOR DISORDERS OF HEMOSTASIS**

DISORDER	LABORATORY ALTERATIONS							
	PLATELET COUNT	BLEEDING TIME	PT/INR	aPTT	TT	FSP	FVIII	FIX
Idiopathic thrombocytopenic purpura	↓	Prolonged	N	N	N	N	N	N
Hemophilia A	N	N/Prolonged	N	↑	↑	↓	↓	N
Hemophilia B	N	N/Prolonged	N	↑	↑	N	N	↓
von Willebrand disease	N	Prolonged	N	↑	↑	N	↓	N
Vitamin K deficiency	N	Prolonged	↑	N/↑	↑	N	N	N/l
Disseminated intravascular coagulation	↓	Prolonged	↑	↑	↑	↑	↓	↓
ASA/NSAIDs	N	Prolonged	N	N	N	N	N	N
Heparin	N/l	Prolonged	N	↑	↑	N	N	N
Coumadin	N	Prolonged	↑	N/↑	↑	N	N	N
Vascular purpura	N	N/Prolonged	N	N	N	N	N	N
Liver disease	N/l	Prolonged	↑	N/↑	N	N	N	N/l

aPTT, Activated partial thromboplastin time; ASA, acetylsalicylic acid; FIX, factor IX; FSP, fibrin split products; FVIII, factor VIII; INR, International normal ratio; N, normal; NSAIDs, nonsteroidal antiinflammatory drugs; PT, prothrombin time; TT, thrombin time.

cell count (CBC), including a platelet count and peripheral blood smear, bleeding time, prothrombin time (PT) or international normalized ratio (INR), activated partial thromboplastin time (aPTT), and thrombin time. These screening tests evaluate both primary and secondary hemostasis. The CBC determines if anemia is present, the platelet count determines the number of platelets, and the peripheral smear indicates the number and gross morphologic characteristics of platelets. The bleeding time evaluates vascular status and platelet function. The PT and INR assess the extrinsic pathway of coagulation, and the aPTT assesses the intrinsic pathway. Reporting prothrombin activity as a percentage of PT in seconds can pose difficulty in the adjustment of anticoagulation therapy because the PT varies with each laboratory and the reagent used at that lab. Laboratories have tried to compensate for this variation by using the ratio of the patient’s value to the laboratory’s control value, which again varied with the reagent. The INR is a standardized PT value used worldwide that controls for this reagent variability. Thrombin time measures the time needed to convert fibrinogen to fibrin; this reflects the quantity and quality of fibrinogen as well as the influence of any inhibitors. The D-dimer assay reflects fibrinolysis.

Further laboratory investigation is necessary if abnormalities are identified on the screening tests or if, despite normal screening test results, a bleeding problem obviously exists. Specific tests are available to assess abnormal platelet function, the presence of circulating anticoagulants or fibrin split products, and the levels of individual coagulation factors. Table 14-4 reflects the alterations in laboratory values seen with the major disorders of hemostasis.

**KEY POINTS**

- Bleeding tendencies may be inherited or acquired. Abnormal bleeding, liver disease, and anticoagulant drug use may be important risk factors. Physical findings of petechiae, purpura, ecchymoses, telangiectasia, and occult or frank bleeding are indicative.
- Usual laboratory tests include platelet count, bleeding time, PT/INR (extrinsic pathway), and activated partial thromboplastin time (intrinsic pathway).

**VASCULAR AND PLATELET DISORDERS**

**Vascular Disorders**

Vascular disorders of hemostasis and coagulation are those in which the primary cause of bleeding is a problem with the vascular component of primary hemostasis. The vascular defect may be acquired (e.g., related to ingestion of a specific drug) or inherited.

**Vascular Purpura**

**Etiology.** Vascular purpura is a disorder in which purpura—patches of petechiae, or pinpoint hemorrhages, on the skin—are present. The primary cause of the purpura, or more extensive bleeding in some cases, is an abnormality of the vessels or the tissues that support them (see Figure 14-7).

Allergic purpura (anaphylactoid purpura, Henoch-Schönlein purpura) is most often seen in children between the ages of 4 and 7.<sup>9-11</sup> Drug-induced purpura may result from many drugs, including atropine, chloral hydrate, and other sedatives; sulfa drugs; procaine penicillin; and warfarin (Coumadin). Purpuric lesions and perhaps severe hemorrhage are components of Ehlers-Danlos syndrome and osteogenesis imperfecta, both of which are inherited disorders of connective tissue.<sup>12,13</sup> Acquired disorders of connective tissue such as scurvy (vitamin C deficiency), senile purpura (seen in the elderly), and corticosteroid purpura (associated with chronic steroid drug therapy) may also result in purpuric lesions.

**Pathogenesis.** The allergic purpuras are thought to result from an autoimmune process that produces inflammation or vasculitis of small vessels. As a result, perivascular infiltration and serosanguineous effusion occur into surrounding tissues to produce the characteristic purpuric lesion. The pathophysiologic process of drug-induced purpura is not well understood. An autoimmune process has been proposed.

Structural abnormalities of vessels and perivascular supportive tissue provide the mechanism for bleeding in many of the vascular purpuras. These abnormalities may be inherited or acquired. In Ehlers-Danlos syndrome and osteogenesis imperfecta, the vascular abnormality is thought to result from decreased amounts or poor quality of collagen and elastin; both are necessary for perivascular support.

Vitamin C deficiency, which causes scurvy, results in defective collagen synthesis. The lack of proper collagen support for the vessels leads to bleeding. In the elderly (senile purpura), loss of subcutaneous fat and changes in connective tissue allow for more mobility of the skin. Shearing force then causes rupture of small vessels. Steroids induce catabolism of proteins in supportive tissues, decreasing the mechanical strength of the microvasculature.

**Clinical manifestations.** The purpuric lesions characteristically appear and fade or disappear in groups. The lesions are not elevated and do not blanch with pressure.

With allergic purpura, the lesions tend to be palpable and are found on the proximal extremities, especially on the legs and buttocks; they may be accompanied by fever, pruritus, arthralgia, and paresthesia. Bleeding from the lesions themselves and generalized bleeding are uncommon. Usually, allergic purpura is self-limited, and the prognosis is good.

Generalized purpura is characteristic of drug-induced vascular purpura. The lesions quickly subside when the drug is discontinued. Other bleeding manifestations are uncommon.

The purpuric lesions associated with inherited connective tissue disorders, such as Ehlers-Danlos syndrome, often are accompanied by large ecchymoses and hematomas. Although not common, bleeding into the brain tissue may result in cerebrovascular accident (stroke).<sup>12,13</sup>

The purpuric lesions seen with scurvy typically occur around hair follicles and on the medial surfaces of the thighs and buttocks. Ecchymoses and large hematomas may also occur.

Senile purpura and corticosteroid purpura generally occur on the dorsum of the hands and forearms and are aggravated by trauma. Other bleeding is uncommon.

**Diagnosis and treatment.** The diagnosis of vascular purpura is one of exclusion after platelet disorders and coagulation disorders have been ruled out. An abnormal tourniquet test (positive Rumpel-Leede test) in the setting of a normal or increased bleeding time, normal platelet count, and normal coagulation study results suggest a problem with the vascular component of hemostasis. The tourniquet test is an assessment for abnormal capillary fragility. To perform the test, a blood pressure cuff is applied and inflated to a point between the systolic and diastolic blood pressures for 5 minutes. The test is positive if there are more than 20 petechiae per square inch.

Treatment for vascular purpura includes removal or avoidance of the causative agent if one is identified (e.g., penicillin) and interventions to relieve symptoms such as pruritus. If more extensive bleeding accompanies the purpura, identification of the cause and interventions to control the bleeding are necessary.

### Hereditary Hemorrhagic Telangiectasia

**Etiology.** A telangiectasia is a dilated or tortuous small blood vessel, found in the skin or mucous membranes, that has a tendency to bleed spontaneously or following minor trauma (see Figure 14-9). Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease) is transmitted as an autosomal dominant trait; the vascular abnormalities can be seen in children but become more prominent after puberty, peaking between the fourth and fifth decades. As the telangiectases—the skin spots resulting from the vascular lesion—become more prominent, the frequency and severity of the bleeding increase.<sup>14</sup>

**Pathogenesis.** The telangiectases result from an abnormality in vascular development. The vessel wall is composed of a single layer of endothelium; thus, support and contractile properties are deficient, leading to spontaneous bleeding or bleeding as a result of minor trauma.<sup>14</sup> Any mucosal surface (e.g., respiratory, gastrointestinal, and genitourinary tracts) may be involved. Arteriovenous malformations in the lung, liver, and brain are the most serious complications.<sup>14,15</sup>

**Clinical manifestations.** Bright red or purple lesions, ranging from pinpoint to 3 mm in diameter, can be found on the nasal mucous membranes, lips, palate, tongue, face, trunk, palms of the hands, and the soles of the feet. A hallmark symptom is recurrent nosebleeds (epistaxis), with increasing frequency as the patient ages. The severity of the disorder is linked to age of onset.<sup>14,15</sup> Typically the lesions are flat and blanch with pressure. The most common clinical problem is mucous membrane bleeding, especially epistaxis. However, bleeding may occur from telangiectases in any area. Frequent bleeding episodes may result in anemia.<sup>14,15</sup>

**Diagnosis and treatment.** The diagnosis is confirmed by the presence of multiple telangiectases, repeated episodes of bleeding, or a family history of bleeding in both genders. If telangiectases are not easily visible, the diagnosis is more difficult to make.

Treatment is primarily supportive and includes humidification of the nasal cavity, use of topical hemostatic agents or cauterization if the bleeding site is accessible, tamponade of the nasal cavity, use of iron replacement therapy, laser treatment for cutaneous lesions, embolization, and administration of estrogen or estrogen with progesterone for epistaxis. Tranexamic acid is used for controlling severe hemorrhage.<sup>14,15</sup> Blood transfusions or surgical intervention for uncontrolled bleeding may be considered in selected cases.<sup>14,15</sup>

### Platelet Disorders

Platelet disorders of hemostasis and coagulation are those in which the primary cause of bleeding is an abnormality in the quantity or the quality of platelets.

#### Thrombocytopenia

**Etiology.** **Thrombocytopenia** is a common cause of generalized bleeding. Some of the many causes of thrombocytopenia are listed in Box 14-1.

Immune thrombocytopenia (ITP), previously called idiopathic thrombocytopenic purpura, is an acquired immune-mediated disorder. Formerly classified as either “acute” or “chronic,” ITP is now

#### BOX 14-1 SOME CAUSES OF THROMBOCYTOPENIA

##### Decreased Platelet Production

- Folate/B<sub>12</sub> deficiency
- Radiation therapy
- Chemotherapy
- Drugs (e.g., alcohol, thiazides, phenytoin)
- Aplastic anemia
- Cancer in bone marrow

##### Decreased Platelet Survival

- Drugs (e.g., thiazides, digoxin, heparin, furosemide, certain antibiotics)
- Mechanical prosthetic heart valves
- Viral and bacterial infections
- Circulating immune complexes
- Increased destruction in the spleen
- Disseminated intravascular coagulation

##### Splenic Sequestration (Pooling)

- Splenomegaly
- Hypothermia

##### Platelet Dilution

- Massive transfusions with blood stored for more than 24 hours

classified according to the duration of the disease: “newly diagnosed,” “persistent” (lasting 3 to 12 months), or “chronic” (lasting 12 months or longer). ITP occurs at any age and in both genders until mid-life, when it is more common in women 30 to 60 years of age.<sup>16-18</sup> ITP in children may follow a viral illness or have no evidence of previous illness, and typically spontaneously resolves in 6 months.<sup>17,18</sup> ITP in adults has a more insidious onset and tends to be more chronic.<sup>16,18</sup> A pregnant woman with ITP can deliver a thrombocytopenic infant because the antiplatelet antibody crosses the placenta. Adult ITP may precede or occur in association with diseases of altered immunity, such as systemic lupus erythematosus (see Chapter 10), lymphoproliferative disease (see Chapter 11), or acquired immunodeficiency syndrome (AIDS) (see Chapter 12).

**Pathogenesis.** Four general mechanisms are responsible for thrombocytopenia: decreased platelet production, decreased platelet survival, splenic sequestration (pooling), and intravascular dilution of circulating platelets (see Box 14-1). Regardless of the mechanism responsible, there are fewer platelets available, and inadequate hemostasis is the potential result.

Platelets are produced by bone marrow megakaryocytes. Production declines when the number of megakaryocytes is reduced or when the process of platelet production (thrombocytopoiesis) is ineffective. Although numerous causes of decreased platelet production are listed in Box 14-1, drugs are often responsible. Bone marrow suppression from chemotherapy, recent immunizations, and alcohol ingestion are common causes of platelet level reduction.<sup>16,18</sup>

The average life span of a platelet is 7 to 9 days. Decreased platelet survival may be the result of an antibody-mediated immune mechanism that destroys platelets (e.g., ITP, a possible adverse effect of heparin) or the result of increased consumption of platelets, as seen in DIC. Direct trauma to platelets from vascular or valvular prostheses also may be responsible for decreased platelet survival.

Normally, about 25% of the total number of platelets can be found in the spleen and the remaining 75% are circulating. When the spleen is enlarged (splenomegaly), as much as 90% of the platelets may be pooled or sequestered in the spleen; thus, the circulating number of platelets is markedly decreased.<sup>3,5</sup> If the spleen cannot be palpated on physical examination, platelet sequestration can be ruled out as the primary mechanism of the thrombocytopenia.

The final mechanism responsible for thrombocytopenia is dilution of circulating platelets by administration of massive transfusions. Platelets degenerate in stored blood after 24 hours; thus, when a large amount of blood deficient in platelets is transfused, thrombocytopenia results.

**Clinical manifestations.** Clinical manifestations of thrombocytopenia are generally absent<sup>3,5</sup> until the platelet count drops below 100,000/mm<sup>3</sup>. Petechiae and purpura are prominent with platelet counts below 50,000/mm<sup>3</sup>. Spontaneous mucosal, deep tissue, and intracranial bleeding<sup>3,5</sup> may be seen with platelet counts less than 20,000/mm<sup>3</sup>, though recent evidence suggests serious bleeding<sup>17,18</sup> is more likely to occur at platelet counts less than 10,000/mm<sup>3</sup>.

New research is exploring fatigue as a common symptom among patients with ITP.<sup>19</sup>

**Diagnosis.** Thrombocytopenia is diagnosed by the presence of a low platelet count on peripheral blood laboratory examination. The bleeding time is prolonged and clot retraction is poor or absent. PT/INR, partial thromboplastin time, and other coagulation studies are normal. The CBC will indicate if the thrombocytopenia is isolated or if an associated problem, such as anemia or leukopenia, is present. Gross morphologic analysis of platelets, evaluated from the peripheral blood smear, and bone marrow examination provide additional information regarding the mechanism for the thrombocytopenia. Because many

drugs are associated with thrombocytopenia, careful review of all medications the patient is taking is also necessary in the search for the cause of the thrombocytopenia.

**Treatment.** The treatment for thrombocytopenia is based on the identified cause or mechanism and may include any of the following: discontinuation of any suspected drug; avoidance of aspirin and pharmacodynamically similar drugs that alter normal platelet function; and administration of corticosteroids, immunosuppressants, intravenous immunoglobulin (IVIg), rituximab, and thrombin receptor agonists such as romiplostim and eltrombopag to increase platelet production.<sup>18</sup> Splenectomy may be helpful in some cases because it results in removal of a major site of platelet destruction and eliminates a source for production of antiplatelet antibodies.

### Thrombocytosis

**Etiology.** Thrombocytosis is generally defined as a platelet count greater than 400,000/mm<sup>3</sup>. Transitory thrombocytosis is seen following stress or physical exercise. Secondary or reactive thrombocytosis occurs as a response to hemorrhage, inflammatory diseases, malignancy, infection, hemolysis, or splenectomy. Primary thrombocytosis is seen with polycythemia vera and chronic granulocytic leukemia.<sup>3,5</sup>

**Pathogenesis.** In all types of thrombocytosis, the number of platelets is increased, but the mechanism of the increase varies. Transitory thrombocytosis results from release of preformed platelets, not increased production. As the name implies, the elevation in platelet count is transient. Secondary thrombocytosis results from an actual increase in platelet production via an unknown mechanism. With primary thrombocytosis, there is abnormal proliferation of megakaryocytes in the bone marrow, resulting in as much as a 15-fold increase in platelet production.

**Clinical manifestations.** In general, transitory thrombocytosis and secondary thrombocytosis do not result in hemorrhage or thrombotic complications. Hemorrhage into the skin and mucous membranes and gastrointestinal bleeding may be seen with primary thrombocytosis. The pathogenesis of excessive bleeding in the presence of excessive levels of platelets is not well understood. Thrombosis resulting in peripheral vascular ischemia or pulmonary embolism may further complicate the clinical picture. Thromboembolic events are the most common cause of death. However, the course of thrombocytosis is benign in most patients.

**Diagnosis and treatment.** The diagnosis is made on the basis of a high platelet count. Bleeding time may be normal or prolonged, and platelet aggregation is normal or impaired. The history and clinical presentation, as well as additional laboratory tests such as bone marrow examination, aid in determining the type of thrombocytosis.

No treatment is necessary with transitory and secondary thrombocytosis. To manage primary thrombocytosis, the use of cytotoxic agents or interferon may be used.<sup>4</sup> Antiplatelet therapy (e.g., aspirin or dipyridamole) also may be used. In the presence of acute bleeding or thrombosis, plasma exchange may be used to temporarily control the platelet count.

### Qualitative Platelet Disorders

**Etiology.** Although the number of platelets may be normal, the ability of the platelets to function in the hemostatic process may be abnormal; thus, a qualitative platelet disorder is present. Inherited defects in platelet function, such as Bernard-Soulier syndrome (giant platelet syndrome), von Willebrand disease, and thrombasthenia (Glanzmann disease), are rare. In contrast, acquired disorders of platelet function are common; they are often associated with drugs, especially aspirin; with renal failure; or with a coexisting hematologic disease, such as leukemia.

**Pathogenesis.** Whether the qualitative platelet disorder is inherited or acquired, at least one aspect of platelet function (adhesion, aggregation, or release reaction) is abnormal and a bleeding tendency results. In both Bernard-Soulier syndrome and von Willebrand disease, platelet adhesion is abnormal. Platelet aggregation is the problem in thrombasthenia, owing to the absence of the fibrinogen receptor necessary for normal platelet aggregation. Aspirin and other nonsteroidal antiinflammatory agents inhibit production of thromboxane  $A_2$  and thus impair both platelet aggregation and the platelet release reaction.

**Clinical manifestations.** The clinical presentation of a qualitative platelet disorder is some form of bleeding tendency, such as petechiae or purpura on skin and mucous membranes, epistaxis, gastrointestinal bleeding, or menorrhagia. Acquired platelet function defects also may result in excessive bleeding during and following surgical procedures.

**Diagnosis and treatment.** With qualitative platelet defects, the bleeding time is prolonged but the platelet count and other routine coagulation screening test results are normal. Although a bleeding time greater than 10 minutes is associated with a slight increase in bleeding tendency, the risk is not significantly increased until the bleeding time exceeds 15 or 20 minutes.<sup>5,7</sup>

Special laboratory tests that more specifically evaluate platelet function, such as platelet aggregation studies, are necessary to determine the exact cause of bleeding.<sup>7</sup> Coexisting hematologic defects may make diagnosis of a platelet defect difficult.

If the platelet disorder is drug induced, the offending drug is discontinued. Transfusion with normal platelets is the usual intervention if treatment is necessary because of bleeding. Administration of desmopressin or cryoprecipitate is the treatment of choice when von Willebrand disease is the underlying cause of bleeding, as well as for patients with aspirin overdose and cirrhosis.<sup>5,7</sup> von Willebrand disease is described in greater detail in the following section.

#### KEY POINTS

- Disorders of the vasculature that result in altered hemostasis include inflammation (allergic purpura), structural abnormalities (collagen diseases), and weakened vessel walls (telangiectasia).
- An insufficient quantity of platelets (fewer than 50,000/mm<sup>3</sup>) results from decreased production, sequestration, increased destruction, or dilution. Important causes of thrombocytopenia include autoimmune destruction (ITP), DIC, and mechanical destruction (artificial valves).
- Excessive quantity of platelets (more than 400,000/mm<sup>3</sup>) results from excessive production (proliferation of bone marrow cells). Thrombocythemia may result in excessive coagulation with thrombosis or excessive bleeding.
- A normal platelet count does not ensure adequate platelet function. Platelet adhesion, aggregation, and degranulation may be abnormal, resulting in a prolonged bleeding time. The usual cause is drug related (e.g., aspirin); rarely, the platelet defect is inherited (e.g., von Willebrand disease).

## COAGULATION DISORDERS

Coagulation disorders or **coagulopathies** are defects of the normal clotting mechanism. They may cause bleeding as a result of problems with the formation, stabilization, or lysis of the fibrin clot. Alternatively, the coagulation disorder may be attributable to inappropriate activation of the coagulation cascade, producing excessive clot formation.

## Hemophilia

**Etiology.** Hemophilia is rare in the general population, but it is the most common severe inherited coagulation disorder. Excessive bleeding following circumcision or the formation of a hematoma after vitamin K injection leads to the diagnosis in the neonate. Some children will not develop bleeding problems until they begin crawling or walking.

Hemophilia A, the classic form of the disease, accounts for approximately 85% of cases of clinical hemophilia. Hemophilia A is caused by factor VIII deficiency.<sup>1,20-22</sup> The majority of patients inherit this X-linked recessive disorder; hemophilia is transmitted by an asymptomatic carrier female to an affected son. Approximately 20% of patients with hemophilia A have a negative family history because of a spontaneous mutation of the hemophilic gene.

Less common than hemophilia A is hemophilia B, also known as Christmas disease. Factor IX is deficient in this form of hemophilia.<sup>20,21</sup>

Hemophilia is often classified according to the extent to which the specific coagulation factor (factor VIII or IX) is deficient. Patients with severe hemophilia have less than 1% normal coagulation factor activity; patients with moderate hemophilia, 1% to 5% normal coagulation factor activity; and patients with mild hemophilia, 5% to 40% normal coagulation factor activity.<sup>20,22</sup>

Of critical concern in the hemophilic patient is intracranial hemorrhage and other serious bleeding episodes. Because of advances in treatment, however, a normal life span is possible for many.

**Pathogenesis.** Hemophilia A results from factor deficiency or the abnormal function of factor VIII. Hemophilia B results from factor deficiency or the abnormal function of factor IX. A deficiency or malfunction in either factor interferes with the normal sequence of events in the intrinsic pathway of coagulation and, in turn, the eventual production of a fibrin clot. Inability to form a fibrin clot results in bleeding.

**Clinical manifestations.** Once clinical evidence of bleeding is present, hemophilia A and hemophilia B are indistinguishable. Patients with mild hemophilia may not experience symptoms until stressed by surgery or trauma. Prolonged bleeding from relatively minor trauma and occasional spontaneous bleeding episodes are characteristic of moderate hemophilia. With severe hemophilia, frequent episodes of spontaneous bleeding are likely.

Any of the following clinical manifestations may occur: easy bruising, prolonged bleeding from the nasal or oral mucosa, deep tissue hematomas, hemarthrosis, bleeding into muscles in the extremities, spontaneous hematuria, gastrointestinal bleeding, and intracranial bleeding. The hallmark of hemophilia is hemarthrosis. Knees, ankles, and elbows are the most often affected. Repeated episodes of hemarthrosis may result in joint deformity.<sup>4,20-22</sup>

Major long-term complications of hemophilia include progressive joint deformity as a result of repeated hemarthroses, hepatitis B or C, cirrhosis, and HIV infection related to repeated transfusions or administration of virus-contaminated factor concentrates.

**Diagnosis and treatment.** Hemophilia is considered as the cause of bleeding when the family history is positive for bleeding in males, there is a history of joint bleeding and hematomas, and joint deformity is present on physical examination. Laboratory tests consistent with hemophilia include a normal or slightly prolonged bleeding time, a normal PT/INR, and a prolonged aPTT. Factor assay verifies a deficiency in factor VIII or IX. Early in pregnancy, chorionic villus biopsy or amniocentesis may be done to identify factor deficiency, making prenatal diagnosis of hemophilia possible.<sup>5</sup>

The patient and family must learn about hemophilia, including recognition and appropriate response to bleeding episodes, lifestyle changes that will be necessary, and the genetic nature of disease transmission. Prevention of injury and avoidance of aspirin and aspirin-like drugs, which

alter platelet function, are important parts of treatment. Joint bleeding is managed by immobilization of the limb and application of ice.

With dental procedures requiring administration of a local anesthetic, prophylactic administration of factor VIII should be considered in the patient with hemophilia A. Bleeding episodes from hemophilia A are managed primarily by the administration of cryoprecipitate or other preparations of factor VIII concentrate. Recombinant DNA-derived factor concentrates contain no viruses and are now available. In addition, desmopressin and antifibrinolytics (e.g., tranexamic acid and aminocaproic acid) are possibilities to treat mild bleeding episodes.<sup>20,22</sup> The goal of therapy is to obtain a factor VIII level of at least 40% to 60% for joint and most muscle bleeding, and 80% to 100% for iliopsoas muscle, throat or neck, central nervous system (CNS), or gastrointestinal bleeding.<sup>20</sup> Up to 20% of patients with severe hemophilia develop factor VIII inhibitor, an antibody that rapidly inactivates transfused factor VIII.<sup>20,22</sup> Plasmapheresis and immunosuppressive therapy are sometimes necessary to maintain adequate factor VIII levels in these patients.

Mild to moderate bleeding resulting from hemophilia B is managed with the administration of fresh or fresh frozen plasma or cryoprecipitate. Use of Konyne 80 or Proplex T, both of which are concentrates containing factors II, VII, IX, and X, is another therapeutic option. These concentrates are now treated in a variety of fashions (heat, pasteurization, solvent detergents, immunoaffinity purification) to prevent transmission of viruses. Their use was previously associated with the transmission of human immunodeficiency virus (HIV) and hepatitis viruses.<sup>20,22</sup> Mononine is a newer, highly purified factor IX concentrate that appears to be safe in terms of both adverse effects and viral transmission.<sup>20</sup>

### von Willebrand Disease

**Etiology.** von Willebrand disease is inherited as an autosomal dominant disorder of factor VIII carrier protein and platelet dysfunction. In rare cases, von Willebrand disease is an autosomal recessive disorder.<sup>7,23,24</sup> Several less common subtypes of the disease have been identified, but all have some defect in von Willebrand factor, a plasma protein. von Willebrand disease occurs in both females and males. Bleeding manifestations of the disease tend to become more severe with age.

**Pathogenesis.** von Willebrand factor and factor VIII normally circulate in plasma as a complex. von Willebrand factor is necessary for stabilization of factor VIII in the circulation and for normal adherence of platelets to damaged vascular endothelium.<sup>7,23,24</sup> In von Willebrand disease, the level of von Willebrand factor is decreased or absent. Serum levels of factor VIII range from mildly to severely reduced. Absence of platelet adhesion at the site of vascular injury and deficient factor VIII activity in the intrinsic coagulation pathway contribute to the bleeding seen in von Willebrand disease.

**Clinical manifestations.** Epistaxis, mucosal bleeding, ecchymoses, gastrointestinal bleeding, and menorrhagia are common clinical manifestations of von Willebrand disease. Once hemostasis is achieved, it can usually be maintained. Hemarthrosis is rare. Although not common, von Willebrand disease should be considered as a possible cause of excessive surgical bleeding. Bleeding manifestations may decrease during pregnancy because levels of von Willebrand factor and factor VIII rise during this time.<sup>23</sup>

**Diagnosis and treatment.** The history and clinical presentation initially suggest the possibility of von Willebrand disease as the cause of bleeding. Laboratory tests consistent with the disease include a prolonged bleeding time, prolonged aPTT, normal platelet count, and normal PT/INR. More specialized testing will verify that the level of plasma von Willebrand factor is decreased and that factor VIII activity is reduced.

Mild forms of classic von Willebrand disease can be managed with desmopressin, which causes release of von Willebrand factor and factor VIII from vascular endothelial cells.<sup>7,23</sup> Excessive menstrual bleeding can be treated with hormonal suppression therapy. Severe bleeding is addressed by using cryoprecipitate that contains both factor VIII and von Willebrand factor. Humate-P, a recombinant replacement therapy, is now available. Aspirin and aspirin-containing drugs, which inhibit normal platelet function in hemostasis, should be avoided in patients with von Willebrand disease.<sup>7,22,24</sup>

Complications of therapy for severe von Willebrand disease include hepatitis and AIDS, related to transfusions with blood products. Antibodies that inhibit the activity of von Willebrand factor may develop, but this is rare.

### Vitamin K Deficiency Bleeding in Infancy

**Etiology.** As the name implies, this coagulation disorder is seen in the newborn, typically 48 to 72 hours after birth, through 6 months of age.<sup>25,26</sup> Hemorrhagic disease of the newborn is more common in breast-fed babies (who do not receive vitamin K supplement) than in formula-fed babies. It is rare in Western countries because of routine administration of vitamin K to newborns.

**Pathogenesis.** This bleeding disorder results from a deficiency of the vitamin K-dependent coagulation factors II, VII, IX, and X. The levels of these factors are approximately 50% of normal in umbilical cord blood and they decline rapidly after birth, reaching their lowest levels at 48 to 72 hours. In a small number of infants, the decline is so significant that severe bleeding occurs. After 72 hours, the levels of these coagulation factors gradually increase over the course of several weeks. This increase is primarily caused by absorption of vitamin K from the diet. The vitamin K content of human milk is very low compared with standard infant formulas; therefore, breast-fed babies need vitamin K supplementation.<sup>25,26</sup>

Hepatic immaturity may also contribute to hemorrhagic disease of the newborn. The liver may be unable to initially produce adequate levels of the vitamin K-dependent coagulation factors.<sup>27</sup>

**Clinical manifestations.** Evidence of bleeding, such as melena (tarry, black feces composed of partially digested blood), bleeding from the umbilicus, and hematuria, appears on the second or third day of life. Life-threatening complications include intracranial hemorrhage and hypovolemic shock.

**Diagnosis and treatment.** The diagnosis is primarily based on the clinical presentation, particularly the timing of the onset of bleeding. The PT/INR is prolonged; levels of vitamin K-dependent clotting factors are decreased.

Prophylactic administration of vitamin K to the newborn prevents the severe decline of the vitamin K-dependent coagulation factors and largely eliminates this coagulation disorder.

If evidence of hemorrhage is present, vitamin K should be administered. For severe hemorrhage, fresh plasma will replenish the deficient coagulation factors and stop the bleeding. Fresh whole blood will correct severe anemia and shock.

Premature infants may experience bleeding attributable to platelet abnormalities and a deficiency in several coagulation factors. Because of hepatic immaturity, vitamin K is ineffective therapy in these infants. Fresh plasma is the treatment of choice for the premature infant with bleeding complications.

### Acquired Vitamin K Deficiency

**Etiology.** Acquired vitamin K deficiency may result in bleeding as a result of a coagulation defect. Vitamin K, a fat-soluble vitamin, is obtained by the ingestion of specific foods (e.g., liver, cheese, butter, egg yolks, and green, leafy vegetables) and by a synthetic process occurring

in the intestinal flora. Vitamin K is then absorbed by the intestine and stored in the liver. Normal absorption is dependent on bile acids and adequate mucosal function in the intestine. Vitamin K is necessary for normal synthesis and function of coagulation proteins (factors II, VII, IX, and X) as well as coagulation inhibitors (proteins C and S).

Vitamin K deficiency, with its associated risk for bleeding, may occur with the following: malnutrition, malabsorption (including biliary disease), chronic hepatic disease, antibiotic therapy, and oral anticoagulation therapy.

**Pathogenesis.** One of the many functions of the liver is the synthesis and transport of bile, which is necessary for fat digestion and normal absorption in the small intestine. Vitamin K is a fat-soluble vitamin; if fat malabsorption occurs because of a lack of bile, vitamin K is not absorbed, resulting in a vitamin K deficiency. In the newborn, especially the premature infant, vitamin K deficiency may be related to liver immaturity and the lack of vitamin K synthesis by the intestine until the gut is colonized with the flora that produce vitamin K. Coumadin-type drugs are vitamin K antagonists that inhibit the normal activity of vitamin K in the synthesis of clotting factors. The net effect is decreased clotting factor activity.

Although vitamin K is deficient, the liver continues to synthesize the vitamin K–dependent coagulation factors. However, the coagulation activity of these factors is impaired, resulting in bleeding.

**Clinical manifestations.** Evidence of bleeding may present in a variety of ways, including mucosal and gastrointestinal bleeding, ecchymoses, menorrhagia, and hematuria. Surgical bleeding may be a significant problem in the patient with a vitamin K deficiency.

**Diagnosis and treatment.** Vitamin K deficiency should be considered as the cause for bleeding when the PT/INR is increased but other coagulation studies are normal. Of the vitamin K–dependent clotting factors, factor VII (extrinsic pathway) has the shortest half-life; thus, the PT/INR is prolonged first. Ultimately, the aPTT also will be prolonged as clotting factors in the intrinsic pathway become deficient.

Parenteral administration of vitamin K rapidly restores levels in the liver.<sup>25,26</sup> Fresh frozen plasma, with an immediate supply of clotting factors, is the treatment of choice for severe hemorrhage. Correction or removal of the cause of vitamin K deficiency also is an important part of therapy.

### Disseminated Intravascular Coagulation (DIC)

**Etiology.** DIC is an acquired hemorrhagic syndrome in which both clotting and bleeding occur simultaneously (Figure 14-10). This syndrome is also known as “disseminated intravascular coagulopathy” or “disseminated intravascular consumption” in some references. Widespread clotting in small vessels leads to consumption of the clotting factors and platelets, which in turn leads to bleeding. DIC is either chronic or acute. The chronic form is seen mainly in the cancer patient with malignancy and presents in a less severe form with bleeding tendencies that are mild to moderate and thrombotic episodes.<sup>27,28</sup> The liver and bone marrow have sufficient time to replenish consumed factors and platelets, which leads to a more pronounced thrombotic problem.<sup>8</sup> Acute DIC occurs secondary to a variety of factors, including malignancy, sepsis, snake bite, abruptio placentae, trauma and crushing injuries, transfusions of incompatible blood, burns, shock, and severe liver disease.<sup>5,27,28</sup> DIC is estimated to occur in 1 of every 900 to 2400 adult admissions in large, urban hospitals. Death rates are reported to range from 50% to 80%.

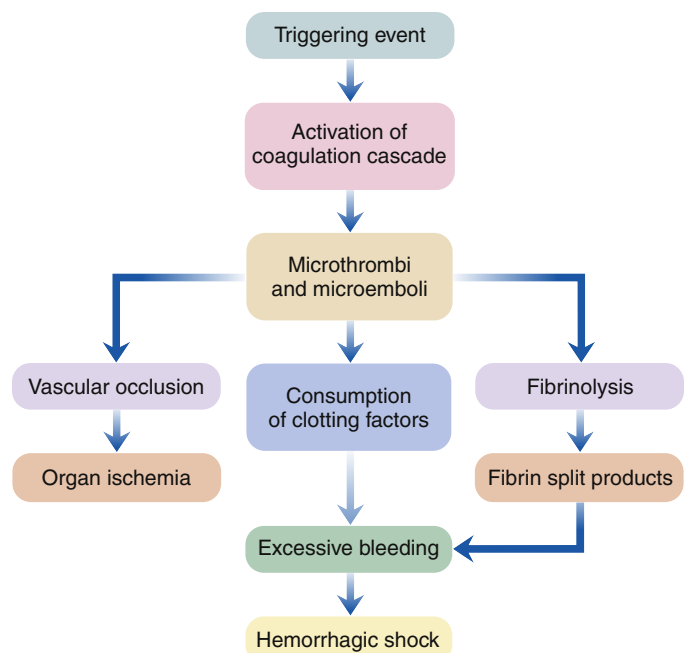

**Pathogenesis.** DIC represents a paradox of both thrombosis and hemorrhage. Accelerated intravascular clotting in small vessels is initiated by contact of the blood with damaged vascular endothelium (sepsis, burns), release of procoagulant substances into the blood (snake venom, malignancy), generation of procoagulants in the blood

(incompatible blood transfusion), or stagnant blood flow (shock). Coagulation factors, especially prothrombin, platelets, factor V, and factor VIII, are rapidly consumed. At the same time, the fibrinolytic system is activated to break down the clots. The fibrin degradation products or fibrin split products that result act as circulating anticoagulants. The combination of coagulation, anticoagulation, and fibrinolysis ultimately leads to hemorrhage.<sup>27,28</sup>

**Clinical manifestations.** Although both bleeding and clotting are part of the syndrome, initially bleeding is more apparent clinically. Petechiae and ecchymoses on skin and mucous membranes, as well as bleeding from orifices and any site of injury, such as venipuncture and injection sites, may be present. Acrocyanosis (cold, mottled fingers and toes) may be apparent attributable to thrombi formation in the microvasculature of the extremities. Thrombi in the pulmonary microcirculation (small vessels) may result in dyspnea, hemoptysis, and crackles or rales, as blood fills alveoli. Patients with DIC are also predisposed to acute renal failure because of the presence of microthrombi in the renal microvasculature.

**Diagnosis and treatment.** The diagnosis of DIC is based on a high index of suspicion drawn from the history and presenting signs and symptoms. The typical clinical picture described previously, plus the presence of a predisposing cause, should make DIC a consideration in the differential diagnosis. Abnormal coagulation studies that help confirm the diagnosis include increased values for bleeding time, PT/INR, aPTT, fibrin split products, and thrombin time as well as decreased measurements for the fibrinogen level and platelet count. D-Dimer (a fibrin degradation product) is one of the most useful tests to measure fibrinolysis; this in conjunction with an elevated antithrombin complex is indicative of DIC.<sup>7,27,28</sup>

The cornerstone of treatment for DIC is removal or correction of the underlying cause and support of major organ systems. Replacement of depleted clotting factors with fresh frozen plasma, packed red blood cells, platelets, or cryoprecipitate may be necessary. Antifibrinolytics (aminocaproic acid) may be used if there is life-threatening hemorrhage.<sup>25</sup> Some studies have had promising results in decreasing

**FIGURE 14-10** Pathophysiology of disseminated intravascular coagulation. Clotting and bleeding occur simultaneously, resulting in organ ischemia and hemorrhagic shock.

## CHAPTER 14 Alterations in Hemostasis and Blood Coagulation

mortality with administration of antithrombin concentrate or activated protein C. Improved mortality was seen in the groups with higher severity ratings.<sup>28</sup> Although controversial, heparin may be used to minimize further consumption of clotting factors. The purpose of heparin therapy is to stop thrombin formation, thus preventing microemboli. Low-dose subcutaneous heparin appears to be as effective as high-dose heparin with fewer complications. Heparin has been found useful in chronic DIC.<sup>28</sup>

### Hepatic Disease

**Etiology.** A common complication of many hepatic disorders is abnormal hemostasis. With the exception of part of the antihemophilic factor, all plasma protein clotting factors and fibrinolytic factors and their inhibitors are synthesized totally or predominantly by the liver.<sup>3,5,25</sup> If liver function is altered by disease, bleeding is one manifestation.

**Pathogenesis.** Several factors may contribute to the abnormal hemostasis seen in liver disease. Liver disease alters the synthesis and transport of bile, which is necessary for normal fat digestion and absorption. Impaired absorption and metabolism of vitamin K, which is fat soluble, results in decreased hepatic synthesis of coagulation factors II, VII, IX, and X. Altered liver function also results in decreased synthesis of fibrinogen and factors V and XI.<sup>28</sup> A deficiency in any of the coagulation factors can interrupt the normal process of fibrin clot formation. In addition to synthesis of coagulation factors, the liver also has a role in removing activated coagulation and fibrinolytic proteins from the circulation. Failure to filter these proteins adequately may result in an imbalance between clot formation and clot dissolution (fibrinolysis), manifesting clinically as DIC.<sup>25,28</sup> Liver disease also may alter normal production of inhibitors of coagulation (antithrombin III, proteins C and S), which contributes to the hypercoagulable component of DIC.<sup>27</sup>

Another factor contributing to the bleeding associated with liver disease is thrombocytopenia. A low platelet count is common in liver disease. The exact mechanism is unknown but may relate to the splenomegaly associated with portal hypertension.<sup>27</sup> Sequestration of platelets in the enlarged spleen depletes the number of platelets circulating and available for normal hemostasis. The portal hypertension that develops as blood flow through the liver is retarded adds to the bleeding problem. While pressure in collateral circulatory beds increases, bleeding is manifested as esophageal varices and hemorrhoids (see Chapter 38).

**Clinical manifestations.** Patients with chronic, rather than acute, liver disease are more likely to have clinical evidence of a bleeding

problem. Typical clinical features may include any of the following: petechiae, ecchymoses, spider telangiectasia, bleeding from venipuncture sites or esophageal varices, and gastrointestinal bleeding. DIC may complicate the clinical presentation. Bleeding may not be a problem until the patient has surgery or a biopsy.

**Diagnosis and treatment.** The patient with liver disease and associated bleeding will commonly have a decreased platelet count, normal or decreased fibrinogen levels, and prolonged PT/INR and aPTT values. More specific coagulation studies may be indicated in some situations.

Treatment may be instituted prophylactically before surgery or biopsy, or it may be mandated by a bleeding episode. The degree of abnormality on coagulation tests or the severity of the bleeding will influence the aggressiveness of therapy. Because of the high likelihood of vitamin K deficiency, administration of vitamin K may be the initial intervention. Platelet infusions are appropriate if significant thrombocytopenia is present. Fresh frozen plasma is the primary replacement product used to supply coagulation factors. Administration of large quantities of plasma carries the risk of precipitating hepatic encephalopathy and fluid overload. Transfusions of whole blood or, more commonly, packed red blood cells may be necessary to manage anemia from bleeding of significant proportions.

### KEY POINTS

- Coagulation disorders result from defects in the clotting cascade or fibrinolytic process. These disorders may be inherited or acquired.
- Hemophilia is an inherited bleeding disorder that results from deficient clotting factor production. The most common types are hemophilia A (factor VIII) and hemophilia B (factor IX).
- von Willebrand disease is an inherited bleeding disorder caused by abnormal factor VIII carrier protein production. The disease results in a deficiency of factor VIII in the circulation and decreased platelet function.
- Vitamin K deficiency is associated with several coagulation disorders, including hemorrhagic disease of the newborn and bleeding related to malnutrition and liver disease. Vitamin K is a necessary cofactor for liver production of factors II, VII, IX, and X.
- DIC is an acquired bleeding syndrome associated with a number of etiologic factors, including trauma, malignancy, burns, shock, and abruptio placentae. DIC is characterized by widespread clot formation in small vessels. Clotting factors and platelets are consumed, leaving the patient with deficient resources for appropriate clot formation. The platelet count and fibrinogen levels are typically decreased, and values for PT, aPTT, thrombin time, bleeding time, and fibrin split products are elevated.

### SUMMARY

The presence of unexpected overt or covert bleeding may signal an acquired or inherited problem with hemostasis. A review of normal hemostasis, as well as information on selected disorders of hemostasis and coagulation, has been presented in this chapter. With a sound

knowledge base, the health care professional is in a position to play a key role in the recognition, diagnosis, and management of a bleeding problem.

The primary functions of the circulatory system are the transportation of oxygen and nutrients and the removal of metabolic waste products within the body. To perform these functions, a complex circuitry of vessels traverses the body (Figure 15-1), powered by the pumping action of the heart. Propulsion of blood through the lungs is provided by the right ventricle, whereas systemic blood flow is driven by the left ventricle.

Nutrients are absorbed into the blood as it moves through the gastrointestinal tract via the splanchnic circulation. Oxygen uptake and the release of carbon dioxide occur in the specialized vascular bed of the pulmonary circulation. The liver, with its extensive blood supply, has a major role in metabolism and generation of metabolic waste products. These, and other metabolic by-products, are carried by the

**FIGURE 15-1** The primary systemic arterial and venous circulatory networks. *a.*, Artery; *v.*, vein. (From Black JM, Hawks J: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1273.)

blood to the kidneys for elimination. Inadequate circulation in the lungs, liver, or kidneys may interfere with the removal of metabolic wastes from the body. Effective transportation of oxygen and nutrients and removal of waste materials depend on proper functioning of the circulatory system.

Aging produces significant changes in the circulatory system, altering the ability of the system to carry out its functions and increasing susceptibility to certain disease processes. The effects of the aging process on the circulatory system are summarized in Geriatric Considerations: Changes in the Circulatory System.

## ORGANIZATION OF THE CIRCULATORY AND LYMPHATIC SYSTEMS

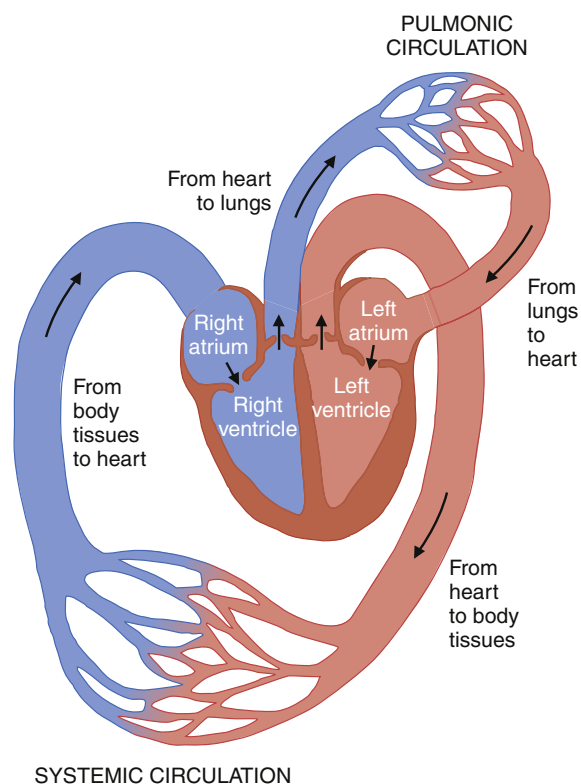

After passing through the pulmonary circulatory system and leaving the left ventricle, blood flows through a graduated series of tubes to tissues of the body before returning to the right side of the heart. The powerful left ventricle propels the blood to the aorta, arteries, arterioles, and, finally, to the capillary beds. Here the proximity of capillary endothelium to the other cells of the body facilitates movement of nutrients and oxygen into the cells and removal of cellular metabolic wastes. Capillary blood is then collected by venules, which flow into

veins, returning blood to the venae cavae and the right side of the heart (Figure 15-2). The complete process, moving approximately 5 L of blood through the entire circuit, takes only about 1 minute.

The lymphatic circulation is a specialized system of channels and tissues (nodes). It is not arranged in a circuit, as is the vascular system. Instead, the lymphatic vessels begin blindly, deep in the connective tissue. One of the functions of the lymphatic system is to reabsorb fluid that leaks out of the vascular network into the interstitium and return it to the general circulation. During the process of cellular exchange within the capillary bed, some fluid moves into the interstitium and fails to return to the vascular bed. This lost fluid can amount to as much as 2 to 4 L/day. At this circulatory level, lymphatic vessels lie in close proximity to the capillary vasculature. The fluid, now called *lymph*, is absorbed by the lymphatic vessels and returned to the venous circulation by way of the thoracic duct and the right lymphatic duct (Figure 15-3). Lymphatic drainage of the breast is illustrated in Figure 15-4.

### Vessel Structure

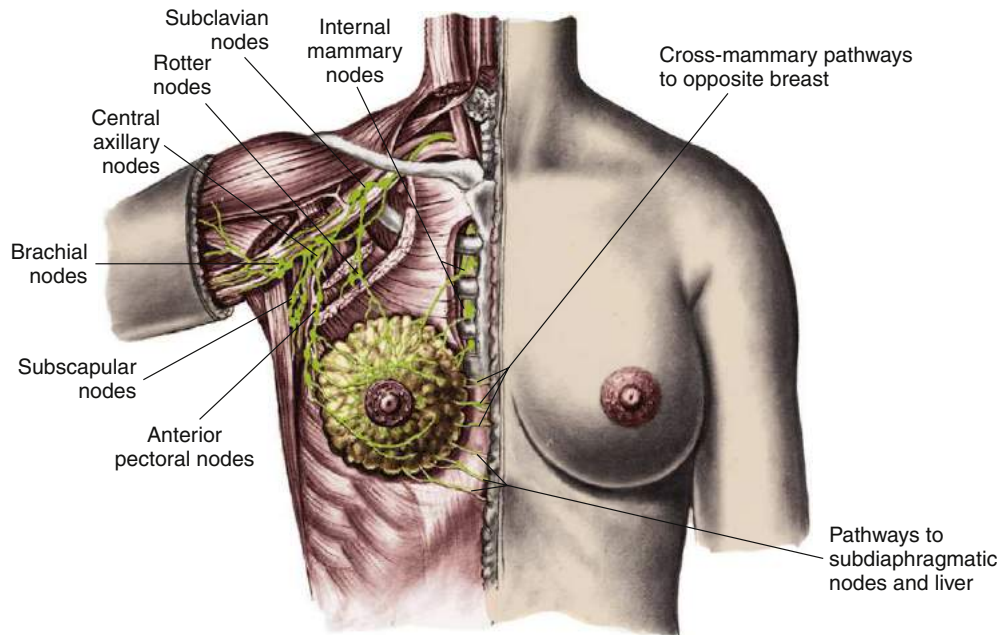

To perform their specialized functions, the blood and lymphatic vessels are different in their structure. Knowledge of the morphology of these vessels is essential for an understanding of the alterations in function produced by disease.

**FIGURE 15-2** The circulatory system. Beginning from the body tissues, blood returns to the right side of the heart, through the right atria to the right ventricle, which propels it into the lungs. In the lungs, the metabolic waste carbon dioxide is removed and oxygen is replenished. Oxygenated blood leaves the pulmonic circulation and returns to the heart via the left atrium and then to the left ventricle. From the left side of the heart, the oxygenated blood enters the systemic circulation, where oxygen is delivered to the tissues in exchange for metabolic wastes. (From Black JM, Hawks J: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1344.)

**FIGURE 15-3** Anatomy of the lymphatic system. Lymphatic capillaries collect the excess fluid from the vascular capillaries, returning it to the venous circulation at the junction of the internal jugular and subclavian veins. (From Monahan FD et al: *Phipps' medical-surgical nursing: health and illness perspectives*, ed 8, Philadelphia, 2007, Mosby, p 936.)

**FIGURE 15-4** Lymphatic drainage of the breast to the axillary and subclavian nodes, then to the jugular and subclavian veins. (From Monahan FD et al: *Phipps' medical-surgical nursing: health and illness perspectives*, ed 8, Philadelphia, 2007, Mosby, p 1661.)

The primary differences between the smaller arterial and venous vessels are in terms of the quantities of muscle and connective tissue present. In arterioles, the principal tissue is smooth muscle, whereas in venules, smooth muscle is scarce and connective tissue dominates. The composition of the walls and the size and shape of the vessels also vary in larger arteries and veins. Capillary walls are composed of a single layer of endothelial cells. These simple structures carry out extraordinarily complex functions.

### Anatomy of Arteries and Veins

The walls of both arteries and veins are composed of three microscopically distinct layers, or tunicae: the intima, the media, and the adventitia. The histologic constituents of these tunicae are similar in arteries and veins (Figure 15-5). Generally, the walls of veins are not as thick as the walls of arteries, but the lumina are larger.

The intima consists of a layer of endothelial cells that is in direct contact with the blood as it flows through the vessel. Periodically, the intimal layer of veins protrudes into the lumen, creating valves that prevent the backflow of blood. Arterial intima is characterized by an inner elastic membrane next to the endothelial cells. This elastic membrane is thickest in the aorta and decreases in density until only scattered elastic fibers can be identified in the smallest arterioles. With increasing age, the intimal arterial wall becomes thicker and less elastic. This interferes with diffusion of nutrients into the wall, causing the internal elastic membrane to degenerate and calcify.

The media, or middle layer, exhibits the greatest difference between arteries and veins. In arteries the media is the thickest of all the tunicae. Large arteries have smooth muscle fibers arranged in a circular pattern and interspersed with elastic fibers. Progressing from arteries to ever-smaller arterioles, the smooth muscle remains but the elastic tissue disappears. This thick, smooth muscle layer is responsible for the firmness and limited distensibility of arterial vessels. With advancing age, changes in the intima result in decreased nutrition reaching

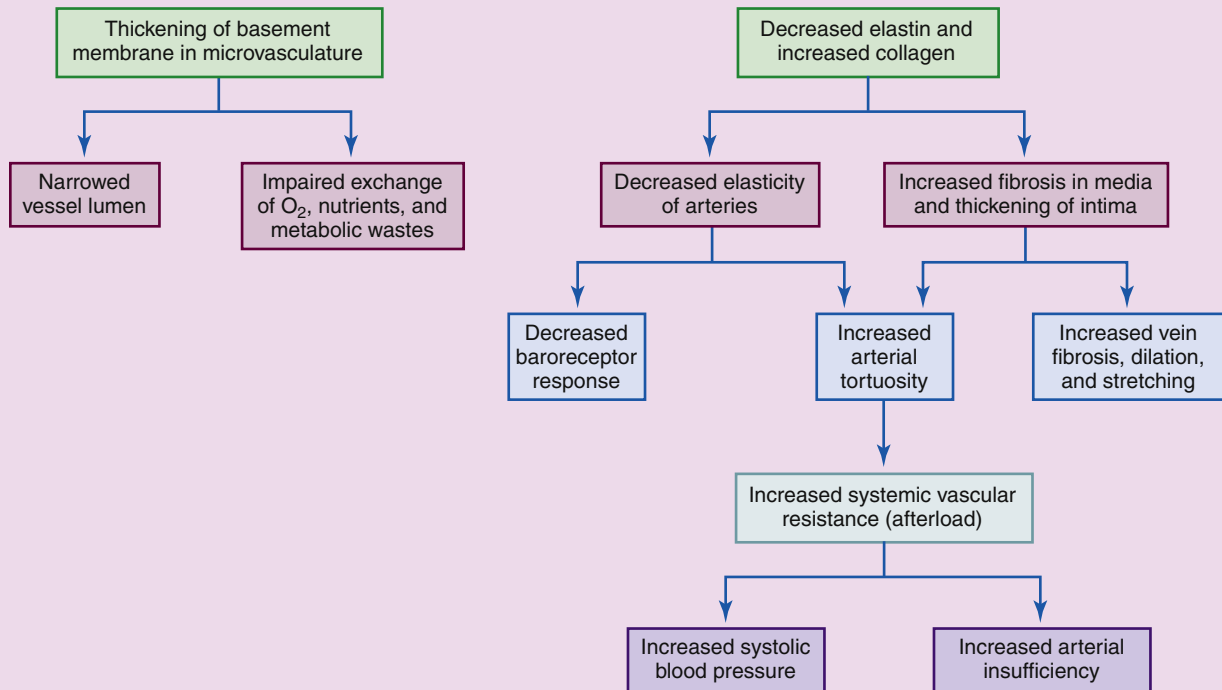

**FIGURE 15-5** Tunicae of arteries and veins showing the thicker walls of the arteries.

the media, causing degeneration of the smooth muscle tissue. In veins, the media also has smooth muscle, usually arranged in a circular pattern with some longitudinal strands. The quantity of smooth muscle decreases as the veins become larger. Venous media also contains collagenous connective tissue, but elastic tissue is rare except in the largest veins.

In veins, the adventitia is the thickest of the tunicae. It is composed of collagenous connective tissue and longitudinal smooth muscle. In larger arteries there is a discernible external elastic membrane in the adventitia. This membrane disappears as the arteries decrease in diameter. Arterial adventitia consists predominantly of collagenous

## GERIATRIC CONSIDERATIONS

## Changes in the Circulatory System

In the aging individual, changes occur throughout the vascular bed. The microvascular bed demonstrates thickening of the basement membrane. This change narrows the vessel lumen and impairs the free exchange of oxygen, nutrients, and metabolic wastes at the cellular level.

In both arteries and veins, the vascular changes occur first in the proximal portions. The intima becomes fibrotic and the endothelial cell variation increases. In the media, the amount of elastin and smooth muscle is reduced, whereas the amount of fibrotic and collagen tissue increases. With collagen cross-linking, the vessel walls lose elastic flexibility and recoil, becoming more stiff and less

compliant. They become inflexible tubes with an increase in systemic vascular resistance (SVR). The increased SVR causes a reduction in tissue and organ blood flow and decreased perfusion.

Baroreceptor function is reduced because of decreased sensitivity of the receptors and diminished responsiveness of the vessels attributable to their rigidity. These factors decrease the body's ability to respond to hypotensive and hypertensive stimuli. The decreased compliance of the systemic vascular system increases afterload, forcing the left ventricle of the heart to work harder to meet the metabolic demands of the body.

connective tissue. Some larger vessels also contain isolated, longitudinally arranged fibers of smooth muscle.

### Anatomy of Capillaries

Capillaries are composed of a single thickness of endothelial cells attached to a protein network called the basement membrane. Moving from the end of an arteriole to the beginning of a venule, capillaries narrow to a diameter barely sufficient for a single red blood cell (RBC) to pass through the aperture. In some tissues, one or two smooth muscle cells form a precapillary sphincter that controls flow through the vessel (Figure 15-6).

There are spaces between the endothelial cells that vary in size among organ systems. These spaces, or pores, permit certain constituents to pass in and out of the capillaries. For example, capillary beds in the brain have little or no spaces and permit the passage of only certain molecules. The space between endothelial cells of the brain is so small that it is referred to as the *blood-brain barrier*. In parts of the kidneys, however, capillaries are more porous, allowing much larger molecules to move between the circulation and the filtrate (urine). The size of these spaces determines the *capillary permeability* of a specific capillary bed.

### Lymphatic Structure

Lymphatic vessels are thin walled and most resemble veins in their appearance. Like their counterparts in the circulatory system, they range in size from lymphatic capillaries to vessels of increasing diameter. Like veins, lymphatics have intermittent valves composed of folds of their inner layer that extend into the lumen (Figure 15-7). The walls of lymphatic capillaries contain contractile fibers that are stimulated when stretched, causing the vessels to contract and propel lymph along the vessel.

#### KEY POINTS

- Arteries and veins have three distinct layers. The intima, the innermost layer, is composed of a single layer of endothelial cells. The media, or middle layer, is composed of smooth muscle and elastin. Media is thicker in arteries than in veins. The adventitia, the outermost layer, is composed of supporting connective tissue.
- Capillaries have only a single layer of endothelial cells attached to a basement membrane. The permeability of capillaries is determined by the tightness of the endothelial cell connection.
- Lymphatic vessels resemble veins, having thin walls and valves.

## PRINCIPLES OF FLOW

### Hemodynamics of the Circulatory System

The principles of blood flow are known as circulatory **hemodynamics**. These principles govern the quantity of blood passing by a given point in a specific period. Therefore, blood flow is measured as a given number of liters, milliliters, or cubic centimeters per second, minute, or hour. A discussion of the hemodynamics of the circulatory system includes the concepts of pressure, resistance, velocity, laminar and turbulent flows, wall tension, and compliance.

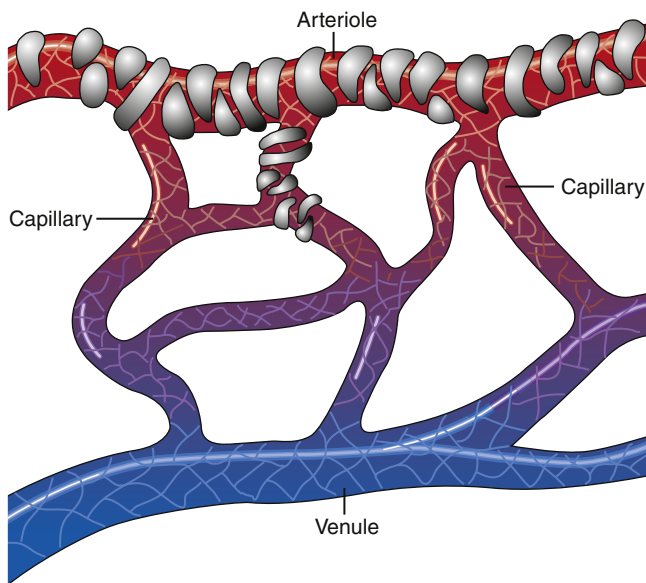

FIGURE 15-6 Capillary network.

### Blood Flow, Pressure, and Resistance

Blood flow is accomplished by movement along a pressure gradient within the vascular bed. This means that blood moves from an area of higher pressure to an area of lower pressure. The arterial and arteriolar walls with their muscular media coats provide the high-pressure end of the gradient. Seeking a lower pressure, blood moves toward the venous system. The thinner, more pliable walls of the venous bed furnish the low-pressure portion of the pressure gradient. The greater the pressure difference, the greater the rate of blood flow.

The movement of blood through the vascular system is opposed by the force of *resistance*. The relationship between blood flow and resistance is an inverse one: as resistance increases, blood flow decreases. This force has several determinants, each of which can change resistance considerably; these determinants are represented in physiology by *Poiseuille's law*:

$$\text{Resistance} = \frac{8nl}{\pi r^4}$$

The number 8 is a mathematical constant, as is the value of  $\pi$ ;  $n$  represents blood viscosity,  $l$  represents the length of a given vessel, and  $r$  is the radius of the vessel. Using this formula, the effects of changes on the components of resistance are very predictable.

Two of the determinants of resistance are *vessel length* and *vessel radius*. As predicted by Poiseuille's law, resistance changes directly with the length of the vessel, and these changes in resistance significantly affect flow. As illustrated in Figure 15-8, given three vessels of the same radius, doubling the length increases the resistance and reduces the flow ( $Q$ ) by 50%. Reducing the vessel length by half decreases resistance and increases the flow by 100%. These changes in flow occur when the pressure gradient remains constant and are caused solely by variations in vessel length. Resistance decreases as the radius of a vessel increases and resistance is inversely related to the fourth power of the radius of a vessel, or  $r^4$ . Therefore, increasing a vessel's radius markedly

FIGURE 15-7 Lymphatic network. The lymphatic system is integrally related to the systemic vascular system. Excess fluid and plasma diffuse between the capillaries, interstitial spaces, and lymphatic vessels. Because lymphatic capillaries have larger spaces between endothelial cells, they can remove excess interstitial fluid or plasma that venous capillaries cannot reabsorb.

reduces resistance and produces an exponential increase in blood flow. Figure 15-9 demonstrates the effect of doubling the radius of a vessel on the flow of blood if all other factors related to flow are held constant. The resulting flow of blood is 16 times greater in the greater diameter vessel.

Although there is variability in the length of vessels throughout the circulatory system, vessels are incapable of altering their own length. They do, however, possess a considerable ability to change their diameters, and many disease processes (e.g., arteriosclerosis) and drug therapies (e.g., vasopressors) are associated with changes in the size of the vessel lumen. Even minor changes will produce major alterations in resistance and, hence, blood flow. This makes changes in diameter the most important determinant of resistance.

The third determinant of resistance is the *viscosity* of the blood itself, represented in Poiseuille's law as  $n$ . Viscosity is defined as the thickness of a fluid. When the blood is more viscous, the friction between the cells and the liquid increases, and an increase in resistance to flow is produced. Blood is composed of a suspension of cellular material and plasma. Approximately 99% of the cellular constituents of the blood are RBCs. The ratio of RBCs to plasma is presented in the laboratory value *hematocrit*. Increasing the number of RBCs or decreasing the plasma component results in more viscous blood (increased hematocrit value), more resistance, and a slowing of blood flow. This is what occurs in dehydration, when the plasma component is relatively decreased, or in polycythemia, when the number of RBCs increases.

$Q = 10 \text{ ml/sec}$

$Q = 5 \text{ ml/sec}$

$Q = 20 \text{ ml/sec}$

**FIGURE 15-8** Relationship of vessel length to blood flow ( $Q$ ) with a constant pressure gradient.

$Q = 10 \text{ ml/sec}$

$Q = 160 \text{ ml/sec}$

**FIGURE 15-9** Relationship of vessel radius ( $r$ ) to blood flow ( $Q$ ) with a constant pressure gradient.

The relationship between the variables of driving pressure and resistance and their effect on blood flow is expressed by *Ohm's law*, as follows:

$$Q = P/R$$

Here,  $Q$  is the blood flow,  $P$  is the pressure difference between two points, and  $R$  is resistance. Altering any one of the determinants of resistance (vessel length, vessel radius, or blood viscosity) produces a change in flow. According to Ohm's law, a change in the pressure difference within the circulatory system also results in a change in the flow of blood. The arterioles are the major site of resistance in the vascular system and require a greater pressure to maintain blood flow. As the resistance decreases across the systemic vasculature, less pressure is necessary to maintain blood flow (Figure 15-10). *Total peripheral resistance* refers to the resistance throughout the entire vascular system. It can be calculated on the basis of the pressure difference between the arteries and the veins. Clinically, systemic vascular resistance (SVR) is used to specifically denote resistance peripheral to the heart and lungs. Because the primary determinant of SVR is the resistance vessels (arterioles), diseases or drug therapies that affect these vessels have the most profound impact on the SVR. Any condition that produces an increase in SVR, such as hypertension, requires more work for the heart to overcome the elevated resistance and eject its volume of blood (see Chapter 16). This increased workload means that the heart needs more oxygen and nutrients. When SVR is pathologically decreased, the blood is distributed over a larger area and blood flow slows dramatically. Individual organs, such as the kidney and brain, may not obtain sufficient blood flow to meet metabolic needs. This is what occurs in distributive shock states (see Chapter 20).

### Velocity and Laminar and Turbulent Flow

As previously discussed, blood flow is defined as the volume of blood that passes by a given point in a given unit of time. *Velocity* is a measure

**FIGURE 15-10** Mean pressure changes within the systemic vasculature. A significant decrease in pressure occurs as blood flows through the arterioles into the capillaries. The figure illustrates the role of the arterioles in the determination of vascular resistance. Because of the large number of capillaries, total resistance is not increased with the decreased radius of the capillaries.

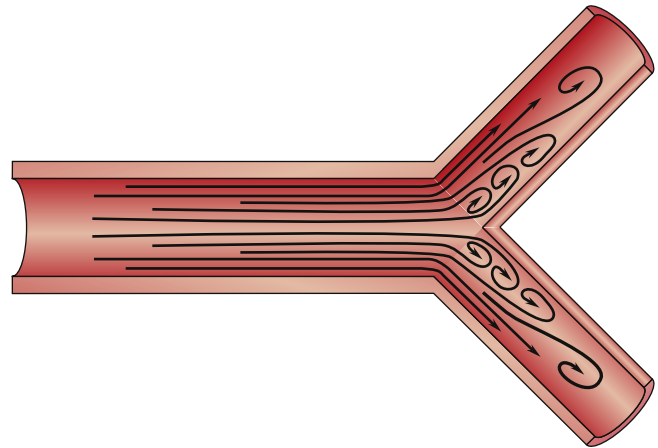

**FIGURE 15-11** Effect of increasing cross-sectional area on the velocity of blood flow. Increased cross-sectional area in the capillary bed results in a significant decrease in velocity when compared to the arterial and venous networks.

of the distance traveled in a given interval of time and is usually expressed in centimeters per second. Velocity is governed by the total cross-sectional area and varies inversely with it. An increase in the total cross-sectional area produces a decrease in velocity, whereas a decrease in the total cross-sectional area produces an increase in velocity. The total cross-sectional area of the aorta and vena cava is small and they have the most rapid rate of flow, whereas the capillary beds combine to produce the greatest total cross-sectional area and have the slowest flow rate. The dividing and subdividing of vessels within the circulatory system results in greater velocity in the arterial and venous beds than in the capillary bed (Figure 15-11). An understanding of the concept of velocity enhances discussion of laminar and turbulent flow.

When blood flows through a long, smooth-walled vessel, it does so in layers. The velocity of the layers varies, with blood in the center moving much faster than blood in the outer layers. The blood in the center layer moves the most quickly because it is in contact with blood only. The outermost layer is also in contact with the intima of the vessel wall, which exerts friction against the cellular components of the blood. Many blood cells stick to the intima; this layer may flow only minimally. Layers of blood between this outer layer and the central core of blood slide over one another with increasing velocity. This is referred to as the *parabolic profile of laminar flow* and is illustrated in Figure 15-12.

**FIGURE 15-12** Parabolic profile of laminar blood flow.

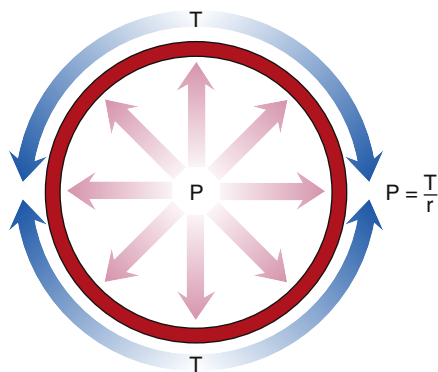

**FIGURE 15-13** Turbulent flow generated at a blood vessel bifurcation.

The streamlined nature of laminar flow is disrupted by normal anatomy and by pathologic processes creating turbulent flow. Turbulent flow is an interruption in the forward current of blood flow by crosswise flow (Figure 15-13). The propensity for turbulent flow increases with increasing velocity and increased vessel radius, so that some turbulence can be predicted at the aortic root and in the branches of major arteries. The same process can be seen in a river, where boulders interrupting the flow produce whirlpools and the characteristic roar of rapids. In the human body, turbulent flow through blood vessels can be auscultated as a **bruit**. Sometimes it can be palpated as well, and then it is called a **thrill**. This turbulence may be the result of a normal increase in velocity or be attributable to blood moving through vessels that branch at a sharp angle. Pathologically, turbulence results if blood flows around an obstruction in the vessel or over a roughened intimal surface. Regardless of cause, turbulent flow alters the parabolic profile seen with laminar flow, slowing velocity around the source of the turbulence. This slowing can cause cellular components of the blood to adhere to one another, to the turbulent focus itself, and to the intimal wall, promoting the formation of a blood clot (**thrombus**).

### Wall Tension and Compliance

The relationship between distending pressure and wall tension is expressed by the *law of Laplace* and is illustrated in Figure 15-14. This physical principle has broad applications in physiology; however, the present discussion focuses on its implications for blood vessels. The distending pressure ( $P$ ) is the transmural pressure, or pressure on one side of the vessel wall minus the pressure on the other side of the blood vessel. It is equal to the wall tension ( $T$ ) divided by the radius of the blood vessel ( $r$ ). In summary, an increase in radius or distending pressure results in increased wall tension.

When the pressure of the blood in the vessel begins to decline, wall tension forces exceed distending forces, the radius decreases, flow rate declines, and resistance increases. The distending pressure may fall to a point at which it is no longer possible to hold the blood vessel open. If

**FIGURE 15-14** Law of Laplace as applied to a blood vessel. Distending pressure ( $P$ ) is the difference between the pressures on either side of the vessel and is equal to the wall tension ( $T$ ) divided by the radius of the blood vessel ( $r$ ).

the pressure reaches 20 mm Hg, a point called the *critical closing pressure*, blood flow ceases entirely.

The smaller the radius of the blood vessel, as in a capillary when compared to an artery or a vein, the less tension is needed in the wall to equalize the distending pressure. Wall tensions decrease rapidly from 170,000 dynes/cm in the aorta to 16 dynes/cm in the capillaries, rising to 21,000 dynes/cm in the vena cava.

Wall tension is a product of the elasticity of the vessel and is a force that opposes the distending pressure. The manner in which wall tension in a given vessel responds to changes in distending pressures is based on its compliance. Compliance reflects the distensibility of a blood vessel—its ability to accept an increased volume of blood. The large quantity of muscle tissue in much of the arterial system limits its distensibility. Veins, however, are highly distensible and compliant, capable of holding a large quantity of blood at a low pressure. Because of this quality, veins are referred to as *capacitance vessels*. When the body is at rest, 75% of the total blood volume is found in the systemic venous system.

### Dynamics in the Microcirculation: Capillaries and Lymphatics

The smallest vessels of the vascular system and the lymphatic vessels are commonly referred to as the *microcirculation*. The primary function of the capillary bed is essentially the essence of the entire circulatory system: the exchange of gases and nutrients. Blood flow in the capillary bed is largely laminar, with minimal turbulence at bifurcations. Within each organ or tissue in the body, capillary blood flow is related to the driving force, which is the difference between arterial and venous pressures, and inversely related to resistance.

The exchange of materials across the capillary endothelium through the interstitial space, to or from the cells, occurs on an ongoing basis. Substances pass between tissue interstitial fluid and capillary blood by moving along a concentration gradient (diffusion), whereas fluid moves according to a pressure gradient (filtration). As fluid moves through the interstitial space, most of it returns to the capillary bed. Normally, approximately 10% of the fluid remains in the interstitium and is absorbed by the adjacent lymphatic system to be returned to the general circulation. Alteration in the pressure gradient responsible for filtration can allow an excessive amount of fluid to escape into the interstitial space. Increased fluid accumulation in the interstitial space also can occur when the lymphatic flow is impaired or when capillaries become more permeable and “leak” fluid. These are the pathophysiologic mechanisms that result in **edema**.

**FIGURE 15-15** Components of the capillary pressure gradient. Filtration reflects the difference between the combined forces that push fluid out of the capillary (capillary pressure and interstitial fluid colloid osmotic pressure) and those that attempt to hold fluid in the capillary (plasma colloid osmotic pressure and interstitial fluid pressure).

The pressure gradient between the capillary and the interstitium is produced and maintained in accord with the balance of four distinct forces or pressures: (1) capillary hydrostatic pressure ( $P_{cap}$ ), (2) interstitial fluid colloid osmotic pressure ( $\pi_{tissue}$ ), (3) plasma colloid osmotic pressure ( $\pi_{cap}$ ), and (4) interstitial fluid pressure ( $P_{tissue}$ ) (Figure 15-15). This delicate balance of forces is summarized by *Starling's hypothesis*, which states that the net filtration is equal to the combined forces fostering filtration minus the combined forces opposing filtration. Using the normal values shown in Figure 15-15, each component of the formula and the resulting net filtration pressure are shown below:

$$\begin{aligned} \text{Pressures favoring filtration} &= P_{cap} + \pi_{tissue} \\ (+17.3 \text{ mm Hg}) + (+8.0 \text{ mm Hg}) &= 25.3 \text{ mm Hg} \\ \text{Pressures opposing filtration} &= P_{tissue} + \pi_{cap} \\ (-3.0 \text{ mm Hg}) + (28 \text{ mm Hg}) &= 25.0 \text{ mm Hg} \\ \text{Net filtration pressure} &= (P_{cap} + \pi_{tissue}) - (P_{tissue} + \pi_{cap}) \\ (+25.3 \text{ mm Hg}) - (+25.0 \text{ mm Hg}) &= +0.3 \text{ mm Hg} \end{aligned}$$

Clinically, capillary fluid pressure and plasma colloid osmotic pressure are the most important concepts to a discussion of pathophysiology. Capillary fluid pressure is the blood pressure in the capillary. It is the force pushing fluid from the capillary into the interstitium and is often called the *hydrostatic pressure*. The strength of this force depends on the blood pressure and the resistance within the arterial and venous systems. Pathologic conditions resulting in an increase in either the blood pressure or the resistance to flow can alter this force, increasing it and propelling more fluid into the interstitial space, resulting in the formation of edema.

Plasma proteins are responsible for the plasma colloid osmotic pressure, the primary force resulting in fluid remaining in the capillary. Most plasma proteins normally remain in the capillaries because they are such large molecules that they cannot move through the capillary spaces. The vast majority of plasma protein, by weight, is albumin. Although globulins and fibrinogen have greater molecular weight, albumin is present in plasma in greater quantity. The number of dissolved molecules in the plasma determines the *plasma colloid osmotic pressure*. The number of dissolved molecules in the interstitial space

establishes the interstitial fluid colloid osmotic pressure. Plasma has nearly four times the concentration of proteins than does the interstitium. For that reason, plasma colloid osmotic pressure normally exceeds that in the interstitium, favoring fluids remaining in the capillaries.

As previously illustrated, the net filtration pressure in a typical capillary is 0.3 mm Hg. This pressure difference is responsible for producing the fluid excess in the interstitial space, which is then normally absorbed by the lymphatic system for eventual return to the systemic vascular circulation. If the pressures are altered, an even greater pressure gradient may be produced and more fluid moves from the capillaries into the interstitial space. Likewise, a change in the permeability ( $K$ ) of the capillary wall that allows plasma proteins to leak out, or a reduction in lymphatic flow will allow fluid to collect in the interstitium. In each case, the result is edema, which can occur with many pathologic conditions. When the pathology is an impairment of lymphatic flow allowing fluid to collect in the interstitium, it is more specifically termed **lymphedema**.

Once absorbed into the lymphatic system, interstitial fluid is referred to as *lymph*. It is similar in composition to interstitial fluid but has a lower concentration of protein. Molecules of fat and bacteria are also found in lymph. Lymph circulates throughout the body at a rate of approximately 3 L/day. Lymphatic flow can be increased in several ways: by increasing the capillary pressure, decreasing the plasma colloid osmotic pressure, increasing the interstitial fluid colloid osmotic pressure, or increasing the permeability of the capillaries. The interstitial fluid hydrostatic pressure increases (becomes less negative) when any of these factors changes, producing an increase in lymphatic flow.<sup>1</sup>

#### KEY POINTS

- Physical laws govern the flow of blood through the circulatory system. Predictions regarding blood flow, blood pressure, and resistance to flow can be made using these laws. The important relationships may be summarized as follows:
  - Flow = pressure/resistance
  - Blood pressure = flow (cardiac output)  $\times$  resistance
  - Resistance = pressure/flow
- The main factors affecting resistance to flow are the radius and length of the vessels, and blood viscosity and turbulence. Usually, the radius of the vessel is the most important determinant of resistance. It affects resistance inversely and to the fourth power. A small decrease in radius results in a large increase in resistance.
- The velocity of blood flow varies inversely with the total cross-sectional area of the vascular bed. The capillaries have the greatest total cross-sectional area and, therefore, the slowest flow.
- Laplace's law describes the relationships among wall tension, distending pressure, and vessel radius ( $P = T/r$ ;  $T = Pr$ ). An increase in radius or distending pressure results in increased wall tension. At critical closing pressure, wall tension overwhelms distending pressure and blood flow ceases.
- The transcapillary exchange of fluid and nutrients is accomplished by the processes of diffusion and filtration. Diffusion refers to movement of solute and is determined by capillary permeability and the size of the concentration gradient. Filtration refers to movement of fluid and is affected in the following ways:
  - Increased capillary fluid pressure and interstitial fluid colloid osmotic pressure enhance filtration.
  - Increased interstitial fluid pressure and plasma colloid osmotic pressure oppose filtration.
  - Increased permeability ( $K$ ) enhances filtration.

## CONTROL OF FLOW

Blood flow throughout the periphery is controlled by central mechanisms that are mediated by the autonomic nervous system, the venous and thoracic pumps, and intrinsic autoregulatory mechanisms. Lymphatic flow is controlled by increasing interstitial fluid colloid osmotic pressure and by the stimulation of the contractile fibers (often called *lymphatic pumps*) as they are stretched. In healthy people, these mechanisms of control respond to changes in the internal and external environments and compensate rapidly and efficiently; however, during states of illness these mechanisms may be inadequate to compensate for alterations in flow.

### Control of Blood Flow

#### Extrinsic Mechanisms

The autonomic nervous system provides the primary extrinsic control of blood flow through the sympathetic nervous system (SNS). Although parasympathetic nervous system (PSNS) innervation is important to the regulation of the heart, it is not important to the regulation of peripheral resistance. Within the medulla, groups of neurons form the *vasomotor center*. This area plays a major role in the maintenance of blood pressure (see Chapter 16). The vasomotor center responds to direct stimulation and to afferent stimuli of both an excitatory and an inhibitory nature. A basal rate of discharge from the vasomotor center results in a continuous minimal level of contraction of vascular smooth muscle, referred to as *vasomotor tone*.

All blood vessels except the small venules and capillaries contain smooth muscle that is innervated by adrenergic fibers from the SNS. Because arteries have the most smooth muscle, they are most affected by SNS stimulation. Veins, by contrast, have little neural innervation, and venoconstriction has a minor role in controlling blood flow except in the skin and the splanchnic circulatory bed of the gut. In general, the release of norepinephrine, the SNS postganglionic neurotransmitter, results in arterial vasoconstriction via the  $\alpha_1$  receptors located on the vascular smooth muscle walls. Likewise, drugs that mimic the  $\alpha_1$ -receptor response ( $\alpha_1$  agonists) produce vasoconstriction, increasing vasomotor tone and diastolic blood pressure. Administration of an  $\alpha_1$  antagonist results in the blockade of these receptors and results in vasodilation of the arterial bed, reducing blood pressure.

Although the  $\beta_2$ -adrenergic receptors located on blood vessels in skeletal muscle produce vasodilation when stimulated, they are only minimally affected by endogenous norepinephrine from the SNS. Epinephrine, the endogenous catecholamine released by the adrenal medulla, or its exogenous pharmacologic equivalent (adrenalin), stimulates these receptors, producing vasodilation. Therefore, their major role is not so much to maintain vasomotor tone but to increase nutrient and oxygen supplies to skeletal muscles during periods of increased demand.

Blood flow through the venous system into the right side of the heart is maintained by the pressure gradient from the veins and by the venous and thoracic pumps. Blood is propelled through the circuit, pushed by the force of left ventricular contraction, and moves forward toward the low-pressure side of the pump on the right side of the heart. In the peripheral veins, what is known as the *venous pump* is activated by skeletal muscle activity. Folds in the intimal wall of the veins create valves. Contraction of the skeletal muscles bordering the veins compresses them, forcing the valves open and propelling venous blood back toward the heart. Instigation of the venous pump significantly facilitates venous return. Patients who are immobilized by bed rest lose this valuable mechanism, which results in a decrease in cardiac preload to the right heart and increased work of the heart to maintain the cardiac output. The *thoracic pump* acts to increase venous return to the

heart as intrathoracic pressure changes with breathing. Inspiration increases negative intrathoracic pressure, resulting in more venous return (see Chapter 17).

### Intrinsic Mechanisms

*Autoregulation* refers to the ability of blood vessels within organs to maintain a relatively constant blood flow, regardless of changes in arterial pressure. This flow is *relatively* constant because it does have limits; there is a range within which it is maintained, and the range varies slightly from organ to organ. Several processes contribute to the autoregulation of perfusion to meet the needs of individual organs within the body.

It is known that as vascular smooth muscle is stretched, it contracts. Therefore, as arterial pressure rises and arterial walls stretch, contraction is stimulated, producing vasoconstriction. Resistance to flow is also increased with stretch by early closing of precapillary sphincters. This process certainly may contribute to autoregulation, but it is not the primary mechanism.

Over the past several decades, a great deal has been learned about the endothelium of blood vessels. The previous perceptions of the endothelium as an inactive structure, whose function was no more than acting as a barrier between the blood and the more functional layers of the vessel wall, have been proven incorrect.<sup>2</sup> We now understand that the endothelium is a major participant in vascular tone and growth of vascular smooth muscle.<sup>2</sup> The endothelium tissue plays an active role in the immune and inflammatory processes (see Chapter 9), platelet activity in normal coagulation and thrombus formation (see Chapter 14), and arteriosclerosis,<sup>2-4</sup> discussed later in this chapter. In a discussion of autoregulation, the key is the endothelial role in modulating vascular smooth muscle to produce vasoconstriction or vasodilation. The endothelium is capable of sensing alterations of a chemical or physical nature within the vessel and responding to these stimuli directly or through the release of signals that initiate change.<sup>3</sup> Almost all of the vasodilation occurs because of the effect of nitric oxide (NO). NO is a gas present in most body tissues and is produced by the cells of the vascular endothelium. As a gas, it diffuses from the endothelium to the smooth muscle cells, binding to intracellular receptors to impact cytoplasmic  $Ca^{++}$  concentration and produce vasodilation.<sup>3-5</sup> Deficits of nitric oxide, or a decreased responsiveness, have been the focus of considerable recent research into the pathogenesis of hypertension (Chapter 16) and heart disease (Chapter 18).<sup>2-7</sup> Other relaxing factors produced by the endothelium include prostacyclin, and endothelium-derived hyperpolarizing factor.<sup>6</sup> Angiotensin II, endothelin, oxygen-derived free radicals, prostacyclin  $H_2$ , and thromboxane  $A_2$  are among the constricting factors. The role of angiotensin II (AII) as a constricting factor has been the focus of considerable recent research.<sup>7</sup> Because drugs that block the effects of AII are available and in widespread use, the ability of these drugs to improve peripheral vascular blood flow has been an important finding.<sup>7</sup> In addition to substances produced by the endothelium itself, metabolic by-products (metabolites) or substrates have been found to exert a direct effect, altering blood flow to the area.<sup>1</sup> Metabolites might include carbon dioxide or lactic acid. Histamine and prostaglandins are examples of metabolic substrates. Other substances, such as acetylcholine, bradykinin, histamine, and substance P, exert their effect by increasing the formation of nitric oxide or are themselves generated by nitric oxide.<sup>7</sup> These various chemicals create a balance of forces in health. They may also be affected by aging, disease, or pharmacologic interventions.

A local increase in blood flow is referred to as **hyperemia**. The increase in local blood flow in response to increased metabolic demand is called *active* or *functional* hyperemia. *Reactive* hyperemia occurs when a temporary reduction in blood flow is reversed. The body

responds by briefly increasing circulation to the area, resulting in the characteristic flushing seen, for instance, when a tourniquet is removed. The *tissue pressure hypothesis* of autoregulation postulates that an acute increase in the pressure within the arterial system causes an increase in interstitial volume and pressure. This increased tissue pressure, external to the vasculature, results in compression of small vessels, which increases resistance and reduces flow.

### Control of Lymphatic Flow

The movement of lymph is expedited by lymphatic pumps. This is a general concept that encompasses the pumping action of the lymphatics themselves and the pumping effect on the lymphatic vessels produced by activity external to them. Like veins, lymphatic vessels have valves on their intimal surface that allow forward movement of fluid to join the venous return to the systemic circulation. Compression of lymphatic channels by adjacent skeletal muscles, the smooth muscle of organs, and the pulsatile movement of arteries force lymph forward. Intrathoracic pressure changes related to breathing increase lymphatic return as well as venous return. Lymphatic flow is therefore enhanced by increased physical activity, increased blood pressure, or increased respiratory rate. Lymphatic contractions are thought to be the primary factor in lymphatic flow. Lymph is propelled forward when lymphatic capillaries contract in response to being stretched. The rate of contractions increases as the volume of lymph increases.

#### KEY POINTS

- The blood flow through a particular vascular bed is regulated centrally by the autonomic nervous system and locally by the organ or tissue.
- In most vascular beds, the SNS causes constriction, which increases resistance and reduces flow. Smooth muscle cells in these vascular beds have  $\alpha_1$  receptors that bind the SNS neurotransmitter norepinephrine, causing contraction. There is no significant parasympathetic innervation of systemic vessels.
- Autoregulation refers to a tissue's ability to regulate its own flow. Autoregulation allows a tissue to maintain optimal flow despite changes in blood pressure or metabolic demands. In instances of high blood pressure or decreased metabolic demand, the arterioles and precapillary sphincters that control flow to the tissue constrict, reducing flow. In instances of low blood pressure or high demand, vessels dilate, increasing flow.
- Lymphatic vessels maintain flow by contracting when stretched with lymph. Intraluminal valves prevent backflow. External compression by contracting muscles enhances lymph flow.

### GENERAL MECHANISMS THAT CAUSE ALTERED FLOW

A reduction in flow through the systemic vasculature results in the impaired ability to transport gases and nutrients to and from body tissues. Cells of the body vary in their oxygen demands. *Hypoxia*, an insufficient supply of oxygen, can occur for many reasons, such as a decrease in hemoglobin formation (see Chapter 13) or diminished oxygen transport in the lungs (see Chapter 21). When hypoxia is a result of a decrease in flow through the arterial system, it is called *ischemia*. Impairment in flow through the venous system interferes with the removal of metabolic waste products and causes fluid pressure to accumulate in the system, a condition known as *venous engorgement* or *venous obstruction*. When the lymphatic circulation is altered, the resulting fluid and pressure changes may be visible locally or systemically.

## Blood Vessels: Obstructions

Pathologic processes affecting blood flow may involve impedance of the arterial or venous system. Some obstructions to flow are specific to either the arterial or the venous portion of the system, but most can occur in some form in both. Obstructions to flow that may interfere with arterial or venous flow are presented in detail in the following discussion. Those that are specifically related to one or the other are detailed more fully later in the chapter.

### Thrombus

A thrombus is a stationary blood clot formed within a vessel or a chamber of the heart. Thrombosis is initiated by a change in the blood vessel resulting in localized stasis of flow. Inflammation of blood vessels may be the stimulus for thrombosis in either arteries or veins.

**Etiology.** Thrombosis refers to the pathologic formation of clots at these sites, to differentiate it from the clotting process that takes place as a homeostatic mechanism. Thrombi (blood clots) are composed of aggregated platelets, clotting factors, and fibrin that adhere to vessel walls.<sup>1,8</sup> Thrombi may form in the chambers of the heart in association with certain abnormal heart rhythms (see Chapter 19), following a myocardial infarction, or as a result of damage to heart valves or replacement of heart valves with artificial ones (see Chapter 18). More commonly, thrombi develop in either the arterial or the venous peripheral circulatory systems. Activation of the coagulation cascade within the vessel produces a hypercoagulable state resulting in thrombosis (see Chapter 14, Figure 14-4). Certain drugs, such as oral contraceptives, increase the tendency to form thrombi as well. Thrombosis is also more likely to occur when blood flow slows dramatically or becomes more turbulent, or if there is damage to intimal walls, creating a roughened surface.

### Pathogenesis

**Arterial.** The significance of thrombosis rests in the ability of a clot within a blood vessel to reduce flow and increase turbulence, which enhances thrombus enlargement and the formation of more thrombi. The results of reduced blood flow vary depending on whether the arterial or venous system is involved. If the thrombus forms in the arterial system, decreased distal flow can result in **ischemia**. This is significant in several pathologic conditions, such as acute arterial occlusion (discussed in this chapter). Other examples of arterial thrombosis are explored elsewhere in this text (e.g., myocardial infarction, Chapter 18; stroke, Chapter 44).

**Venous.** In the venous system, thrombosis alters venous return, impairing removal of metabolic wastes and producing swelling (edema). When inflammation occurs in a vein (**phlebitis**) and is accompanied by the formation of a thrombus, it is called **thrombophlebitis**. The most common cause of thrombophlebitis is the inflammation produced by the presence of a needle or catheter used for intravenous therapy. Thrombosis may also be initiated by a generalized reduction in flow and the accompanying release of vasoactive substances that occur in shock states (see Chapter 20). Systemic derangement in coagulation takes place in disseminated intravascular coagulation, resulting in thrombosis in the microcirculation throughout the body (see Chapter 14). Risk factors associated with both arterial and venous thrombosis are listed in Box 15-1.

**Clinical manifestations and treatment.** Arterial thrombosis is usually manifested by intermittent claudication (pain with activity) in the affected limb that improves with rest. The limb might also be cool to touch and cyanotic. A late sign is a painful arterial ulcer found usually around one toe.<sup>8</sup>

Symptoms for venous thrombosis may be absent or may be life threatening secondary to pulmonary embolism. Other signs include calf or groin tenderness and swelling of the affected limb with associated

## BOX 15-1 RISK FACTORS COMMONLY ASSOCIATED WITH THROMBOSIS

### General (Arterial and Venous)

Hypercoagulable conditions

- Polycythemia
- Dehydration
- Platelet aggregation

Pump failure

- Heart failure
- Shock

Dysrhythmias

Aging

Trauma, including surgery

Drugs

- Anesthetic agents
- Oral contraceptives
- Tobacco

### Arterial

Arteriosclerosis/atherosclerosis

### Venous

Immobilization/sedentary lifestyle

increased skin temperature. Pain in the calf with dorsiflexion of the foot (Homan sign) appears in 10% of those with thrombophlebitis.

Interventions in the management of thrombus formation may be medical or surgical. Ideally, thrombosis is prevented in high-risk individuals through pharmacologic and other medical interventions. The prophylactic (preventive) interventions may include oral or parenteral anticoagulant therapy, or drugs to block platelet activation and/or aggregation.<sup>9</sup> Risk factors must be addressed. Once a thrombus has formed, anticoagulant therapy at a therapeutic level is initiated to prevent the enlargement of the thrombus and formation of further thrombi. However, these drugs are not effective in dissolving an existing clot. These clots must be removed by the body's own fibrinolytic process, surgically removed, or dissolved by intravenous thrombolytic agents. Anticoagulant therapy is currently used for patients with thrombi in coronary and pulmonary arteries, peripheral arteries in the legs, and cerebral arteries. Their use must be closely supervised; patients receiving thrombolytic therapy are usually in critical care settings.<sup>9</sup> Additional medical prophylactic interventions may include the use of antiembolic stockings or sequential compression devices for immobilized patients, and initiation of ambulation as soon as possible. Surgical interventions, such as removal of the thrombus, may be an option.

Because thrombi partially or completely occlude flow through the involved vessel, they can produce ischemia distal to that point in an artery or congestion proximally in a vein. A thrombus that only partially occludes a vessel continues to be affected by the force of blood flow. Eventually, it may break free from the vessel wall and become an embolus.

### Embolus

An embolus is a collection of material that forms a clot within the bloodstream. This traveling clot is propelled forward in the circulatory system by blood flow to a distant point, where it lodges to produce a new site of obstruction.

**Etiology and pathogenesis.** An embolus is most often a blood clot, a **thromboembolus**, having begun as a thrombus that was subsequently dislodged from the vessel intima or from the valvular leaflets in the heart, or having formed within a chamber of the heart. Thromboemboli from the left side of the heart exit the aorta and most commonly lodge in a cerebral artery, resulting in a *stroke* (see Chapter 44). But most thromboemboli originate in the deep veins of the pelvis and lower extremities. They traverse the venous circulation and return to the right side of the heart, eventually lodging in the arterial side of the pulmonary vasculature and resulting in a pulmonary embolism (see

Chapter 21). A thromboembolus from the right side of the heart will also result in a pulmonary embolism. Thromboemboli from the venous circulation are the most common cause of pulmonary emboli, but the cause may be nonthrombotic, as is the case for tumor, fat, air, amniotic fluid, or bacterial emboli; these are less frequent and are further examined later in this discussion.

**Clinical manifestations.** An embolism exiting the left ventricle may lodge in the cerebral vasculature, leading to an ischemic stroke. Manifestations differ depending on the area of the brain affected. Symptoms include loss of cognitive function, motor changes, and different levels of sensory loss (see Chapter 44). More often, an embolism leaving the right ventricle lodges in the pulmonary vasculature. This pulmonary embolism may be asymptomatic or present with various signs and symptoms, many of which are vague and nonspecific.<sup>10</sup> Most common is the sudden onset of shortness of breath (dyspnea), increased respiratory rate, and chest pain. It may be a cause of sudden death.<sup>10</sup>

**Treatment.** *Embolectomy*, the surgical removal of an embolus, is usually confined to thromboemboli. The use of this surgical technique is contingent on the location of the embolus. In patients who experience repeated emboli, usually originating from the peripheral venous system, a filter (e.g., Greenfield filter) may be surgically implanted in the inferior vena cava.<sup>10</sup> As the blood passes through the filter, emboli are trapped and cannot progress into the pulmonary circulation. The body's own thrombolytic enzyme, plasmin, then destroys the trapped emboli.

**Emboli produced by other causes.** Various other materials, some totally foreign to the bloodstream, can also form emboli if present in sufficient quantity. Fat emboli are aggregates of fat molecules released into the blood after trauma or surgery involving bone. Most frequently the long bones of the legs are the source of these emboli. Increased pressure generated within the traumatized bone by the inflammatory response forces molecules of fat from the interior of the bone into the bloodstream. Malignant neoplasms can metastasize by various means, one of which is via the blood as tumor emboli. Collections of bacteria and infectious exudate may break free from a source within the circulation, such as the leaflets of the valves of the heart in bacterial endocarditis. Once in the bloodstream, the bacterial emboli continue to travel, eventually occluding circulation and becoming a new site of infection. Air from the external environment is a foreign material when found in the bloodstream as air emboli. Bubbles of air, having most likely entered the blood through an intravenous catheter, come to rest in small blood vessels and obstruct perfusion. It is difficult to identify the specific volume of air that can sufficiently obstruct flow to result in deleterious effects in humans. In animal studies, the quantity of air needed to produce death varies, partially affected by the speed with which it is injected. Under some circumstances, a 5-ml injection of air will result in death of animal models. At other times, a 100-ml bolus of air will not produce adverse effects.<sup>11</sup>

Increased pressure in the abdomen generated during labor and delivery may force amniotic fluid into the bloodstream as emboli. Here the emboli cause a different set of problems. Amniotic fluid cannot perform the functions of the blood in carrying gases and nutrients, but as a fluid, it does not produce obstruction to flow. Instead, the proteins and cells in amniotic fluid act as antigens, initiating an immune response.

## Vasospasm

**Vasospasm** is a sudden constriction of arterial smooth muscle that results in an obstruction to flow. In some cases, vasospasm is sufficient to produce hypoxia distally, as in variant (Prinzmetal) angina (see

Chapter 18) or vasospasm of cerebral vessels following a hemorrhagic stroke (see Chapter 44). Frequently, the cause of vasospasm is unknown. Certain individuals may be unusually sensitive to hormonal changes or food additives, which may result in vasospasm of cerebral arteries. The vasodilation following cerebral vasospasm is thought to contribute to migraine headaches. Vasospasm may also be mediated by environmental factors, such as exposure to cold or emotional stress, producing a localized response.

## Inflammation

**Vasculitis** is inflammation of the intima of an artery. Inflammation of the lining of a vein is called **phlebitis**. If superficial, these inflammations may be visible as reddened, tender streaks on the skin. Of more significance is their potential to serve as foci for the thrombotic process.

**Arteritis** (*angitis*) is a specific term that identifies an inflammatory process of autoimmune origin in arteries. The initiating stimulus is frequently an infectious process that is viral or bacterial (especially streptococcal), or an adverse response to drugs such as sulfonamides or phenothiazines.

## Mechanical Compression

A variety of forces external to the vascular system may result in partial or complete obstruction of blood flow. Trauma may produce direct pressure on a blood vessel, resulting in occlusion. This same effect may result from constriction from casts or tight dressings. Swelling secondary to bleeding or edema within a fascial compartment created by fascial tissue surrounding groups of muscle, or external compression of the compartment by a tight cast, eventually compromises the circulation distally, producing *compartment syndrome* (see Chapter 51). Prolonged occlusion produces neurovascular alterations that can be assessed before the ischemia is irreversible. These alterations are identical to those of acute arterial occlusion, discussed later in this chapter. In an untreated patient, compartment syndrome can result in prolonged hypoxia, ischemia, and necrosis of tissues.

## Blood Vessels: Structural Alterations

An assortment of conditions affecting blood vessel structure will produce alterations in blood flow. The structure of arteries or veins may be changed secondary to congenital anomalies or pathologic processes triggered later in life.

### Types of Structural Alterations

**Valvular incompetence.** The intimal folds of veins that form the valves can be damaged, interfering with the effective flow of blood through a portion of the venous system (**valvular incompetence**). The subsequent pathologic processes may affect superficial veins (**varicose veins**) or deep veins (**chronic venous insufficiency**), resulting in severe tissue hypoxia and venous stasis ulcers.

**Arteriosclerosis/atherosclerosis.** **Arteriosclerosis** is a complex condition that produces structural changes in arteries. **Atherosclerosis**, a specific type of arteriosclerosis, produces an increase in the number of smooth muscle cells and a collection of lipids within the intima of medium- and large-size arteries. This process eventually narrows the lumina and decreases their ability to dilate. Atherosclerotic changes are responsible for or contribute to many diseases throughout the body such as hypertension, renal failure, coronary artery disease (CAD), and cerebrovascular disease.

**Aneurysms.** An **aneurysm** is a localized dilation of an arterial wall. Aneurysms vary in the severity of their consequences, depending on their size, type, and location. All aneurysms produce an alteration in flow attributable to the changes in vessel diameter. More significant,

however, is the fact that the aneurysm represents a weakened area in the artery that may eventually rupture.

**Arteriovenous fistulas.** An **arteriovenous fistula (AVF)** is an abnormal communication between arteries and veins. It is usually congenital in origin but may result from traumatic injury. Symptoms depend on the size and location of the fistula. Because AVFs provide a shortcut between the two vascular systems, they can result in alterations in oxygenation to the involved tissues and systemic hemodynamic changes. One of the most common and serious types of AVFs is an **arteriovenous malformation (AVM)**. An AVM is a tangled knot of arteries and veins found most commonly within the brain vasculature. AVMs may be the underlying cause of such conditions as headaches, hemorrhagic stroke, dementia, or seizures (see Chapters 44 and 45).

### Lymphatic Vessels

The lymphatic collection system may be overwhelmed when changes in capillary or interstitial oncotic pressures increase filtration into tissues. The result is **edema**, the collection of an excessive amount of fluid in the interstitial spaces. A wide variety of conditions can result in edema.

When lymphatic flow is altered because of impairment in the circulation of lymph itself, the condition is called **lymphedema**. The result is also an excessive quantity of fluid in the interstitium, but the underlying cause is an obstruction to flow.

#### KEY POINTS

- Altered blood flow results from obstructive processes. Obstruction results in reduced flow beyond the obstruction (downstream) and increased pressure before the obstruction (upstream).
- In the arterial system, obstruction manifests primarily as distal ischemia. In the venous system, obstruction manifests as edema.
- The causes of vessel obstruction include thrombi, emboli, vasospasm, external compression (e.g., compartment syndrome), and structural alterations (e.g., atherosclerotic plaques, aneurysms).
- Alterations in pressures within the circulatory system or interstitium produce edema, whereas an impairment of the lymphatic system results in lymphedema.

## ALTERATIONS IN ARTERIAL FLOW

Alterations in arterial flow result from obstruction (arteriosclerosis/atherosclerosis, inflammation, vasospasm, thrombi, emboli, and acute occlusion) or mechanical alterations (AVFs and aneurysms).

### Arteriosclerosis/Atherosclerosis

**Etiology and pathogenesis.** **Arteriosclerosis** is a generic term meaning “hardening of the arteries” and broadly includes three pathologic processes: Mönckeberg sclerosis (medial calcific sclerosis), arteriolar sclerosis, and atherosclerosis. Mönckeberg sclerosis is a noninflammatory, degenerative disorder in which the media of small- and medium-size arteries becomes calcified.<sup>12</sup> The disease is a risk factor for cardiovascular disease, but the pathology is independent of atherosclerosis. The intimal layer is not a part of the pathogenesis; although the vessel becomes increasingly thickened and rigid, it remains patent because of the changes in the medial layer.<sup>12</sup> Arteriolar sclerosis is characterized by thickening and luminal narrowing of the small arteries that occurs in association with hypertension. However, because hypertension is primarily associated with atherosclerotic changes, this particular pathology is rarely addressed. Atherosclerosis, the most common arteriosclerotic process, affects intermediate-size and large arteries. Smooth muscle cells and lipids collect along the intimal surface, producing a narrowing of the luminal diameter and a reduction in flow (Figure 15-16).

Atherosclerosis is the dominant type of arteriosclerosis. The word is derived from two Greek words: *athero* (gruel or paste) and *sclerosis* (hardness).<sup>13</sup> It is the pathologic origin for the vast majority of arterial disease that is ultimately the leading cause of death in the United States and western Europe, and is increasing in developing countries.<sup>14</sup> Atherosclerosis tends to develop in large- and medium-size arteries, most frequently the coronary, cerebral, carotid, and femoral arteries and the aorta. Most of the mortality associated with atherosclerosis is the result of occlusion of coronary arteries (CAD), producing myocardial ischemia and infarction.<sup>15</sup> The remainder of atherosclerosis-related deaths is secondary to thrombotic or hemorrhagic processes, primarily in the brain (stroke) and extremities, although other organ systems including the kidneys, liver, and gastrointestinal tract are also affected. When atherosclerosis involves the peripheral vascular system, it is most often the lower extremities, and the disease process may be called

**FIGURE 15-16** Atherosclerotic plaque rupture. **A**, Plaque rupture without superimposed thrombus, in a patient who died suddenly. **B**, Acute coronary thrombosis superimposed on an atherosclerotic plaque with focal disruption of the fibrous cap, triggering a fatal myocardial infarction. In both panels **A** and **B**, an *arrow* points to the site of plaque rupture. (**A**, From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 351. **B**, Reproduced from Schoen FJ: *Interventional and surgical cardiovascular pathology: clinical correlations and basic principles*, Philadelphia, 1989, Saunders, p 61.)

**atherosclerosis obliterans.**<sup>8,16,17</sup> Box 15-2 lists the manifestations of this arterial peripheral vascular disease. With arterial occlusion, patients may complain of pain with activity (*intermittent claudication*; Figure 15-17) and also have pain at rest with advanced disease. Peripheral pulses are diminished. Ulceration may occur (Figure 15-18).<sup>8,16-18</sup> Research results from the classic Framingham Study identified the development of lower extremity arterial disease in 5% of the subjects over the course of the 24-year data collection interval.<sup>18</sup>

### BOX 15-2 CLINICAL MANIFESTATIONS OF ARTERIAL PERIPHERAL VASCULAR DISEASE

#### Skin Assessment

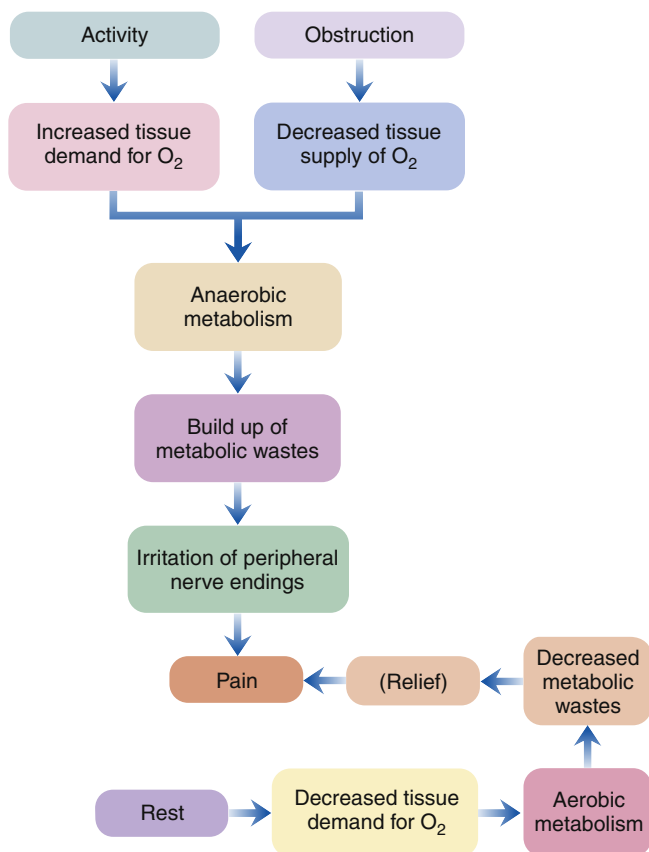

- Cool or cold to touch
- Decreased or absent hair growth
- Dry, thin, glossy appearance
- Thickened nails
- Pallor when elevated, rubor when dependent
- Diminished or absent pulses

#### Pain Assessment

- Sharp and stabbing
- Intensified with activity
- Relieved by rest or dependency

#### Ulcer Assessment

- Severely painful
- Pale, gray base
- Well-defined edges
- Located on heels, lateral malleolus, between distal portions of phalanges, pretibial area

**FIGURE 15-17** Pathophysiologic process of intermittent claudication and its relief.

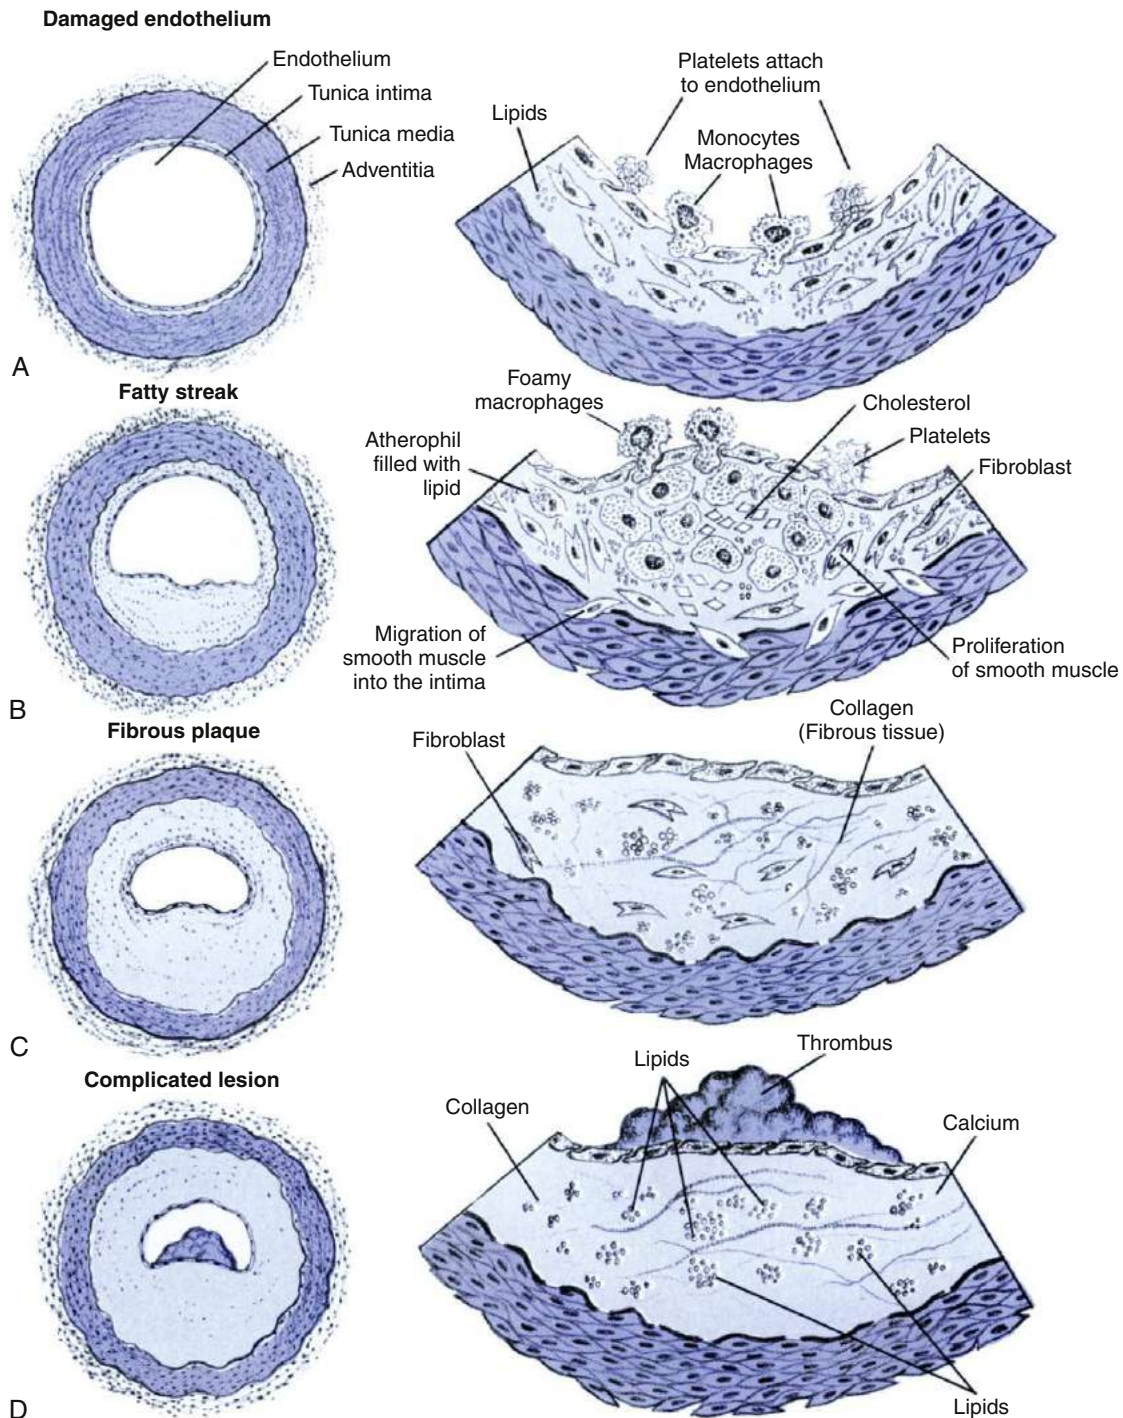

Because of the breadth of diseases known to be associated with atherosclerosis, a great deal of research has been accomplished and an understanding of many of the significant aspects of its pathogenesis has evolved. These are summarized in Figure 15-19. The process is initiated by damage to the endothelial surface of the arterial intima, initiating an inflammatory response and an increase in the vessel wall permeability.<sup>19</sup> Many of the risk factors for atherosclerosis discussed later may be initiators of this vessel injury. The increased permeability of the vessel wall allows low-density serum lipoproteins to breach the intimal layer. Leukocytes also are drawn to the site, and along with the endothelial cells, they oxidize the lipids, producing further damage to the vessel wall. Simultaneously, platelets aggregate at the site of injury. They are activated, releasing platelet-derived growth factor (PDGF), which stimulates growth of smooth muscle cells. Media smooth muscle cells, normally confined to the other tunicae, are drawn to the intima where they proliferate. The result is an atherosclerotic *plaque*, primarily composed of smooth muscle cells, lipoproteins, and inflammatory debris. While the plaques slowly enlarge, the orifice of the artery is decreased and perfusion is diminished. In coronary artery disease, the plaque may also acutely rupture, initiating thrombus formation and acute loss of perfusion (see Chapter 18).

**Risk factors.** Risk factors for the development of atherosclerosis are categorized as modifiable or nonmodifiable, according to the degree to which they can be altered (Box 15-3). Historically, health care has focused on preventing atherosclerosis by the manipulation of predisposing modifiable factors. It often is difficult to isolate the effect of a single risk factor because they usually occur in combination.

The most frequently cited prospective research into atherosclerotic risk factors began in 1948 in Framingham, Massachusetts.<sup>18</sup> Initially, 5209 men and women between the ages of 30 and 59 volunteered to be subjects in the study, the purpose of which was to identify factors associated with the development of atherosclerosis over time. The Framingham Study remains ongoing, with researchers now studying the children and grandchildren of the original participants. Much of the available information regarding atherosclerotic risk factors has its origins in the results of this research.

**FIGURE 15-18** Arterial ulcer. (From Zipes DP et al: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 7, Philadelphia, 2005, Saunders, p 1444.)

**FIGURE 15-19** Pathogenesis of atherosclerosis. **A**, In response to trauma or irritation to the intima, injury stimulates platelet aggregation and the inflammatory response. **B**, Medial smooth muscle proliferates and migrates into the intima; LDL cholesterol leaks into the vessel wall. **C**, A fibrous cap forms over the plaque; the lesion slowly grows to decrease vessel diameter. **D**, Additional injury may cause rupture of the plaque, resulting in thrombus formation and manifestations of acute occlusion. (From Monahan FD et al: Phipps' medical-surgical nursing: health and illness perspectives, ed 8, Philadelphia, 2007, Mosby, p 750.)

**Modifiable risk factors.** Fortunately, there are far more modifiable risk factors than nonmodifiable ones and the changes individuals make have documented effects in risk reduction for cardiovascular disease. Unfortunately, lifestyle changes are often difficult to make and to maintain.

Tobacco use in any form is atherogenic, but most of the research addresses cigarette smoking. Cigarette smoke contains more than 4000 elements; nicotine and carbon monoxide are the 2 with the most documented damage to blood vessels.<sup>20</sup> Exposure to both active and passive smoke has been found to cause injury, although the precise mechanisms

### BOX 15-3 RISK FACTORS ASSOCIATED WITH ATHEROSCLEROSIS

#### Modifiable Risk Factors

- Smoking
- Elevated blood pressure
- Glucose intolerance
- Elevated cholesterol and low-density lipoproteins
- Decreased physical activity
- Obesity
- Weight fluctuations
- Ineffective stress management

#### Nonmodifiable Risk Factors

- Age
- Gender
- Ethnicity
- Heredity

have not yet been elucidated. What is known is that cigarette smoking produces injury to the endothelium, generates superoxide anions, decreases both the production and the bioavailability of nitric oxide, and increases the production and release of endothelin. The result is dysfunction of the endothelium, increased tendency to form thromboses, and accelerated atherosclerosis.<sup>20,21</sup> Nicotine also elevates levels of low-density lipoprotein (LDL) cholesterol and triglycerides, and decreases levels of high-density lipoproteins (HDLs). It produces vaso-spasm and increased platelet aggregation, which can decrease myocardial oxygen supply. Endogenous catecholamines are released with smoking, increasing blood pressure and heart rate, which produce an increase in myocardial oxygen demand. Specifically, smoking increases the risk of coronary heart disease to two to four times normal. Even smoking only a few cigarettes per day is correlated with an increased risk.<sup>22</sup> This risk is even greater if the individual has hypertension, hypercholesterolemia, glucose intolerance, or diabetes because these conditions have a synergistic effect with smoking. Death rates after a myocardial infarction are higher among smokers. Cessation of smoking results in a 50% risk reduction from coronary heart disease within the first year, and a risk equal to that in nonsmokers after 10 years.

Hypertension is both a risk factor for the development of atherosclerosis and an outcome of it.<sup>23</sup> Increases in both systolic and diastolic blood pressure are associated with an increased incidence of atherosclerosis. Diastolic blood pressure elevations are probably more significant because they represent the status of the cardiovascular system when it is at rest. Control of hypertension reduces the injury it produces to the vessel walls and, at a minimum, decreases the rate of atherosclerotic formations. Hypertension is often found in the presence of other risk factors.<sup>23</sup> (See Chapter 16 for a discussion of hypertension.)

Cholesterol, the lipoproteins, and triglycerides are important in the discussion of atherosclerosis. Cholesterol is a necessary component of cellular membranes and is used in the manufacture of steroids within the body.<sup>1</sup> Approximately 40% to 50% of the body's cholesterol is absorbed; the remainder is synthesized by the liver utilizing dietary saturated fats.<sup>24</sup> Cholesterol, like other fats in the bloodstream, is highly insoluble and is transported to and from the body's cells within lipoprotein shells.<sup>24</sup> Although there are several forms of lipoproteins, low-density lipoprotein (LDL) and high-density lipoprotein (HDL) are most important in the discussion of atherosclerosis. Receptors on the surface of the LDL molecule bind with receptors on cell membranes, allowing the molecule to be absorbed into the cell. These receptors abound in the muscle cells of arteries. The protein coat is dissolved and the cholesterol is then used to meet the body's cellular needs. The excess cholesterol that is not removed is stored and acts as a cellular irritant, participating in endothelial injury and plaque formation. Since the early 1990s, evidence of the cardiovascular benefit of controlling serum lipid levels has been mounting.<sup>25</sup> The precise mechanism is

unclear, but the correlation between high serum levels of LDL and cholesterol is clearly significant in the development of atherosclerosis.<sup>24-27</sup> HDL seems to serve as a protective mechanism in the formation of atherosclerosis.<sup>25,26</sup> It is postulated that HDL can remove cholesterol from formations in the arterial walls and transport it back to the liver.<sup>1</sup> Consequently, serum lipid profiles are closely supervised. An acceptable total cholesterol level for an adult who has no coronary disease is less than 200 mg/dl.<sup>27</sup> Levels of LDL-C (low-density lipoprotein cholesterol) are felt to be detrimental if greater than 160 mg/dl. In those with known coronary disease, an LDL-C value of less than 100 mg/dl is thought to be beneficial. Protective levels of HDL are those greater than 45 mg/dl for men and greater than 55 mg/dl for women. A major intervention related to atherosclerosis is encouraging the consumption of a low-fat diet, with those fats being primarily polyunsaturated (from vegetable sources as opposed to animal). Additionally, exercise and weight control are effective in improving lipid profiles. Pharmacologic management of elevated levels of serum lipids is encouraged as a prophylactic intervention.<sup>27</sup>

Glucose intolerance/metabolic syndrome and diabetes mellitus have been found to be associated with elevations in LDL levels and reduced levels of HDL, hypertension, and atherosclerosis.<sup>25,28,29</sup> Glucose intolerance is often a precursor of diabetes mellitus, a disease in which an absolute lack of or a significantly decreased response to insulin produces a derangement in metabolism (see Chapter 41). Atherosclerosis is highly correlated with glucose intolerance, probably because of the alterations in carbohydrate and fat metabolism and the direct damage to vessel basement membrane with elevated blood glucose levels. The incidence of atherosclerotic diseases is much higher among those with diabetes mellitus than in the general population. It does not appear to be related to the degree of hyperglycemia, yet glycemic control has been found to decrease the incidence of acute myocardial infarction.<sup>23,27,28</sup>

Obesity, defined as a body weight 30% or greater than ideal, is thought to be a contributing risk factor for atherosclerosis in that it may accelerate the process. Abdominally distributed obesity is a greater risk than an increase in BMI (body mass index).<sup>22</sup> A desirable waist circumference for men is less than 40 inches, and less than 35 inches for women. Weight gain is associated with increasing serum cholesterol and LDL levels, increasing systolic blood pressure, glucose intolerance, and a sedentary lifestyle.<sup>22</sup>

Physical activity has been found to increase HDL levels, collateral circulation, and vessel size, and to decrease total cholesterol levels, glucose intolerance, body weight, and blood pressure.<sup>22</sup> Clearly, all these findings can retard the development and mitigate the severity of atherosclerosis. Research likewise substantiates physical inactivity as a risk factor for cardiovascular disease.

Stress and mental health have historically received considerable attention as risk factors for atherosclerosis, and this continues to be the case.<sup>22</sup> It is extremely difficult to isolate these factors and examine them quantitatively and qualitatively. Stress results in the release of endogenous catecholamines that contribute to the increased work of the cardiovascular system. Subjectively, the rushed, stressed person is less inclined to exercise and eat wisely and more inclined to smoke and be hypertensive. Recently, depression has been identified as a cardiovascular risk factor.<sup>22</sup> Both stress and depression also may contribute to a delay in seeking treatment.

The importance of managing modifiable risk factors in the reduction of cardiovascular risk cannot be overstated. Recent research continues to substantiate the interrelationship of these risk factors.<sup>29</sup> When dietary fat intake is reduced, concomitant reductions in total serum cholesterol, LDL levels and body weight are predicted. These factors all interact with exercise to predict a decrease in the perception

of stress. Stress management is related both to decreased measurements for body weight, total cholesterol and triglycerides, and hemoglobin A<sub>1C</sub> (an indicator of diabetic glycemic control) and to increased measurements of HDL. Clearly, not only is the reduction of a single risk factor meaningful, but also there is an interactive, additive effect among risk factors.<sup>29</sup>

**Nonmodifiable risk factors.** Certain risk factors are not modifiable and cannot be manipulated for prevention or to decrease the severity of atherosclerosis and cardiovascular disease. Age, gender, ethnicity, and genetics are interrelated, and their impact as risk factors can be modulated by lifestyle changes.

With aging, changes occur in the arterial walls (see Geriatric Considerations) that predispose to the development of atherosclerosis. Men have a higher incidence of atherosclerosis earlier in life than women, but following menopause, the incidence and prevalence of cardiovascular disease equalize.<sup>15,22</sup> Postmenopausal status is often seen as an independent risk factor for cardiovascular disease, generating increased attention in research regarding the potential cardioprotective role of estrogen.<sup>22,30</sup> At this time, studies indicate postmenopausal women taking either estrogen alone or in combination with progesterone have an increased risk of thrombotic events (myocardial infarction, deep vein thrombosis, ischemic stroke) and of breast cancer. Consequently, such interventions are not recommended for cardiovascular risk reduction.<sup>30</sup>

A strong family history of CAD is an important predictor of its occurrence and subsequent prognosis.<sup>22</sup> The specific mechanism is uncertain, but most likely it is a combination of genetic and environmental factors. Certain of the modifiable risk factors are also known to have a genetic component.

Studies of ethnicity as a nonmodifiable risk factor associated with atherosclerosis have predominantly focused on the increased incidence of CAD and hypertension among black Americans compared with white Americans.<sup>15</sup> Degree of risk differs between Caucasians, African-Americans, Hispanics, and Asians.<sup>31</sup> Prevalence of smoking, diabetes, and hypertension is greater for African-Americans and Hispanics, whereas Caucasians are more likely to have abnormal serum lipid levels. After correction for age, gender, risk factors, and pharmacologic treatment of hyperlipidemia, one study reported the least amount of coronary artery calcification to be among Asian men and women.<sup>31</sup> Historically, American Indians have had very low rates of cardiovascular disease.<sup>32</sup> However, it is now the leading cause of death in this population, with the majority of cardiovascular disease cases in those with diabetes, which has a very high incidence in this population.<sup>32</sup> These disparities highlight the overlap of genetic and environmental factors and illustrate how ethnicity, as an isolated independent variable, is very difficult to evaluate.

**Clinical manifestations and diagnosis.** Disease manifestations vary with the tissues involved and the severity of altered flow. Atherosclerosis is an underlying pathologic condition for much of the hypertension, renal disease, cardiac disease, peripheral arterial disease, and stroke seen in health care practice.

Approaches to diagnosis and treatment of decreased organ or tissue function vary. Patient history and physical assessment provide significant information. Noninvasive tests such as Doppler flow studies may identify areas of occlusion or diminished flow.<sup>28,33</sup> *Plethysmography* may be used to measure changes in the relative size of extremities associated with blood flow. Ankle pressures are obtained with a blood pressure cuff and Doppler ultrasonography and compared with brachial blood pressures in the ankle-brachial (A/B) index. A normal A/B index is greater than or equal to 1.0; an index less than 1.0 is indicative of diminished arterial flow in the lower extremities. Exercise or stress testing may be performed to evaluate the pain of arterial occlusive disease

(intermittent claudication). Angiography—the radiologic study of blood flow—is the most frequently used diagnostic examination.<sup>28,33</sup> (See Chapter 18 for a discussion of coronary artery disease, Chapter 16 for a discussion of hypertension, Chapter 28 for a discussion of renal failure, and Chapter 44 for a discussion of stroke.)

**Treatment.** Identification of and interventions directed toward modifiable risk factors are the major thrusts of treatment, regardless of the organs or tissues affected. Nonpharmacologic interventions, such as reduction of body weight, cessation of smoking, implementation of an exercise program, and consumption of a low-fat diet, are the first-line actions.<sup>22,28</sup> Drug therapy to decrease hypercholesterolemia is considered when the nonpharmacologic approaches are found to be ineffective or inadequate, or the presence of additional risk factors indicates that the patient would benefit from such interventions.<sup>22,25,27,28</sup>

A wide variety of additional interventions may be undertaken, depending upon the specific disorder and organ involved. Balloon angioplasty, the surgical radiologic fragmentation of atherosclerotic plaques by inflation of a specially equipped catheter, is commonly performed on both coronary and peripheral arteries.<sup>28</sup> Laser angioplasty is being combined with balloon angioplasty to create an opening in significantly obstructed peripheral vessels before the balloon is inflated. Balloon angioplasty with stent placement is being used. Currently, when balloon angioplasty of the coronary arteries is unacceptable or fails to result in satisfactory improvement, coronary artery bypass graft (CABG) surgery is performed. Peripheral arterial bypass grafts are common interventions for the lower extremities and are named for their sites of origin and termination (e.g., aortofemoral, femoropopliteal).

### Thromboangiitis Obliterans (Buerger Disease)

*Thromboangiitis obliterans (Buerger disease)* is a rare inflammatory condition affecting both small- and medium-size arteries and veins of the upper and lower extremities, producing varying degrees of obstruction.<sup>34,35</sup> Although both arteries and veins are involved, the signs and symptoms relate to obstruction of arterial flow (see Box 15-2).<sup>34,35</sup> The rarity of this disease impacts the availability of research funding; therefore, progress in understanding the pathogenesis is limited.<sup>34</sup> What is known is that this vasculitis is strongly associated with smoking, and that smoking cessation is essential to effective treatment.<sup>34,35</sup> Additionally, pharmacologic interventions currently use prostaglandins. New approaches to angiogenesis have resulted in the development of significant collateral circulation and marked clinical improvement. If patients do not abstain from smoking, the disease is progressive and amputation may be necessary.<sup>34,35</sup>

### Raynaud Syndrome

An extreme vasoconstriction producing cessation of flow to the fingers and toes produces the characteristic signs and symptoms of Raynaud syndrome.<sup>36,37</sup> Sometimes earlobes or the tip of the nose are also affected.<sup>37</sup> Attacks are recurrent, usually beginning in adolescence.<sup>36</sup> They are most often initiated by cold or emotional distress.<sup>36,37</sup> The phenomenon is classically characterized by a series of color changes in the involved area, starting with white, corresponding to the vasoconstriction.<sup>37</sup> The affected area then becomes cyanotic, with the desaturation of blood remaining in the area. Finally, the tissue flushes red (reactive hyperemia) with the resumption of perfusion. The attack also commonly affects local nerve function, causing pain and/or numbness.<sup>37</sup>

Raynaud syndrome is more prevalent among women, presenting between puberty and menopause, and there appears to be a genetic predisposition.<sup>36,37</sup> Women have an increase in sympathetic tone of the vessels of the skin, causing young women to have basal cutaneous flows that are half those of young men.<sup>37</sup> Knowledge regarding the complex regulation of local perfusion has expanded over the

years since the condition was identified by Maurice Raynaud in 1862.<sup>36,37</sup> The pathogenesis is an interplay of intrinsic structural factors (e.g., inflammatory activation and damage), extrinsic neuroregulation, locally produced mediators, and soluble mediators (including estrogen).<sup>36,37</sup>

Various treatment modalities have been used with differing degrees of success.<sup>36,37</sup> Because the precise cause of Raynaud syndrome is unknown, interventions have been directed to enhancing the circulation. Biofeedback and relaxation techniques may be beneficial. The most widely used drugs are calcium channel blockers, which produce vasodilation by interfering with calcium influx into vascular smooth muscle cells. Sympatholytic drugs have been studied and found to be more effective than placebos. Prostaglandin therapy has proved helpful. Persons with the syndrome are urged to protect themselves from cold temperatures, vibration, and nicotine, and to use stress reduction interventions.<sup>36,37</sup>

### Aneurysms

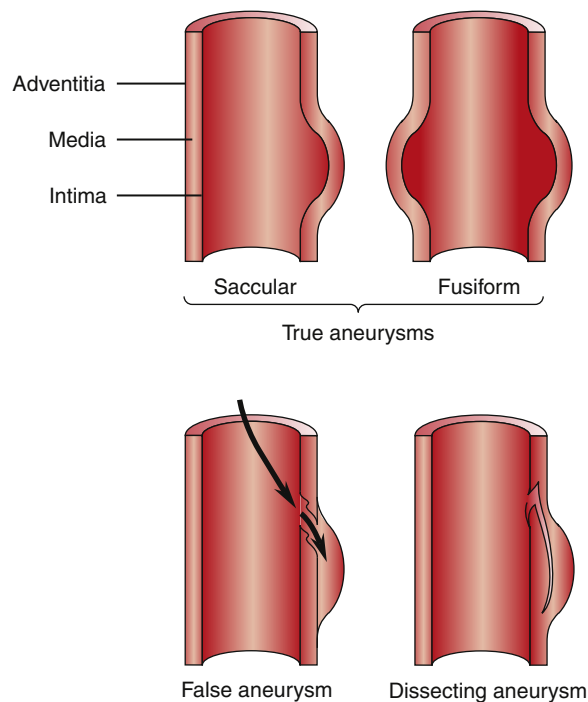

As described previously, aneurysms are localized arterial dilations. The arterial wall deteriorates until it is weakened sufficiently to bulge outward. The underlying cause may be atherosclerotic changes in the vessel, a congenital weakness, or a weakening induced by infection, inflammation, or traumatic injury.<sup>38,39</sup> Aneurysms are most frequently found in the cerebral circulation (circle of Willis or posterior circulation) and in the thoracic and abdominal aorta.<sup>38</sup> Estimates are that between 10 and 15 million individuals are treated for cerebral aneurysms annually, with rupture occurring in 30,000. Mortality and morbidity associated with ruptured cerebral aneurysms are high, so early diagnosis and treatment are most desirable.<sup>38</sup>

**Classifications.** Aneurysms are classified as true or false, depending on the layers of the arterial wall involved (Figure 15-20). In *true aneurysms*, all three tunicae are involved (intima, media, and adventitia), whereas in *false aneurysms*, at least one tunica is left unaffected. In a false aneurysm, the muscle tissue and fascia often confine the leaking blood, which enhances thrombus formation. False aneurysms are most often caused by trauma rather than vessel disease. True aneurysms are further divided by their shape and their size. In *saccular aneurysms*, the weakening is confined to one side of the vessel, producing a lateral ballooning. *Fusiform aneurysms* represent weakening on both sides of the vessel wall—a central ballooning. A *berry aneurysm* is the most common cerebral aneurysm; it is shaped like a berry, with a neck or stem.<sup>38</sup>

All aneurysms can affect blood flow. Cerebral aneurysms are addressed in detail in Chapter 44. Of significant clinical concern is the *dissecting aortic aneurysm* (see Figure 15-20). Here the tear in the arterial wall creates a channel for blood flow. The tear may be between the intima and media or between the media and adventitia. As more blood escapes into the space, the layers are separated from one another in both directions from the leak, and as the vessel becomes progressively weaker, it may rupture. Rupture can be explained by the law of Laplace—as the radius of the vessel increases, the tension in the wall increases. Rupture of a major vessel such as the aorta carries a high mortality.<sup>39</sup>

**Clinical manifestations and diagnosis.** Signs and symptoms of a leaking or ruptured cerebral aneurysm are associated with increasing intracranial pressure and hemorrhagic stroke. Dissecting aortic aneurysms often present as sudden, severe, tearing pain that radiates into the back or abdomen. The patient may show signs and symptoms of shock. Renal blood flow or perfusion of the spinal nerves may be compromised, if the descending abdominal aorta is affected. Renal failure or paraplegia may result. If the ascending aorta is affected, arterial blood flow to the head and upper extremities may be affected.

Diagnostic tests are somewhat dependent upon location.<sup>33</sup> Computed tomography (CT) and transesophageal echocardiography (TEE)

**FIGURE 15-20** Classification of aneurysms. All three tunicae are involved in true aneurysms (fusiform and saccular). In false aneurysms, blood escapes between tunica layers and they separate. The muscle and fascia confine the leak; a thrombus forms and seals the leak. In a dissecting aneurysm, a tear in the intima creates a channel into which blood leaks, creating a hematoma. Continued expansion of the hematoma further separates the intima from the other layers, weakening the vessel.

are the most common diagnostic modalities for aortic aneurysms. TEE has proven to be reliable and is immediately available in an emergency setting. For cerebral aneurysms, CT, magnetic resonance imaging (MRI), and cerebral angiography are used.<sup>33,38</sup>

**Treatment.** Dissecting aortic aneurysms are emergency situations and may be managed medically, surgically, or both. Medical intervention is directed at lowering the blood pressure to decrease the speed and severity of the dissection. Vasodilators are often administered parenterally. Surgical intervention involves resection (removal) of the aneurysm and insertion of a prosthetic graft. This procedure may require an open approach, but as with many surgeries, it may be done with a series of smaller incisions in an endovascular approach.<sup>39</sup> If the aneurysm is extremely large, it may be inoperable.

A variety of interventions are used for cerebral aneurysms; these are briefly addressed in Chapter 44.

### Acute Arterial Occlusion

Acute arterial occlusion is an emergency, because it may result in such profound ischemia that the involved limb becomes gangrenous and sepsis may result. Acute arterial occlusion may be caused by a thrombus or embolus lodging in a major artery, or by external mechanical compression producing compartment syndrome. The result is an effective absence of arterial circulation to the extremity. Although it is usually attributable to a thrombus or an embolus, it may occur with vasospastic disease or trauma, as a complication of vascular surgery, or from swelling within a cast or tight dressing.<sup>40</sup>

The classic signs and symptoms of acute arterial occlusion are known as the *six Ps*. *Pallor* occurs in the involved extremity. The patient may complain of *paresthesia*, and some degree of *paralysis* may be

noted, owing to the lack of oxygen to nerve cells. *Pain* is intense, continuous, and unrelated to activity. The skin is cold to touch (*polar*) and may be *pulseless* by palpation, although often a weak pulse may be noted by Doppler.

Perfusion must be restored or necrosis will develop because of ischemia to the extremity. The specific interventions vary with the etiology. Dressings may be loosened or casts cut if the cause is mechanical compression. If the cause is thrombotic or embolic, anticoagulant therapy is initiated to prevent enlargement and the formation of further thrombi. Bypass surgery or revascularization through thrombolytic therapy is usually attempted. Surgical removal of an embolism (*embolectomy*) may be necessary. If these approaches are not successful or ischemia is prolonged, amputation may be required.

#### KEY POINTS

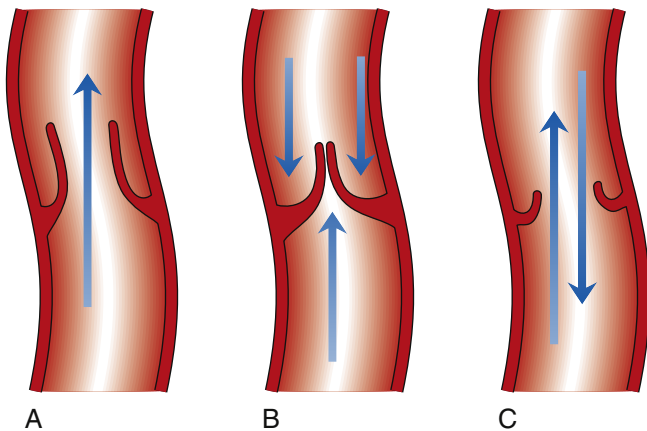

- Common causes of arterial obstruction are atherosclerosis, inflammation, vasospasm, and aneurysms. Emboli are the usual cause of acute arterial occlusion.
- Atherosclerosis is the most common cause of chronic progressive arterial obstruction. Several risk factors for the development of atherosclerosis have been proposed, among them smoking, hyperlipidemia, male gender, advancing age, sedentary lifestyle, obesity, glucose intolerance, and a family history of cardiovascular disease.
- Acute arterial obstruction is accompanied by the classic manifestations known as the six Ps: pallor, paresthesia, paralysis, pain, pulselessness, and polar (cold to touch).

## ALTERATIONS IN VENOUS FLOW

Pathologic venous conditions are the result of obstruction to flow (deep vein thrombosis) or structural alterations (valvular incompetence) and are primarily seen in the lower extremities.

### Valvular Incompetence

**Etiology and pathogenesis.** The intimal surface of veins periodically folds into valves to facilitate efficient flow (Figure 15-21). When the valves are open, blood is propelled forward by the pressure changes exerted by the skeletal muscles and the intraabdominal and intrathoracic pumps. When this pressure decreases, backward flow of blood is prevented by proper closure of the valves (valvular competency). Valvular

**FIGURE 15-21** The venous valves. **A**, Open valves permit forward blood flow. **B**, Closed valves prevent backflow of blood. **C**, Incompetent valves, unable to close fully, allow blood to flow backward, producing venous insufficiency.

incompetence results in *venous insufficiency*. When the superficial veins are involved, the disorder is called **varicose veins**. **Chronic venous insufficiency** occurs when the deep veins are affected.

The cause of valvular incompetence is the overstretching of the valves as a result of excessive venous pressures. Veins are designed as low-pressure systems. After the blood leaves the high-pressure arterial bed, it passes into the fine capillary network, which slows flow and reduces the pressure. Blood flow through the veins is essentially accomplished by forces outside the veins—the skeletal muscle, intraabdominal and intrathoracic pumps. The highly distensible vein walls are capable of expanding to create a reservoir of blood. When the pressure against which the pumps must push is elevated for a prolonged period, the veins stretch and the valve cusps can no longer meet. Backflow results in further engorgement of the involved veins. The process is most frequently seen in people whose occupations require them to stand for long periods. The effect of gravity on venous flow accentuates the problem. Obesity and pregnancy also elevate venous pressure and may contribute to varicosity formation. As much as 10% of the European and North American population have valvular incompetence.<sup>41</sup>

**Clinical manifestations and treatment.** Symptoms may include a feeling of heaviness or tension and pruritus. Thrombi can promote valve obstruction and further thrombus formation. In prolonged insufficiency, edema and stasis dermatitis (discoloration along the lower calf to ankle) may develop. Long-term insufficiency can lead to ulcer formation.<sup>41,42</sup>

Prevention interventions include stopping smoking and beginning a walking program. Regular exercise has been shown to decrease future cardiovascular events.<sup>28</sup> Drugs that interfere with platelet aggregation may be initiated, or revascularization procedures may be attempted.<sup>9,28</sup>

### Varicose Veins

**Etiology and pathogenesis.** Varicosities are superficial, darkened, raised, and tortuous veins (Figure 15-22). The greater saphenous vein is primarily affected, although varicosities may also develop in the

**FIGURE 15-22** Varicose veins. Varicosities are best observed when the patient is standing because standing increases the pressure and causes the tortuous veins to become more visible. (From Black JM, Hawks J: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1336.)

lesser saphenous veins. Impaired venous return results in increased capillary pressure, and the involved limb may become edematous.

**Clinical manifestations and treatment.** Patients may complain of an aching, heavy discomfort, but they are primarily disturbed by the appearance of the varicosities. Venous ulcers may develop.<sup>41,42</sup>

Many of the diagnostic tests used for the arterial system are used for the identification of venous disease. The patient history and physical assessment provide important baseline information. Doppler ultrasound and impedance plethysmography are among the most frequently used assessment tools.<sup>33</sup>

Conservative medical interventions are designed to reduce venous pressure and enhance the venous pump, especially the skeletal muscle pump. Patients are encouraged to elevate their legs whenever possible and to avoid standing for long periods. Elastic stockings can facilitate venous return by enhancing the skeletal muscle pump. When sitting, patients are urged to not cross their knees or ankles. Exercise, particularly walking or swimming, is suggested. If appropriate, weight reduction is recommended.

More aggressive interventions may be initiated in severe cases, as illustrated in Figure 15-22. *Sclerotherapy* involves the injection of a chemical that initiates an inflammatory process and subsequent compression dressings force the lumen to collapse.<sup>28</sup> The intima adheres to itself and heals, and the vein is obliterated. Collateral venous circulation meets the need for venous return from the extremity. Surgical interventions include *vein stripping* and *vein ligation*. These are commonly performed as outpatient procedures and are often combined with sclerotherapy. Both of these treatment modalities depend on the presence of adequate deep venous structures to provide alternate routes for venous drainage.<sup>28</sup>

### Chronic Venous Insufficiency

**Etiology and pathogenesis.** Chronic venous insufficiency results when valvular incompetence involves the deep veins (superficial femoral, anterior and posterior tibial, peroneal) of the legs.<sup>42</sup> Communicating or perforating veins provide direct access between the superficial and deep veins.<sup>1,42</sup> Because the pressure in the superficial veins remains elevated for a prolonged period, the deep veins are eventually affected.<sup>42</sup> Individuals with chronic venous insufficiency often also have heart disease and a history of extremity trauma and phlebitis. Previous deep vein thrombosis is a risk factor.<sup>42</sup>

**Clinical manifestations and treatment.** Venous stasis ulcers also develop as superficial veins rupture with the increased pressures associated with activity.<sup>41,42</sup> The skin pigmentation becomes brown as small veins rupture, leaking red blood cells, which are eventually broken down. Defining characteristics of chronic venous insufficiency are listed in Box 15-4.

Chronic venous insufficiency is primarily diagnosed clinically, but if necessary, ultrasound is considered the best method of evaluation.<sup>42</sup> Many of the diagnostic techniques described for varicose veins may prove helpful, including Doppler ultrasound and impedance plethysmography.<sup>42</sup> Treatment of venous ulcers is challenging and incorporates the use of compression as its foundation.<sup>41,42</sup> Venous ulcers are prone to secondary infection, usually by *Staphylococcus aureus*, *Pseudomonas aeruginosa*, or  $\beta$ -hemolytic streptococci, requiring systemic antibiotic therapy.<sup>41</sup> Other interventions previously described for superficial varicosities also are used for chronic venous insufficiency.

### Deep Vein Thrombosis

**Etiology and pathogenesis.** The pathophysiologic process of thrombus formation has been previously described. Acute venous obstruction is most frequently secondary to a thrombus in a deep vein

of the lower extremities. Upper extremities are less frequently affected by deep vein thrombosis.

**Clinical manifestations and treatment.** Deep vein thrombosis of the legs may be asymptomatic. Signs and symptoms, if present, typically include edema, manifestations of local inflammation, and possible dilated superficial veins secondary to the increased venous pressure.<sup>28</sup> Pain may be present owing to pressure on adjacent nerves and the inflammatory process.

Deep vein thrombosis is treated aggressively; deep vein thrombosis of the lower extremities and pelvic veins is the most frequent source of pulmonary emboli. Patients are often hospitalized so that intravenous anticoagulation therapy may be initiated; otherwise, they are treated on an outpatient basis with oral anticoagulants.<sup>9,28</sup> Patients who have previously developed deep vein thromboses are at risk for further hypercoagulation and may undergo long-term prophylactic anticoagulation with antiplatelet therapy and parenteral anticoagulants with subsequent hospitalization for any reason.<sup>9,28</sup>

#### KEY POINTS

- Common causes of venous obstruction are incompetent valves (as may occur with obesity, pregnancy, right heart failure, or prolonged standing), producing varicose veins and chronic venous insufficiency, and obstruction by deep vein thrombosis.
- Edema, venous stasis ulcers, and pain usually accompany chronic venous obstruction.
- Deep vein thrombosis is potentially life threatening because of the likelihood of embolization to the pulmonary circulation. It is treated aggressively with the administration of anticoagulants.

## ALTERATIONS IN LYMPHATIC FLOW

### Lymphedema

**Etiology and pathogenesis.** Lymphedema occurs when the normal flow of lymph is obstructed or altered in some fashion (Figure 15-23).<sup>43</sup> This results in the collection of lymphatic fluid in the interstitium, initiating an inflammatory response, hypertrophy of subcutaneous adipose tissue, and fibrotic changes.<sup>43</sup> Primary lymphedema

#### BOX 15-4 DEFINING CHARACTERISTICS OF CHRONIC VENOUS INSUFFICIENCY

##### Skin Assessment

- Warm, tough, and thickened to touch
- Pigmented areas, reddish brown
- Edema, especially at end of day
- Visible healed ulcers
- Evidence of varicose veins may be present

##### Pain Assessment

- Aching, cramping
- Sometimes decreases with ambulation
- Relieved by elevation

##### Ulcer Assessment

- Moderately painful
- Pink-red base
- Irregular, uneven edges
- Located on medial malleolus

**FIGURE 15-23** Types of lymphedema. **A**, Lymphedema of an arm secondary to surgical alterations in the lymphatic system associated with mastectomy. **B**, Lymphedema of a leg. (From Black JM, Hawks J: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1339.)

is related to a congenital anomaly or dysfunction of the lymphatic system. Secondary lymphedema develops in association with a disease process or is iatrogenic (a consequence of medical intervention) in origin. Throughout the world, secondary lymphedema is most commonly caused by an infection by filarial worms that migrate to the nodes of the lymphatic system, producing an obstruction of flow. Infection by this nematode (*Wuchereria bancrofti*) affects more than 90 million people worldwide. In the United States, secondary lymphedema is most frequently caused by the surgical removal of lymph nodes, as with breast cancer, or by the destruction of the lymphatics from radiation therapy in the management of various malignancies.<sup>43</sup> This has been reported to develop in 24% to 49% of women after mastectomy and in 4% to 28% of women after lumpectomy.<sup>43</sup>

**Clinical manifestations, diagnosis, and treatment.** Most often, lymphedema affects the extremities, but it may be found in the region of the head and neck, trunk, or genitalia.<sup>43</sup> Initially it presents as a soft, pitting edema but as it progresses the inflammatory response is activated and lipogenesis, fat deposition, and fibrotic changes occur.<sup>43</sup> Without early diagnosis and treatment, lymphedema may progress from an acute problem to a chronic one, where congestion produces thick and roughened skin (*brawny edema*) and a large deformed limb.

Diagnosis is primarily one of exclusion, with other causes of localized edema being ruled out.<sup>43</sup> A complete history and physical examination will allow the elimination of cardiac, renal, and peripheral

vascular etiologies. The primary diagnostic test uses the injection of radioisotopes (lymphoscintigram) to assess the overall function of the lymphatic system. Ultrasound, duplex ultrasound, CT, and MRI are additional options and produce unique results.<sup>43</sup>

There is no cure for lymphedema; interventions are both medical and surgical.<sup>43</sup> Medical treatment includes use of external pneumatic compression devices, elastic stockings, and exercise. Decongestive lymphatic therapy (DLT) or complete decongestive physiotherapy (CDP) combines skin care, massage, compression dressings, and exercise. For many individuals, this therapy results in a 40% to 60% reduction in edema. At this time, no medication has been approved for lymphedema therapy by the Food and Drug Administration (FDA); although diuretics have been used with minimal effect, they are not recommended. Surgical interventions are limited to very select patients, as they may actually be harmful. Resections (debulking) remove subcutaneous tissue and bypass procedures use lymphatic-venous anastomosis.<sup>43</sup> A new approach involves the use of liposuction for the removal of subcutaneous fatty tissue.<sup>43</sup>

#### KEY POINTS

- Obstruction of lymph flow is most commonly the result of surgical removal of, or radiation damage to, lymphatic vessels during treatment of cancer.
- Manifestations of lymphatic obstruction include regional edema and thickened subcutaneous tissue.

## SUMMARY

The circulatory system is organized to facilitate its dual functions of oxygen and nutrient transport and metabolic waste product removal. The arrangement and unique structure of the circulatory vessels permit these functions to be accomplished.

An understanding of the principles and control of flow aids in the comprehension of the pathologic conditions that result in alterations in flow. Principles of flow, or the hemodynamics of the circulation, include concepts and physical laws relating to relationships of flow, pressure and resistance, velocity, laminar and turbulent flow, and wall tension and compliance. Control of blood flow occurs through both extrinsic and intrinsic mechanisms. Lymphatic flow is controlled through the lymphatic pump system, governed by skeletal muscle, and the smooth muscle of organs and arteries.

Pathophysiologic changes that result in alterations in blood flow can be classified as being caused by either obstruction (thrombosis, emboli, vasospasm, inflammation, mechanical compression) or structural alterations (valvular incompetence, arteriosclerosis/atherosclerosis, aneurysms, AVFs). Conditions that produce alterations in arterial or venous flow are the result of one of these primary processes. Pathology of the lymphatic system is essentially the result of disruption of the normal pressure relationships or an obstruction within the circulatory system; proper functioning of the lymphatic system depends on the appropriate functioning of the vascular system.

Meeting the needs of the body's tissues for oxygen and nutrients requires both adequate blood flow at the tissue level and sufficient perfusion pressure systemically to force that blood forward. The systemic arterial blood pressure provides that momentum, and the tissues depend on its preservation to ensure their metabolic needs are met. This maintenance requires a complex regulatory system. The body's organs can be damaged if the perfusion pressure is insufficient or if it is excessive.

## ARTERIAL BLOOD PRESSURE

As described in Chapter 15, oxygenated blood is propelled from the left side of the heart into the arterial circulatory system, and following a pressure gradient, travels to the capillary beds of the body's tissues (Figure 16-1). There, oxygen and nutrients are exchanged for metabolic wastes, and the blood then returns to the right side of the heart via the venous circulatory system, where it passes through the lungs to

**FIGURE 16-1** Normal pressures throughout the vascular system in the supine position. (From Hall JE: *Guyton and Hall Textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

repeat the process. It is the pressure difference between the left and right sides of the heart that produces the gradient allowing this systemic movement of blood. The arterial blood pressure is produced by the force of left ventricular contraction overcoming the resistance of the aorta to open the aortic valve, and is the pressure maintained in the arterial system throughout the cardiac cycle.

### Determinants of Systemic Blood Pressure

The systemic arterial blood pressure is the physiologic result of the cardiac output and the resistance to the ejection of blood from the heart.<sup>1</sup> Cardiac output (CO) is the product of two variables: stroke volume (SV) and heart rate (HR) ( $CO = SV \times HR$ ). SV is the specific volume of blood leaving the heart with each contraction, which itself is determined by the volume of blood in the heart before systole (end-diastolic volume) and the contractility of the myocardium.<sup>1</sup> The end-diastolic volume is determined by the amount of blood returned to the heart between contractions, and is typically called the heart's *preload*. Stroke volume multiplied by the number of contractions of the heart per minute (heart rate) determines the amount of blood leaving the heart—the cardiac output, measured in liters per minute. The resistance to ejection into the arterial circulation is known as the *systemic vascular resistance* (SVR) and is determined by the radius of arteries and the degree of vessel compliance. SVR is synonymous with cardiac *afterload*, and can be altered by constricting or relaxing (dilating) arterial smooth muscle. It can be calculated by using a derivation of Poiseuille's law (see Chapter 15). This physical law states that in a tube with laminar flow, resistance is primarily determined by three factors: the radius of the tube, the length of the tube, and the viscosity of the fluid. Applied to SVR, because the viscosity of the blood and the total length of the arterial system are normally relatively constant, the radius of the arterioles becomes the major determinant of resistance. Therefore, the formula for blood pressure is:  $BP = CO \times SVR$ . Alteration in any one of these variables will result in a change in blood pressure. This basic concept is important to normal physiologic function, disorders of blood pressure, and the therapeutic interventions undertaken to treat them. The pulmonary vascular bed contributes minimally to total systemic

resistance and is seen as a separate resistance system, called pulmonary vascular resistance (PVR). It has its own pathology discussed in Chapter 21.

### Measurement of Blood Pressure

#### Components of Blood Pressure Measurement

Arterial blood pressure is measured from its highest point during cardiac systole to its lowest during diastole. These are referred to as *systolic pressure* and *diastolic pressure*, respectively, and are measured in millimeters of mercury (mm Hg). During ventricular contraction, the pressure in the aorta rises to an average peak value of approximately 110 mm Hg in the adult<sup>1</sup> (see Figure 16-1). Whatever this peak pressure may be, it is referred to as the systolic blood pressure. The smooth muscle of the aorta passively recoils from this point, ejecting blood forward into the peripheral arteries at that given pressure. Stroke volume is the primary factor impacting systolic pressure; an increase or decrease in SV produces a corresponding change in systolic blood pressure. During ventricular diastole, the pressure in the arterial system falls to an average minimum value of 70 mm Hg in the adult. The value of this minimum pressure is called the *diastolic blood pressure*. SVR is the major determinant of diastolic blood pressure; an increase or decrease in diastolic pressure is the result of a corresponding increase or decrease in arterial resistance (SVR). The difference between systolic and diastolic blood pressure is termed the *pulse pressure*.<sup>1</sup> Therefore, the pulse pressure for a systolic pressure of 110 mm Hg and a diastolic pressure of 70 mm Hg would be 40 mm Hg.

Systolic and diastolic values are normed by age. Standards for the identification of normal blood pressure and levels of abnormal elevation have been established. The most precise standards for children are those based on height, age, and gender<sup>2,3</sup> (Table 16-1). Standards for blood pressure have likewise been determined for the adult<sup>4</sup> (Table 16-2).

*Mean arterial pressure* (MAP) is the calculated average pressure within the circulatory system throughout the cardiac cycle. Because more time is spent in diastole than in systole, MAP is not the arithmetic average of diastolic and systolic pressure but rather reflects the relative

**TABLE 16-1 BLOOD PRESSURE CLASSIFICATION IN CHILDREN AND ADOLESCENTS**

SBP and DBP <90th percentile*	Normal for children and adolescents
Average SBP and/or DBP ≥90th percentile but <95th percentile†	Prehypertension in children or adolescents
SBP ≥120 and/or DBP ≥80 mm Hg	Prehypertension in adolescents‡
Average SBP and/or DBP ≥95th percentile†	Hypertension in children and adolescents

Selected data from the Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents, *Pediatrics* 114(2):555-576, 2004.

DBP, Diastolic blood pressure; SBP, systolic blood pressure.

\*For age, height, and gender.

†For age, height, and gender measured on at least three separate occasions.

‡The same criteria used for prehypertension in adults are also applied to adolescents.

**TABLE 16-2 BLOOD PRESSURE CLASSIFICATION IN ADULTS**

CATEGORY	SBP (mm Hg)*	DBP (mm Hg)*
Normal	<120	<80
Prehypertension	120-139	80-89
Stage 1 hypertension	140-159	90-99
Stage 2 hypertension	≥160	≥100

From Chobanian AV: Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 Complete Report, *Hypertension* 42:1206-1252, 2003.

DBP, Diastolic blood pressure; SBP, systolic blood pressure.

\*Classification determined by the higher value.

time spent in each portion of the cardiac cycle.<sup>5</sup> The calculation may be performed by computer during direct arterial blood pressure measurement, as described below, but is most conveniently determined by a simple formula using the values of blood pressure obtained indirectly. Several formulas are available, and they may use systolic, diastolic, or pulse pressures; the most common formula uses the systolic and diastolic pressures as follows:

$$\frac{(2 \times \text{diastolic pressure}) + \text{systolic pressure}}{3}$$

For a person with a systolic pressure of 110 mm Hg and a diastolic pressure of 70 mm Hg, the MAP would be:

$$(2 \times 70) + 110 = 250/3 \text{ or approximately } 83 \text{ mm Hg}$$

MAP is used clinically as part of cardiovascular assessment and in the incremental adjustment (titration) of parenterally administered vasoactive drugs.

### Direct Measurement of Blood Pressure

Direct measurement of blood pressure is one aspect of hemodynamic monitoring and requires an intraarterial catheter and specialized equipment to transduce the arterial fluid pulsations into electrical signals. The catheter most often is placed in the radial artery. These signals are then displayed on a computer screen as waveforms, and the systolic, diastolic, and MAPs are digitally represented. This is the most

accurate method of measuring blood pressure available, but is typically only performed in controlled settings, such as surgical or critical care units, and carries its own risk of measurement error.<sup>5</sup> A detailed discussion of hemodynamic monitoring is beyond the scope of this text.

### Indirect Measurement of Blood Pressure

Blood pressure is most commonly measured by indirect means at the brachial artery, using a mercury sphygmomanometer and a stethoscope for auscultation or an automated oscillometric system such as Dinamap® or the Welch Allyn Spot Vital Signs®. Wrist or finger monitors are not recommended because of the inaccuracy of the values obtained compared with brachial measurements.<sup>6</sup> Specific, evidence-based standards are available for the correct use of these noninvasive automated systems for adults and children including scheduled calibration,<sup>6-8</sup> and they are inherently less accurate if the blood pressure is significantly increased or decreased, or if there are cardiac dysrhythmias.<sup>8</sup> Because the values in blood pressure references are based on the auscultatory method, and it is the easiest method and least stressful to patients, it is the preferred measurement technique.<sup>7,9</sup> Although the brachial artery is typically used for convenience, certain assessment procedures require recording the blood pressure at other arterial sites (e.g., ankle-brachial index). Several studies have reported differences between the right and left arm pressures, but no pattern of differences is evident.<sup>6</sup> Other studies report that in the absence of disease, systolic pressures do not differ significantly at a clinical or statistical level between the right and left arms.<sup>10</sup> In practice, it is recommended that blood pressures be initially taken in both arms and the arm with the highest value be recorded.<sup>6</sup> In situations such as a shock state, when systolic and diastolic pressures cannot be auscultated, the systolic pressure alone may be obtained by palpation or by amplification of the pulse using ultrasound technology (Doppler pressure).

Auscultated and oscillometric blood pressure measurements are burdened with the potential of measurement error, in both reliability and validity (Table 16-3). This dictates the need for careful technique, and in most cases enhances the value of trend data as opposed to individual readings. The individual patient's heart rate, degree of arterial compliance, and dynamics of blood flow may vary over time. Inappropriate blood pressure cuff size, arm position, and both the visual and auditory acuity of the clinician may impact the accuracy of individual readings.<sup>9</sup> An additional source of error has been named the "white coat effect" for the elevation of blood pressure when taken in a clinic or office environment.<sup>3,11</sup> First described in 1897 by Scipione Riva-Rocci, who was the first to document assessing the systolic pressure by palpating the brachial artery,<sup>12</sup> these situational elevations in blood pressure are of concern because treatment may be initiated based on inaccurate data.<sup>11</sup> This condition is most common in older individuals of either gender, but may occur at any age.<sup>6</sup> Pickering and colleagues report that in approximately 15% to 20% of patients with stage I hypertension, elevated blood pressure may only be persistent under these circumstances. Significant pressure differences have been found using the automatic noninvasive technology between the supine, 45-degree elevation of the head of the bed, and sitting position in the same patient,<sup>13</sup> and between multiple body positions using the auscultatory method.<sup>6,14</sup> Normal values are based on the subject being seated, with the back supported and the arm at heart level. Specific recommendations regarding all aspects of indirect measurement are provided by the American Heart Association,<sup>6</sup> and sources of error within pediatric populations also have been documented.<sup>15</sup>

The recommended approach for obtaining an auscultated blood pressure is a two-step approach, beginning with inflating the cuff to the point at which the pressure obliterates the palpated radial pulse (systolic pressure). The pressure is completely released and after 15 to

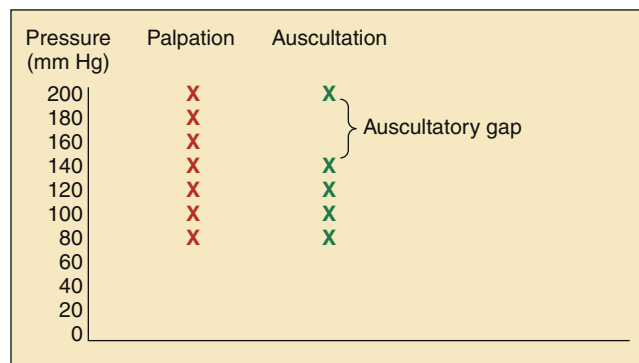

**TABLE 16-3 INTRINSIC AND EXTRINSIC FACTORS THAT INFLUENCE INDIRECT BLOOD PRESSURE ACCURACY**

FACTOR	EFFECT ON BLOOD PRESSURE MEASUREMENT
<b>Intrinsic Factors</b>	
Heart rate	Elevated or decreased
Arterial compliance	Elevated or decreased
Alterations in flow dynamics	Elevated or decreased
Respiratory rate	Normal increase on inspiration
<b>Extrinsic Factors</b>	
Cuff	
Too small	Falsely elevated
Too large	Falsely decreased
Supine position	≈5 mm Hg lower DBP
Seated, back not supported	≈6 mm Hg increased DBP
Crossed legs	Increased SBP 2-8 mm Hg
Seated, arm position	
Above heart	Falsely decreased
Below heart	Falsely elevated
Inadequately supported	Falsely elevated
Excessive stethoscope pressure	Diastolic pressure falsely decreased
<1 min between measurements	Falsely elevated
Deflation rate >3 mm Hg/sec	Falsely decreased SBP and increased DBP
Exercise, eating, smoking, intake of caffeine ≤30 minutes before measurement	Falsely elevated
Talking during measurement	Falsely elevated
"White coat effect"/anxiety	Falsely elevated
Decrease in recorder auditory or visual acuity	Falsely elevated or decreased
Recorder bias	Falsely elevated or decreased

30 seconds the cuff is reinflated to 30 mm Hg above that point, and then gradually deflated while the clinician listens through the stethoscope with the diaphragm placed over the brachial artery and monitors the position of the mercury in the sphygmomanometer. The return of blood flow through the artery is signaled by the sounds produced by the turbulent flow through the partially occluded artery and named after the Russian physician who first described them in 1905 (*Korotkoff sounds*).<sup>12</sup> This sound is recorded as the systolic pressure. As the pressure continues to be released, sounds change in intensity until the point at which the Korotkoff sounds disappear, which is noted as the diastolic pressure (Table 16-4). Nurse researchers in Britain found statistically significantly lower diastolic values using this approach compared with a one-step approach.<sup>9</sup> In this approach, the systolic pressure was estimated by palpating the brachial artery during cuff inflation, and inflation continued 30 mm Hg beyond that point before proceeding with deflation. It was postulated that the first inflation and occlusion produced a reactive vasodilation that could be responsible for this difference.<sup>9</sup> Regardless, the auscultation of Korotkoff sounds results in systolic values that are lower than those obtained by direct, intraarterial blood pressure measurement.<sup>6</sup> Older patients often have a period during measurement when the Korotkoff sounds disappear, returning 20 to 40 mm Hg later. This *auscultatory gap* may be attributed to

**TABLE 16-4 KOROTKOFF SOUNDS**

PHASE	DESCRIPTION
I	Initiation of clear tapping sounds—systolic blood pressure
II	Murmuring or swishing sounds
III	Increase in intensity and crispness of sounds
IV	Muffling of sounds
V	Disappearance of sounds—diastolic blood pressure

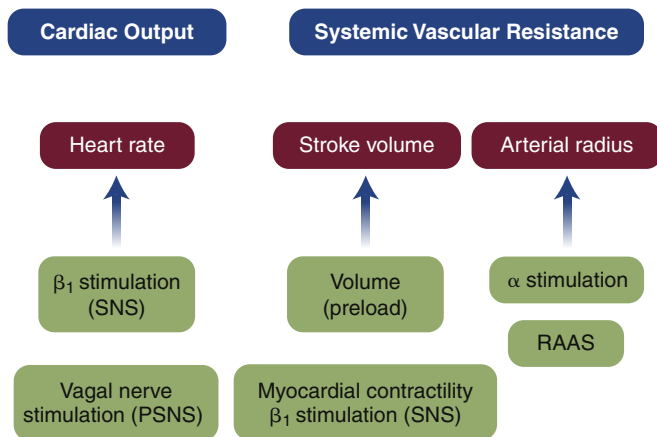

**FIGURE 16-2** Auscultatory gap. Palpating the blood pressure (BP) before auscultation allows assessment of the true systolic BP. Palpated BP equals 200/P. The same result can often be obtained by elevating the arm overhead for 30 seconds before inflating the cuff. Auscultated BP when the cuff is inflated to only 180 mm Hg results in a falsely low value of 140/80 mm Hg.

intraarterial pressure fluctuations associated with hypertension (Figure 16-2) and can often be eliminated by elevating the arm above the level of the head for 30 seconds before cuff inflation. This approach is postulated to enhance the audibility of Korotkoff sounds by increasing arterial flow following the increase in venous return.<sup>6</sup>

Increasingly, self-monitoring of blood pressure is being performed at home. Potential sources of error as well as optimal schemes of measuring and recording have been identified.<sup>16-18</sup> It has been found that the values documented in this setting are more accurate, if correctly obtained, because of the elimination of the white coat effect.<sup>3,11,18</sup>

**KEY POINTS**

- Systemic arterial blood pressure varies with the cardiac cycle. The highest pressure (systolic) corresponds to ejection of blood from the left ventricle into the aorta. The lowest point in pressure (diastolic) occurs at the end of diastole, just before the next ventricular contraction.
- Blood pressure is the product of the CO (HR × SV) and SVR. Changes in any of these variables will change blood pressure. The arterioles create most of the resistance in the vascular system; changes in the diameter of these vessels profoundly affect SVR and therefore blood pressure.
- The difference between the systolic and diastolic pressures is called the *pulse pressure*. The average pressure within the systemic arterial system is the MAP, mathematically derived from the two pressure values.
- Blood pressure can be directly measured by placement of a catheter within an artery and utilization of specific computer software. More routinely it is measured by auscultation. Systolic pressure is recorded as the onset of the Korotkoff sounds, and their disappearance is recorded as the diastolic pressure.
- Erroneous blood pressure values may be obtained because of a missed auscultatory gap, hydrostatic pressure changes associated with arm position, inappropriate cuff size, observer error, and other factors.

**FIGURE 16-3** Systemic arterial blood pressure is controlled through influences on each of its variables: heart rate, stroke volume, and SVR. Some of these provide short-term adjustments, whereas others affect the long-term management of blood pressure. *PSNS*, Parasympathetic nervous system; *RAAS*, renin-angiotensin-aldosterone system; *SNS*, sympathetic nervous system.

## MECHANISMS OF BLOOD PRESSURE REGULATION

Arterial blood pressure is physiologically controlled on both a short-term and a long-term basis. Regulation of blood pressure is achieved through changes in factors that impact the primary determinants of blood pressure: heart rate, stroke volume, and SVR (Figure 16-3). These variables are affected by a complex interplay between neural, humoral, and renal factors to maintain stability in the face of ever-changing internal and external environmental demands. An understanding of these mechanisms is essential to exploring pathophysiologic alterations. Blood pressure normally fluctuates over the course of 24 hours owing to physiologic changes associated with circadian rhythm.

### Short-term Regulation of Systemic Blood Pressure

Changes in blood pressure must occur quickly to accommodate behavioral changes (e.g., position changes, exercise), emotional changes (e.g., fear, anxiety), and physiologic changes (e.g., fever, volume depletion). Changes in physical activity require the most frequent alterations, and rapid adjustments are initiated in seconds so that the arterial blood pressure may be increased to twice the normal value within 5 to 10 seconds.<sup>1</sup> This short-term regulation is mediated by the sympathetic branch of the autonomic nervous system (the sympathetic nervous system, SNS). Activation of the SNS influences both heart rate and SVR. The force of contraction is primarily a factor of the circulating volume (preload) and affects long-term regulation of arterial blood pressure.

Modifications in systemic blood pressure are made by activation of the SNS directly or indirectly through stimulation of the baroreceptor reflex. (Autoregulatory changes in pressure at a local level, at the tissues of body organs, are discussed in more detail in Chapter 15.) These SNS activities related to the distribution and pressure of blood are directed through the vasomotor center in the medulla of the brainstem while the lower centers of the brain monitor the body's internal and external environments.<sup>1</sup> The vasomotor center is directly activated by such stimuli as fever or external stressors to evoke increased activity and elevate systemic arterial blood pressure.

The autonomic nervous system maintains a basal level of arteriolar smooth muscle tone through the SNS, and provides heart rate control through a balance of SNS and parasympathetic nervous system (PSNS) activity. Stimulation of the SNS results in the increased release of the

neurotransmitters epinephrine and norepinephrine. At the smooth muscle of the arterial system, these neurotransmitters bind to  $\alpha_1$  receptors to initiate vasoconstriction and an increase in SVR. Stimulation of the PSNS has almost no effect on most systemic vessels, other than venodilation in localized areas such as the face, producing a blush.<sup>1</sup> Receptors within the brain ( $\alpha_2$ ) provide negative feedback regulation, decreasing the central release of epinephrine and norepinephrine in response to stimulation. In the heart, the binding of these neurotransmitters to  $\beta_1$  receptors results in an increase in the rate of firing at the sinoatrial (SA) node, increasing the heart rate in response to increased demands. The PSNS is responsible for maintaining a slower heart rate during periods of rest.<sup>1</sup>

Indirectly, the vasomotor center is stimulated by a decreased rate of discharge by *baroreceptors*. Pressure-sensitive receptors (baroreceptors) are found in the vessel walls of nearly all large arteries in the thorax and neck, but are particularly plentiful in the sinuses of the carotid arteries and in the arch of the aorta.<sup>1</sup> Signals from the aorta travel through cranial nerve X and those from the carotids are transmitted through cranial nerve IX; both terminate in the vasomotor center of the medulla. These specialized receptors are sensitive to changes in MAP. They transmit impulses continuously, altering their rate of discharge in response to changes in MAP. Their response to these changes is very brisk, especially when pressure changes occur rapidly, which makes them the perfect mechanism to respond to variations in body position and minimize the gravity-induced decreases in pressure in the upper body.<sup>1</sup> A decrease in sensed pressure induces a decrease in action potential formation by the baroreceptors. This causes the vasomotor center to increase SNS outflow to the heart and arterial bed and to decrease PSNS stimulation to the heart. The net result is an increase in both heart rate and SVR, producing an increase in blood pressure. An increase in sensed pressure results in an increased rate of firing by the baroreceptors and a negative feedback response, lowering systemic arterial pressure. The responsiveness of the baroreflex declines with age; age-related stiffening of the arterial walls has been implicated along with contributions from pathologic conditions such as hypertension and diabetes mellitus, which are more common in the older population.<sup>1,19</sup> The results of animal studies indicate that the overall effect of the baroreflex is a reduction of the minute-to-minute fluctuations in arterial blood pressure by 33% of what it would be without this mechanism.<sup>1</sup> There is abundant evidence that within 1 to 2 days of exposure to chronic elevations of blood pressure, baroreceptors reset to the new level and the rate of discharge begins to decrease and then slowly returns to the norm despite an elevated baseline pressure.<sup>11,19</sup> This finding suggests that the baroreflex may contribute to long-term blood pressure regulation through the SNS stimulation of the kidneys<sup>1</sup> discussed in the next section.

Receptors in the carotid and aortic arteries respond to chemical signals of hypoxia ( $H^+$  and  $CO_2$  level elevations) that occur when arterial pressure declines. These chemoreceptors stimulate the medullary vasomotor center to increase SNS activity. However, this mechanism responds significantly only when systolic pressures decrease below 80 mm Hg, so blood pressure can be prevented from falling even lower.<sup>20</sup>

### Long-term Regulation of Systemic Blood Pressure

The regulation of arterial blood pressure on a long-term basis, week after week and month after month, is accomplished through the interplay of neural, hormonal and renal interaction<sup>21,22</sup> and is intimately connected with the body's fluid volume homeostasis.<sup>1</sup> The balance of the intake of water and sodium with their excretion by the kidney remains the central feature of long-term blood pressure maintenance. Historically, the role of the renin-angiotensin-aldosterone system

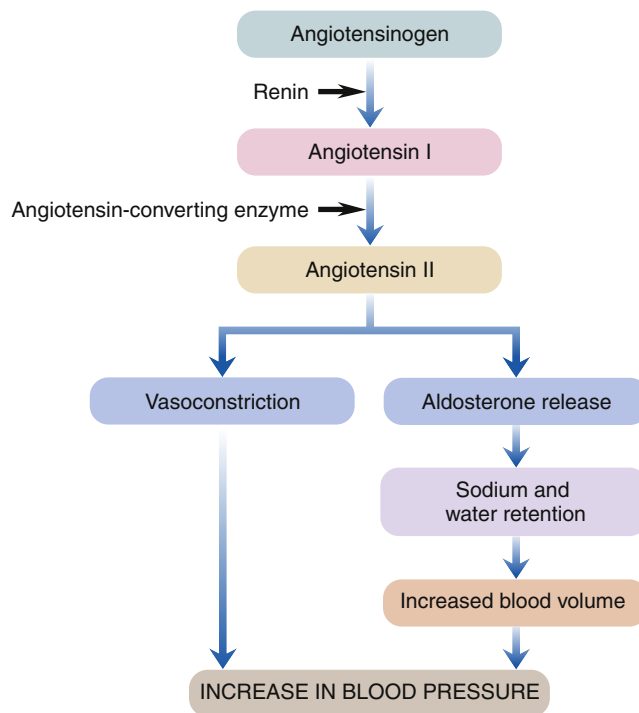

**FIGURE 16-4** Mechanism by which an increase in extracellular fluid volume results in an increase in systemic arterial pressure. (From Hall JE: *Guyton and Hall Textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders.)

(RAAS) has been seen as the primary contributor to this process, and although it continues to be a major determinant, mechanisms involving the baroreflex and the vasomotor center in the brainstem as well as localized renal systems are receiving increased attention in research.<sup>1,21,22</sup>

An increase in extracellular fluid (ECF) volume, because of increased intake or decreased excretion, results in an increase in cardiac output; when combined with the volume-induced increase in systemic vascular resistance, this results in an elevation in the arterial blood pressure (Figure 16-4). Body tissues initiate their local autoregulation mechanisms, constricting arterioles to protect against high-flow damage, which further contributes to the overall arterial resistance in the body. Unless fluid intake or renal functions are abnormal, this increase in systemic vascular resistance will not result in a prolonged elevation in arterial pressure.<sup>1</sup> The kidneys will respond quickly, increasing excretion of sodium and water and normalizing pressure within a matter of hours. This physiologic regulatory response may be disrupted if the renal vasculature is constricted, as occurs in hypertension.<sup>1</sup>

Because sodium is not as rapidly eliminated by the kidney as water, elevations in sodium intake are more likely to elevate arterial pressure.<sup>1</sup> Excess sodium also adds to the body's fluid volume by several mechanisms. Sodium increases the osmolality of the ECF and activates the central thirst center, causing an increase in water intake. The increased serum osmolality will be sensed by the hypothalamus and posterior pituitary, causing the release of antidiuretic hormone (ADH) into the bloodstream. Once ADH arrives in the renal vasculature, it binds to receptors in the collecting ducts, resulting in the enhanced reabsorption of water in order to decrease osmolality (Chapter 26).

**FIGURE 16-5** The renin-angiotensin-aldosterone system (RAAS) and its systemic effects.

The physiologic mechanisms of the RAAS are tightly controlled and interdependent (Figure 16-5). Prorenin, the inactive form of renin, is synthesized and stored by specialized smooth muscle cells located in the afferent arterioles of the kidney situated immediately proximal to the glomeruli.<sup>1</sup> Known as the *juxtaglomerular cells*, these cells are stimulated by a decrease in arterial pressure to enzymatically cleave the precursor, and release the activated renin enzyme into the vascular bed of the kidney. Most of the renin travels into the general circulation where it acts on a circulating plasma protein called *angiotensinogen*, resulting in the release of angiotensin I, a peptide possessing minimal vasoconstrictive capacity.<sup>1</sup> Angiotensin I continues to be created by renin for about 30 to 60 minutes, until renin is removed from the body. While the blood carrying angiotensin I circulates through the pulmonary vessels, an enzyme produced by the vascular endothelium (angiotensin-converting enzyme [ACE]) comes in contact with angiotensin I, and two amino acids are fragmented from angiotensin I to produce angiotensin II.<sup>1</sup> Inactivated in minutes by angiotensinases, continued production of angiotensin II maintains the profound effects it initiates. Angiotensin II is an extremely potent vasoconstrictor, primarily of the arterial bed but also slightly affecting the venous system. The SVR is therefore increased, raising blood pressure. The vasoconstrictive response to angiotensin II requires about 20 minutes to reach maximal capacity, but is capable of elevating arterial pressure to 50% of normal after severe hemorrhage.<sup>1</sup> The enhanced venous return attributable to the elevated SVR improves cardiac function by increasing myocardial fiber stretch, producing increased contractility and therefore stroke volume. Angiotensin II also is an intermediary for an additional means of raising blood pressure—increasing circulating volume to significantly increase venous return to the heart and therefore stroke volume. Angiotensin II in the general circulation reaches the cortex of the adrenal glands, stimulating the release of the hormone aldosterone. Aldosterone circulates to the kidneys where it binds to receptors in the renal tubules, causing the kidneys to reabsorb more sodium. Water follows the sodium back into the bloodstream. The result is an increase in

blood volume and further elevation in blood pressure. Excessive amounts of angiotensin in the bloodstream have been found to effectively reset this mechanism of blood pressure control to a higher-than-normal level,<sup>1</sup> potentially contributing to hypertension.

Some of the renin released by the juxtaglomerular cells exerts local effects within the kidney to elevate blood pressure.<sup>1,23</sup> Renin receptors in the mesangium of the glomerulus and below the endothelial cells of the renal arteries are activated to enhance the conversion of angiotensinogen to angiotensin I.<sup>23</sup> Angiotensinogen has been isolated in tubular and mesangial cells, and angiotensin-converting enzyme is found both in vascular endothelium and in the epithelium of the tubular cells.<sup>1,23</sup>

Other influences on long-term arterial blood pressure control include the activity of the SNS, levels of natriuretic peptides, and regulation of intrarenal mechanisms such as renal medullary endothelin production.<sup>1,23</sup> Renin release is increased when neurotransmitters released by the sympathetic nervous system bind to  $\beta_1$  receptors in the kidney. Additional local SNS effects include decreased glomerular filtration rate as a result of renal arteriolar constriction and increased tubular reabsorption of sodium and water caused by increased quantities of angiotensin II and aldosterone.<sup>1,23</sup> These effects contribute to the increased systemic blood pressure associated with severe prolonged stress. Increased SNS activity has been documented to be present in hypertension, and its role is confirmed because antihypertensive drugs that affect autonomic control of heart rate and systemic vascular resistance are so clearly effective in treatment.<sup>1</sup> A number of natriuretic hormones play a role in arterial pressure through their effects on ECF volume regulation; most important of these is atrial natriuretic peptide (ANP).<sup>1</sup> Increased volume in the atria of the heart triggers stretch receptors and stimulates the release of ANP into the bloodstream by cardiac muscle fibers. ANP causes the kidneys to increase water and sodium excretion by increasing glomerular filtration rate (GFR) and decreasing sodium reabsorption so both sodium and water remain in the filtrate.<sup>1</sup> This diuretic effect reduces circulating volume and therefore blood pressure. Endothelin-1 (ET-1) is a peptide produced in the renal medulla.<sup>22</sup> ET-1 binds to receptors within the kidney, initiating an autocrine-induced vasodilatory response affecting renal perfusion, water and electrolyte movement, and release of renin. This makes ET-1 an important participant in normal systemic blood pressure control, and levels have been found to be decreased in hypertension.<sup>22</sup> Most likely, long-term blood pressure control is a reflection of the unified contributions of all the factors discussed here, and more are yet to be identified.

### Normal Fluctuations in Systemic Blood Pressure

Many homeostatic mechanisms of the body undergo daily variations in their function governed by an area of the brain called the *suprachiasmatic nuclei*—the body's internal clock. Brain wave activity, cell regeneration, cortisol release, body temperature, heart rate, and blood pressure are only a few of the more than 100 circadian rhythms.<sup>24</sup> In the case of blood pressure, it is known that it rises before awakening (morning surge), is highest in the middle of the morning, then begins to fall, and reaches its lowest level at night (nocturnal dip).<sup>25</sup> In their recent review of the available research, Peixoto and White<sup>25</sup> found these basic fluctuations to be primarily determined by internal neural and hormonal regulation, as well as by external environmental factors such as sodium intake and physical activity. Additional factors known to impact the normal rhythmic changes in blood pressure include lifestyle influences such as alcohol consumption and cigarette smoking, as well as cognitive activity and emotional state. Elevated blood pressure levels at specific points within the circadian rhythm have been documented to be associated with the development of diabetic nephropathy

and of cardiovascular conditions such as an increased incidence of sudden cardiac death, myocardial infarction, and unstable angina, as well as stroke.<sup>25</sup>

#### KEY POINTS

- Blood pressure is regulated on a short-term basis through the interaction of the carotid and aortic baroreceptors, the vasomotor center in the brainstem, and the activation of the SNS and inhibition of the PSNS influences on the heart and smooth muscle in the arterioles. Short-term regulation primarily involves heart rate and SVR.
- Regulation of blood pressure on a long-term basis is complex, involving the influence of the nervous system, release of hormones, and responses of the kidneys to pressure changes. The vasomotor center and activation of  $\alpha_1$  receptors in the smooth muscle of the arterioles and the  $\beta_1$  receptors of the heart continue to be involved when pressure changes are sensed by the baroreceptors.
- Secretion of ADH in response to osmolality and of aldosterone from the activation of the RAAS affects fluid balance, whereas angiotensin II produces an increase in SVR. Natriuretic peptides and intrarenal mechanisms contribute to the process of long-term blood pressure management. Long-term regulation involves all of the blood pressure variables: heart rate, stroke volume, and systemic vascular resistance.
- Normal fluctuations of blood pressure occur in a cyclic pattern attributable to changes in the body's internal and external environments.

## HYPERTENSION

The current and projected global prevalence of hypertension is stunning. Hypertension is the most common primary diagnosis in the United States.<sup>4</sup> About 30% of adults in the United States have high blood pressure. The prevalence of high blood pressure remains higher among non-Hispanic black adults compared with non-Hispanic white and Mexican-American adults.<sup>26</sup> In 2000, more than 25% of the entire world population was hypertensive.<sup>26</sup> Using the 2000 estimate of 972 million adults with hypertension, projections are for this number to increase by 60%—to 29% of the 2025 world population, that is, 1.56 billion individuals! Changes in the standard of living of those in developing countries mirror the trends in economically developed ones: increasing obesity and sedentary lifestyles.<sup>26</sup> Increased consumption of alcohol, cigarette smoking, and diets deficient in fruits and vegetables will contribute further to the problem of escalating hypertension worldwide.<sup>27</sup> Hypertension will soon affect more than 50% of the adult population in the majority of the world. India and Asia have the lowest current and projected prevalence, whereas the former Socialist Republics, sub-Saharan Africa, the Caribbean, and Latin America have the highest rates.<sup>26</sup> Given that the risks to health begin with blood pressure elevations of 115/75 mm Hg, the future impact of hypertension is profound.<sup>26</sup> Hypertension increases morbidity and mortality associated with heart disease, kidney disease, peripheral vascular disease, and stroke.<sup>27</sup> It is responsible for a worldwide annual death rate of 7 million,<sup>27</sup> and it will be the most common risk factor worldwide by 2020.<sup>27</sup> An understanding of the types and causes of hypertension and the interventions associated with its treatment is essential to having an impact on the current and future effects of this disease.

### Definition and Classification

The standard for the definition and classification of hypertension in adults continues to be drawn from the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*, published in 2003.<sup>4</sup> For those individuals

age 18 years and older, normal blood pressure is defined as <120 mm Hg systolic and <80 mm Hg diastolic; stage 1 hypertension begins at a systolic pressure of 140 mm Hg or a diastolic pressure of 90 mm Hg (see Table 16-2). The range of pressures between normal blood pressure and stage 1 hypertension has been identified as *prehypertension* as part of efforts to initiate interventions early enough to prevent or at least slow the progression of the disease process. These values differ from those established by the World Health Organization, International Society of Hypertension, and European Society of Hypertension/European Society of Cardiology<sup>6</sup> in that those used in the United States are more conservative, identifying both normal and elevated levels at lower values. Standards for children and adolescents also have been established (see Table 16-1). Differing etiologies and risk factors have led to the differentiation of two major types of hypertension: primary and secondary.

### Primary Hypertension

*Primary hypertension*, also called *essential hypertension*, does not have a clearly identifiable known etiology and is therefore an idiopathic disorder. This differentiates primary from secondary hypertension, in which blood pressure elevation occurs secondarily to another, identifiable cause. Primary hypertension is by far the most common form of the disease, representing somewhere between 90% and 95% of the known cases.<sup>1</sup> Early diagnosis and intervention for adults with hypertension has been a major focus of health care for many decades; the more recent escalating incidence in children has generated alarm. Primary hypertension is increasing in prevalence among children and adolescents and is associated with positive family history of hypertension, obesity, and lifestyle factors. The prevalence of HTN in children and adolescents is determined to be 3.5%.<sup>28,29</sup> Primary hypertension is rare before children reach the age of 10 years. At this point, most of the hypertension diagnosed in preadolescents has a secondary etiology; by adolescence, 85% to 95% of the cases are primary hypertension.<sup>31-33</sup>

### Subtypes

Primary hypertension has one of several presentations: isolated systolic hypertension (ISH) in which the systolic BP is  $\geq 140$  mm Hg and the diastolic pressure remains <90 mm Hg; isolated diastolic hypertension (IDH) in which the diastolic pressure is  $\geq 90$  mm Hg with a systolic pressure of <140 mm Hg; and the combination of systolic and diastolic hypertension (SDH) occurring when both systolic and diastolic pressures exceed prehypertension values. The differing subtypes are more prevalent in specific populations, and researchers increasingly focus on subtypes in long-term outcome predictions and interventions.<sup>6,33-34</sup> The evidence overwhelmingly supports SBP as the major risk for subsequent cardiovascular disease.<sup>4</sup>

### Risk Factors

In Western populations, there is a 90% lifetime risk for the development of hypertension.<sup>26</sup> Many of the risk factors for hypertension have been known for decades and because so many are modifiable by lifestyle changes, targeted interventions are urged to address them. Other factors remain nonmodifiable, yet predictive of the development of hypertension. Ample data indicate that primary hypertension arises as a consequence of the interplay of several genes and environmental factors.<sup>35</sup> Hypertension risk factors are listed in Table 16-5.

Increasing age is a nonmodifiable risk and an independent risk factor for hypertension beginning at mid-adulthood.<sup>35</sup> Normal aging produces a rising systolic pressure over the course of a lifetime, whereas diastolic pressure increases for approximately 50 years, levels off during the sixth decade, and remains stable or declines thereafter.<sup>4,34</sup> ISH is the dominant subtype of hypertension in those older than age 55.<sup>34</sup> Changes normally associated with aging are profiled in Geriatric

**TABLE 16-5 RISK FACTORS FOR THE DEVELOPMENT OF PRIMARY HYPERTENSION**

NONMODIFIABLE RISK FACTORS	MODIFIABLE RISK FACTORS
Increasing age	Obesity
Family history	Sedentary lifestyle
	Metabolic syndrome
	Dietary factors
	<ul style="list-style-type: none"> <li>• Increased fat intake</li> <li>• Increased sodium intake</li> <li>• Inadequate potassium intake</li> <li>• Inadequate calcium intake</li> </ul>
	Tobacco use
	Laboratory data
	<ul style="list-style-type: none"> <li>• Elevated blood glucose</li> <li>• Elevated total cholesterol</li> <li>• Elevated triglycerides</li> <li>• Decreased high-density lipids (HDL)</li> <li>• Elevated low-density lipids (LDL)</li> </ul>

Considerations: Changes in the Circulatory System in Chapter 15. The level of the systolic pressure, MAP, and the difference between systolic and diastolic pressures (pulse pressure), among other factors, are used to guide pharmacologic interventions.<sup>6</sup> Given this normal age-related development of hypertension, most early and subsequent data related to the increased risk of mortality and morbidity are based on this population, and systolic pressure elevation clearly affects risk more than diastolic, as noted in the earliest and most famous cardiovascular research in the Framingham Study.<sup>4</sup>

Age is not a risk factor for hypertension in childhood or adolescence. Hypertension does occur in these age groups, however, and the distribution of subtypes and the proposed bases and prognosis are worth noting. Determination of hypertension is based on the normal expectations for the child's age, gender, and height (see Table 16-1). Although isolated diastolic hypertension (IDH) is more common among younger adults, ISH can occur.<sup>6,36</sup> ISH in adolescents and young adults (<45 years of age) has been attributed to the increased elasticity of their arteries in the face of rapid growth; this produces an increase in brachial systolic pressure, although aortic pressure is unchanged.<sup>6</sup> Others have found an increase in stroke volume with or without aortic stiffening to be the basis of ISH in this age group.<sup>37,38</sup> IDH often seems to develop in prehypertensive young adults,<sup>33</sup> and the prognosis remains open to debate.<sup>6,33,39,40</sup> One study found that IDH does not appear to predict the development of ISH but is a strong predictor of the later development of SDH.<sup>33</sup> The report of a review of the literature indicated that below the age of 50, diastolic pressure was a greater predictor of coronary artery disease (CAD), whereas CAD risk in those age 60 and older was greater with elevated systolic pressure.<sup>40</sup> In children, hypertension is a risk both for adult hypertension and for subsequent development of adult cardiovascular disease.<sup>31,36</sup>

Another significant nonmodifiable risk factor is ethnicity, which combines race with genetics. Adult African Americans have the highest risk, but there is controversy about this finding for the pediatric population.<sup>36</sup> A concrete reason for this finding in adults continues to elude researchers, although increased salt sensitivity seems most likely.<sup>37</sup> The number of individual genes and their signaling pathways and organizational arrangements that affect the control of blood pressure are vast<sup>39</sup> and beyond the scope of this book. Despite the identification of the

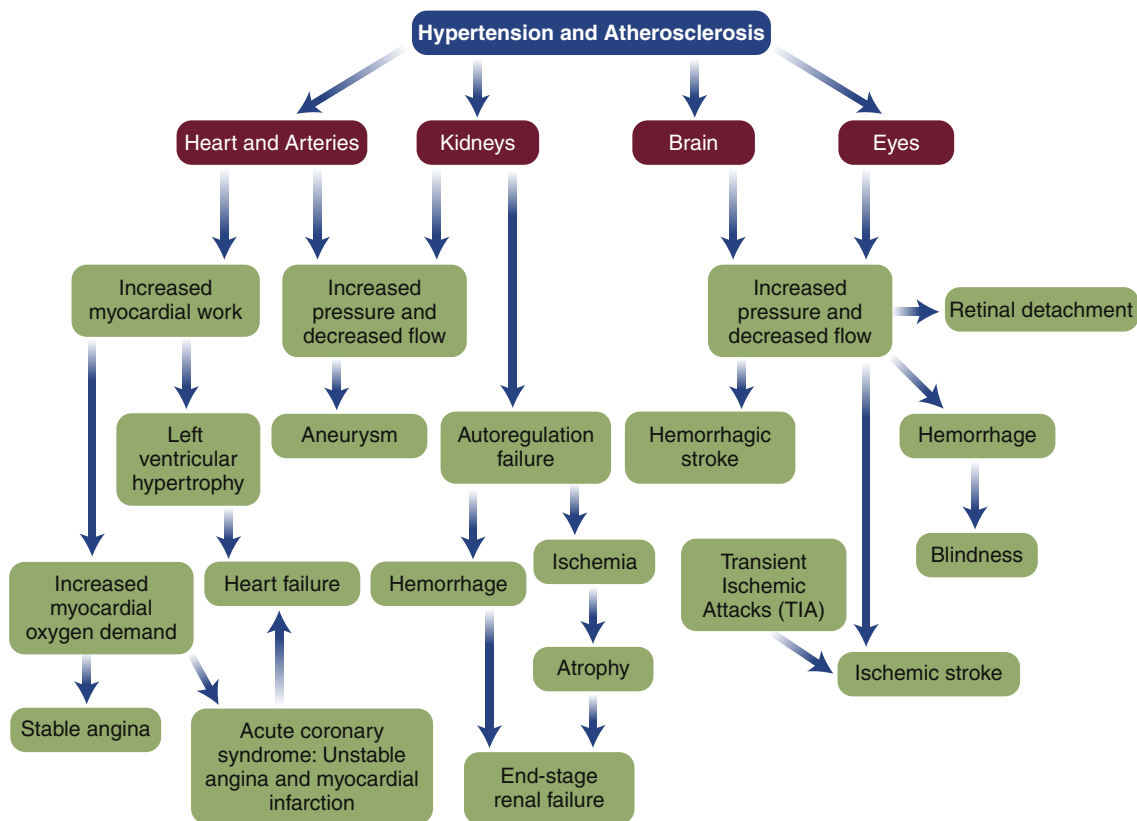

FIGURE 16-6 Effects of chronic hypertension and atherosclerosis on target end-organs.

genetic role in hypertension, specifying the mechanisms themselves is a challenge.<sup>39</sup> Genetics may be responsible for low renin levels and salt sensitivity, heightened responses to angiotensin II, altered amounts or responses to local tissue factors such as endothelin and nitric oxide, and any number of mechanisms accounting for primary hypertension that have been proposed.<sup>22,37</sup> At the same time, none of the currently identified genetic disorders has been demonstrated to be accountable for a noteworthy quantity of hypertension in the general population, either as individual genes or as several genes working in concert.<sup>4</sup> A family history of hypertension is a risk factor in both adults and children.<sup>32</sup>

Modifiable risk factors are often called *lifestyle factors* in acknowledgment of the role of individual choice in both their development and their control. Both weight gain and obesity are significant risk factors for all subtypes of primary hypertension at all ages.<sup>32,33,41</sup> Obesity has reached epidemic proportions and represents between 65% and 75% of the overall risk for the development of hypertension.<sup>1,41</sup> Diet and activity levels contribute to the development and continuation of obesity in all age groups. Diets high in fat and sodium and low in potassium and in fruits have been found to increase the risk of developing hypertension.<sup>1,31,36,37</sup> Obesity not only increases the risk of hypertension but also is a risk factor for hyperlipidemia, salt sensitivity, and insulin resistance.<sup>31</sup> Known as *metabolic syndrome* and characterized by elevated circulating insulin and lipid levels, hypertension, and obesity, this condition was previously only identified as a risk factor for hypertension in adults but is now becoming more common in children. It has been estimated that the prevalence of metabolic syndrome is 7% in adolescents at risk for becoming overweight, 29% in overweight adolescents, and 50% in severely obese adolescents.<sup>42</sup> Elevated blood glucose levels, diabetes mellitus, and elevated total cholesterol level, as well as smoking and excessive alcohol intake, are all implicated as risk factors for hypertension.<sup>4,27,31,40</sup>

Recently, the apparent increased incidence of childhood and adolescent hypertension has spawned research into predictors of the development of hypertension from the maternally-provided intrauterine environment through the childhood and adolescent period. Maternal smoking, pregnancy-induced hypertension, and maternal dietary habits have been shown to influence the later development of hypertension.<sup>41-42,44</sup> Low birth weight,<sup>31</sup> followed later by rapid growth in both height and weight, seems to be more common in the history findings of patients with hypertension.<sup>43</sup> Lower socioeconomic level of the mother<sup>43</sup> and inadequate dietary calcium intake during pregnancy appear to increase the risk for later development of hypertension,<sup>46</sup> whereas breast feeding seems to act as a protective factor against hypertension.<sup>42,43</sup>

### Outcomes

**End-organ damage.** The great concern for the prevention, early identification, and treatment of hypertension is because of the harm it may cause in body tissues and organs and the resulting significant morbidity and mortality (Figure 16-6). This end-organ damage is a function of both the stage of hypertension and its duration.<sup>4</sup> Unfortunately, early hypertension causes no overt clinical manifestations, and individuals may have considerable end-organ damage before the diagnosis is made. This has earned hypertension the moniker of the “silent killer” and explains the rationale for screening programs to encourage early diagnosis. Hypertension is an important independent risk factor for the development of renal failure, stroke, and CAD.<sup>4,40</sup> CAD and hypertension heighten the risk of angina, myocardial infarction, and heart failure. As the systolic and diastolic pressures rise from normal levels, mortality from ischemic heart disease and stroke also increases linearly and progressively.<sup>4</sup>

Cardiovascular disease is the most commonly recognized outcome of hypertension. For those older than age 50 years, SBP  $\geq 140$  mm Hg

presents a far greater risk for the development of cardiovascular disease than does an elevated diastolic blood pressure. Risk for the initial occurrence of cardiovascular disease begins with a blood pressure of 115/75 mm Hg, and with each incremental increase of 20/10 mm Hg, the risk doubles.<sup>44-46</sup>

Hypertension itself is directly harmful to the arterial system, but it also acts in concert with the other risk factors associated with the development and acceleration of atherosclerosis.<sup>31,35,40</sup> Atherosclerosis is the underlying pathophysiologic basis of coronary artery disease (see Chapter 15). Evidence of atherosclerosis has been found in adolescents and very young children.<sup>31</sup> The increased tension that high blood pressure generates on the walls of arteries precipitates an increase in the accumulation of collagen as well as reduction, fragmentation, and breakage of elastin fibers.<sup>40</sup> An ongoing low level of inflammation occurs in arteries exposed to hypertension, and combined with the dyslipidemia commonly seen, the development of atherosclerotic plaques is escalated.<sup>40</sup> CAD predisposes to stable angina and the acute coronary syndrome of unstable angina and myocardial infarction (see Chapter 18).

Hypertension reflects an elevation in SVR; rising afterload increases myocardial oxygen demand and overall cardiac workload. In an effort to compensate for this increased effort, the left ventricle hypertrophies.<sup>40</sup> The development of left ventricular hypertrophy also has been noted in children and adolescents.<sup>4</sup> The CAD typically found in association with hypertension limits the supply of oxygen to the heart, and this combination of increased demand and decreased supply predisposes the heart to ischemia.<sup>40</sup> Ischemia may result in stable or unstable angina, or myocardial infarction. Myocardial infarction and left ventricular hypertrophy increase the risk for the development of heart failure (see Chapter 19). Patients may seek health care intervention because of these conditions so that the presence of hypertension is discovered only secondarily.

The atherosclerotic process described previously with coronary artery disease (Chapter 15) is likely to be the basis for the damage to the microcirculation of the kidneys that develops with chronic hypertension.<sup>40</sup> Within a proscribed MAP, healthy kidneys are able to autoregulate blood flow delivered to the glomerulus, but with prolonged or severe hypertension this regulatory ability is lost and glomerular damage ensues.<sup>1,35</sup> Damage to the glomerulus allows large molecules not normally filtered out of the bloodstream to appear in the urine. The presence of microalbuminuria (proteinuria) is reflective of increased glomerular permeability and an early indicator of hypertensive renal injury. At this point, the patient is usually asymptomatic, but if interventions for blood pressure control are not initiated, renal impairment progresses, culminating in end-stage renal disease (ESRD), which requires long-term renal dialysis or transplantation.<sup>47</sup>

Identifiable damage to the kidneys is often preceded by changes in the microcirculation of the retina of the eye.<sup>35</sup> Atherosclerosis also contributes to the retinal injury produced by hypertension. The result may be retinal detachment or hemorrhage, which can cause blindness.

Hypertension and the accelerated development of atherosclerosis affect arteries of all sizes throughout the body. Decreased flow or rupture of weakened blood vessels within the brain results in strokes. Ischemic strokes are associated with atherosclerosis, whereas hypertension is the major risk factor for hemorrhagic strokes. This type of stroke results in high morbidity and mortality. Hypertension is also the primary risk factor for the development and rupture of aortic aneurysms. The peripheral arteries of the lower extremities are common targets of atherosclerosis, and the resulting peripheral vascular arterial disease is the source of significant impairment of independence and mobility and potential amputation in the elderly.<sup>35</sup>

## Treatment Interventions

Effective treatment of hypertension results in decreased morbidity and mortality associated with cardiovascular, cerebrovascular, and renal disease.<sup>4,35,47</sup> However, the goal of normal systolic and diastolic pressures is not attained for many patients with hypertension. The problem appears to be even greater in Europe, where only 5% to 12% achieve control compared with 27% in the United States.<sup>48</sup> Cumulative data from clinical drug trials indicate the risk of stroke can be reduced 35% to 40% by decreasing blood pressure, myocardial infarction 20% to 25%, and heart failure by more than 50%.<sup>4</sup> Approaches to treatment are affected by several factors including the patient's age, stage of hypertension, identified risk factors, concomitant disorders, ethnicity, and medication history. Interventions fall into two categories: lifestyle alterations and pharmacologic interventions. The overall approach to treatment is detailed in Figure 16-7. Although an in-depth discussion of treatments is beyond the scope of this book, they are summarized in the following text.

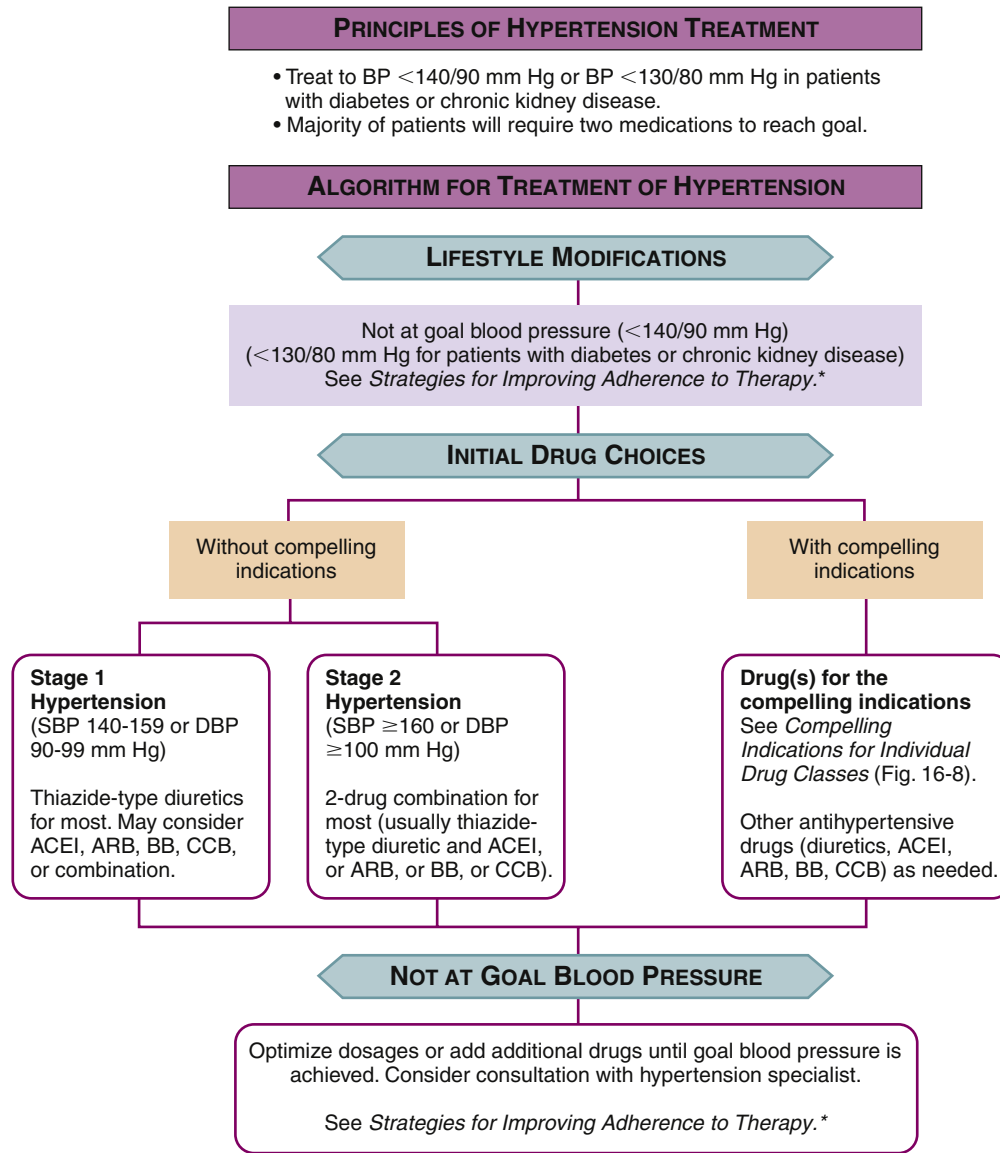

Lifestyle alterations assume special importance because addressing modifiable risk factors has a documented effect in preventing hypertension from developing, as well as treating it in adults<sup>4</sup> and children.<sup>2</sup> Primary prevention of hypertension could have a profound influence on the morbidity and mortality associated with end-organ damage throughout the world and includes lifestyle changes and effective screening procedures to facilitate early diagnosis. These lifestyle changes are listed in Table 16-6. Weight loss is clearly an important intervention, with profound evidence that it reduces cardiovascular mortality.<sup>41</sup> The efficacy of exercise in blood pressure control is also well substantiated by research.<sup>49</sup> Brisk exercise of at least 30 minutes most days of the week plus the acceptance of the Dietary Approaches to Stop Hypertension (DASH) diet address a number of hypertensive risk factors.<sup>4</sup> Because they have been found to augment drug efficacy, these lifestyle adjustments also are included for those who require medication interventions for primary hypertension<sup>4</sup>; however, it is unlikely that lifestyle interventions alone will be sufficient for those with stage 1 hypertension.<sup>26</sup>

Drug therapy for hypertension addresses one or more of the variables responsible for blood pressure: heart rate, SVR, and stroke volume, which is primarily a function of the volume of blood returned to the heart during diastole. This is reflected in how the classifications of oral medications used in the treatment of hypertension are listed in Box 16-1. Figure 16-8 identifies comorbid conditions that require the use of specific medications.<sup>4</sup> Combination drugs, taking advantage of the effects of more than one classification without increasing the total number of medications a patient is taking, are becoming increasingly popular.<sup>35</sup> Because there is considerable variation in individual response to antihypertensive drug therapy, long-term monitoring is essential and alterations in treatment may be necessary.<sup>35,50</sup>

## Secondary Hypertension

When hypertension is found to have a specific identifiable cause, it is termed *secondary hypertension*. The cause may be a specific pathology or condition that results in hypertension, or the development of high blood pressure may be the result of the ingestion of certain drugs, foods, or chemicals. Conditions associated with secondary hypertension are listed in Box 16-2. Some common substances that increase blood pressure are shown in Box 16-3.

In infants and preschool children, hypertension is usually of a secondary etiology and primary hypertension is rare.<sup>31,36</sup> In a study of 220 hypertensive children, 85% of the cases were found to be of a secondary etiology.<sup>36</sup> The four variables independently associated with primary hypertension were absence of signs and symptoms, normal serum creatinine level, family history of hypertension, and elevated body weight.<sup>36</sup> In the diagnostic assessment of adults, secondary

**\*Strategies for Improving Adherence to Therapy:** Clinician empathy increases patient trust, motivation, and adherence to therapy. Physicians should consider their patients' cultural beliefs and individual attitudes in formulating therapy.

**FIGURE 16-7** Treatment recommendations for primary hypertension. etiologies should be ruled out, but from the age of 18 years, primary hypertension is far more common. Interventions for secondary hypertension are directed at removing the cause, if possible. Drug therapy may be indicated, using the same agents previously discussed in the treatment of primary hypertension. As with primary hypertension, both the severity of the elevation as well as its duration must be considered because they heighten the risks for end-organ damage. The most common etiologies of secondary hypertension are discussed next.

Renal disease may be the result of a disease process either involving the parenchyma of the kidney or involving its vascular system. Hypertension is a risk factor for the development of renal failure, but it can

also develop secondary to renal pathologies. In adults with renal disease, hypertension is common and develops early, primarily as a result of heightened SNS activity.<sup>21</sup> In children one of the most common causes of hypertension is renal disorders; however, by the age of 12 to 18, the major cause becomes idiopathic primary hypertension.<sup>31</sup> As renal disease progresses, the kidneys' ability to excrete sodium effectively is lost and the renin-angiotensin-aldosterone system as well as the SNS are inappropriately activated. Renal artery stenosis should be considered in the diagnostic evaluation of new-onset hypertension in patients younger than 30 or older than 55 years, and an abdominal bruit is often found on auscultation.<sup>4</sup>

**TABLE 16-6 LIFESTYLE MODIFICATIONS TO PREVENT AND TREAT PRIMARY HYPERTENSION IN ADULTS\***

MODIFICATION	RECOMMENDATION	RANGE OF SBP REDUCTION†
Weight reduction	Attain and maintain BMI of 18.5-24.9 kg/m <sup>2</sup>	5-20 mm Hg/10 kg
DASH diet	High in fruits and vegetables and low-fat dairy products with decreased total and saturated fat	8-14 mm Hg
Decreased sodium intake	No more than 100 mmol/day (2.4 gm sodium or 6 gm sodium chloride)	2-8 mm Hg
Exercise plan	Regular aerobic activity for at least 30 min/day most days of week	4-9 mm Hg
Moderate intake of alcohol	≤2 drinks/day for men ≤1 drink/day for women	2-4 mm Hg

BMI, Body mass index; DASH, Dietary Approaches to Stop Hypertension.

\*Smoking cessation increases the overall reduction in cardiovascular risk.

†Results vary based on individual response, amount, and time of modification accomplished.

Another common cause of hypertension in children younger than age 6, along with renal disease, is coarctation of the aorta.<sup>31</sup> Without treatment, median life expectancy is only 31 years, with death from hypertension-related systemic effects.<sup>48-51</sup> It is for this reason that palpation of peripheral pulses and measurement of blood pressure in both arms are recommended both in routine pediatric physical examinations and in physical examinations in those whom hypertension is present.<sup>2,52</sup> Early diagnosis facilitates early surgical intervention, reducing both premature mortality and end-organ damage.<sup>52</sup> Hypertension persists after surgical repair in 20% to 30% of patients, but the pathophysiologic basis of this finding has yet to be determined.<sup>51,53</sup> Unfortunately, this means that these individuals remain at risk for the long-term effects and increased mortality associated with hypertension.

Hypertension arises in 5% to 12% of all pregnancies, depending upon the source,<sup>6</sup> and is the most frequent medical diagnosis for this condition.<sup>6</sup> Hypertension during this time is of foremost concern because of increased risk of maternal, fetal, and neonatal morbidity and mortality.<sup>4</sup> Preterm labor, abruptio placentae, disseminated intravascular coagulation, hemorrhagic stroke, liver failure, and acute renal failure are all potential outcomes of hypertension during pregnancy.<sup>54</sup> When hypertension is diagnosed during pregnancy, it is classified into one of four categories: chronic hypertension (preexisting), preeclampsia, chronic hypertension with superimposed preeclampsia, or gestational hypertension.<sup>4,54</sup> Pharmacologic interventions are used cautiously, and lifestyle interventions such as limiting salt intake and avoiding the use of alcohol or tobacco may be sufficient.<sup>4,54</sup>

Obstructive sleep apnea (OSA) is closely associated with obesity; it is found in 2% to 4% of adults, and hypertension is present in 45% to

**BOX 16-1 DRUG CLASSIFICATIONS USED TO TREAT HYPERTENSION AND THE VARIABLES THEY AFFECT**

**Reduce Stroke Volume**

- Thiazide diuretics
- Loop diuretics
- Potassium-sparing diuretics
- Aldosterone receptor blockers
- Angiotensin (ACE) inhibitors
- Angiotensin II receptor blockers
- Venodilators

**Reduce Systemic Vascular Resistance**

- Combination  $\alpha_1$ - and  $\beta$ -blockers
- Angiotensin-converting enzyme (ACE) inhibitors
- Angiotensin II receptor blockers
- Calcium channel blockers
- $\alpha_1$ -Blockers
- Central  $\alpha_2$  agonists
- Direct-acting vasodilators (arterial)

**Decrease Heart Rate**

- $\beta$ -Blockers
- Combination  $\alpha_1$ - and  $\beta$ -blockers

Compelling Indication	Recommended Drugs

60% of those diagnosed with OSA.<sup>4,55</sup> Historically, there has been debate as to whether OSA itself was an etiologic factor in hypertension, or whether obesity simply increased the risk of both. Researchers now take the position that the potential causality between hypertension and OSA entails both an independent role of OSA in chronic blood pressure elevation as well as the obesity-hypertension linkage.<sup>4</sup> Certain molecular mechanisms including increased vasomotor activity mediated by angiotensin II, endothelin, and nitric oxide may occur in both.<sup>56,57</sup> Obstructive sleep apnea increases the risk of obesity in patients who were not originally overweight.<sup>4</sup> The severity of OSA has a direct relationship to the level of blood pressure elevation<sup>4</sup> and when untreated mortality and morbidity resulting from cardiovascular pathologies is increased.<sup>55</sup> A milder form of OSA is found in children, and evidence is increasing that it too is associated with discernible cardiovascular abnormalities including hypertension, decreased arterial distensibility, and left ventricular hypertrophy.<sup>58,59</sup>

Increased intracranial pressure\*

#### Other

Systemic arteritis (e.g., Henoch-Schönlein purpura)  
Sleep apnea\*

\*Also seen in children

Pheochromocytoma is a catecholamine-secreting tumor of the adrenal medulla that generates hypertension on either a short-term or a long-term basis.<sup>60</sup> The condition is rare, although well-recognized; it can result in angina, myocardial infarction, acute heart failure, dilated cardiomyopathy, cerebral ischemia or hemorrhagic stroke, and cardiac dysrhythmias.<sup>61</sup> Treatment involves control of blood pressure pharmacologically, and then surgical removal of the tumor.

Hypertension is a predictable finding in primary hyperaldosteronism. Most frequently it is caused by a hypersecreting benign adenoma of the adrenal cortex or either unilateral or bilateral idiopathic adrenal hyperplasia.<sup>62</sup> Although evidence exists that aldosterone is produced by other body tissues, hormone from the adrenal gland represents by far the majority of circulating aldosterone.<sup>63</sup> The ratio of aldosterone to renin may be genetically influenced, but this has not been consistently documented.<sup>64</sup> For decades, hyperaldosteronism was thought to be a rare cause of hypertension; it is now known to be the most common form of secondary hypertension,<sup>62</sup> responsible for at least 12% of all cases, and it is believed that this number would be higher with improved screening.<sup>65</sup> Screening for hyperaldosteronism is recommended for hypertensive patients with decreased potassium levels or those found to be refractive to three or more antihypertensive agents.<sup>65</sup> Diagnosis requires measurement of serum aldosterone and renin levels.<sup>62</sup> Surgical removal of the involved adrenal gland results in a cure for 30% to 60% of cases and improved blood pressure levels in the remainder. Removal of one or both adrenal glands in bilateral disease rarely appears curative, so bilateral disease is treated medically with agents that block aldosterone's binding sites in the kidney.<sup>62</sup>

### Hypertensive Emergencies and Urgency

Acute rises in blood pressure are identified by several names, complicating discussion of the condition. *Hypertensive crisis* was the term introduced to replace the initial term *malignant hypertension*, which originated as early as 1914.<sup>66</sup> Sixty-five million Americans have been diagnosed with hypertension, and about 1% of these will experience a hypertensive crisis during their lifetime.<sup>66</sup> At least 500,000 Americans are evaluated for hypertensive crises annually.<sup>66</sup> Most cases seem to be

### BOX 16-3 SUBSTANCES KNOWN TO CAUSE HYPERTENSION

#### Over-the-Counter Drugs, Prescription Drugs, and Illicit Drugs

Sympathomimetic agents (e.g., decongestants, amphetamines)  
Glucocorticoids  
Cocaine  
Calcineurin inhibitors (e.g., cyclosporine, tacrolimus)  
Oral contraceptives, especially if high in estrogen  
Nonsteroidal antiinflammatory drugs  
Erythropoietin  
Antidepressants  
Phenylpropanolamine analogues (e.g., ma huang, "herbal ecstasy")  
Nicotine (and withdrawal)  
Anabolic steroids  
Narcotic withdrawal  
Ergotamine  
St. John's wort

#### Foods

Foods containing tryptophan or tyramine

Lead  
Mercury  
Lithium salts  
Thallium and other heavy metals

caused by secondary hypertension or poorly or uncontrolled primary hypertension.<sup>66</sup> Some other notable etiologies for hypertensive crisis include autonomic dysfunction, as is seen in Guillain-Barré syndrome, and autonomic dysreflexia, which can manifest in patients with high spinal cord injuries as well as in patients discontinuing certain drugs, such as  $\beta$ -blockers.<sup>66,67</sup> When *hypertensive crisis* is used today, two subgroups are differentiated: *hypertensive emergency* and *hypertensive urgency*. In both cases, the DBP is usually  $>120$  mm Hg.<sup>66</sup> Hypertensive emergencies are situations characterized by a sudden increase in either or both systolic and diastolic pressures accompanied by evidence of acute end-organ damage.<sup>66-68</sup> These same references use the term *hypertensive urgency* to describe similar blood pressure elevations, but without the end-organ damage. The differentiation is necessary because it is the presence of end-organ damage and not the level of the blood pressure that usually determines the treatment.<sup>66,68-69</sup>

Hypertensive emergencies can occur in the previously undiagnosed patient or the patient with chronic hypertension; these emergencies are twice as common in males as in females,<sup>70</sup> and elderly African Americans have the highest incidence.<sup>69</sup> Hypertensive emergencies can occur at any age and are estimated to be responsible for more than 25% of emergency department visits.<sup>71</sup> Of all the end-organ damage with which hypertensive emergencies are associated, abnormalities of the

central nervous system are the most frequent. These include ischemic stroke, encephalopathy, and subarachnoid or intracerebral hemorrhages. Acute heart failure, including acute pulmonary edema, myocardial infarction, and aortic dissection are the common cardiovascular complications, and retinopathy is a frequent finding.<sup>66</sup> From a pathophysiologic standpoint, hypertensive emergencies are the result of multiple factors including an abrupt release of catecholamines, mechanical stress producing endothelial damage, inappropriate activation of the renin-angiotensin-aldosterone system, and oxidative stress.<sup>66</sup> These changes overwhelm the normal autoregulatory mechanisms and result in a sudden and significant increase in systemic vascular resistance, initiating an inflammatory response.<sup>66</sup> Because of the evidence of end-organ damage, recommendations are for the rapid but controlled reduction of blood pressure using primarily parenteral antihypertensive agents closely monitored in a critical care setting.<sup>66-68,72</sup> The standard goal is to decrease the DBP to 100 to 110 mm Hg or about a 25% decrease in the MAP.<sup>66,67</sup>

Hypertensive urgency is actually more common than hypertensive emergency.<sup>66</sup> The approach to treatment of hypertensive urgency, when end-organ damage is not evident, is quite different. Once measurement error is eliminated, other sources of rapid-onset reactive hypertension should be ruled out. These may include anxiety, pain, abrupt withdrawal of alcohol or antihypertensive medications, postoperative hypertension especially following cardiac and vascular surgery, and full bladder.<sup>66-68</sup> In some of these cases, interventions other than antihypertensive drugs are indicated. In patients with hypertensive urgency, rapidly decreasing blood pressure has been associated with a substantial mortality.<sup>66</sup> Blood pressure in these patients is usually brought under control over 24 to 48 hours through the use of oral medications,<sup>66,67</sup> although there are indications for more aggressive intervention with parenteral agents.<sup>67,72</sup>

### KEY POINTS

- Primary hypertension has no identifiable etiology, but risk factors include age; dietary factors including excess sodium and obesity; ethnicity and family history; sedentary lifestyle; and tobacco use.
- In adults, a normal blood pressure is <120 mm Hg systolic and <80 mm Hg diastolic pressure. Stage 1 hypertension begins with a systolic pressure of 140 mm Hg or a diastolic pressure of 90 mm Hg. Between these values, the individual is said to have prehypertension, and interventions related to lifestyle changes should be initiated for primary hypertension.
- Treatment of primary hypertension includes lifestyle modifications and drug therapy. Lifestyle changes address the modifiable risk factors. Drug therapy targets one or more of the variables of blood pressure: heart rate, stroke volume, and SVR.
- In secondary hypertension, the elevated blood pressure is the result of identifiable pathologic conditions, or certain drugs or foods. It is less common in adults, but is the major cause of hypertension in children. The underlying cause must be treated; drug interventions may also be necessary.
- Hypertension is usually asymptomatic until there is significant damage to vulnerable organs or tissues. This process is augmented by atherosclerosis in the coronary, renal, and cerebral arteries. Ultimately, hypertension increases the risk of stroke, angina, myocardial infarction, heart failure, renal failure, and blindness caused by retinopathy.
- Extreme and rapidly developing hypertension is divided into two groups: emergency, where there is evidence of end-organ damage; and urgency, where there is not. Urgencies are treated more slowly and with oral medications; emergencies require hospitalization and more rapid-acting interventions.

## LOW BLOOD PRESSURE

The mechanism for short-term maintenance of blood pressure described previously is designed to respond rapidly to changes in both internal and external environments. Over the course of the day, this system of increased autonomic activity usually accommodates changes in activity, especially changes in position. Recall that when moving from a supine position to sitting or standing, gravity pulls blood away from the upper body and stimulates the baroreceptors in the carotid arteries and aortic arch; 500 to 1000 ml of a person's circulating blood volume pools in the venous system of the lower extremities.<sup>73</sup> Messages transmitted from these receptors to the vasomotor center of the brain result in SNS activation, increasing both heart rate and arterial smooth muscle tone. The effect of these SNS-mediated responses to position change is the rapid increase in blood pressure and improved perfusion to the upper body, especially the brain. When this mechanism fails to produce this response in a timely fashion, the drop in blood pressure with position change is called *orthostatic hypotension*, and may have serious consequences.

Orthostatic hypotension (OH) (postural) is a widespread but often unrecognized disorder with potentially serious consequences. It has been reported to occur in 6% to 30% of healthy elderly persons with normal blood pressures.<sup>74-77</sup> When perfusion is not rapidly returned to the brain, dizziness, blurred vision, fainting (syncope), and injury from falls are familiar outcomes.<sup>74-76</sup> But OH can have even more serious consequences. It has been demonstrated to be associated with cardiovascular disease, and research results indicate it may predict stroke, cognitive impairment, and death.<sup>75,79</sup>

The standard definition of orthostatic hypotension is a decrease in systolic blood pressure of  $\geq 20$  mm Hg or a decrease in systolic pressure that is  $\geq 10$  mm Hg within 3 minutes of moving to an upright position.<sup>74-76</sup> Other references state that an excessive increase in heart rate, by 20 to 30 beats/minute, is also diagnostic.<sup>75</sup> Some researchers have found that the response can be delayed well beyond that timeframe in the elderly, perhaps up to 10 minutes or more.<sup>76</sup>

An ineffective response to position change may be associated with problems within the nervous system resulting from a number of pathologies, a vasovagal reaction, depletion in circulating volume, or cardiac dysrhythmias.<sup>75</sup> It can also occur as an adverse effect of drug therapy, most frequently antihypertensive, tricyclic antidepressant, and pain medications.<sup>73,77</sup> The elderly are at special risk of OH when they are taking these medications. They also commonly have an inadequate fluid intake, age-related decreases in autonomic nervous system function, and disorders such as Parkinson disease and diabetes with which postural hypotension is associated.<sup>75</sup> Orthostatic hypotension also is more common in the presence of arterial stiffness, which may be caused by an alteration in baroreceptor sensitivity.<sup>19</sup> Alcohol ingestion and exposure to heat will also cause vasodilation and may precipitate orthostatic hypotension.<sup>73</sup>

A normal response to the SNS activation by the baroreceptors depends on effective functioning of all components of the system. Damage to the vasomotor center or neurons within the central or peripheral nervous system may be responsible for a lack of sufficient response. This may be caused by disease or blunted responses associated with normal aging, prolonged bed rest, or medications. The prevalence of OH in Parkinson disease has been reported to be 37% to 58%.<sup>75</sup> Direct damage to nerve fibers by elevated blood glucose levels in diabetes or an autoimmune injury as in multiple sclerosis can blunt the response, as well as impaired transmission

resulting from spinal cord injury. Altered sensitivity of the baroreceptors has been well documented.<sup>77</sup> The vasovagal response is a paradoxical increase in parasympathetic activity and a decrease in sympathetic activity resulting in bradycardia and vasodilation rather than an increase in heart rate and vasoconstriction. This contradictory response can be triggered by other stimuli such as stress, painful or unpleasant events, and activities such as coughing that increase intraabdominal or intrathoracic pressures. Dysrhythmias that impair cardiac output or an inadequate volume in the vascular space to respond to vasoconstriction signals will both also produce OH. Volume depletion as occurs in hemorrhage, burns, or severe diarrhea may reach a point where normal compensatory responses to position changes are inadequate; this happens after about a 30% volume loss.<sup>1</sup> The development of postural changes in vital signs is a useful clinical indicator of inadequate circulating volume.

Because orthostatic hypotension is often caused by physiologic conditions that are not amenable to modification, patients must be taught how to make changes to avoid initiating the response or reducing its impact. In addition to changing positions slowly to reduce the initial drop in blood pressure, patients are encouraged to avoid hot environments (baths or saunas), because of their vasodilating effects, and large or carbohydrate-heavy meals, because postprandial hypotension can result from the increased blood volume drawn to the splanchnic bed. When symptoms begin, before fainting, actions can be taken to prevent the progression of OH. Squatting, bending forward to lower the head, or crossing the legs while tightening calf, thigh, and buttocks muscles may counter the effects. Elastic

compression stockings and abdominal binders have documented value, as does elevating the head of the bed. Unless contraindicated, liberal intake of both salt and fluids is encouraged.<sup>78-79</sup> Medication history should be carefully reviewed; a thorough history and physical examination, chemistry panel and blood count, and 12-lead electrocardiogram (ECG) should be carried out. Elderly patients may find use of a cane with a folded tripod seat or a walker equipped with a seat helpful to reduced OH-related falls.

#### KEY POINTS

- Orthostatic hypotension is an extreme response to the change from supine to upright position, where the activation of the short-term control mechanisms is slow or inadequate in its response. Heart rate and diastolic and systolic blood pressures are more affected by gravitational effects of position change than is normally expected.
- Orthostatic hypotension results in dizziness, blurred vision, confusion, and possible syncope, which may cause injuries secondary to falls. OH is associated with cardiovascular disease and is a risk factor for stroke, cognitive impairment, and death.
- Orthostatic hypotension may be the result of a number of pathologies involving the baroreceptor response, damage to the vasomotor center or the peripheral nervous system, a vasovagal reaction, or cardiac dysrhythmias, or it may be an adverse drug effect. Most often it occurs because of insufficient circulating volume.
- Nonpharmaceutical interventions may be used if the cause cannot be ameliorated.

## SUMMARY

Adequate perfusion of body organs and tissues depends on the maintenance of arterial blood pressure. This is accomplished through the highly orchestrated interaction of multiple systems on both a short-term and a long-term basis.

Blood pressure may be elevated secondary to other pathologic conditions, or to food or drug ingestion. Secondary hypertension is treated by managing the causative factors, although medication also may be necessary. More commonly the etiology is not discernible, although risk factors are identified, and primary hypertension is diagnosed.

Primary hypertension affects millions of Americans and is a public health concern worldwide. Once identified, lifestyle modifications and pharmaceutical interventions are initiated to avoid the significant pathologic outcomes to body organs.

When the mechanism for short-term blood pressure regulation fails to adequately respond to position changes, the resulting orthostatic hypotension can cause syncope and potential injury. If the cause cannot be identified and treated, accommodations can be used to decrease its occurrence and minimize risks.

## KEY QUESTIONS

- How are events of the cardiac cycle reflected in pressure and volume changes within the cardiac chambers?
- What factors affect the blood supply to myocardial tissue?
- How does sarcomere cross-bridge formation lead to muscle cell contraction?
- What is the process of excitation-contraction coupling in heart muscle cells?
- How are action potentials generated and conducted in myocardial and pacemaker cells?
- How does the electrocardiogram relate to impulse conduction through the heart?
- How do heart rate, preload, afterload, and contractility affect cardiac output and cardiac workload?
- What diagnostic tests are used to evaluate cardiac structure and function?

The primary function of the heart is to produce the driving force that propels blood through the vessels of the circulatory system. Along with the lungs, the heart works to distribute oxygenated blood and nutrients to tissues and organs of the body. Complex regulatory mechanisms function to match the cardiac output with the metabolic needs of the tissues. Cardiac dysfunction can lead to abnormal function or death of cells in tissues throughout the body. Cardiovascular disease is the leading cause of mortality in the United States, and a significant proportion of the population suffers from physical limitations associated with impaired cardiac function. Familiarity with cardiac anatomy and physiology is requisite to understanding cardiac diseases and therapy.

## CARDIOVASCULAR ANATOMY

### Heart

The heart is located in the **mediastinum**, suspended between the lungs, behind the sternum, and in front of the vertebral column, thoracic aorta, and esophagus (Figure 17-1).<sup>1</sup> When viewed from the front, the heart appears to be rotated to the left, so that the right atrium and right ventricle are most anterior. The base of the heart protrudes somewhat into the right side of the chest and is relatively fixed in place by its attachments to the great vessels. The apex of the heart lies primarily in the left side of the chest and is directed forward toward the anterior chest wall. With each heartbeat, a characteristic thrust, or point of maximal impulse (PMI), is generated and can be palpated where the apex strikes against the chest. The PMI is normally located on the left side of the chest where the fifth intercostal space and midclavicular line intersect. Variations in heart size and position within the chest may be related to age, body size, shape, weight, or pathologic conditions of the heart and other nearby structures.

Functionally important cardiac tissues include connective tissues, which form the fibrous skeleton and valves; cardiac muscle, which produces the contractile force; and epithelial tissue, which lines the cardiac chambers and covers the outer surfaces of the heart. The fibrous skeleton includes an extensive network of matrix that supports cardiac cells and four rings that provide a firm scaffold for attachment of the cardiac valves. Four cardiac valves control the direction of blood flow through the heart (Figure 17-2). The **mitral valve** (bicuspid) directs blood flow from the left atrium to the left ventricle, whereas the **tricuspid valve** directs blood from the right atrium to the right ventricle. The edges of these atrioventricular (AV) valves are attached to rings formed by the fibrous skeleton. Valve leaflets are tethered to papillary muscles of the ventricular chambers by connective tissues called **chordae tendineae**. **Papillary muscles** attach to ventricular walls and help prevent the valve leaflets from bending backward into the atria during ventricular contraction (Figure 17-3). The AV valves open passively during diastole when the pressure of blood in the atria exceeds that in the ventricles. Ventricular contraction reverses the pressure gradient and causes AV valves to snap shut, preventing blood from flowing backward into the atria.

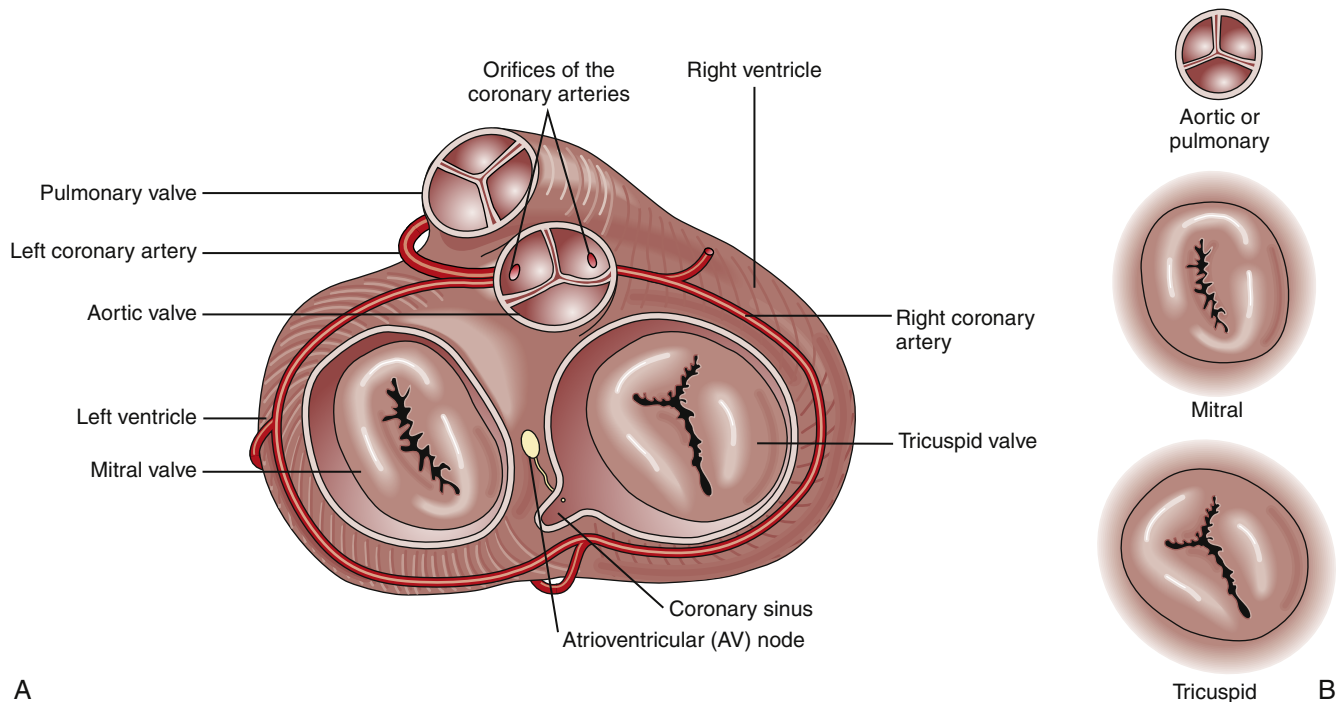

Two semilunar valves are located in the ventricular outflow tracts. The **pulmonic valve** lies between the right ventricle and pulmonary artery, and the **aortic valve** lies between the left ventricle and aorta. Compared to the AV valves, the semilunar valves are thicker and are not supported by fibrous cords. They open and close passively according to pressure gradients, just as the AV valves do. When intraventricular pressures exceed pulmonary and aortic pressures, the semilunar valves remain open and then close when ventricular pressures fall below aortic and pulmonary artery pressures.

The cardiac muscle layer (**myocardium**) produces the contractile force that pushes blood through the circulatory system. Heart muscle

**FIGURE 17-1** Position of the heart in the mediastinum. The base of the heart protrudes into the right side of the chest, whereas the apex lies in the lower left side of the chest.

**FIGURE 17-2** **A**, Position of the heart valves as viewed from above. **B**, Configuration of the heart valves showing the two cusps of the mitral valve and the three cusps of the tricuspid valve. The pulmonary and aortic valves have three leaflets.

**FIGURE 17-3** Chordae tendineae and papillary muscles attach the mitral and tricuspid valve leaflets to the ventricular myocardium.

is organized into four separate chambers of varying muscular wall thickness, reflecting the degree of pressure each chamber must generate to pump blood. Atria serve primarily as conduits and have a thinner layer of muscle than the ventricles. The left ventricular muscle is two to three times thicker than that of the right ventricle because higher pressures are required to eject blood into the systemic circulation than into the pulmonic system. Normal chamber pressures are

**TABLE 17-1** NORMAL PRESSURES IN THE HEART

LOCATION	PRESSURE (mm Hg)*
Right atrium	0-8
Right ventricle	15-28/0-8
Pulmonary artery	15-28/4-12
Left atrium	4-12
Left ventricle	100-120/4-12
Aorta	100-120/60-80

\*Right and left atrial pressures listed as means; other pressures written as systolic/diastolic.

shown in Table 17-1. Alterations in chamber pressures may reflect pathologic cardiovascular changes such as valvular disorders, blood volume abnormalities, and heart failure (see Chapters 18 and 19).

Cardiac chambers and valves are lined by a layer of squamous epithelial cells called the **endocardium**. The endocardial layer provides a smooth surface that prevents clotting and minimizes trauma to red blood cells. The endocardium is continuous with the endothelium of the vascular system. Outer surfaces of the heart are also covered by a layer of epithelial cells called the **epicardium**, which is part of a protective covering called the **pericardium**. The **pericardium** is composed of two layers that envelop the heart like a sac (Figure 17-4). The inner layer (visceral pericardium or epicardium) is attached directly to the heart's outer surface, whereas an outer layer (parietal pericardium) forms a sac around the heart. The parietal pericardium is composed of an epithelial layer and a tough fibrous layer.

Visceral and parietal pericardial layers are separated by a thin, fluid-filled space (pericardial space) that usually contains 10 to 30 ml of serous fluid. This fluid lubricates pericardial surfaces and reduces friction while

**FIGURE 17-4** Pericardial sac is composed of two layers separated by a narrow fluid-filled space. The visceral pericardium (epicardium) is attached directly to the heart's surface, whereas the parietal pericardium forms the outer layer of the sac.

the layers slide against one another during cardiac contraction. Accumulations of fluid in the pericardial space or inflammation of the pericardial sac can restrict cardiac filling and impair cardiac output.

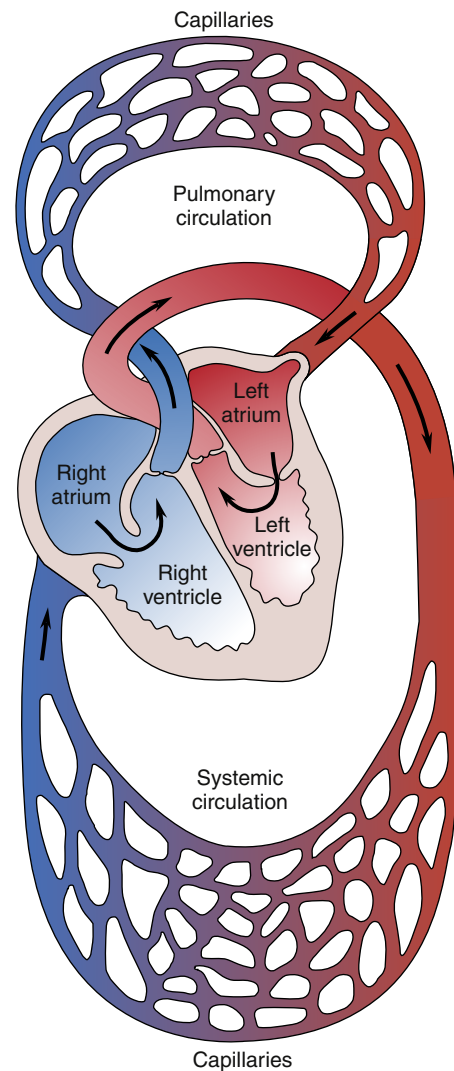

### Circulatory System

The circulatory systems of the lungs and body can be viewed as two separate but interdependent systems (Figure 17-5). The left-sided heart chambers produce the force to propel blood through the vessels of the systemic (body) circulation. The left atrium receives oxygenated blood from the lungs by way of the pulmonary veins and delivers it to the left ventricle. This oxygenated blood is pumped by the left ventricle into the aorta, which supplies the arteries of the systemic circulation. Venous blood is collected from capillary networks of the body and returned to the right atrium by way of the vena cavae. Blood from the head returns to the right atrium through the superior vena cava; blood from the body returns via the inferior vena cava. There are no valves between the vena cavae and the right atrium, and the atrial pressure waves that are generated during the cardiac cycle cause characteristic visible pulsations in the jugular veins. An increased right atrial pressure may be observed as distention within the jugular veins.

The right side of the heart receives deoxygenated blood from the systemic circulation and pumps it through the lungs by way of the pulmonary artery. The pulmonary artery divides into left and right branches, which subdivide to supply blood to pulmonary capillary beds. Exchange of respiratory gases occurs at the pulmonary capillaries so that blood delivered to the left atrium by the pulmonary veins is well oxygenated.

Blood flow through the left and right heart chambers is connected in series such that the output of one becomes the input of the other. Thus, the functions of the right and left sides of the heart are interdependent. Failure of one side of the heart to pump efficiently soon leads to dysfunction of the other side.

Characteristic changes in the anatomy and physiologic functioning of the heart and circulatory systems occur with aging (see Geriatric Considerations: Changes in the Heart). In general, these changes result in a decreased cardiac reserve and a greater predisposition to cardiac muscle ischemia.

**FIGURE 17-5** Systemic and pulmonary circulations viewed as separate but interdependent systems. The right ventricle pumps blood through the pulmonary vasculature, whereas the left ventricle pumps blood through the systemic circulation.

#### KEY POINTS

- Blood flows from the right atrium to the right ventricle through the tricuspid valve. The pulmonic valve lies between the right ventricle and the pulmonary artery. Blood flows from the left atrium to the left ventricle through the mitral valve. The aortic valve lies between the left ventricle and the aorta.
- Heart muscle (myocardium) is lined with endothelium on the inner surface and covered with epicardium on the outer surface.
- The pericardial sac envelops and protects the heart from friction.
- The right-sided heart chambers pump deoxygenated (venous) blood through the lungs. The left-sided heart chambers pump oxygenated blood through the systemic circulation.

### CARDIAC CYCLE

Each heartbeat is composed of a period of ventricular contraction (**systole**) followed by a period of relaxation (**diastole**). The interval from one heartbeat to the next is called a **cardiac cycle** and includes ventricular, atrial, and aortic (or pulmonic) events. Each of these events is associated with characteristic pressure changes within the cardiac chambers.<sup>2</sup>

**FIGURE 17-6** Events of the cardiac cycle showing relationships among left atrial and ventricular pressures, ventricular volume, and aortic pressure. An identical set of events occurs on the right side of the heart, although pressures are lower.

Pressure changes result in valvular opening and closing and unidirectional movement of blood through the heart. The various events of the cardiac cycle are illustrated as a function of time in Figure 17-6. Another method of graphing ventricular function is the pressure-volume loop (Figure 17-7). Pressure-volume loops are useful for assessing the relationships between pressure and volume at various points in the cardiac cycle to evaluate left ventricular function. Abnormalities in these waveforms may occur with diseases of the cardiac valves, changes in blood volume, or changes in pumping capacity of the heart (see Chapter 18). These waveforms are commonly monitored with specialized cardiac catheters in patients with cardiac or hemodynamic disorders.

The cardiac cycle can be described sequentially, beginning with ventricular filling. During diastole the ventricles are relaxed and blood flows in from the atria through open AV valves. Initially, ventricular filling occurs passively because of a pressure gradient between the atria and ventricles. Toward the end of ventricular diastole, the atria contract, squeezing more blood through the AV valves into the ventricles. The “atrial kick” provided by atrial contraction is particularly important during fast heart rates, when the time for ventricular filling is shortened; the atrial contraction helps to load the ventricle quickly to prevent a reduction in stroke volume. Ventricular events include isovolumic contraction, ejection, and isovolumic relaxation. Each of these cycle events is further described in the following sections.

### Isovolumic Contraction

Immediately following atrial systole the ventricles begin to contract, causing intraventricular pressure to rise and the AV valves to close. AV

**FIGURE 17-7** Pressure-volume loop showing changes in left ventricular volume and pressure during the cardiac cycle.

valve closure produces a sound that can be heard at the chest wall and is termed  $S_1$ . Ventricular pressure rises rapidly during isovolumic contraction because all four cardiac valves are closed, and the volume of blood within the ventricular chamber is forcefully compressed by the powerful ventricular myocardium (see Figure 17-6, red tracing). Volume remains constant during this phase. The rate of rise in pressure is

an indication of the contractile state of the heart. The greater the change in pressure per unit time ( $dP/dt$ ), the higher the contractile state. Sympathetic nervous system activation increases  $dP/dt$  whereas conditions such as heart failure are characterized by a slower rate of pressure development. The term *inotropy* is commonly used interchangeably with contractility and is reflected by the velocity and degree of cardiac muscle shortening during systole.

### Ventricular Ejection

Ventricular contraction results in a rapid rise in ventricular pressure. As ventricular pressure exceeds aortic pressure (or pulmonic),

the valve is forced open and a period of rapid ejection of blood from the ventricle follows. The rapid ejection phase is followed by a period of reduced ejection as aortic (or pulmonic) pressure rises and ventricular pressures and volumes fall. The amount of blood ejected with each contraction of the ventricle is called the *stroke volume* (SV). The volume of blood in the ventricle before ejection is the *end-diastolic volume* (EDV) and the amount of blood that remains in the ventricle after ejection is the *end-systolic volume* (ESV). Thus, stroke volume equals EDV minus ESV. An important and commonly used index of pumping effectiveness is the ejection fraction (EF), which is calculated by dividing SV by EDV. A normal EF is

## GERIATRIC CONSIDERATIONS

### Changes in the Heart

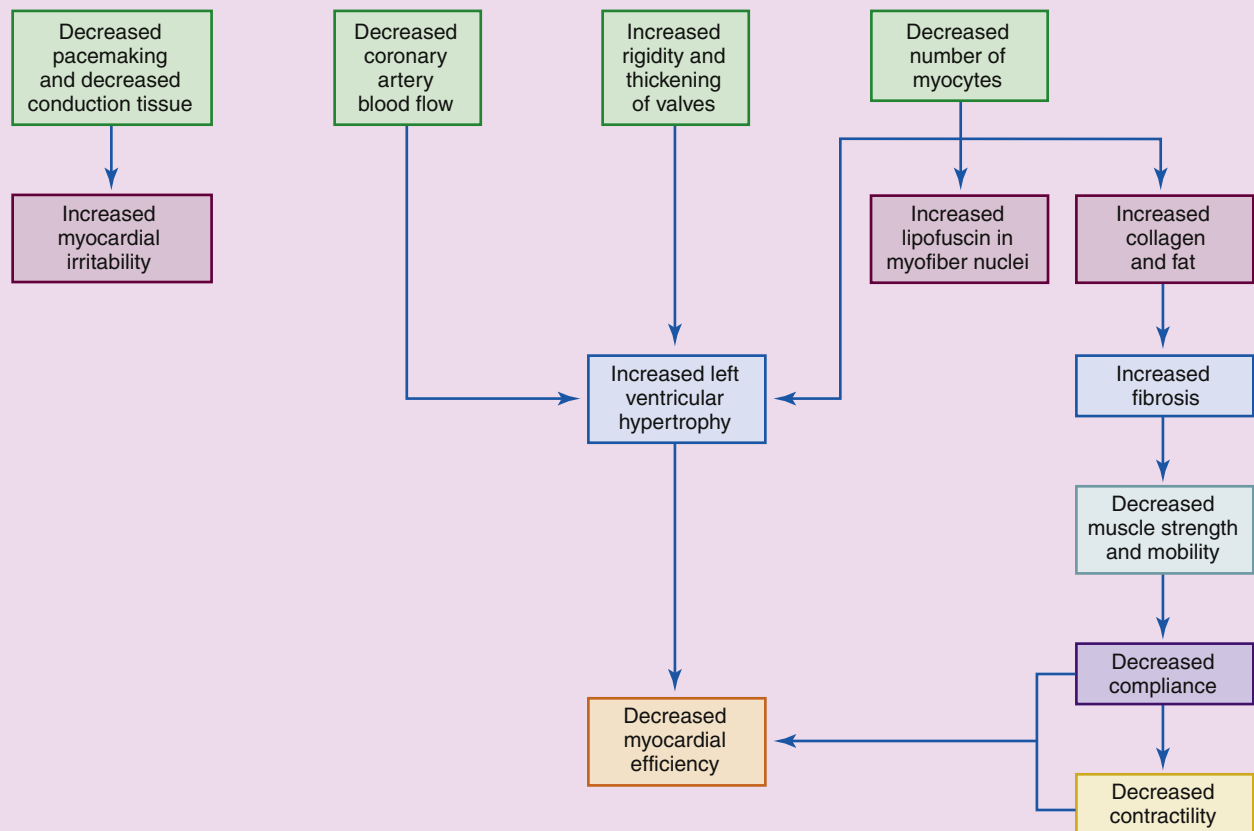

With aging, there is a decrease in the number of myocytes, but normally the heart size does not change appreciably. With the loss of overall cardiac muscle tissue, a corresponding expansion occurs in myocardial collagen and fat. The left ventricular muscle wall becomes thicker, with a resulting increase in oxygen demand. The endocardium becomes fibrotic and sclerosed. Cross-linking of the collagen tissue within the heart muscle increases myocardial stiffening, which causes decreased compliance. The decrease in compliance produces a decline in cardiac contractility, which reduces the heart's pumping ability. The rate of ventricular relaxation decreases.

Fibrotic changes in cardiac valves result from a combination of hemodynamic stress and generalized thickening. There is also a decrease in coronary artery blood flow to the myocardium, which affects myocardial oxygen and nutrient supply. The myocardial cells increase in size, with increased lipofuscin pigment and lipid deposition.

Within the specialized electrical conduction tissue, there is loss of myocytes and fibrosis of conduction pathways, especially in the sinoatrial (SA)

node, AV node, and bundle of His. There is a decreased number of pacemaker cells in the SA node, resulting in less responsiveness of that node to adrenergic stimulation. Myocardial cell irritability increases. On the ECG, the P wave may be notched or slurred. The PR interval is longer, and the QRS amplitude decreases. The axis may shift left as a result of left ventricular muscle thickening (hypertrophy). The T wave may be notched, and the amplitude may decrease.

The changes previously noted affect cardiac function. The resting heart rate in the elderly is unchanged. During stress or exercise, the aging heart is unable to respond quickly with an elevated rate, and the maximal heart rate elevation is reduced. Once the heart rate is elevated, it takes a much longer time for the heart rate to return to the resting level. The cardiac stroke volume and cardiac output generally decrease with age. Oxygen consumption in the myocardium is reduced, resulting in less efficient function when stressed and an overall decreased cardiac reserve.

60% to 80%; patients with systolic heart failure often have an EF of less than 40%.

### Isovolumic Relaxation

The isovolumic relaxation phase begins with semilunar valve closure in response to falling ventricular pressures and ends when the AV valves open to allow ventricular filling. Ventricular blood volume remains constant during this period because all four cardiac valves remain closed. Closure of the semilunar valves causes the second heart sound,  $S_2$ . Opening of the AV valves signals the beginning of rapid ventricular filling and the start of another cardiac cycle. The rate of ventricular relaxation is indicated by the drop in ventricular pressure per unit time and is called the  $-dP/dt$ . The rate and degree of ventricular relaxation is called *lusitropy* and is an energy-requiring process that reflects the efficiency of calcium removal from the cytoplasm. Rapid relaxation is necessary to allow the ventricle to fill quickly and at a low pressure before the next systole. Impaired relaxation (lusitropic dysfunction) is a common finding in patients with heart failure and contributes to the symptoms of congestion (see Chapter 19). Because relaxation of the ventricle is an energy-requiring process, it may become impaired when blood flow and oxygen delivery to the heart are inadequate.

### Atrial Events

Atrial pressure waves have three characteristic curves: *a*, *c*, and *v* (see Figure 17-6, green tracing). The *a* wave corresponds to atrial contraction, which immediately precedes AV valve closure. The *c* wave occurs early in ventricular systole and is thought to represent bulging of AV valves into the atrial chambers. The *v* waves have a gradual incline, which represents filling of the atrium as blood returns from the circulation. The *v* wave drops rapidly as atrial pressure is relieved by AV valve opening. A large *v* wave is often associated with inadequate closure of the AV valve, resulting in regurgitation of ventricular blood back into the atrium during ventricular systole. The mean right atrial pressure, also called the *central venous pressure* (CVP), is commonly measured as an indicator of the blood volume in the heart, which is dependent in part on the amount of blood being returned from the systemic circulation.

### Aortic and Pulmonary Artery Events

Aortic and pulmonary artery pressures rise and fall in relation to the cardiac cycle. Arterial pressures fall to their lowest value just before semilunar valve opening. This lowest pressure is called *diastolic blood pressure*. Arterial pressure reaches its maximum during ventricular ejection and is called *systolic blood pressure*. A characteristic notch (*dicrotic notch*) in the arterial pressure curve may be seen as the semilunar valves close (see Figure 17-6, blue tracing).

The difference in aortic pressure between systole and diastole is partly dependent on the aorta's elastic characteristics. During systole, the aorta stretches to accommodate blood ejected by the ventricle. The stretched aorta has "stored" or potential energy that is released during diastole to maintain driving pressure and to keep blood flowing continuously through the circulation. Aortic stiffening, as occurs with aging or arteriosclerosis, may result in higher systolic and lower diastolic blood pressures attributable to loss of aortic elastic properties.<sup>3</sup> When aortic or pulmonic pressures are chronically elevated, the ventricles must generate more pressure to open the semilunar valves and eject the stroke volume. Over time this extra effort required to increase the pressure can damage the heart muscle and lead to hypertrophy or failure.

### KEY POINTS

- Characteristic pressure wave changes that occur during the cardiac cycle may be useful in diagnosing cardiac disease and volume status.
- The atria have three characteristic waves: *a*, *c*, and *v*. The *a* wave corresponds to atrial contraction, the *c* wave corresponds to the AV valve bulging during ventricular contraction, and the *v* wave corresponds to atrial filling.
- The ventricles have four important phases: isovolumic contraction, ejection, isovolumic relaxation, and diastolic filling. The rate and amplitude of these pressures reflect chamber volume, contractility, and valvular function. Left ventricular pressure/volume relationships are frequently used to diagnose heart failure.
- Pressure changes in the aorta during a cardiac cycle are partly dependent on the elasticity of the aorta. Differences between systolic and diastolic pressures are less with a compliant aorta. Aortic stiffness results in higher systolic and lower diastolic pressures.

## CORONARY CIRCULATION

### Anatomy of the Coronary Vessels

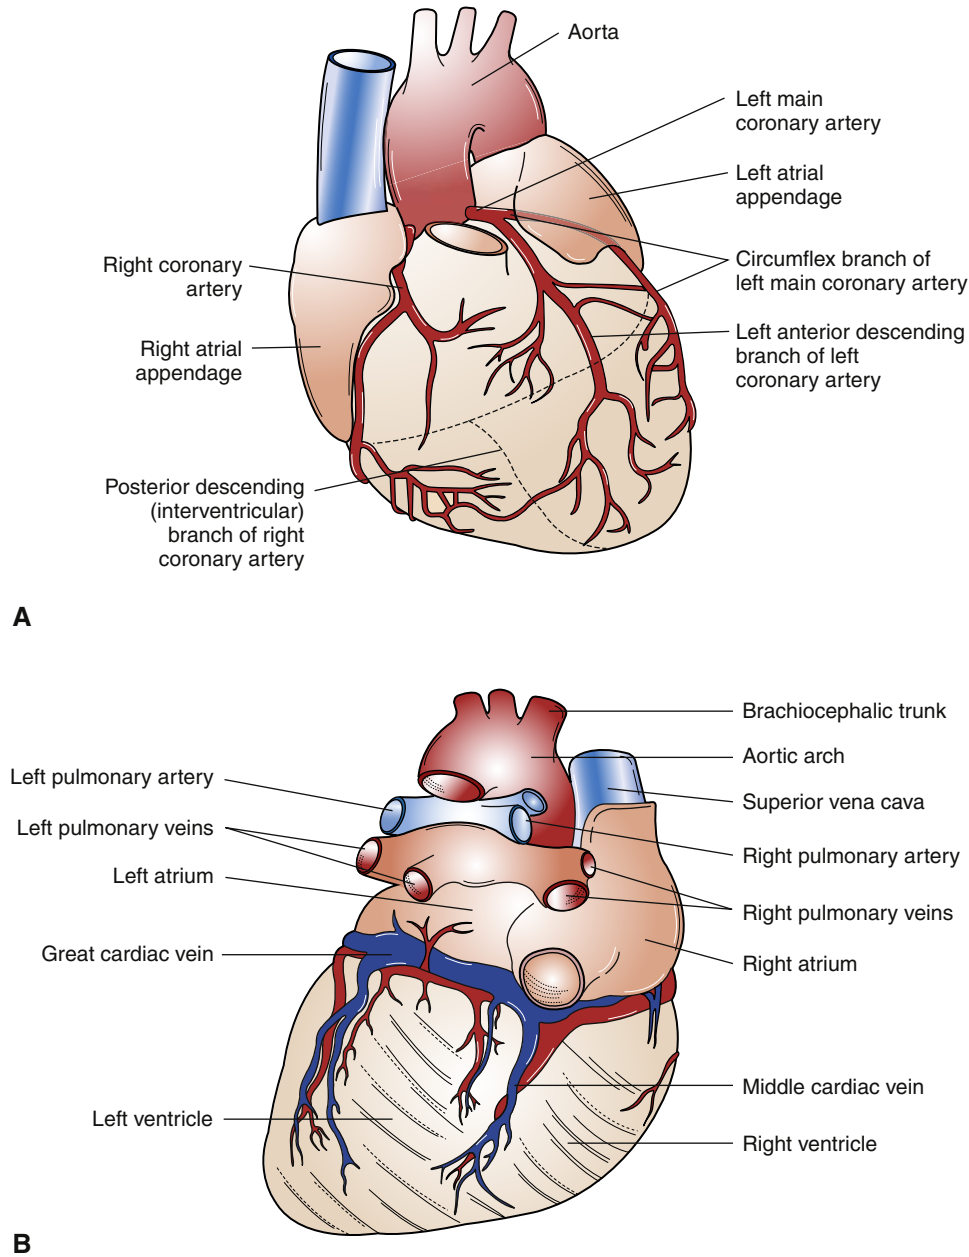

The blood supply to heart muscle is provided by the coronary arteries (Figure 17-8). Right and left coronary artery openings are located in the sinuses of Valsalva, in the aortic root, just beyond the aortic valve.<sup>2</sup> The right coronary artery originates near the aortic valve's anterior cusp and passes diagonally toward the right ventricle in the AV groove. In approximately 50% of the population, the right coronary artery gives rise to a posterior descending vessel that supplies blood to the heart's posterior aspect. In 20% of the population, the left coronary artery is dominant in supplying blood to the ventricles, and in 30% of the population the right and left coronary arteries deliver about the same amount of blood and neither is dominant.<sup>3</sup> The *left main coronary artery* arises near the aortic posterior cusp and travels a short distance anteriorly before dividing into the *left anterior descending* and *circumflex* branches. The anterior descending branch supplies septal, anterior, and apical areas of the left ventricle, whereas the circumflex artery supplies the lateral and posterior left ventricle. The three major coronary arteries give rise to a number of smaller branches that penetrate the myocardium and branch into small arterioles and capillaries. Regular exercise and stable atherosclerotic plaques in the coronary arteries are thought to stimulate the development of more extensive collateral circulation in the heart. Collateral vessels may help limit infarct size in patients suffering acute coronary occlusions (see Chapter 18). Areas supplied by divisions of the coronary arteries are listed in Table 17-2. Most of the heart's capillary beds drain into the coronary veins, which then empty into the right atrium through the coronary sinus (Figure 17-9).

### Regulation of Coronary Blood Flow

Blood flow through coronary vessels is determined by the same physical principles that govern flow through other vessels of the body, namely, driving pressure and vascular resistance to flow.<sup>3</sup> According to Ohm's law, an increase in driving pressure (*P*) increases blood flow (*Q*), whereas an increase in resistance (*R*) reduces blood flow:  $Q = P/R$  (see Chapter 15). Driving pressure through the coronary arteries is determined by aortic blood pressure and right atrial pressure. This relationship can be expressed in the following equation:

$$\text{Coronary driving pressure } (P) = \text{ABP} - \text{RAP}$$

where ABP is aortic blood pressure and RAP is right atrial pressure. Thus, an increase in aortic pressure enhances coronary blood flow, whereas an increase in right atrial pressure opposes coronary flow.

**FIGURE 17-8** Coronary arteries supplying the heart. The right coronary artery supplies the right atrium, ventricle, and posterior aspect of the left ventricle in most individuals. The left coronary artery divides into the left anterior descending and circumflex arteries, which perfuse the left ventricle. **A**, Anterior view. **B**, Posterior view.

Coronary vascular resistance ( $R$ ) has two major determinants: (1) coronary artery diameter and (2) the varying degrees of external compression attributable to myocardial contraction and relaxation. Coronary artery diameter is continuously adjusted to maintain blood flow at a level adequate for myocardial demands. **Autoregulation** is the term used to describe the intrinsic ability of the arteries to adjust blood flow according to tissue needs. Vessel dilation (*vasodilation*) occurs in response to increased tissue metabolism or reduced driving pressure, whereas decreased metabolic activity or increased driving pressure results in a decreased vessel diameter (*vasoconstriction*).

The mechanism of autoregulation can be explained by the metabolic hypothesis, which proposes that increased metabolism, reduced

oxygen concentration, or decreased blood flow results in a buildup of vasodilatory chemicals in the vessel. Smooth muscle encircling the vessel relaxes in response to the presence of the chemicals, increasing vessel diameter. Several vasodilating substances have been proposed, including potassium ions, hydrogen ions, carbon dioxide, nitric oxide, prostaglandins, and adenosine. The endothelial cells that line vessels are known to secrete a variety of relaxing and constricting factors, which may contribute to autoregulation.<sup>4</sup> Vasodilatory substances are washed away as blood flow increases in response to increased vessel diameter. A declining level of vasodilatory chemicals results in vasoconstriction. Thus, vessel diameter is continuously adjusted according to concentrations of vasodilatory chemicals, which are directly related to the tissue's metabolic activity.

**TABLE 17-2 AREAS SUPPLIED BY THE CORONARY ARTERIES**

ARTERY	AREA SUPPLIED
Right coronary	Right atrium (55% of persons) Right ventricle Intraventricular septum Sinus node (55% of persons) Atrioventricular node Bundle of His
Left anterior descending	Right atrium (45% of persons) Right ventricle (minor) Left ventricle (anterior, apex) Anterior papillary muscles Right and left bundle branches
Left circumflex	Intraventricular septum Left atrium Left ventricle (posterior, anterior) Sinus node (45% of persons)

**FIGURE 17-9** Venous drainage of the heart. Coronary veins drain blood from the myocardial capillary bed and deliver it into the right atrium.

One mechanism for autoregulation of coronary blood flow involves an ATP-sensitive potassium channel in vascular smooth muscle.<sup>5</sup> When ATP levels rise in response to increased coronary flow, the channel closes, making it easier to depolarize the cell and contract vascular smooth muscle. Contraction of vascular smooth muscle reduces the diameter of the coronary arteries and reduces blood flow. The opposite also occurs: a reduction in ATP level, due to low flow or increased metabolism, opens the  $K^+$  channels. Potassium then leaks out of the vascular smooth muscle and short-circuits the depolarizing influences. This inhibits vascular contraction, leading to vasodilation and increased coronary blood flow. Adenosine also contributes to regulation of the ATP-sensitive  $K^+$  channels, causing vasodilation when adenosine levels are elevated.

Nitric oxide (NO) produced by endothelial cells lining the coronary arteries is an important regulator of coronary blood flow. NO is a diffusible gas produced by the enzyme inducible nitric oxide synthase in

response to numerous stimuli including hypoxemia and platelet factors. NO is a potent vasodilator, and inhibition of its production is associated with reduced coronary blood flow. Many known risk factors for coronary heart disease have been shown to impair nitric oxide-dependent vasodilation of coronary arteries.<sup>5</sup>

Vessel diameter also is regulated by the autonomic nervous system. The coronary arteries are primarily innervated by sympathetic nerves, but they also receive a small amount of parasympathetic innervation. The sympathetic neurotransmitter norepinephrine (NE) binds to both  $\alpha_1$  and  $\beta_2$  receptors in coronary arteries;  $\alpha_1$  stimulation results in vasoconstriction, whereas  $\beta_2$  stimulation dilates. Under normal conditions the vasodilator response predominates, but in pathologic states, excessive  $\alpha_1$ -mediated constriction can occur. The increased metabolic activity associated with sympathetic nervous system stimulation generally causes autoregulatory vasodilation and overrides the direct effect of norepinephrine on the vessels. Parasympathetic activity contributes to vasodilation by promoting the production of nitric oxide by coronary endothelial cells.

In addition to vessel diameter, coronary resistance is affected by myocardial contraction. During systole, cardiac muscle compression creates a marked rise in coronary resistance that reduces coronary blood flow (perfusion). Blood flow to the left ventricle is greatly decreased during systole because of the pressures generated by the thick muscular layer. Blood vessels that penetrate the myocardium to supply the innermost endocardial areas are more compressed during contraction than are outer epicardial vessels. Even though coronary artery driving pressure is greatest during ventricular systole, little blood flow reaches the left ventricle because of the high external pressure applied to the coronary vessels as the myocardium contracts. Therefore, most myocardial blood flow occurs during the diastolic interval between ventricular contractions. The time the heart spends in diastole is directly related to heart rate. Faster heart rates reduce diastolic time and decrease coronary artery blood flow.

Cardiac muscle needs a continuous supply of oxygen and nutrients to perform its pumping functions. A disruption in cardiac blood flow (*ischemia*) generally results in some degree of pump failure and damage to cardiac tissues. Myocardial ischemia may be caused by conditions that reduce coronary blood flow or increase myocardial demands for oxygen. These include (1) reduced driving pressure (e.g., low aortic blood pressure or high right atrial pressure), (2) reduced vessel diameter (e.g., myocardial hypertrophy, arteriosclerosis, thrombosis, vasoconstricting chemicals), (3) reduced perfusion time (e.g., high heart rates, some dysrhythmias), and (4) increased metabolic demands (e.g., fever, sepsis, anemia).

#### KEY POINTS

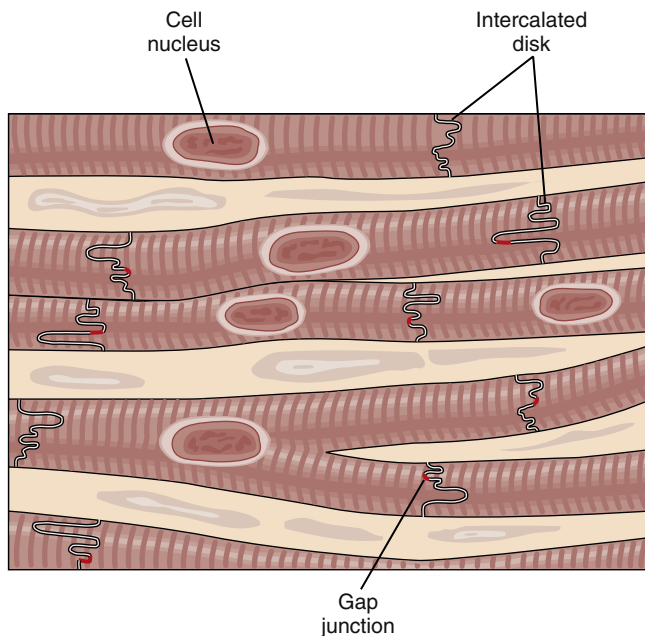

- The right and left coronary arteries originate from the aortic root, within the sinuses of Valsalva. In most people the right coronary artery perfuses the right ventricle, AV node, sinoatrial (SA) node, and right atrium.
- The left coronary artery divides into the left circumflex artery and left anterior descending artery, which perfuse the left atrium and ventricle.
- Coronary blood flow is regulated centrally by the autonomic nervous system and locally by autoregulation. The amount of coronary flow depends on driving pressure and coronary resistance. Coronary resistance is dependent on vessel diameter.
- Adenosine and nitric oxide are two important vasodilating chemicals that are produced in response to inadequate oxygen delivery to the heart and help to increase blood flow to meet metabolic demands.
- Although driving pressure is highest during systole, there is little coronary flow to the left ventricle because of vessel compression by the contracting myocardium. Most coronary blood flow to endocardial areas of the ventricles occurs during diastole.

## CARDIAC MYOCYTES

Cardiac muscle cells are divided into two general types: working cells, which have primarily mechanical pumping functions, and electrical cells, which primarily transmit electrical impulses. Both types are *excitable*: they are able to produce and transmit action potentials. Working myocardial cells are packed with contractile filaments and compose the bulk of the atrial and ventricular muscle. Electrical cells function to initiate and coordinate contraction of the working cells. Differentiated cardiac myocytes are unable to enter the cell cycle to proliferate; however, they can increase in size and synthesize more contractile proteins (hypertrophy). New myocardial cells can be formed from stem cells that have the potential to divide. Stem cells may be recruited from the circulation and stimulated to divide and mature into myocytes within the myocardium. Conditions that increase myocardial cell death are thought to stimulate recruitment of stem cells into the myocardium. A high turnover rate of cardiac myocytes occurs, and increases with age, suggesting that the entire population of cells within the heart is completely replaced 11 to 15 times over a lifetime.<sup>6</sup> When the rate of myocardial cell loss exceeds replacement by stem cells, the condition of heart failure may ensue (see Chapter 19).

### Myocyte Structure

Typical myocardial cells (myocytes) are illustrated in Figure 17-10. Cardiac myocytes are described as muscle “fibers” because of their long, narrow shape. The plasma membrane (sarcolemma) of one cardiac cell is joined end-to-end with its neighbors by intercalated disks, which contain gap junctions that allow the rapid passage of electrical impulses from one cell to the next. The intercalated disks permit the many separate cells of the myocardium to function together in a coordinated

**FIGURE 17-10** Myocardial cells, showing long narrow shape and interconnecting junctions, forming a functional syncytium. The end of one muscle cell is fused to the next by intercalated disks. Within these connections are specialized proteins that form a fluid-filled pore (gap junction) between the fused cells. Ions can travel through the gap junctions to transport changes in membrane potential from one cell to the next.

manner. This arrangement is called a *functional syncytium*. The sarcolemma also forms membrane-lined channels that penetrate the cell and become the transverse tubules (T tubules) (Figure 17-11). The T tubules permit extracellular fluid and ions to diffuse near intracellular structures. Movement of ions across the sarcolemma is an essential part of cellular excitation and the subsequent contraction of intracellular elements. Cellular contractile elements are simultaneously activated because signals at the cell surface are rapidly transmitted internally by the T tubules.<sup>7</sup>

The sarcoplasmic reticulum (SR) is an extensive labyrinth of hollow membrane that stores significant amounts of intracellular calcium. It contains  $\text{Ca}^{2+}$ -sensitive channels that open briefly during depolarization and allow calcium ions to flow into the cytoplasm. An action potential traveling along the T tubule opens voltage-sensitive calcium ion channels (L type) in the plasma membrane. The  $\text{Ca}^{2+}$  ions that enter the cell through these channels interact with receptors on the SR membrane called *ryanodine receptors* (see Figure 17-11, B). Activation of these receptors opens calcium gates on the SR, and  $\text{Ca}^{2+}$  rushes into the cytoplasm to initiate contraction. The SR also contains powerful sarcoplasmic endoplasmic reticulum calcium ATPase (SERCA) pumps that recover calcium ions from the cytoplasm and return them to the SR. Inside the SR, calcium is bound to specialized proteins including calsequestrin. This helps keep the free calcium concentration in the SR lower such that the calcium transporters have a lower gradient to pump against.

Cardiac muscle cells are packed with numerous mitochondria that are strategically positioned along the contractile fibers of the cell. The heart is also endowed with an extensive capillary network, approximately one capillary per muscle cell. The large number of mitochondria and abundant oxygen supply are necessary to keep pace with the high ATP requirements of the contractile elements and ion pumps.

### Structure of the Contractile Apparatus

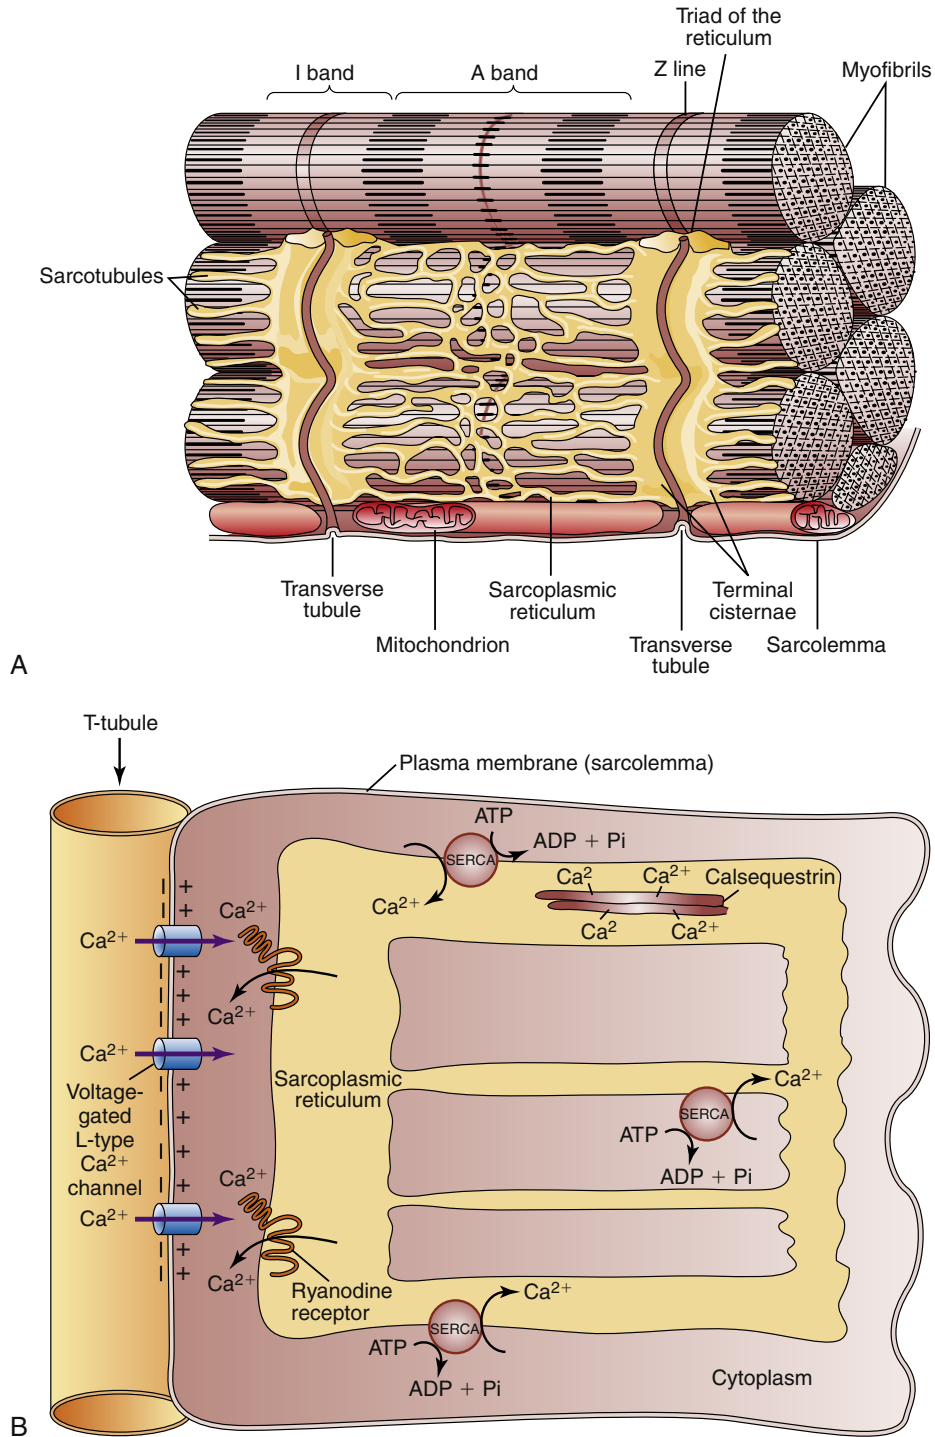

Microscopic inspection of the cardiac myocyte reveals a typical pattern of banding called *striation*.<sup>8</sup> This striated appearance is due to an organized structure of the proteins (myofibrils) of the contractile apparatus (Figure 17-12). The contractile proteins, actin and myosin, are called *filaments* because they are long and narrow. **Myosin** filaments are larger and referred to as *thick filaments*. *Thin filaments* are actually composed of several different types of protein bundled together. **Actin** is the primary constituent of thin filaments, with smaller amounts of the proteins **tropomyosin** and **troponin** bound to it.

The thick and thin filaments are specifically arranged in contractile units called *sarcomeres* (Figure 17-13). Sarcomeres are defined by dark bands called *Z disks* (also called Z lines), which lie perpendicular to actin and myosin filaments. A sarcomere extends from one Z disk to the next. Thin actin filaments are attached to Z disks and extend from them. The I bands (isotropic) are light in color and correspond to the position of thin actin filaments extending in both directions from the Z disk. Thick myosin filaments lie parallel to and between the thin filaments. They are held in place by a very large and elastic protein called *titin* that extends from the Z disk to the center of the sarcomere. Each myosin filament is surrounded by six thin filaments (see Figure 17-13). An efficient, synchronized contraction is enhanced by this precise arrangement of contractile elements.

### Characteristics of Contractile Filaments

Myosin molecules are composed of six polypeptide chains: two heavy (H) chains and four light (L) chains. These light and heavy

**FIGURE 17-11** **A**, Schematic diagram of a portion of a cardiac myocyte showing the transverse tubules (T tubules), which extend at right angles from the plasma membrane (sarcolemma) into the cell interior. The T tubules are extensions of the plasma membrane that bring the extracellular fluid into juxtaposition with the terminal ends of the sarcoplasmic reticulum (SR). The T tubule with the SR on either side of it is called the *triad of the reticulum*. **B**, Calcium ions that enter the cytoplasm through voltage-gated L-type channels on the T-tubule membrane interact with the ryanodine receptors on the sarcoplasmic reticulum. The activated ryanodine receptors allow calcium ions to flow into the cell cytoplasm where they initiate contraction. As soon as they are released, calcium ions are rapidly captured by the sarcoplasmic endoplasmic reticulum calcium ATPase (*SERCA*) pumps on the SR membrane.

**FIGURE 17-12** Electron micrograph of muscle fibrils showing characteristic banding pattern. The dark vertical lines are the Z disks. A sarcomere extends from one Z disk to the next. Compare with the schematic drawing in Figure 17-13. (From Fawcett DW: *The cell*, Philadelphia, 1981, Saunders.)

chains are organized into a tail region and two globular “head” areas (Figure 17-14). The myosin heads interact with actin filaments to produce muscle contraction. Thick filaments consist of many myosin molecules with tail regions bundled together and heads protruding at intervals along the bundle. The head regions are flexible and can bend and pull on actin filaments to accomplish muscle contraction. Myosin heads are oriented in opposite directions on either side of the center tail region (see Figure 17-14). Myosin heads have enzymatic properties and can cleave ATP to release energy necessary for muscle contraction. Different forms of myosin have varying rates of ATP hydrolysis, which affects how quickly the muscle contracts. The serum level of thyroid hormone is known to affect the type of myosin produced in heart cells. Hyperthyroidism is associated with a fast-cycling type and hypothyroidism with a slow type of myosin. The rate of myosin cycling can also be regulated at the light chain of the myosin protein. Cellular enzymes that attach a phosphate to the light chain accelerate the rate of cycling. Phosphorylation is increased by activation of myocardial  $\beta_1$  receptors and enhances contractility.<sup>8</sup>

Thin filaments are composed of several different proteins, including actin, nebulin, tropomyosin, and troponin. Actin filaments

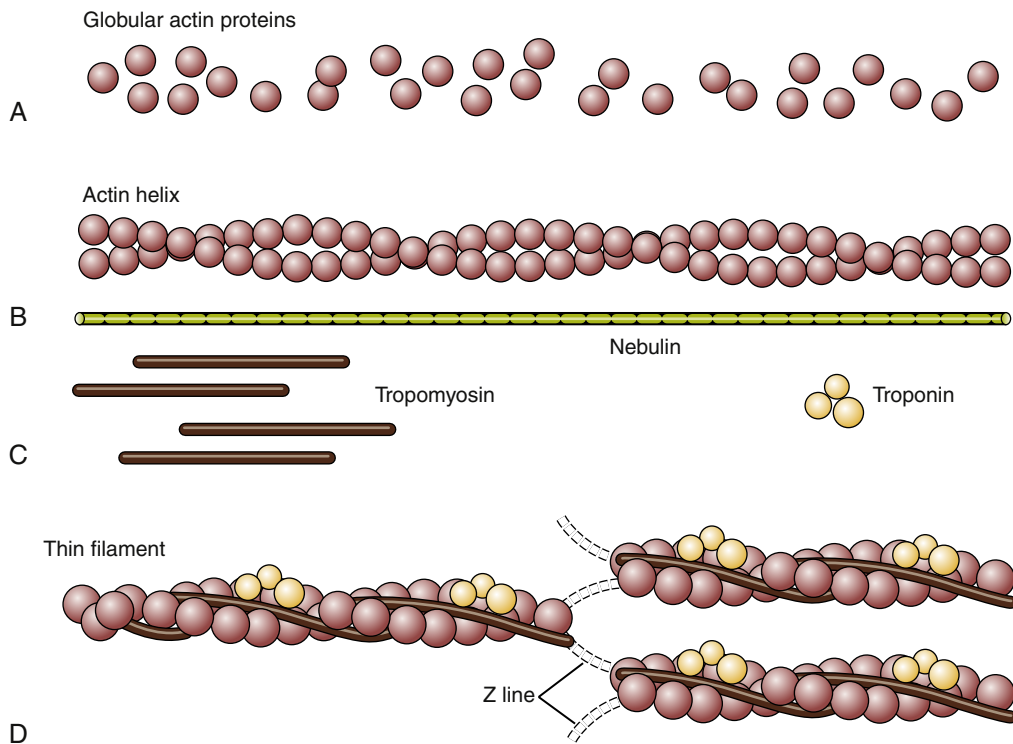

**FIGURE 17-13** Thick and thin filaments are organized into contractile units called *sarcomeres*. A sarcomere extends from one Z disk to the next and represents the fundamental unit of muscle contraction. See text for description of bands, zones, and lines. Overlap of thick and thin filaments in each area is shown in cross-section at the bottom. Each thick filament interacts with six thin filaments that surround it.

are actually polymers of many globular actin proteins that are attached end-to-end, like two strings of beads, and then twisted together to form a helix (Figure 17-15). Each of the actin beads has a site that can bind with myosin heads. Nebulin is a long protein that extends the entire length of the thin filament and is thought to regulate the length of the actin polymer such that all of the thin filaments are the same size. Tropomyosins are long, slender proteins that bind to a string of six or seven actin beads.<sup>9</sup> When myocardial muscle is relaxed, tropomyosin molecules inhibit the myosin-binding sites on the actin beads. A third protein complex, troponin, is attached to the thin filament and regulates the availability of

binding sites on the actin filament by controlling the position of tropomyosin. Each troponin is composed of three subunits, called troponins T, I, and C. Troponin T binds to tropomyosin, troponin I participates in the inhibitory actions of tropomyosin, and troponin C binds up to four molecules of  $\text{Ca}^{2+}$ . As described in the following section, tropomyosin and troponin are important regulatory proteins that control the activities of actin and myosin filaments. The specific isoforms (amino acid sequences) of troponins T and I present in heart tissue differ from those in other types of cells, and their presence in the serum can be used to detect myocardial infarction (see Chapter 18).

**FIGURE 17-14** Thick filament of the sarcomere is composed of myosin proteins. Myosin head groups are oriented in opposite directions on either side of the center tail region. Phosphorylation (*P*) of the regulatory light chain increases myosin activity and rate of cross-bridge cycling.

**FIGURE 17-15** Schematic drawing of the proteins that comprise the thin filament. **A**, Globular actin proteins combine to form long double-helix filaments. **B**, Nebulin (nebulin) is a long cytoskeletal protein that extends the length of the thin filament and is thought to regulate filament length. **C** and **D**, The proteins troponin and tropomyosin combine with the actin helix to form the thin filament.

**KEY POINTS**

- The myocardial cells of the heart behave as a syncytium because they are joined by gap junctions within the intercalated disks that permit the flow of ions from one cell to the next.
- Myocytes are packed with actin and myosin proteins that form the contractile apparatus. The thick filaments are composed of myosin proteins. Myosin has enzymatic activity and splits ATP, releasing energy needed for movement of the filaments. Titin is a flexible protein that attaches the thick filament to the Z disk.
- The thin filament is composed of actin and two regulatory proteins, troponin and tropomyosin. At rest, tropomyosin inhibits myosin-binding sites on actin. The position of tropomyosin is regulated by the calcium-binding protein troponin. Nebulette is another actin-associated protein that helps regulate thin filament length.

**MOLECULAR BASIS OF CONTRACTION****Overview of Contraction**

The heart's pumping action is accomplished by the additive contractions of the many myocytes that form the cardiac chambers. Because each myocyte contributes only a small amount to overall muscle shortening, all cells of the chamber must shorten simultaneously to produce a forceful contraction. The specialized cells of the conduction system function to stimulate myocardial contraction in a coordinated way. An action potential traveling down the conduction system is the usual trigger for contraction. Cardiac myocyte depolarization causes ion channels in the plasma membrane and T tubules to open, permitting sodium and calcium entry and release of calcium from the SR. The presence of free calcium in the sarcoplasm (muscle cytoplasm) results in contraction. These events describe the process of *excitation-contraction coupling*.

**Sliding Filament/Cross-Bridge Theory of Muscle Contraction**

The sliding filament, or cross-bridge, theory of muscle contraction is suggested by the anatomic configuration of the sarcomere described earlier. Muscle shortening is accomplished by increasing the amount of overlap of actin and myosin filaments. The Z disks at the ends of the sarcomere move closer together as overlapping actin and myosin filaments pull past one another. Myosin heads grip binding sites on the actin beads and pull the thin filaments toward the sarcomere's center. Each time a myosin head binds an actin bead, it forms a so-called **cross-bridge**. Flexible myosin heads move in a ratchet-like manner to tug on the actin filaments (Figure 17-16). Each ratcheting motion moves actin filaments only minutely, and many sequential cross-bridge formations are required to shorten the entire sarcomere. Thus, myosin heads bend back and forth, binding and pulling on the actin filaments in a steplike fashion. Actin filaments are prevented from slipping back to their original position because some myosin-actin bonds are forming while others are disengaging. The making and the subsequent breaking of each actin-myosin cross-bridge requires one molecule of ATP. Consequently, tremendous quantities of ATP are hydrolyzed with each cardiac contraction.

ATP hydrolysis, which occurs at the myosin head region, provides the energy for contraction and also affects the capability of myosin to bind actin.<sup>7</sup> Myosin has two functional states or conformations: (1) a low-affinity state in which it binds weakly and (2) a high-affinity state in which it avidly binds actin. The affinity of the myosin head for actin depends on whether ATP is bound (low affinity) or ADP and inorganic phosphate ( $P_i$ ) are bound (high affinity). A proposed sequence of cross-bridge cycling is as follows (see Figure 17-16):

1. Free myosin heads bind ATP and hydrolyze it to ADP and  $P_i$ , which remain on the myosin. Myosin heads now have a high affinity for actin and are in a high-energy conformation.
2. If binding sites on actin are accessible, myosin binds to the actin.
3. Binding results in release of ADP and  $P_i$  and a ratchet movement of the myosin as it assumes its low-energy conformation, which shortens the sarcomere (power stroke).
4. With loss of ADP and  $P_i$ , myosin can bind another molecule of ATP. The myosin heads with ATP bound now have a low affinity for actin and are released from the binding site. ATP is again hydrolyzed to ADP and  $P_i$ , and another cross-bridge cycle is initiated.

Continued cross-bridge cycling is dependent on the availability of ATP and calcium ions. A lack of ATP results in fewer cross-bridge cycles and inability of the muscle to shorten normally.

**Role of Calcium in Muscle Contraction**

Muscle contraction is dependent on the presence of an adequate amount of calcium ions in the cytoplasm. In the absence of free intracellular calcium, muscle contraction will not take place, even though myosin head groups have high affinity for actin-binding sites. This phenomenon can be explained in the following way. At rest, myosin heads are prevented from binding to actin by tropomyosin proteins, which inhibit actin-binding sites. The position of tropomyosin protein is controlled by troponin. When calcium is absent, troponin induces tropomyosin to inhibit the actin-binding sites. When calcium binds to troponin C, the troponin complex induces tropomyosin to move and expose the binding sites (see Figure 17-16, A and B). Cross-bridge formation immediately ensues because myosin heads have high affinity for these sites in the relaxed state. The concentration of free calcium ions in the myocardial cell determines how many actin sites are exposed and for how long, and therefore, determines the number of cross-bridges and extent of contraction. The release of  $Ca^{2+}$  into the cytoplasm is regulated by numerous neurotransmitters and hormones that affect contractility as described in later sections of this chapter.

**Energy of Muscle Relaxation**

Although muscle relaxation is generally viewed as a passive phenomenon, it actually requires significant energy to pump calcium ions out of the cytoplasm. As calcium levels fall, calcium diffuses away from the troponin molecules and tropomyosin is induced to cover the actin-binding sites. With actin-binding sites covered, myosin heads are unable to initiate cross-bridge formation, and thick and thin filaments slide back to their resting positions. Removal of calcium ions is an energy-requiring process. Membrane pumps located in the sarcolemma and SR actively move calcium out of the sarcoplasm against a concentration gradient (Figure 17-17). The sarcolemma contains two different calcium pumps: one that requires ATP and one that uses the potential energy of the sodium gradient to remove calcium from the cell ( $3 Na^+$  for  $1 Ca^{2+}$ ). Calcium pumps on the SR (SERCAs) require ATP. Thus energy deficiency attributable to myocardial ischemia can impair diastolic relaxation as well as systolic contraction of the heart muscle.

**KEY POINTS**

- Cardiac myocytes are terminally differentiated cells, incapable of proliferation. New myocytes are formed from stem cells that are recruited from the circulation.
- Contraction of cardiac muscle is accomplished by shortening of individual sarcomeres. This is due to increased overlap of actin and myosin filaments. Myosin heads bind to specific sites on actin and pull the thin filaments toward the center of the sarcomere.

**FIGURE 17-16** Cross-bridge cycle of muscle contraction. **A**, The myosin head has hydrolyzed its bound adenosine triphosphate (ATP) to adenosine diphosphate (ADP) and inorganic phosphate ( $P_i$ ), which remain on the myosin. In this state the myosin has high affinity for actin but cannot bind because the actin-binding sites are not accessible. **B**, When calcium ions enter the cell and bind to troponin, the tropomyosin-blocking protein moves to allow myosin to bind actin, forming a cross-bridge. **C**, The act of binding changes the shape of myosin so that ADP and  $P_i$  are released. The "power stroke" is accomplished by movement of the myosin neck region. **D**, When a new molecule of ATP binds to the myosin, it changes to a low-affinity state and releases from the actin. ATP is again hydrolyzed to ADP and  $P_i$  to restart the cycle. Each cross-bridge cycle uses one ATP molecule.

- ATP hydrolysis provides the energy for cross-bridging and also affects the affinity of myosin for actin. Myosin has high affinity for actin when ADP and  $P_i$  are bound, and low affinity when ATP is bound. Myosin cycles between high- and low-affinity states, making and breaking cross-bridges with the actin filament.
- The presence of intracellular free calcium ion ( $Ca^{2+}$ ) is necessary for muscle contraction to occur. When  $Ca^{2+}$  is absent, actin-binding sites are inhibited and inaccessible for cross-bridging. Binding of  $Ca^{2+}$  to troponin induces the movement of tropomyosin to expose actin-binding sites and allow cross-bridge formation.
- Muscle relaxation (lusitropy) is due to removal of  $Ca^{2+}$  from the cytoplasm. This is an energy-requiring process.

## CARDIAC ENERGY METABOLISM

The heart, like other tissues in the body, utilizes energy from ATP hydrolysis to drive its energy-requiring functions. Synthesis of ATP in cardiac muscle cells is accomplished by the same glycolytic and oxidative reactions described in detail in Chapter 3.

### Oxygen Utilization

Because the heart is continuously active, its energy requirements are considerable. Very little ATP is stored in myocardial cells, so that a continuous supply of oxygen and nutrients is necessary to support ongoing ATP synthesis. Even under normal resting conditions, the heart extracts a large portion of oxygen from the blood perfusing it.

**FIGURE 17-17** Calcium ions ( $Ca^{2+}$ ) are removed from the cardiac muscle cell cytoplasm by energy-dependent protein transporters in the plasma membrane and sarcoplasmic reticulum (SR) membrane. Thus cardiac relaxation is an energy-requiring process. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate;  $P_i$ , inorganic phosphate.

Conditions of increased oxygen demand, therefore, must be met by increasing the rate of coronary blood flow. When oxygen delivery is insufficient to meet requirements for oxidative phosphorylation, the cell must rely on ATP produced by glycolysis. Unfortunately, glycolysis results in production of only enough ATP to maintain the cell for seconds to minutes. In addition, anaerobic glycolysis results in local buildup of lactic acid, which may further impair cardiac performance.

Under conditions of relative ATP excess, myocardial cells are able to transfer energy to a storage form called *creatine phosphate* (CP). This transfer is accomplished by the enzyme **creatine kinase** (CK or CPK), in the following reaction:

Although amounts of cellular CP are limited, they provide an immediate source of energy when cellular ATP levels drop acutely. Under conditions of ischemia, the enzymatic reaction would proceed in reverse, utilizing CP and adenosine diphosphate (ADP) to produce ATP, for immediate use by the cell. This phosphate transfer reaction is important during fluctuations in ATP supply because it does not require the presence of oxygen.

The enzyme CK is also useful in the diagnosis of myocardial cell damage. Myocardial cells that lose membrane integrity (necrosis) leak their enzymes into extracellular fluid and eventually into the bloodstream. Elevated levels of blood CK are indicative of the degree of acute myocardial cell death. Different types of tissue contain different forms of CK (isoenzymes). The MB form of CK is found in cardiac muscle, and elevated serum levels of this enzyme are indicative of myocardial infarction.<sup>9</sup> Other intracellular proteins, including troponin and myoglobin, are released during myocardial cell death and also can be used as markers of myocardial infarction (see Chapter 18).

### Substrate Utilization

The primary foodstuffs that provide fuel for energy-producing enzymatic processes in cardiac muscle are glucose and fatty acids.<sup>7</sup> Amino acids are less important metabolic substrates for cardiac muscle except during states of starvation. The amount of fatty acids and glucose utilized by heart muscle cells depends on their relative concentrations in the blood. Fatty acids are the preferred fuel, particularly in a fasting

state, when glucose levels are lower. Under fasting conditions, fatty acids account for approximately 85% of myocardial fuel and glucose contributes only 15%. After eating, when blood glucose levels rise, glucose utilization may increase to about 50%. Fatty acid metabolism requires oxygen and is therefore not useful under conditions of ischemia. The heart is also able to use lactate and ketones as sources of energy when they accumulate in the circulation. Lactate is derived from pyruvate under conditions of anaerobic metabolism, whereas ketones are formed from lipid metabolism when carbohydrate supplies are low. Thus, the heart is equipped to use a variety of substrates to produce ATP under varying metabolic conditions.

### KEY POINTS

- CP is an immediately available storage form of energy. Under conditions of low ATP availability, CP is converted to ATP by the enzyme CK.
- The primary energy substrates for the heart are fatty acids and glucose, but the heart can utilize a variety of sources to produce energy depending on the nutrients available in the circulation.

## CARDIAC ELECTROPHYSIOLOGY

The plasma membranes of cardiac cells are endowed with special ion channels that make the cells excitable. Excitable tissues are capable of generating and conducting action potentials. The heart is rhythmically activated by action potentials, which are generated and transmitted by a specialized conduction system. Spread of an action potential over cardiac muscle cell surfaces results in myocardial contraction. An understanding of the electrophysiologic properties of the heart is important because many cardiac disorders result in disturbances in electrical function that produce abnormal conduction pathways, dysrhythmias, and conduction blocks.

### Cardiac Resting Potential

Like other cells, resting cardiac cells are negatively charged on the inside with respect to the outside (see Chapter 3). A difference in potassium ion concentration across the cell membrane is the primary determinant of the resting membrane potential. Atrial and ventricular muscle cells generally have a resting membrane potential of  $-85$  to  $-95$  mV. Pacemaker cells in the SA node are less polarized, having a resting membrane potential of about  $-60$  mV. An increase in the concentration of extracellular potassium ion tends to hypopolarize the cell (make it less negative), and a lower-than-normal extracellular potassium concentration tends to hyperpolarize the cell (make it more negative). The degree of polarization is an important determinant of the ease with which an action potential can be initiated. Abnormalities in serum potassium level are a common source of cardiac dysrhythmias.

### Cardiac Action Potential

Depolarization of cardiac cells to a threshold point results in activation of voltage-sensitive ion channels in the membrane. A myocardial action potential (Figure 17-18) results from movement of ions through these open voltage-gated channels. The action potential in atrial and ventricular cells has five characteristic phases.<sup>10</sup> Atrial action potentials are shorter in duration because they have a reduced phase 2 compared with ventricular cells.

**Phase 0.** Phase 0 begins when the membrane potential approaches threshold and voltage-gated “fast” sodium channels open momentarily. As a result of a steep electrochemical gradient for sodium entry, rapid influx of sodium ions occurs. Sodium entry depolarizes the cell by neutralizing the difference in charge (polarity) across the membrane. A steep depolarizing deflection (upstroke) is recorded. Class I

**FIGURE 17-18** Ventricular myocardial action potential has five characteristic phases, representing changes in ion movement through the plasma membrane. *Phase 0*: Rapid upstroke attributable to sodium influx. *Phase 1*: Slight repolarization attributable to closure of sodium channels and initiation of potassium efflux. *Phase 2*: Plateau attributable to offsetting influx of calcium and efflux of potassium. *Phase 3*: Rapid repolarization attributable to closure of calcium channels and increased potassium efflux. *Phase 4*: Resting membrane potential reestablished attributable to closure of all voltage-sensitive channels.

antidysrhythmic agents such as quinidine and lidocaine block voltage-gated sodium channels and interfere with phase 0 depolarization (see Chapter 19).<sup>11</sup>

**Phase 1.** Phase 1 is identified as a small repolarizing deflection that corresponds to closure of the fast sodium channels and transient efflux of potassium from the cell through  $K^+$  channels. The interior of the cell is now more positively charged than at rest, which induces potassium ions to leave the cell.

**Phase 2.** Phase 2 is also called the *plateau phase* because little change in membrane potential occurs during this time, even though ions continue to move across the membrane. Phase 2 is primarily associated with an influx of calcium ions, which is offset by an efflux of potassium ions. The ability of  $K^+$  to leave the cell down its electrochemical gradient is inhibited during the plateau phase by a relative inhibition of a subset of potassium channels. This is sometimes called *potassium rectification*. Chloride also may leave the cell during this phase. The voltage-gated calcium channels open and close slowly in comparison to fast sodium channels and are thus referred to as slow channels or L-type channels (long-lasting).

The calcium that enters the cell during phase 2 is linked to muscle contraction as previously described. The L-type calcium channels can be modified by agonists that prolong the open phase, such as catecholamines, and by antagonists that shorten the open phase, such as acetylcholine. Calcium channel–blocking agents (class IV antidysrhythmic agents) are used commonly in patients with cardiovascular diseases to inhibit calcium influx.<sup>11</sup>  $\beta$ -Blockers (class II antidysrhythmics) also reduce calcium ion influx during phase 2 by indirectly inhibiting calcium channels.

**Phase 3.** Phase 3 is characterized by a rapid return to the resting membrane potential. This is accomplished by closure of the slow

calcium channels and continued and even more rapid efflux of potassium ions from the cell through a variety of potassium channels. Sodium channels remain absolutely refractory during phases 1, 2, and early 3. The latter part of phase 3 represents a *relative refractory period*, when sodium channels may be induced to open, but a larger than normal depolarizing stimulus is required. If an abnormally early (premature) depolarization occurs during the relative refractory period, it will be conducted more slowly than usual because few fast  $Na^+$  channels are ready to be activated. Slow conduction through the myocardium predisposes to cardiac dysrhythmias, such as ventricular fibrillation (see Chapter 19). Class III antidysrhythmic agents, such as amiodarone, increase the refractory period by inhibiting opening of potassium channels during phase 3.<sup>11</sup>

**Phase 4.** Phase 4 of the ventricular myocyte action potential corresponds to the period of time between action potentials when no changes in membrane voltage are evident and the resting membrane potential is present. The resting membrane potential in ventricular myocardial cells is flat, and they do not spontaneously depolarize. In contrast, cells in the pacemaker and conduction system automatically depolarize and have a sloping phase 4. The  $Na^+$ - $K^+$  pump and  $Ca^{2+}$  pump work continuously throughout all phases to reestablish the internal and external concentrations of sodium, potassium, and calcium ions.

### Rhythmicity of Myocardial Cells

**Rhythmicity** and automaticity refer to regular, spontaneous generation of action potentials. Rhythmic pacemaker cells have a recognizable action potential that is characterized by a sloping phase 4 (Figure 17-19), in contrast to the flat phase 4 of ventricular muscle cells. A requirement for rhythmicity is that the cell membrane has channels that automatically open during phase 4. These channels begin to open as the membrane potential becomes more negative during the repolarization phase.<sup>10</sup> Progressive channel opening makes the pacemaker cells leaky to  $Na^+$ ,  $Ca^{2+}$ , and  $K^+$ . Gradually the flow of positive ions into a cell offsets the repolarizing currents and depolarizes the membrane, resulting in generation of an action potential. One contributor to the automatic depolarization during phase 4 is the  $I_f$  channel. The  $I_f$  channels originally were named for a “funny” current and later discovered to be sodium channels that are activated by membrane repolarization. Channels that allow calcium and potassium leakage are also operative during phase 4 in pacemaker cells. Late in phase 4, an increase in calcium ion influx occurs through voltage-gated calcium channels called *T type*, for “transient.” These channels open and close more quickly than the L-type calcium channels that open during the action potential. Spontaneous release of  $Ca^{2+}$  from the sarcoplasmic reticulum also contributes to depolarization by activating the  $3Na^+/Ca^{2+}$  exchanger and promoting  $Na^+$  influx.<sup>10</sup> Many of these channels can be regulated by various means, including autonomic neurotransmitters, in order to change heart rate. An action potential is initiated when phase 4 depolarization reaches the threshold for opening of voltage-gated, L-type, slow calcium channels. Repolarization is achieved in large part by an exodus of potassium ions from the cell.

The rate of rhythmic discharge is determined by the relative influx of  $Na^+$  and  $Ca^{2+}$  versus the efflux of  $K^+$ . In a normal heart, a cell with the fastest rate of spontaneous depolarization becomes the pacemaker for the rest of the heart. Cells in the SA node, located in the right atrium, generally function as the heart’s pacemaker because they have the fastest rate of spontaneous depolarization. However, other cells in the conduction system are also capable of spontaneous depolarization and may initiate an action potential in certain circumstances.

**FIGURE 17-19** Rhythmic cells **(A)** have a sloping phase 4, in contrast to the flat phase 4 of the atrial **(B)** and ventricular **(C)** muscle cells. Spontaneous depolarization during phase 4 allows pacemaker cells to develop action potentials automatically. SA, Sinoatrial. (Adapted from Hoffman BF, Cranefield PF: *Electrophysiology of the heart*, New York, 1960, McGraw-Hill.)

The steepness of the slope of phase 4 depolarization determines the rate of action potential generation and therefore heart rate. Several factors determine the steepness of the slope, including membrane permeability to sodium, calcium, and potassium. For example, an increase in potassium ions leaving the cell would slow depolarization and result in a slower rate. Rhythmicity may be influenced by the autonomic nervous system, drugs, and electrolyte balance. These conditions are discussed in the following sections.

### Specialized Conduction System of the Heart

Some myocardial cells are specialized to conduct action potentials throughout the heart in an organized and rapid manner. These cells constitute the conduction system of the heart, as shown in Figure 17-20. Normal excitation of the heart follows a pathway beginning with the SA node, atrial internodal pathways, AV node, bundle of His, ventricular bundle branches, and, finally, Purkinje fibers.

The SA node is located in the right atrium near the superior vena cava inlet. It receives innervation from sympathetic and

parasympathetic branches of the autonomic nervous system. The SA node generally serves as a pacemaker for the heart, generating about 70 (range, 60 to 100) action potentials per minute in a resting adult. SA action potentials are spread contiguously through gap junctions to adjacent atrial cells at a rate of about 1.0 m/sec.<sup>10</sup> A fibrous skeleton separates atria from ventricles and prevents spread of impulses from atrial cells to ventricular cells. There are several small bundles of atrial muscle cells that conduct impulses slightly faster than the usual atrial cell. One such bundle, the anterior interatrial band (Bachmann bundle), conducts impulses from the SA node to the left atrium. Atrial depolarization results in atrial contraction, which increases the volume of blood delivered to the still relaxed ventricular chambers.

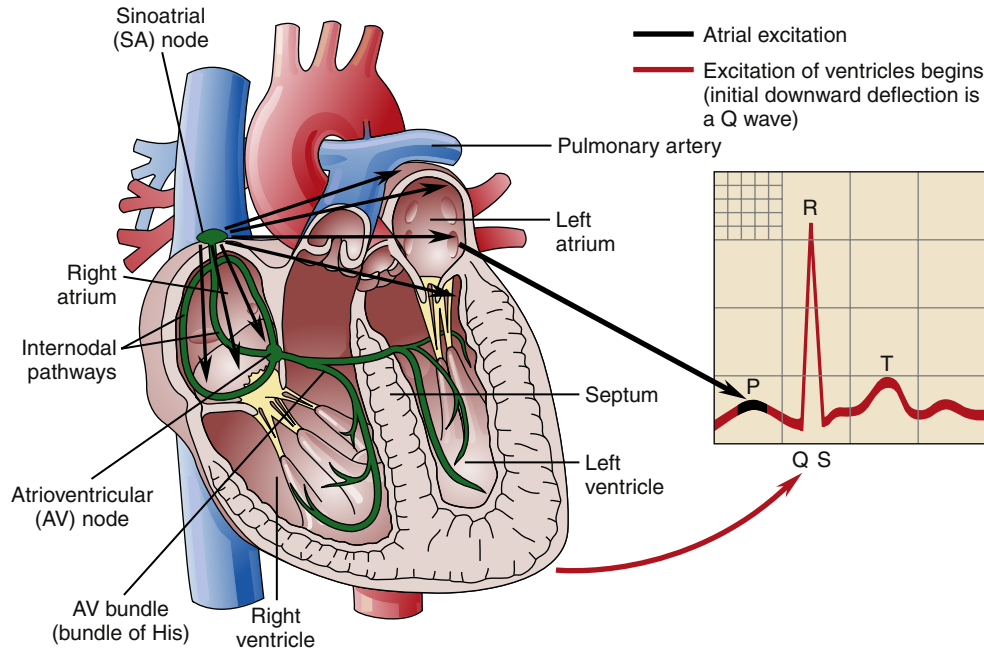

After traversing the atria, the impulse initiated at the SA node arrives at the AV node (AV junction) located in the posterior septal wall of the right atrium just behind the tricuspid valve. There is a characteristic slowing of impulse conduction through the AV node, which allows for completion of atrial contraction before initiation of ventricular systole. The AV node is actually composed of different types of fibers that have somewhat different action potential conduction times. Overall, it normally takes about 0.13 second for an impulse to pass through the AV node. The AV node is richly innervated by the autonomic nervous system. The AV node spontaneously depolarizes at a rate of 40 to 60 times per minute and usually becomes the heart's pacemaker if the SA node fails.

Purkinje cells (fibers), which lead from the AV node to ventricular myocardium, are vastly different from AV nodal cells. They are large and well structured to conduct impulses very rapidly. After penetrating the AV fibrous barrier, the bundle of Purkinje fibers travels 5 to 15 mm down the intraventricular septum toward the apex. The main bundle then divides into left and right bundle branches, which travel down the left and right sides of the intraventricular septum. Successive branches of Purkinje fibers penetrate the ventricular muscle mass from the endocardial side. Intraventricular septal areas are depolarized first, followed by apical muscle and finally the lateral walls (Figure 17-21). Early septal depolarization allows the septum to contract first and provide a stable wall against which the left and right ventricles can contract.<sup>10</sup> The total time elapsed between main bundle branch and terminal Purkinje fiber depolarization is only 0.03 second. Therefore, the entire ventricular endocardium is activated almost simultaneously. Purkinje fibers are capable of spontaneous depolarization at a rate of 15 to 40 times per minute and may become pacemakers for the heart if impulses from the SA and AV nodes are interrupted.

Action potentials are rapidly transmitted from the terminal Purkinje fibers to cardiac muscle fibers and then spread contiguously from cell to cell through gap junctions in the ventricular muscle. Approximately 0.03 second is required for the impulse to be transmitted through the ventricular myocardium.<sup>10</sup> Impulses normally travel from the terminations of Purkinje fibers at endocardial surfaces toward the epicardial surfaces. Depolarization of the right ventricle is accomplished slightly sooner than the left because of differences in muscle mass. Depolarization of the ventricular myocardium is followed by contraction and ejection of blood from the ventricles.

The capability of faster pacemakers to suppress the automatic discharge of slower pacemakers is called *overdrive suppression*. A slower pacemaker may be revealed if the normal pacemaker is suddenly interrupted. Sometimes it takes time for the slower pacemaker to “kick in” and begin pacing at its intrinsic rate. A previously rapid rate of depolarization apparently enhances the activity of membrane  $\text{Na}^+\text{-K}^+$  pumps, resulting in a period of hyperpolarization (more negative

**FIGURE 17-20** Schematic drawing of the conduction system of the heart. An impulse normally is generated in the sinus node and travels through the atria to the AV node, down the bundle of His and Purkinje fibers, and to the ventricular myocardium. Recording of the depolarizing and repolarizing currents in the heart with electrodes on the surface of the body produces characteristic waveforms.

**FIGURE 17-21** Sequence of ventricular depolarization showing septal depolarization in a left-to-right direction (A), followed by apical depolarization in an endocardial to epicardial direction (B), and, finally, depolarization of the lateral walls (C). Repolarization proceeds in the opposite direction.

resting potential) when the faster pacemaker suddenly stops. Thus, it takes slightly longer to reach threshold and initiate the first action potential.

**Autonomic Regulation of Rhythmicity**

Both sympathetic and parasympathetic nerves supply the heart. Sympathetic innervation is widespread to all areas, including the ventricular myocardium. Parasympathetic innervation, by way of the vagus nerves, is localized primarily in SA and AV nodal areas. The right vagus nerve supplies the SA node, whereas the left vagus nerve supplies the AV node.<sup>12</sup> The autonomic nervous system exerts control over heart rate and velocity of impulse conduction. In general, sympathetic activation increases heart rate (*chronotropic effect*) and increases speed of conduction (*dromotropic effect*) as well as inducing heart muscle to contract more forcefully (*inotropic effect*) and relax more quickly (*lusitropic effect*). These effects are achieved by release of NE from sympathetic nerve endings. Binding of NE to  $\beta$  receptors on heart muscle cell membranes increases production of cAMP, which regulates several membrane channels and pumps and increases depolarizing ion currents.

Parasympathetic stimulation primarily results in a reduction in heart rate and speed of action potential conduction. Acetylcholine is the neurotransmitter released by parasympathetic nerve endings. Acetylcholine binding to muscarinic receptors on heart cells inhibits cAMP production and increases membrane permeability to potassium ions, allowing them to leak from the cell. The resulting hyperpolarization makes it more difficult to reach threshold and initiate an action potential. The resting heart is normally under a predominant parasympathetic influence, which results in an SA discharge rate of about 70 beats/min. If parasympathetic activity is blocked, the spontaneous discharge rate of SA nodal cells increases to about 100 beats/min. An increase in vagal activity can reduce heart rate significantly. Breath holding, bearing down during defecation, and pressing on the carotid arteries may increase vagal tone and reduce heart rate. This is sometimes called a *vasovagal response* and may lead to dizziness and fainting.

## KEY POINTS

- The cardiac resting membrane potential is about  $-90$  mV. The resting membrane potential is determined by the ratio of intracellular to extracellular  $K^+$  concentration.
- The five phases of the cardiac action potential are due to changes in ion conductance through the plasma membrane. The main changes in ion conductance result from opening of the fast  $Na^+$  channels (phase 0), slow  $Ca^{2+}$  channels (plateau), and  $K^+$  channels (repolarization) in the plasma membrane.
- Spontaneous generation of action potentials in automatic cells is due to a progressive leak of  $Na^+$  and  $Ca^{2+}$  into the cell via channels that automatically open during repolarization. The rate of cation leak determines the rate of pacemaker discharge. Parasympathetic influence increases  $K^+$  efflux and slows the rate. Sympathetic influence increases influx of  $Na^+$  and  $Ca^{2+}$  and increases the rate.
- The usual conduction pathway for depolarization of the heart begins at the SA node, progresses through the atria, enters the AV node, and activates the bundle of His Purkinje fibers. Purkinje fibers leave the AV node and divide into left and right branches that innervate the endocardial surface of the ventricular myocardium.

## ELECTROCARDIOGRAPHY

As action potentials spread from cell to cell throughout the myocardium, an electrical current is transmitted to the body surface and can be detected by electrodes placed on the skin.<sup>13,14</sup> A recording of these electrical currents is called an *electrocardiogram* (ECG). The ECG is a useful indicator of abnormalities of the heart's conduction system. Irregularities in initiation of impulses, conduction rates, and conduction pathways can be identified. The ECG has a different appearance than the cardiac action potential described previously because it registers depolarizing and repolarizing currents in the whole heart rather than the activity of individual myocytes (Figure 17-22).

Electrical currents traveling through the heart have both direction and magnitude and are often described as *vectors*. At any instant, electrical currents are moving in various directions through different regions of the heart. Waveforms recorded at the ECG electrodes are algebraic sums of all of these vectors. Patterns of electrical activity shown on the ECG vary according to the placement of electrodes on the body. In general, a wave of depolarization moving toward a positive recording electrode will register as an upward deflection on the ECG. A wave of repolarization moving away from a positive electrode also will register as an upward deflection on the ECG. A downward deflection results from a wave of depolarization moving away from a positive electrode (Figure 17-23). Placement of a recording electrode on the lower-left extremity (lead II) results in the typical ECG pattern shown in Figure 17-24. A description of the usual electrode placements is included in the section Tests of Cardiac Function at the end of this chapter.

Each deflection on the ECG has a normal characteristic shape and time interval (see Figure 17-24). The three major wave complexes are the *P wave*, which corresponds to atrial depolarization, the *QRS complex*, which represents ventricular depolarization, and the *T wave*, which reflects ventricular repolarization. The PR interval, between the beginning of the P wave and the beginning of the QRS complex, includes atrial, AV node, and His Purkinje fiber depolarization. The normal sequence of ventricular depolarization begins with the septum, followed by the apex, and, finally, the base of the ventricular walls. Septal depolarization begins on the left septal surface and then travels toward the right, resulting in a small negative deflection, the *Q wave* in lead II (Figure 17-25). A large upright *R wave* corresponds to a wave of

**FIGURE 17-22** Comparison of the action potential from a single ventricular muscle cell, showing rapid depolarization and prolonged repolarization phases, against an electrocardiogram of potentials from the heart as a whole. Ventricular myocytes remain depolarized and refractory throughout the entire QT interval. (Redrawn from Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 122.)

**FIGURE 17-23** Electrocardiographic (ECG) waveforms may be positive (upward) or negative (downward), depending on the location of electrodes on the chest. **A**, A wave of depolarization moving toward a positive electrode results in a positive deflection. **B**, A wave of repolarization moving away from a positive electrode results in a positive deflection. **C**, A wave of depolarization moving away from a positive electrode results in a negative deflection.

depolarization traveling down the ventricles toward the apex. Depolarization of the ventricular base, because it moves in a direction away from the lower limb electrode, is recorded as a negative *S wave*. The ST interval, between the S wave and the beginning of the T wave, is isoelectric (flat), because the entire ventricle is depolarized and no detectable current is flowing. The QT interval, from the beginning of the QRS complex to the end of the T wave, is commonly measured as an indicator of ventricular systole. The T wave is normally upright in lead II, representing a wave of repolarization moving away from a positive electrode. In some patients, particularly those with slow heart rates, the T wave is followed by a small positive deflection, called a *U wave*. Prominent U waves also are a sign of a low potassium level. Abnormalities in

**FIGURE 17-24** Usual electrocardiographic pattern recorded from lead II, showing characteristic waves and intervals.

**FIGURE 17-25** QRS complex results from the sequence of ventricular depolarization. **A**, In lead II, septal depolarization is in a direction away from the positive electrode, resulting in a negative Q wave. **B**, Depolarization of the apex of the heart is in a direction toward the positive electrode, resulting in a large positive R wave. **C**, Depolarization of the lateral walls and base of the ventricles is in a direction away from the positive electrode, resulting in a negative S wave.

any time intervals may indicate abnormal conduction pathways and enhanced or slowed conduction times. Rhythm disturbances are discussed in detail in Chapter 19.

**KEY POINTS**

- The ECG represents an algebraic sum of all depolarizing and repolarizing currents occurring in the heart. ECGs are useful for detecting conduction and rhythm disturbances.
- The major deflections of the ECG are:  
 P wave: atrial depolarization  
 PR interval: atrial, AV node, and Purkinje depolarization  
 Q wave: septal depolarization  
 R wave: apical depolarization  
 S wave: depolarization of lateral walls (base)  
 T wave: ventricular repolarization

**DETERMINANTS OF CARDIAC OUTPUT**

**Cardiac output** is a measure of the amount of blood pumped out of the heart each minute. Because the heart’s primary function is to pump enough blood to circulate oxygen and nutrients to tissues, the cardiac output is an extremely important indicator of cardiovascular health. Normal resting cardiac output is approximately 5 to 6 L/min, but it varies with body size and age. Cardiac output is often indexed to body surface area in an attempt to adjust for these differences (cardiac index = cardiac output/body surface area). A normal cardiac index ranges from 2.8 to 3.3 L/min/m<sup>2</sup>. Regardless of the actual number of liters of blood pumped per minute, the adequacy of tissue perfusion is ultimately important.

Cardiac output is a product of heart rate and stroke volume (CO = HR × SV). **Stroke volume** refers to the amount of blood ejected from the ventricle with each contraction. An increase in heart rate (to a point) and/or an increase in stroke volume will result in a greater cardiac output. Conversely, a low heart rate and/or a decreased stroke volume will cause cardiac output to fall. To a certain extent, a change in one factor can be compensated for by a change in the other, thus maintaining cardiac output at a constant level. For example, it is common

for an individual with limited stroke volume attributable to cardiac disease to have a high resting heart rate. Any physiologic, pharmacologic, or pathologic process that alters heart rate or stroke volume may affect cardiac output and therefore tissue perfusion.

### Determinants of Heart Rate

Heart rate is primarily influenced by the autonomic nervous system. Release of norepinephrine by sympathetic nerve endings results in an increased heart rate. A similar effect results from circulating norepinephrine and epinephrine released from the adrenal gland during sympathetic stimulation. Sympathetic activation of the heart is regulated by several reflex pathways that constantly monitor blood pressure and metabolic activity in the body. In general, detection of inadequate blood pressure, a lack of oxygen, or a buildup of metabolic end products results in activation of the sympathetic nervous system. Specialized sensory nerve endings, called *baroreceptors*, located in the aortic arch and carotid arteries respond to changes in blood pressure and transmit this information to the central nervous system by way of cranial nerves IX and X. A decline in blood pressure causes parasympathetic system inhibition and cardiac sympathetic nerve activation, resulting in a rise in heart rate. Conversely, a rise in blood pressure causes the heart rate to fall because of parasympathetic activation and sympathetic inhibition. Under normal resting conditions, the heart rate is under parasympathetic influence, with a usual rate of approximately 70 beats/min.

In addition to baroreceptors, other sensory fibers that detect pressure are located in the cardiac chambers. These sensory receptors respond to changes in intrachamber pressure, which reflect the volume of blood in the chamber. Atrial or ventricular overdistention suppresses parasympathetic influence and increases heart rate (Bainbridge reflex).<sup>12</sup> Heart rate may also be influenced by higher central nervous system (CNS) activities that do not involve reflex pathways. Anxiety, fear, stress, excitement, trauma, and fever may activate the sympathetic system, for example. A variety of drugs can mimic or block the effects of both sympathetic and parasympathetic systems and therefore influence heart rate (see Chapter 18).

In general, an increase in heart rate results in an increase in cardiac output; however, at very high heart rates, cardiac output may actually fall. At high heart rates (e.g., more than 200 beats/min in the young, even lower in the adult), the time for diastolic ventricular filling can be significantly reduced, resulting in a low stroke volume. The benefit of increased heart rate is therefore undermined by impaired pumping efficiency.

### Determinants of Stroke Volume

Three major factors influence stroke volume: (1) the volume of blood in the heart (**preload**), (2) the contractile capabilities of heart muscle (**contractility**), and (3) the impedance opposing ejection of blood from the ventricle (**afterload**). Each of these factors is in turn influenced by many other physiologic, pharmacologic, and sometimes pathologic variables.

#### Volume of Blood in the Heart (Preload)

The heart can only pump as much blood as is delivered to it by the circulatory system. Blood returning to the heart from the circulation is often called venous return. Normally, venous return is equal to cardiac output because the circulatory system is just that—a circuit. However, there may be inequalities over several heartbeats when changes in blood volume or blood distribution occur. The heart is well suited to adjust to these beat-to-beat changes in venous return such that the healthy heart pumps essentially whatever amount is delivered to it.

**FIGURE 17-26** Force of muscle contraction depends in part on its resting length before activation. At optimal lengths, the greatest tension is developed, and cross-bridge formation is enhanced.

The amount of blood present in the ventricles just before contraction (end-diastolic volume) is an important determinant of stroke volume. The relationship between diastolic volume and the force of myocardial contraction is known as the **Frank-Starling law of the heart**.<sup>2,15</sup> In essence, this law states that an increase in resting muscle fiber length results in a greater development of muscle tension. Ventricular muscle fiber length is determined by the volume of blood it contains, commonly called the *preload*. An increase in preload results in a greater force of contraction and a larger stroke volume. In this way, the ventricle is able to adjust its stroke volume, beat by beat, according to the amount of blood to be pumped.

The Frank-Starling law of the heart (also called the *length-tension relationship*) may be understood by recalling the molecular structure of contractile units of heart muscle. For contraction to occur, the actin and myosin filaments that make up the sarcomere must form cross-bridges and slide together. Stretching the muscle before contraction is believed to optimize the space between the actin and myosin filaments, bringing them closer together, and resulting in more cross-bridge formation (Figure 17-26). Stretching the muscle before contraction also makes the contractile apparatus more sensitive to calcium ions such that a greater contractile force occurs for a given calcium concentration.<sup>2</sup>

The cardiac function curve describes the effects of preload on ventricular stroke volume (Figure 17-27). In practice, stroke volume and ventricular end-diastolic volume are difficult to measure, and other indicators, such as ventricular pressure and cardiac output, may be used. Cardiac function curves can be measured in persons with poorly functioning hearts to determine the best filling volume (preload) for optimizing cardiac output. Often, the failing heart requires a higher than normal preload to maintain a normal cardiac output. However, there are limits to the improvement in stroke volume with increased diastolic filling, and beyond that point the curve will flatten. On the flat part of the curve, an increase in preload increases the workload of the heart, but does not provide an improvement in output. The workload imposed on the heart chambers by preload is sometimes called the *volume work of the heart*. An increase in preload increases the volume

**FIGURE 17-27** Cardiac function curves showing the dependence of ventricular stroke volume on preload. Different hearts have different cardiac function curves and may respond differently to the same degree of preload. *PSNS*, Parasympathetic nervous system; *SNS*, sympathetic nervous system.

work of the heart, which must be met by increased oxygen uptake to maintain adequate ATP production.

### Contractile Capabilities of the Heart (Contractility)

Heart muscle contractility depends on several factors, including (1) the amount of contractile proteins in the muscle cells, (2) the availability of ATP, and (3) the availability of free calcium ions in the cytoplasm. Contractility is, by definition, independent of fiber end-diastolic length and is therefore not affected by preload. Given an adequate ATP supply, the contractile state of the normal myocardium is primarily determined by factors that increase the availability of free calcium ions within the myocardial cell. In general, an increased intracellular free calcium level can be accomplished by enhanced release from internal stores, enhanced entry from extracellular fluid, and reduced rates of extrusion across the plasma membrane.

A variety of agents that increase contractility, called *positive inotropes*, are associated with increased intracellular calcium levels in the heart. These include the sympathetic neurotransmitters norepinephrine and epinephrine, thyroid hormone, caffeine, digitalis, and many others. Agents that depress contractility, called *negative inotropes*, achieve their effects by reducing intracellular calcium levels. These agents include L-type calcium channel blockers, parasympathomimetics, and sympathetic blocking drugs. The baroreceptor reflex, described previously in relation to heart rate, is also an important regulator of stroke volume through its effects on contractility. Positive inotropic agents increase ATP utilization by the myocardium, whereas negative inotropes decrease myocardial workload and reduce ATP requirements.

Cardiac disease may adversely affect contractility because of an inadequate oxygen supply or because of loss of myocardial pumping cells. These disorders are discussed in Chapter 18.

### Impedance to Ejection from the Ventricle (Afterload)

The third major determinant of stroke volume is afterload, which refers to the impedance or resistance that must be overcome to eject blood from the chamber. Left ventricular afterload is determined primarily by aortic blood pressure. Because high blood pressure increases left ventricular afterload, vasodilating agents that reduce blood pressure can significantly decrease afterload. Normally the aortic valve offers little impedance to flow; however, aortic valve narrowing may significantly increase afterload. An increase in afterload will result in a decrease in stroke volume unless contractility or preload (or both) is adjusted to compensate. Conversely, a decrease in afterload will allow a larger than normal volume of blood to be ejected from the heart, requiring less myocardial work. The work done by the heart to overcome afterload is often called the *pressure work of the heart*. An increase in afterload increases pressure work and requires greater tension development within the walls of the chamber (wall stress). Increased wall stress not only increases myocardial workload and oxygen consumption but also, if prolonged, may trigger structural changes leading to hypertrophy of myocytes.

The ventricles normally eject about 60% to 70% of their end-diastolic volume during contraction; the remaining 30% to 40% remains in the ventricle. **Ejection fraction** is influenced by afterload as well as preload and contractile state. A reduced ejection fraction is a common finding in persons suffering from myocardial infarction. Ejection fractions less than 40% indicate significant myocardial impairment and may be associated with systolic heart failure (see Chapter 19).

### Cardiac Workload

The oxygen requirements of the heart are related to the amount of energy (ATP) exerted to perform its pumping function. The four determinants of cardiac output described in the previous section—heart rate, preload, contractility, and afterload—are also the major determinants of cardiac energy requirements. An increase in any of these four factors will increase ATP requirements and therefore cardiac cell oxygen requirements. High afterload is most detrimental, because it greatly increases cardiac work without producing a higher cardiac output. When oxygen supply to the heart is impaired, as in coronary atherosclerosis, it may be beneficial to reduce myocardial oxygen demand by reducing cardiac workload. This may be accomplished by reductions in heart rate, preload, afterload, and contractility.

#### KEY POINTS

- Cardiac output is the product of the heart rate times the stroke volume ( $CO = HR \times SV$ ). An increase in heart rate or stroke volume will increase cardiac output. An increase in heart rate can compensate for a decrease in stroke volume.
- Heart rate is controlled primarily by the autonomic nervous system. Factors that increase heart rate include low blood pressure (baroreceptors), acidemia (chemoreceptors), atrial and ventricular overdistention (Bainbridge reflex), and emotions. Activation of the vagus nerve will decrease heart rate.
- Stroke volume is influenced by preload. According to the Frank-Starling law, increased preload stretches the sarcomere, resulting in more forceful contraction.
- Increased contractility increases stroke volume by causing a greater percentage of the ventricular volume to be ejected. Any factor that enhances the availability of cytoplasmic free  $Ca^{2+}$  will increase contractility.
- Increased afterload will decrease stroke volume. Afterload is determined primarily by the resistance of the arterial system. Vasoconstriction and high aortic pressure increase afterload.
- Any factor that increases heart rate, preload, contractility, or afterload will increase the workload of the heart.

## ENDOCRINE FUNCTION OF THE HEART

In addition to its pumping function, the heart also has an endocrine function: secretion of natriuretic peptides.<sup>16</sup> Atrial natriuretic peptide (ANP) is synthesized by myocytes in the atria and released in response to atrial stretch. Increased atrial stretch occurs when blood volume becomes excessive. The ventricles produce a related peptide called B-type natriuretic peptide (BNP) when they are chronically overdistended. An elevated BNP value is a marker for congestive heart failure.<sup>16</sup> ANP and BNP cause enhanced excretion of sodium and water by the kidney. In general, the effects of the natriuretic peptides are antagonistic to those of the renin-angiotensin-aldosterone system (see Chapter 26).

## TESTS OF CARDIAC FUNCTION

In addition to patient history, laboratory results, and physical assessment, a number of diagnostic tests may be employed to evaluate cardiac function.<sup>17</sup> The ECG is routinely obtained and provides information about the heart's conduction patterns. Echocardiography and nuclear cardiography are tests that use various modes to image the heart. A more direct assessment of cardiac function can be obtained by cardiac catheterization. In addition, a number of methods have been developed to quantify myocardial blood flow. Each of these studies is briefly described in this section.

### Electrocardiography

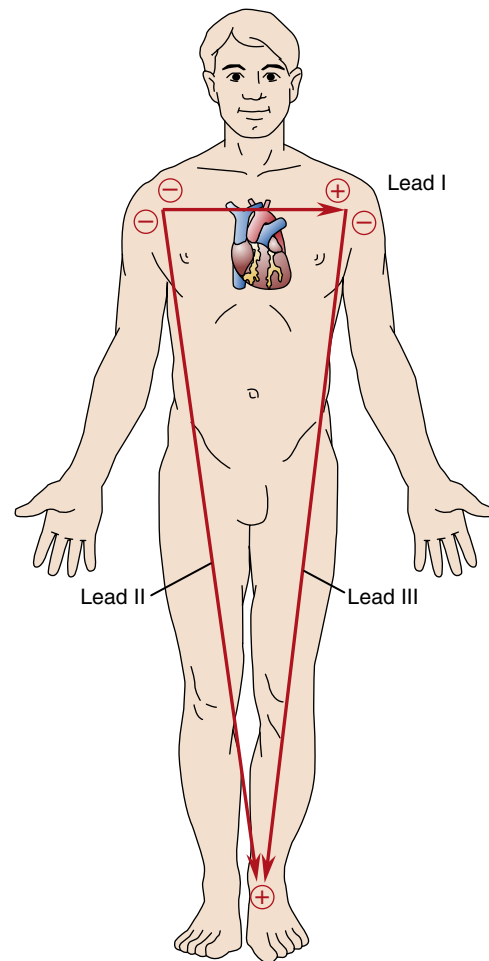

The ECG graphically indicates electrical currents generated by cardiac cells. The current is registered by skin electrodes placed in particular positions on the body.<sup>14</sup> The standard ECG has 12 different leads that are obtained through 10 skin electrodes: 3 standard bipolar limb leads, 3 augmented unipolar limb leads, and 6 unipolar chest leads. Bipolar leads represent a difference in electrical potential between two electrodes, one positive and one negative. Augmented unipolar limb leads represent a difference in potential between one electrode and the average of the other two limb electrodes. Unipolar chest leads represent a difference in potential between the chest electrode and a location at the center of the heart. Each lead provides a different ECG because of its particular “view” of current flow through the heart.

The three standard bipolar limb leads are lead I, lead II, and lead III (Figure 17-28): lead I measures the current between the right arm and left arm, lead II measures the current between the right arm and left leg, and lead III measures the current between the left arm and left leg. A normal ECG from leads I, II, and III is illustrated in Figure 17-29.

Electrode placement for the augmented unipolar limb leads is illustrated in Figure 17-30. Unipolar limb lead electrodes provide the positive pole: lead  $aV_R$  is recorded from the right arm, lead  $aV_L$  is recorded from the left arm, and lead  $aV_F$  is recorded from the left leg. In these leads, *a* stands for augmented; *V* stands for voltage; and *R*, *L*, and *F* indicate the location of the unipolar lead (right arm, left arm, and foot [left]). A normal ECG from these leads is illustrated in Figure 17-31.

Precordial unipolar chest leads are recorded from electrodes placed in six positions over the heart on the anterior chest (Figure 17-32). Chest leads are designated as  $V_1$ ,  $V_2$ ,  $V_3$ ,  $V_4$ ,  $V_5$ , and  $V_6$ . The normal ECG from the chest leads is shown in Figure 17-33. The chest leads provide a horizontal view of the heart, whereas the limb leads provide a view of the frontal plane.

Twelve-lead ECGs are usually recorded for a short period of time when the patient is resting. Sequential ECGs are useful for

**FIGURE 17-28** Positions of standard bipolar limb leads I, II, and III. The positive (+) lead is the recording lead.

**FIGURE 17-29** Normal electrocardiogram recorded from the three standard bipolar limb leads. The R wave is normally upright in leads I, II, and III. (Redrawn from Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 126.)

FIGURE 17-31 Normal electrocardiogram recorded from the three unipolar augmented leads. The  $aV_R$  lead is characterized by a large S wave and an inverted T wave. The  $aV_L$  and  $aV_F$  leads have an upright R wave and T wave.

determining changes over time. In some cases it is necessary to monitor the ECG recording for an extended period to capture rhythm problems that occur infrequently or with particular activities. This is accomplished by continuous ambulatory monitoring (e.g., Holter monitoring) over a 24- to 48-hour period. An ECG can also be recorded during exercise to monitor the effects of exercise stress on cardiovascular function. An exercise test (stress test) is usually performed while the subject progressively increases his or her effort on a treadmill or stationary bicycle. The exercise ECG is particularly useful for assessing the adequacy of coronary circulation when the

FIGURE 17-32 Unipolar chest (precordial) leads  $V_1$  through  $V_6$ .

myocardial workload is increased. Impaired myocardial oxygen delivery may be evident on the ECG as ST segment elevation or depression and abnormal T waves.

### Magnetic Resonance Imaging and Computed Tomography

Magnetic resonance imaging (MRI) and computed tomography (CT) are useful for imaging cardiac structures.<sup>1</sup> Myocardial thickening, pericardial sac disease, valvular structures, and congenital malformations may be visualized by MRI. Contrast-enhanced imaging identifies acute and chronic myocardial infarcts with high specificity and sensitivity. MRI and CT are used to detect coronary plaque burden and assess vulnerable plaque morphology in the arterial walls. Excessive plaque burden and unstable plaques are correlated with a greater degree of coronary atherosclerosis and may be used to predict coronary artery disease risk or progression.

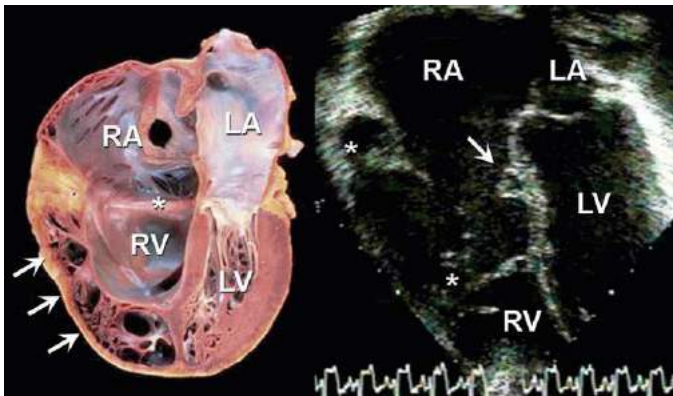

### Echocardiography

Echocardiography uses reflected sound waves (ultrasound) to provide an image of cardiac structure and motion within the chest. The cardiac echo is obtained by placing a blunt probe on the chest surface that transmits and receives high-frequency sound waves. Sound waves traveling through chest and heart structures are reflected back to the receiving probe. The time between sound wave emission and detection of reflected waves is used to calculate distances between the probe and reflecting tissue. The sound waves are not heard or felt by the subject and have no known detrimental effects on tissues. The probe is moved across the chest to assess cardiac structures of interest, and recordings are videotaped for later viewing.

Echocardiograms are particularly useful for diagnosis of heart enlargement, valvular disorders, collections of fluid in the pericardial space, cardiac tumors, and abnormalities in left ventricular motion. Estimations of ejection fraction and assessments of ventricular systolic and diastolic function can be made noninvasively by echocardiogram. An echocardiogram is shown in Figure 17-34.

**FIGURE 17-33** Normal electrocardiogram recorded from the six unipolar chest leads,  $V_1$  through  $V_6$ . Note the R wave progression across the precordial leads as the R waves become increasingly positive. ### Nuclear Cardiology

Radioactive substances injected into the bloodstream can be used to trace the patterns of blood flow in the heart. Radiation exposure is minimal, because very small amounts of radioactive substances are used. Radioactive tracers can be linked to substances that accumulate in normal myocardial cells while the tracer is delivered by coronary blood flow. Areas with impaired perfusion will absorb less radioactivity and appear as “cold spots” on the scan. Scanning usually is done using single-photon emission computed tomography (SPECT), which images numerous slices through the heart, or by planar imaging, which gives an overall picture in one plane only.

Thallium-201 ( $^{201}\text{Tl}$ ) and technetium-99 labeled compounds ( $^{99\text{m}}\text{Tc}$  sestamibi) are used to assess the adequacy of blood flow to cardiac tissues. After injection of the radioactive compound, the heart is scanned to visualize the amount of radioactivity absorbed by cardiac tissues. Healthy cardiac tissues that receive adequate blood supply actively accumulate these isotopes. Areas of inadequate blood flow or infarcted tissue do not accumulate isotopes and appear as cold spots on

the scan. Resting and exercise scanning are done to assess for exercise-induced perfusion defects.

Gated pool scanning (radionuclide ventriculogram) is used primarily to assess left ventricular motion and ejection fraction. Before it is injected intravenously, radioactive technetium is attached to albumin or red blood cells, and therefore it remains in the bloodstream and is not absorbed by cells. Computer imaging is used to analyze blood flow through the chambers of the heart over many cardiac cycles. The dynamics of ventricular motion, such as hypercontractility or hypocontractility, may be visualized. Separate radionuclide ventriculogram evaluation has largely been replaced by SPECT scanning that allows simultaneous evaluation of perfusion and left ventricular function.

Positron emission tomography (PET) scans may also be used to evaluate cardiac perfusion and metabolism. Radiotracers can be incorporated into substances normally used in cellular metabolic processes, such as glucose. Metabolic activity in different areas of the heart can then be tracked over time under different conditions.

### Cardiac Catheterization/Coronary Angiography

Cardiac catheterization/coronary angiography may be used to determine important structural and hemodynamic characteristics because it affords direct measurement of pressures within cardiac chambers; visualization of chamber size, shape, and movement; sampling for blood oxygen content in various heart regions; measurement of cardiac output and ejection fraction; and visualization and management of coronary artery obstructions.<sup>18</sup>

Cardiac catheterization angiography is associated with several serious risks, including bleeding, dysrhythmias, heart perforation, and coronary ischemia. The advent of noninvasive high-resolution MRI, echocardiograms, and SPECT scanning has replaced the need for cardiac catheterization in many instances; however, the value of information supplied is generally believed to outweigh the risks in certain cases. Catheterization is frequently used for interventions to rapidly improve coronary blood supply and to evaluate suspected or confirmed coronary artery disease, valvular dysfunction, congenital defects, left ventricular dysfunction, and coronary bypass graft patency.

Assessment of the left side of the heart, including the coronary arteries, is achieved by passing a catheter through a femoral or

**FIGURE 17-35** Coronary artery angiography. The *arrows* show an area of obstruction of the coronary artery. (From Popma J: Coronary arteriography. In Bonow R et al, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine*, ed 9, vol 1, Philadelphia, 2012, Saunders, p 428.)

brachial artery into the aorta. The catheter is then manipulated into the left ventricle or left atrium to assess chamber pressures, and a ventriculogram is obtained. Contrast dye injected into the ventricular chamber is monitored fluoroscopically to assess ventricular function. The catheter is usually pulled back into the aorta and then advanced into one or more of the coronary arteries. The patency of the coronary arteries can be visualized by injecting contrast dye into them and monitoring by fluoroscopy (Figure 17-35). When contrast dye is in the coronary artery, a period of cardiac ischemia is produced during which the patient may experience angina, dysrhythmias, and coronary spasms. Coronary catheterization may also be done to insert a probe for obtaining intracoronary ultrasounds. Ultrasounds are useful for assessing plaque morphologic characteristics (Figure 17-36).

Right-sided heart catheterization is done to evaluate right-sided heart structures. The catheter is introduced into a vein, usually femoral,

then threaded through the inferior vena cava and into the heart. Pressures and blood samples are obtained as the catheter is advanced into the right atrium, ventricle, and pulmonary artery. Right heart catheterization is useful in assessing tricuspid and pulmonary valve disorders, pulmonary hypertension, septal defects, and right ventricular function.

Coronary angiography is commonly followed by interventions to treat detected abnormalities. The coronary catheter can be used to direct thrombolytic agents to the site of coronary thrombosis and rapidly restore blood flow to ischemic areas. Laser therapy, coronary balloon angioplasty, and stent placement can also be performed during coronary angiography. These methods clear the coronary obstruction through thermal and mechanical means. The success of these approaches to management of coronary obstruction depends largely on how soon after an ischemic event they are performed (Chapter 18).

## SUMMARY

The heart's primary function is to pump sufficient blood to deliver oxygen and nutrients to the body. The heart may be viewed as two separate pumps: a right-sided pump that perfuses the lungs and a left-sided pump that perfuses the systemic circulation. The left ventricle must generate higher pressures and therefore has a thicker myocardial mass and higher energy requirements. Because little ATP storage in cardiac cells is possible, the coronary arteries must deliver a steady supply of oxygen and nutrients. Cardiac contraction can be described by the sliding filament/cross-bridge theory and occurs only in the presence of ATP and free calcium ions. Factors that enhance intracellular calcium ion concentration will result in generation of a greater contractile force.

A coordinated cardiac contraction is possible because the heart's conduction system activates the chambers in a sequential manner. The sinoatrial node is the usual pacemaker because it has the highest intrinsic rate of diastolic depolarization. The diastolic depolarization rate is strongly influenced by the autonomic nervous system. The ECG shows the electrical activity of the heart and is a useful indicator of cardiac conduction abnormalities.

The ultimate indicator of cardiac function is the cardiac output, which is the product of heart rate and stroke volume. The autonomic nervous system is the main regulator of heart rate, whereas stroke volume is influenced by preload, afterload, and contractility. These factors are also the primary determinants of myocardial work and energy expenditure.

- Case Studies
- Key Points Review

### KEY QUESTIONS

- What is the role of injury, inflammation, and lipid oxidation in coronary plaque initiation and progression?
- What factors alter the balance between myocardial oxygen supply and demand?
- How do the clinical features of the coronary heart disease syndromes differ?
- How do valvular disorders alter cardiac pressure dynamics and workload?
- What are the similarities and differences among the cardiomyopathies and myocarditis?
- How do pericarditis and pericardial effusions differ in regard to cause and significance?
- What factors determine whether a congenital heart defect will produce cyanosis?

The incidence of cardiovascular disease (CVD) increased rapidly in the United States during the last century, but the death rates from CVD declined between 1998 and 2008 by 30.6%.<sup>1</sup> Mortality data from 2007 showed that CVD accounted for 32.8% of all deaths. Approximately half of these deaths are due to coronary heart disease (CHD), whereas stroke, high blood pressure, heart failure, and others claim the remainder. Since the late 1960s, however, a decline in cardiac mortality has been achieved in the United States because of improvements in treatment and prevention. More than 16 million people living today have a history of angina pectoris or myocardial infarction (MI).<sup>1</sup> Men and women are equally represented, although women tend to be older when their heart disease becomes apparent. In 2008, the direct and indirect economic cost of cardiovascular diseases, including stroke, was estimated at \$297.7 billion annually.<sup>1</sup> CHD is the most important cardiovascular disorder in terms of numbers affected and economic impact.

## CORONARY HEART DISEASE

CHD is also called ischemic heart disease (IHD) and coronary artery disease (CAD) in some sources. These terms are related because CHD is characterized by insufficient delivery of oxygenated blood to the myocardium (ischemia) because of atherosclerotic coronary arteries (CAD). The American Heart Association compiles statistics under the heading of CHD, which includes the diagnoses of angina pectoris and myocardial infarction. CHD caused about one in six deaths in the United States in 2008.<sup>1</sup> Other sequelae of CHD include dysrhythmias, sudden cardiac death, and heart failure. When metabolic demand for oxygen exceeds supply, the myocardium becomes ischemic, which leads to a dysfunction in cardiac pumping and predisposes to abnormal heart rhythms. If the ischemic episode is severe or prolonged, irreversible damage to myocardial cells may result in MI.

### Etiology of Coronary Heart Disease

Atherosclerosis of coronary arteries is the source of nearly all CHD. Atherosclerosis causes progressive narrowing of the arterial lumen and predisposes to a number of processes that can precipitate myocardial ischemia, including thrombus formation, coronary vasospasm, and endothelial cell dysfunction. Uncommon causes of cardiac ischemia include abnormalities of blood oxygen content (e.g., respiratory failure) and poor perfusion pressure through the coronary arteries (e.g., hypotension, hypovolemia). Occasionally, patients experience the signs and symptoms of cardiac ischemia but show no evidence of significant coronary artery atherosclerosis when evaluated by angiography. These patients are thought to have abnormalities of the microcirculation. Abnormal vascular regulation by endothelial cells in small vessels of the heart has been suggested as a probable mechanism. Endothelial cells secrete variable quantities of vascular relaxing and contracting factors and play a key role in controlling myocardial blood flow. Abnormalities of the microcirculation are more difficult to detect than coronary artery plaque, which is evident on coronary angiography. As evaluation methods improve, disorders of the microcirculation are likely to be more frequently recognized as factors contributing to CHD.

### Mechanisms of Coronary Atherosclerosis

Knowledge about mechanisms of plaque formation in the coronary arteries has rapidly accumulated in recent years. Epidemiologic studies reported in the 1960s suggested associations among certain traits and habits and the development of CHD. More recent studies have confirmed and expanded on these *risk factors*, which include several major risks (e.g., age, family history, abnormal lipid levels, cigarette smoking, hypertension, diabetes, and obesity) and numerous probable risks (Box 18-1).<sup>2</sup> Although males and females succumb to heart disease in equal numbers, male gender is a risk factor for earlier development of heart disease, on average about 10 years earlier. The risk factors for CHD are the same as those for atherosclerosis in other arteries and are discussed in Chapter 15.

The observation that atherosclerotic plaque is composed primarily of lipid prompted the idea that abnormal lipid metabolism was a probable culprit in the development of CHD, and a great deal of attention has

## BOX 18-1 RISK FACTORS FOR CORONARY HEART DISEASE

### Nonmodifiable Risks

- Age:  $\geq 45$  years for men;  $\geq 55$  years for women
- Gender: male
- Family history of premature coronary heart disease
  - Myocardial infarction or sudden cardiac death in male first-degree relative at age less than 55 years or female first-degree relative at age less than 65 years

### Lipid Risk Factors

- Total cholesterol  $>200$  mg/dl
- LDL cholesterol  $>130$  mg/dl
- Triglycerides  $>150$  mg/dl
- HDL cholesterol  $<40$  mg/dl

### Nonlipid Risk Factors

- Hypertension  $>140/90$  mm Hg
- Cigarette smoking
- Thrombogenic state
- Diabetes
- Obesity
- Physical inactivity
- Poor diet (atherogenic)

### Probable Risk Factors (Emerging)

- Lipoprotein(a)
- Small LDL particles (pattern B)
- HDL subtypes
- Apolipoprotein B
- Homocysteine
- Fibrinogen
- High-sensitivity C-reactive protein
- Impaired fasting glucose (100-125 mg/dl)

Data from *NCEP III Guidelines, 2002*, NIH Pub. No. 02-5215.  
*HDL*, High-density lipoprotein; *LDL*, low-density lipoprotein.

**FIGURE 18-1** Serum lipoprotein fractions showing lipid composition and apoprotein components. Binding of lipoproteins to receptors is mediated through apoproteins.

been focused on therapies to reduce levels of serum cholesterol in individuals with dyslipidemia. Lipids are transported through the bloodstream in combination with specific proteins (**apoproteins**). Certain lipid-protein molecules (**lipoproteins**) are associated with a greater risk of atherosclerosis. The five major kinds of lipoproteins are shown in **Figure 18-1**. High levels of low-density lipoproteins (LDLs), which are high in cholesterol, have been associated with the highest risk. Very-low-density lipoproteins, which have large amounts of triglycerides, also appear to increase the risk. High-density lipoproteins, on the other hand, have been correlated with a decreased risk of atherosclerosis.<sup>2</sup>

High-density lipoproteins are thought to transport cholesterol from the peripheral tissues back to the liver, thus removing atheromatous plaque. The role of low-density and, indirectly, very-low-density lipoproteins is to transport cholesterol to the peripheral tissues (**Figure 18-2**). Cholesterol uptake by peripheral cells is mediated by LDL receptors on cell surfaces that bind and promote endocytosis of cholesterol. The liver normally binds and internalizes about 75% of the circulating LDL cholesterol.

Extreme cases of hyperlipidemia occur in individuals who have genetic derangements in lipid metabolism. These disorders run in families, and some are associated with the development of severe coronary atherosclerosis at a young age unless aggressively managed. The most common form of genetic hyperlipidemia (familial hypercholesterolemia) is associated with a defect in the LDL receptor on liver cells.<sup>3</sup> Inability of the liver to efficiently remove cholesterol from the bloodstream results in hyperlipidemia. Genetic disorders of lipid metabolism

**FIGURE 18-2** Schematic of lipoprotein metabolism in the body. Chylomicrons from dietary fat absorption are taken up by the liver and resynthesized into high-density lipoprotein (HDL) and very-low-density lipoprotein (VLDL). HDL circulates to the peripheral tissues and takes up excess cholesterol for transport back to the liver. Triglycerides are removed for tissue use from VLDL, which becomes intermediate-density lipoprotein (IDL). More triglyceride removal leads to the formation of low-density lipoprotein (LDL). LDL is absorbed by peripheral tissues to obtain cholesterol. About 70% of the circulating LDL returns to the liver.

are described in **Table 18-1**. Even when lipid metabolism is normal, a high-fat diet can overwhelm the liver's ability to clear LDL cholesterol from the circulation and results in hyperlipidemia. Dietary fat restriction may be beneficial in reducing cholesterol level in this case.

Atherosclerotic plaque formation is initiated by injury to the coronary artery endothelium. The specific cause of endothelial dysfunction in the early stage of atherosclerosis is uncertain; however, several potential mechanisms have been described. These include chronic hemodynamic wall stress, which may explain the typical localization of plaques at arterial branch points and the role of hypertension as a risk factor; toxins from cigarette smoke; circulating inflammatory cytokines; and hyperlipidemia. Once the injury occurs, the endothelium may become more permeable and recruit leukocytes (**Figure 18-3**). LDLs leak through the endothelium and into the vessel wall (insudation) where they are oxidized by endothelial cells and macrophages.<sup>4</sup> Oxidized lipids are damaging to the endothelial and smooth muscle cells, and stimulate the recruitment of macrophages into the vessel wall, where they engulf the lipids. Lipid-filled macrophages are called **foam cells**. The macrophages and foam cells release inflammatory mediators and growth factors that attract more leukocytes and

stimulate smooth muscle proliferation. Excess lipid and debris begins to accumulate within the vessel wall and to coalesce into a pool called the *lipid core* (Figure 18-4). Atherosclerotic plaques with large lipid cores are fragile and prone to rupture. Rupture of a plaque exposes subendothelial proteins and initiates platelet aggregation and thrombus formation. Thrombi may be asymptomatic if they are small and do not occlude the artery. Components of the thrombus may be incorporated into the plaque, causing it to enlarge. Older plaques have significant collagen and fibrin, which form a cap and tend to make the plaque more stable. Numerous therapies aimed at stabilizing vulnerable plaques and preventing thrombus formation have been studied in clinical trials. Lipid-lowering therapy is a mainstay of treatment and prevention for atherosclerosis. Targets for serum LDL cholesterol levels have been developed by the National Cholesterol Education Program (NCEP) Adult Treatment Panel (NCEP III) based on the presence of known CHD or risk factors (Table 18-2).<sup>5</sup> An update to the NCEP III is expected in 2012. In addition to risk factor modification, therapies to reduce plaque inflammation, inhibit lipid oxidation, and prevent thrombosis are in common use (Table 18-3). A major aim of therapy is to stabilize the plaques, making them less prone to rupture.

Atherosclerotic lesions generally increase in size over many years and progressively occlude the lumen of vessels. A significant reduction in blood flow can result when plaque occupies 75% or more of the arterial lumen. Clinically significant atherosclerotic plaque may be located anywhere within the three major coronary arteries or major secondary branches. All three coronary arteries are often simultaneously affected, although some individuals have only one or two diseased vessels. Surprisingly, the extent and severity of atherosclerotic lesions are not good predictors of the severity of ischemia.

Atherosclerotic coronary lesions have been characterized and attempts made to correlate the anatomic descriptions with plaque development and behavior. Typically atherosclerotic lesions begin as fatty streaks and progress to small regions of medial wall thickening with scattered macrophages at a young age. These lesions are considered to be precursor lesions and are not symptomatic.<sup>6</sup> As the plaques acquire more free lipid within the arterial wall, they are more vulnerable to rupture, thrombus formation, and progressive plaque growth. These are considered to be advanced lesions and carry a significant risk of producing disruptions in coronary blood flow. Critical narrowing of the coronary lumen over time or sudden rupture of a plaque followed by thrombus formation causes the clinical syndromes of CHD, including angina, infarction, ischemic cardiomyopathy, and sudden cardiac arrest.

Stable plaques usually are asymptomatic or may be associated with exercise-induced angina pain (stable angina pectoris). However, plaques are vulnerable to rupture or erosion, which can initiate thrombus formation and acute coronary occlusion. A variety of factors have been identified as markers of increased plaque vulnerability. These factors include (1) active inflammation within the plaque; (2) a large lipid core with a thin cap; (3) endothelial denudation (erosion) with superficial platelet adherence; (4) fissured or ruptured cap; and (5) severe stenosis predisposing to high shear stress.<sup>7</sup> Acute coronary syndrome (ACS), or unstable angina or MI, as well as sudden cardiac arrest, is nearly always associated with acute disruption of a vulnerable plaque. Because the types of plaques that are most vulnerable often do not significantly obstruct the lumen before they rupture, ACS frequently occurs in individuals whose disease had been asymptomatic. Patients with a high risk for or known presence of vulnerable plaques benefit from therapies such as lipid-lowering agents (to stabilize plaques) and antiplatelet agents (to prevent thrombosis).<sup>8</sup>

### Pathophysiology of Ischemia

Ischemia of cardiac cells occurs when the oxygen supply is insufficient to meet metabolic demands. Myocardial cells are unable to store much energy in the form of adenosine triphosphate (ATP) and must therefore continuously receive a supply of oxygen for aerobic synthesis of ATP. ATP is essential for powering myocardial contraction as well as for cell maintenance. Because the heart is unable to slow its activity when ATP supplies dwindle, a steady flow of oxygen is essential.

Factors that decrease myocardial oxygen supply or increase myocardial oxygen demand can upset the balance and result in cellular ischemia. Thus, the critical factors in meeting cellular demands for oxygen are (1) the rate of coronary perfusion and (2) the myocardial workload. Coronary perfusion can be impaired in several ways, including (1) large, stable atherosclerotic plaque, (2) acute platelet aggregation and thrombosis, (3) vasospasm, (4) failure of autoregulation by the microcirculation, and (5) poor perfusion pressure.

Myocardial workload depends on heart rate, preload, afterload, and contractility (see Chapter 17). An increase in any of these variables increases myocardial oxygen requirements and may precipitate ischemia. However, even conditions resulting in very high myocardial oxygen consumption will seldom lead to ischemia unless some underlying impairment in coronary perfusion is present.

**FIGURE 18-3** Sequence of events in the arteriolar wall associated with development of atherosclerosis. Note that smooth muscle cells migrate from the intima through the internal elastic membrane and into the intimal layer where they proliferate in response to growth factors. Macrophages in the intima release signals that alter the endothelial cell layer and induce expression of cell adhesion molecules that recruit monocytes into the tissue. (From Kumar V et al, editors: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 501.)

One or more of the aforementioned mechanisms are operative in producing clinically significant myocardial ischemia resulting in the acute or chronic coronary syndromes. Advanced fibrous plaque is thought to produce intermittent ischemia when 75% or more of the arterial lumen is occluded.<sup>9</sup> Because fibrous plaque progresses slowly over many years, the heart can develop alternative pathways for myocardial blood flow. This collateral circulation can preserve blood flow despite almost total occlusion of the coronary artery. Thus, stable fibrous plaque may produce no symptoms of ischemia unless the demand of the heart for oxygen is suddenly elevated, as occurs in exercise or stress. When the onset of ischemia is predictable with certain activities and subsides with rest, the patient is said to have a chronic coronary syndrome, called *classic* or *stable angina pectoris*.

ACS occurs when sudden obstruction of coronary blood flow results in acute myocardial ischemia. Acute obstruction is usually associated with the formation of a clot in the coronary artery at the site of a vulnerable plaque. Rupture of the plaque exposes a rough area composed of collagen and other molecules that are thrombogenic. A high fibrinogen level, as occurs in smokers, and enhanced platelet adhesiveness, as occurs in hyperlipidemia, may enhance the risk of thrombus

formation. Clot formation begins with adherence of platelets to the ruptured plaque. The platelets that initially attach release chemicals that attract more platelets, which aggregate and form a plug. The coagulation cascade may also be initiated and result in the formation of a platelet-fibrin clot that may occlude the vessel or break loose and travel farther along the vessel. Chemicals released by activated platelets include several vasoactive products (e.g., serotonin, thromboxane) that may contribute to spasm of the coronary vessel, further reducing blood flow.

Thrombosis occurs suddenly and may partially or completely obstruct the artery and cause acute ischemia. The ACS may present as unstable angina, MI, or sudden cardiac arrest. Appreciation of the role thrombus formation plays in coronary obstruction has resulted in the prophylactic use of antithrombotics, such as aspirin. Research indicates that the long-term use of small doses of aspirin reduces mortality from ischemic heart disease.<sup>10</sup>

Vasospasm usually occurs in areas of atherosclerotic plaque, but is also proposed as a mechanism of ischemia in patients who have anginal signs and symptoms but no significant amount of fibrous plaque in the coronary arteries. *Variant*, or *Prinzmetal*, angina is the term applied

**FIGURE 18-4** Pathogenesis of atherosclerosis. 1, Chronic endothelial injury leads to 2. 2, Endothelial dysfunction, permeability, and inflammation. 3, Activated monocytes infiltrate the arterial wall and smooth muscle proliferates. 4, Macrophages engulf lipid to become foam cells. 5, A lipid core forms in the arterial wall and a fibrous cap evolves. **TABLE 18-3** ACTIONS OF THERAPIES TO REDUCE CORONARY HEART DISEASE

THERAPY	MAJOR ACTIONS	OTHER ACTIONS
Angiotensin inhibitors (ACEI, ARB)	Improve endothelial function	Antioxidant (LDL), antiinflammatory
Statins	Decrease LDL-C, increase HDL-C	Improve endothelial function, antiinflammatory, antioxidant (LDL)
Fish oil (omega-3)	Decreases LDL-C, increases HDL-C	Inhibits thrombosis
Fibrates	Improve endothelial function	Increase HDL
Aspirin	Inhibits thrombosis, antiinflammatory	
Exercise	Increases HDL	Improves endothelial function

ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin II receptor blocker; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol.

to vasospasm-initiated anginal symptoms. The etiology of spasm in vessels having no significant atherosclerotic plaques is unclear, but usually responds promptly to vasodilating agents. Intense vasospasm can occur in response to certain drugs, such as cocaine.

As previously mentioned, endothelial cells are important regulators of vascular tone. They secrete variable amounts of constricting and relaxing factors to control tissue perfusion. This autoregulation of blood flow allows the microvasculature to dilate when the need for oxygen in a particular area is increased. Failure of endothelial cells to appropriately regulate flow is a potential mechanism of myocardial ischemia.<sup>11</sup> Endothelial cells can be damaged by circulating toxins from cigarette smoke, immune cells, and infectious agents. Inflammatory disorders that may alter endothelial cell function include lupus erythematosus, Kawasaki syndrome, and polyarteritis nodosa. The importance of inflammatory processes in the pathogenesis of CHD has been recognized, resulting in efforts to find markers (e.g., serum high-sensitivity C-reactive protein) and methods to reduce inflammation in those at risk.

Even if the coronary arteries and microcirculation are functioning properly, coronary perfusion may still be inadequate if perfusion pressure is low. Recall from Chapter 17 that coronary blood flow occurs primarily during diastole and depends on the driving pressure in the aorta. A fall in aortic blood pressure can significantly reduce coronary perfusion, particularly in vessels with high resistance to flow. Conditions such as shock, hemorrhage, and anesthesia may be associated with a decline in blood pressure, which decreases driving pressure and coronary perfusion and results in myocardial ischemia. However, the most common cause of cardiac ischemia is atherosclerotic coronary arteries.

### KEY POINTS

- Cardiac ischemia occurs when the heart's demand for oxygenated blood exceeds its supply. In most cases, ischemia is a result of impaired blood flow through the coronary arteries.
- CHD is associated with coronary atherosclerosis. Risk factors for CHD are the same as those for atherosclerosis of other arteries and include advancing age, male gender, family history, hyperlipidemia, diabetes, smoking, hypertension, and obesity. Endothelial injury and inflammation and lipid accumulation in the intima are thought to be the primary initiators of coronary atherosclerosis.
- Early atherosclerotic lesions are asymptomatic precursor lesions in which lipids begin to accumulate in the arterial wall. Advanced lesions may cause symptoms because of progressive arterial occlusion or acute plaque disruption and thrombus formation.
- Vulnerable plaques may rupture or become eroded, which stimulates clot formation on the plaque. Plaques with a large lipid core, thin cap, or high shear stress are vulnerable plaques.
- Chronic occlusion of a coronary vessel is associated with the clinical syndrome of stable angina. Acute occlusion is associated with plaque disruption and thrombus formation and results in ACS (unstable angina or MI).
- Myocardial ischemia may uncommonly be caused by coronary vasospasm, hypoxemia, or low perfusion pressure from volume depletion or shock.

## Clinical Features and Management of Coronary Syndromes

Five syndromes can be differentiated according to the severity and onset of cardiac symptoms. *Stable angina pectoris* and *ischemic cardiomyopathy* are chronic syndromes that usually progress slowly and are a consequence of chronic obstruction from stable atherosclerotic plaques. ACS has an abrupt onset and life-threatening consequences and is associated with acute changes in plaque morphology and thrombosis. ACS includes *unstable angina* and *MI*. Unstable angina and MI

**FIGURE 18-5** Factors that decrease coronary blood supply or increase myocardial oxygen demand can upset the balance and lead to ischemia and anginal pain.

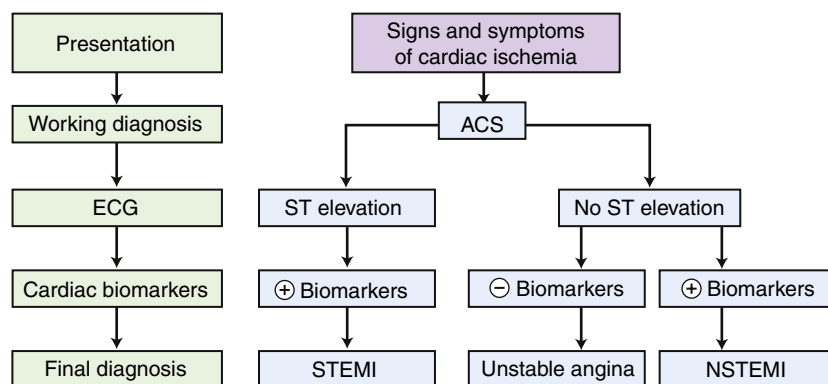

are combined together because they are difficult to differentiate in the acute stage when therapeutic decisions must be made. Any of the coronary heart syndromes may precipitate *sudden cardiac death* and associated dysrhythmias.

### Angina Pectoris

Angina pectoris literally means *chest pain* and is associated with intermittent myocardial ischemia. The length and the severity of the myocardial ischemia are insufficient to result in the acute death of cells. Bouts of chest pain and associated symptoms are generally recurrent and may be precipitated by conditions that increase myocardial oxygen demand, such as exercise, stress, sympathetic nervous system activation, and increased preload, afterload, heart rate, or muscle mass. Ischemic pain receptors from the myocardium travel to the central nervous system with the eighth cervical nerve and the first through fourth thoracic dorsal root ganglia. Sensory neurons from the jaw, neck, and arm also travel in these nerve trunks, so heart pain may be perceived as emanating from these body parts. This phenomenon is called *referred pain*. Anginal pain may be described as burning, crushing, squeezing, or choking. Pain is sometimes represented by expressions such as “an elephant is sitting on my chest” or by the patient placing a tight fist on the chest. Anginal pain may be mistakenly attributed to indigestion or dental pain. In some cases, patients have atypical symptoms of myocardial ischemia, such as back pain, fatigue, or weakness, rather than the classic symptom of chest pain.

Anginal ischemia, although temporary, may result in inefficient cardiac pumping with resultant pulmonary congestion and shortness of breath. Three patterns of angina pectoris have been described: (1) stable or typical angina, (2) Prinzmetal or variant angina, and (3) unstable or crescendo angina. All these patterns are associated with underlying coronary vessel disease and may be exhibited in a particular individual at different times and under different conditions. Unstable angina may progress to acute ischemia and is discussed in the Acute Coronary Syndrome section along with MI.

**Stable angina.** *Stable angina* is the most common form and is therefore called *classic* or *typical angina*. Stable angina is characterized by stenotic atherosclerotic coronary vessels that reduce coronary blood flow to a critical level. The stenosed arteries dilate poorly in response to increased myocardial oxygen requirements. Under conditions of increased myocardial workload, such as during physical exertion or emotional strain, coronary perfusion is inadequate and ischemia results (Figure 18-5). The

**FIGURE 18-6** The etiologies of acute coronary syndrome (ACS) are difficult to differentiate by presenting symptoms because all involve some degree of myocardial ischemia. The electrocardiogram (ECG) is used to distinguish those patients with ST elevation from those with no ST elevation. Serum levels of cardiac biomarkers are then used to make a final diagnosis. Most patients with ACS characterized by ST elevation are diagnosed with MI (STEMI), and a proportion of patients with no ST elevation also will have elevated serum markers and are diagnosed with MI (NSTEMI). Patients who do not exhibit serum enzyme elevations are usually diagnosed with unstable angina.

onset of anginal pain is generally predictable and elicited by similar stimuli each time. Stable angina is generally relieved by rest and nitroglycerin, a drug that causes coronary and peripheral vasodilation, reduces preload, and, consequently, reduces myocardial workload.

**Prinzmetal variant angina.** *Prinzmetal variant angina* is characterized by unpredictable attacks of anginal pain. Although most individuals with Prinzmetal angina have significant coronary atherosclerosis, the onset of ischemic symptoms is unrelated to physical or emotional exertion, heart rate, or other obvious causes of increased myocardial oxygen demand. Vasospasm has been identified as the probable mechanism leading to variant angina, although the cause of the vasospasm is unknown. Proposed mechanisms include atherosclerosis-induced hypercontractility, abnormal secretion of vasospastic chemicals by local mast cells, and abnormal calcium flux across vascular smooth muscle. Variant angina responds well to treatment with calcium channel-blocking drugs, which inhibit vascular smooth muscle contraction.

Patients with angina are at risk for developing ACS and need aggressive treatment for risk factor reduction and therapies to reduce the risk of plaque rupture, thrombosis, and dysrhythmia.

### Acute Coronary Syndrome

Unstable angina and MI are difficult to distinguish on the basis of clinical manifestations and are lumped together as ACS. Both are characterized by chest pain that may be more severe and lasts longer than the patient's typical angina and may occur in individuals whose disease was previously asymptomatic. In both cases, plaque rupture with subsequent acute thrombus development is thought to occur. In unstable angina, the occlusion is partial or the clot is dissolved before the death of myocardial tissue. In MI, the occlusion is complete and the thrombus persists long enough for development of irreversible damage to myocardial cells resulting in necrosis. In the past, differentiation of unstable angina and MI was based on laboratory evaluation of serum biomarker levels (e.g., MB band of creatine kinase [CK-MB], troponins I and T). If cardiac biomarkers were elevated, which is indicative of necrosis, a diagnosis of MI was made; if not, a diagnosis of unstable angina was appropriate. In a time when monitoring and management of complications were the mainstay of treatment, this approach worked well. With the advent of reperfusion therapy, which is effective only if administered early in the course of infarction, the distinction between unstable angina and MI has become less clinically relevant. Because unstable angina and MI present a similar clinical picture in

the acute phase, they have been combined in treatment protocols for ACS (Figure 18-6).<sup>12</sup> Patients with chest pain and evidence of acute ischemia on the electrocardiogram (ECG) (ST-segment elevation [STEMI]) are candidates for acute reperfusion therapy. Patients presenting with symptoms of unstable angina and no ST elevation on the ECG may not benefit from reperfusion strategies, and antiplatelet drugs are a cornerstone of therapy.<sup>13</sup> Differentiation between unstable angina and NSTEMI (non ST elevation MI) is made after obtaining cardiac necrosis markers; those patients with elevations are diagnosed with NSTEMI and those without elevations are diagnosed with unstable angina.

**Etiology and pathogenesis.** MI results when prolonged or total disruption of blood flow to the myocardium causes cellular death by necrosis or apoptosis. Acute MI is an important form of CHD resulting in more than 150,000 deaths annually in the United States.<sup>1</sup> It is estimated that an American male has a greater than 1 in 5 chance of sustaining an MI or fatal ischemic event before the age of 65. An MI may occur at any age, but the frequency rises with advancing age. Females younger than 45 years have a sixfold lesser risk of MI than men of the same age. After menopause, the rate of MI in women approaches that of their male counterparts and becomes essentially equal by age 80.<sup>9</sup>

As previously described, the initiating event in most MIs is believed to be development of a thrombus on top of an ulcerated or cracked atherosclerotic plaque. The initiating event is a sudden change in structure of the plaque. Platelets passing by the surface of the ruptured plaque adhere to it, initiate formation of a platelet plug, and activate the clotting cascade. The resultant thrombus grows until it occludes the vessel and triggers the transmural MI.

The thrombus theory of acute MI was controversial for many years because only 50% of persons dying of MI had a demonstrable thrombus at autopsy. Then DeWood and coworkers<sup>14</sup> demonstrated that about 90% of persons with acute MI had an intracoronary thrombus within 4 hours of the onset of symptoms, but only 60% had thrombi 12 to 24 hours later. This observation suggested that the thrombus was quickly dissolved by natural mechanisms after the occlusive event. Further support for the thrombus theory comes from the effectiveness of reperfusion therapies that successfully restore flow through obstructed coronary vessels and significantly reduce mortality.<sup>15</sup>

The cellular consequences of an acute interruption in blood flow to the myocardium do not occur instantaneously or uniformly. Acute occlusion causes a range of cellular events, depending on the availability

TABLE 18-4 EVOLUTION OF MORPHOLOGIC CHANGES IN MYOCARDIAL INFARCTION

TIME	GROSS FEATURES	LIGHT MICROSCOPIC	ELECTRON MICROSCOPIC
<b>Reversible Injury</b>			
0-½ hr	None	None	Relaxation of myofibrils; glycogen loss; mitochondrial swelling
<b>Irreversible Injury</b>			
½-4 hr	None	Usually none; variable waviness of fibers at border	Sarcolemmal disruption; mitochondrial amorphous densities
4-12 hr	Dark mottling (occasional)	Beginning coagulation necrosis; edema; hemorrhage	
12-24 hr	Dark mottling	Ongoing coagulation necrosis; pyknosis of nuclei; myocyte hypereosinophilia; marginal contraction band necrosis; beginning neutrophilic infiltrate	
1-3 days	Mottling with yellow-tan infarct center	Coagulation necrosis, with loss of nuclei and striations; interstitial infiltrate of neutrophils	
3-7 days	Hyperemic border; central yellow-tan softening	Beginning disintegration of dead myofibers, with dying neutrophils; early phagocytosis of dead cells by macrophages at infarct border	
7-10 days	Maximally yellow-tan and soft, with depressed red-tan margins	Well-developed phagocytosis of dead cells; early formation of fibrovascular granulation tissue at margins	
10-14 days	Red-gray depressed infarct borders	Well-established granulation tissue with new blood vessels and collagen deposition	
2-8 weeks	Gray-white scar, progressive from border toward core of infarct	Increased collagen deposition, with decreased cellularity	
>2 mo	Scarring complete	Dense collagenous scar

and adequacy of collateral blood flow, the relative workload, and the length of time that flow is interrupted. A typical myocardial infarct has several zones composed of cells in various stages of ischemia and death.

Experiments in animal models indicate that complete occlusion of a coronary vessel results in a predictable pattern of cellular dysfunction and death.<sup>9</sup> Depletion of ATP in acutely ischemic cells begins immediately, followed within 1 to 2 minutes by an impaired ability to contract. Within 10 minutes, cellular concentrations of ATP fall to half of normal, and irreversible cell injury occurs after 30 to 40 minutes of complete occlusion (Table 18-4). Ischemic necrosis begins in the subendocardial zone and spreads across the ventricular wall toward epicardial surfaces. Epicardial areas are spared for longer periods because they have the greatest collateral network of arterial vessels. The ultimate size of the infarcted tissue depends on the extent, duration, and severity of ischemia. Areas of necrosis may be intermixed with or surrounded by zones of reversibly injured cells that are marginally perfused by collaterals. Injured cells die both from necrosis and from apoptosis.<sup>3</sup> Restoring perfusion to potentially salvageable cells is an important focus of treatment. (See Chapter 4 for a discussion of necrosis and apoptosis.)

Nearly all infarcts are located in the left ventricular walls. Isolated right ventricular infarction occurs in only 1% to 3% of MIs. Occlusion of the left anterior descending artery causes 40% to 50% of acute MIs, the right coronary artery contributes another 30% to 40%, and the left circumflex contributes 15% to 20%.<sup>9</sup> The locations of the resulting infarcts are shown in Table 18-5. It is common for individuals with coronary heart disease to suffer from more than one MI during their lifetime.

The area of necrosis resulting from MI undergoes a series of morphologic changes as the infarct ages.<sup>9</sup> These morphologic changes generally cannot be detected on gross examination until 6 to 12 hours after infarct. After 18 to 24 hours, the area of infarction becomes paler than surrounding tissues. Thereafter, the area of infarction becomes obvious because it turns yellowish and soft with a rim of red vascular connective tissue (Figure 18-7). At 1 to 2 weeks, the necrotic tissue is progressively

TABLE 18-5 LOCATION OF MYOCARDIAL INFARCTION ACCORDING TO CORONARY ARTERY AFFECTED

ARTERIAL OBSTRUCTION	LOCATION OF INFARCT
Left anterior descending (40-50% of infarcts)	Anterior wall of LV near apex Anterior two thirds of interventricular septum
Right coronary (30-40% of infarcts)	Posterior wall of LV Posterior one third of interventricular septum
Left circumflex (15-20% of infarcts)	Lateral wall of LV

Data from Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 551.

LV, Left ventricle.

degraded and cleared from the site. Infarcted myocardium is particularly weakened and susceptible to rupture at this time. By 6 weeks, the necrotic tissue has been replaced by tough fibrous scar tissue.

**Diagnosis of MI.** The diagnosis of MI is based on three primary indicators: signs and symptoms, electrocardiographic changes, and elevations in the levels of specific marker proteins in the blood. Other diagnostic examinations such as cardiac catheterization, echocardiography, and radionuclide scintigraphy may also be performed to provide additional information (see Chapter 17).

Severe crushing, excruciating chest pain that may radiate to the arm, shoulder, jaw, or back is the harbinger of MI. Pain is commonly accompanied by nausea, vomiting, diaphoresis (sweating), and shortness of breath. In contrast to anginal pain, infarction pain generally lasts more than 15 minutes and is not relieved by rest or nitroglycerin.

**FIGURE 18-7** This photograph of a 5- to 7-day-old posterolateral infarction clearly shows a large, pale yellow lesion surrounded by a dark red zone of inflammation. (From Kumar V et al, editors: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders, p 369.)

In some instances, however, the MI is entirely asymptomatic and may elude detection. Asymptomatic MI has been called *silent MI* and may be detected only serendipitously at a later date. Pain may be difficult to assess in individuals with atypical presentations or a tendency to ignore or deny their symptoms. Thus, although pain is an important indicator of acute ischemia, other clinical information is often needed to correctly distinguish between angina, infarction, and noncardiac sources of pain. Women, the elderly, and patients with diabetic neuropathies more commonly complain of atypical symptoms, including fatigue, nausea, back pain, and abdominal discomfort. Atypical complaints in patients with CHD risk factors should prompt a high suspicion of MI.

**Electrocardiographic changes.** Myocardial ischemia and infarction often result in characteristic changes on ECG waveforms. Injury and ischemia are indicated on the ECG by ST-segment changes. ST-segment elevation is thought to represent acute cellular injury and ischemia. The presence of ST-segment elevation on the ECG indicates that the ischemic injury is ongoing and that efforts to improve perfusion or reduce oxygen demand may be effective in preserving myocardial muscle mass. Until measurements of specific serum markers of infarction are obtained, these patients are regarded as having unstable angina/STEMI in treatment protocols for ACS. Infarcted muscle that is necrotic and no longer electrically active is indicated by the appearance of abnormally deep ( $>0.1$  mV) or wide ( $>0.03$  seconds) Q waves and inverted T waves (Figure 18-8). These changes are very specific for MI and, when present, are diagnostic. Q waves are usually persistent findings, whereas ST-segment and T wave changes may resolve over time. Q waves take time to develop and may not be present in the acute phase of an MI.

Dysrhythmias and the characteristic ST-segment changes that accompany MI are attributed to injured and ischemic cells that have not yet become necrotic. Reversibly injured cells have limited ATP supplies to power membrane pumps and are predisposed to leakage of ions across their cell membranes. Abnormal ion flux may result in continuous current flow even when the heart is at rest. This current leak may be seen on the ECG as ST-segment elevation.

**FIGURE 18-8** **A**, Typical ECG infarction pattern showing abnormally large Q wave, ST elevation, and inverted T wave. **B**, Typical ECG in acute inferior myocardial infarction. Note the Q waves and ST-segment elevation in leads II, III, and  $aV_F$ .

The 12-lead ECG is used to localize the injured region of the left ventricle. Various leads of the 12-lead ECG “view” different regions of the heart. Abnormalities such as Q waves and ST-segment elevation in a particular lead or leads indicate that the damage is localized to the part of the left ventricle “seen” by that lead. MIs may thus be described as anterior, lateral, posterior, septal, inferior, or a combination of these sites. (The 12-lead ECG is described in Chapter 17.)

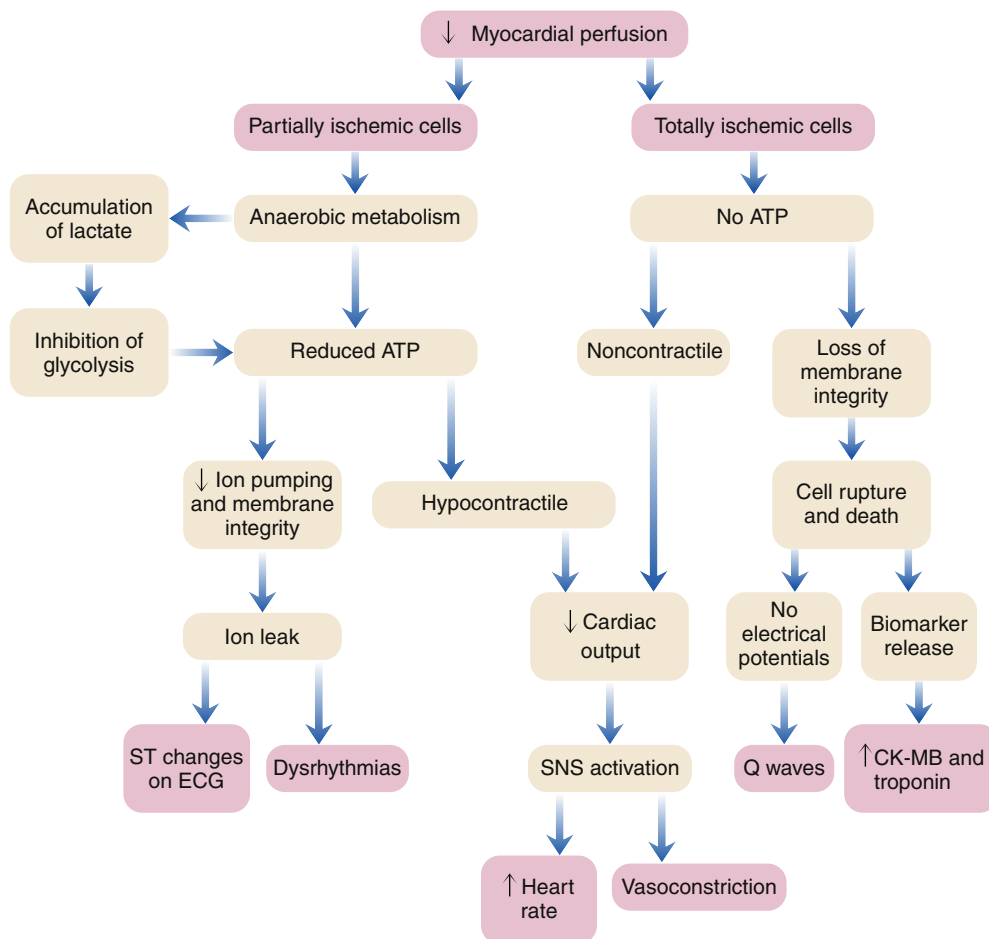

In some cases, patients presenting with ACS do not have ST elevation on the ECG. They may have ST depression or T wave changes. Some of these patients will develop elevated serum markers indicating MI. These patients have NSTEMI. The infarct size is generally smaller, and the outcomes are better than those in patients with STEMI.<sup>13</sup>

**Serum markers.** The appearance of certain proteins in the blood after myocardial cell death is a very sensitive and reliable indicator of MI. Myocardial cell death leads to elevated serum levels of myoglobin, troponin, lactate dehydrogenase, and creatine kinase.<sup>9</sup> Cardiac cells contain particular forms of these proteins called *isoforms*. An increase in the concentration of these proteins suggests leakage from fatally damaged cells that have lost plasma membrane integrity. Cardiac biomarkers have a slightly different amino acid sequence than other cell types. In particular, myocytes contain the isoforms CK-MB, troponin I, and troponin T. An elevated level of serum CK-MB is a highly specific indicator of MI and considered to be diagnostic. However, the level of CK-MB remains elevated for only 48 to 72 hours after MI. Two proteins that comprise part of the cardiac cell contractile apparatus, troponins I and T, have become the markers of choice for detecting MI. Cardiac troponin levels become elevated in serum at about the same time as the CK-MB level, but they remain elevated for a longer period. Cardiac troponins I and T are highly sensitive and specific for cardiac cell death but less helpful in detecting new infarction (reinfarction) because levels remain elevated for a prolonged period (Figure 18-9). Cardiac myoglobin levels are elevated in serum very quickly after MI and may be helpful in early detection; however, cardiac myoglobin is less specific than the other markers. All serum markers are useful diagnostically only during the acute period of MI. Patients with ACS who do not develop elevations of these serum markers are diagnosed with unstable angina.

**Clinical course.** In addition to chest pain, electrocardiographic abnormalities, and serum protein marker elevations, a person experiencing an MI may exhibit signs of cardiac inflammation, including

**FIGURE 18-9** Time course of serum marker protein elevations after acute myocardial infarction. The MB band of creatine kinase (CK-MB) and troponin I are the most specific of the protein markers. Myoglobin is an early marker but is not very specific.

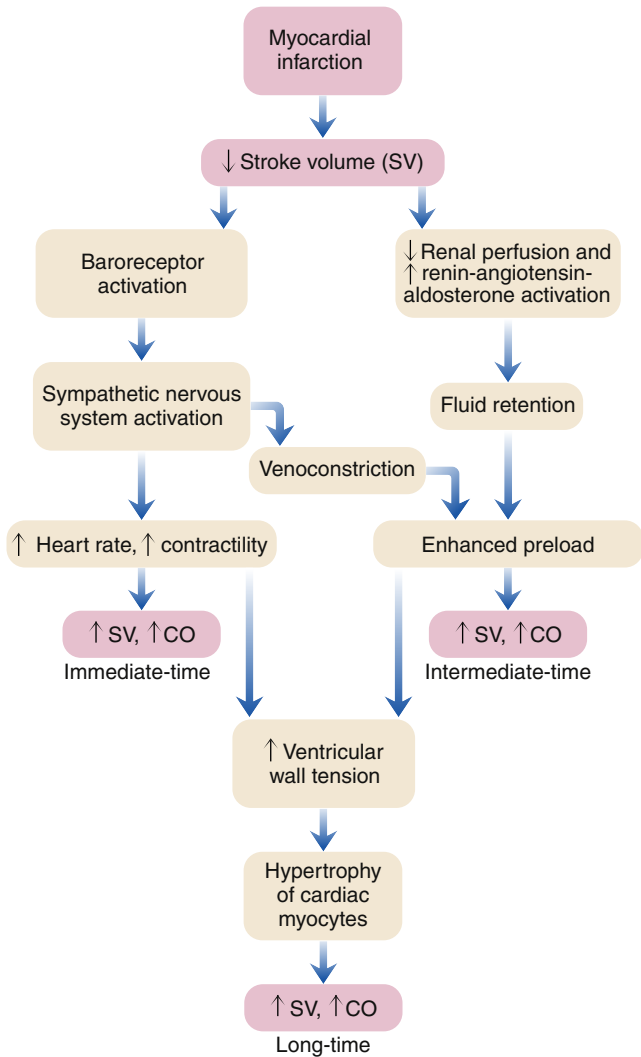

**FIGURE 18-10** Summary of events after myocardial infarction. ATP, Adenosine triphosphate; CK-MB, MB band of creatine kinase; ECG, electrocardiography; SNS, sympathetic nervous system.

fever, leukocytosis, and an elevated sedimentation rate. Symptoms of circulatory inadequacy, including fatigue, restlessness, anxiety, and weakness, may be present.

The events associated with MI are summarized in Figure 18-10. Note that totally ischemic cells, which die and become electrically silent, are the source of the clinical findings of Q waves and also release

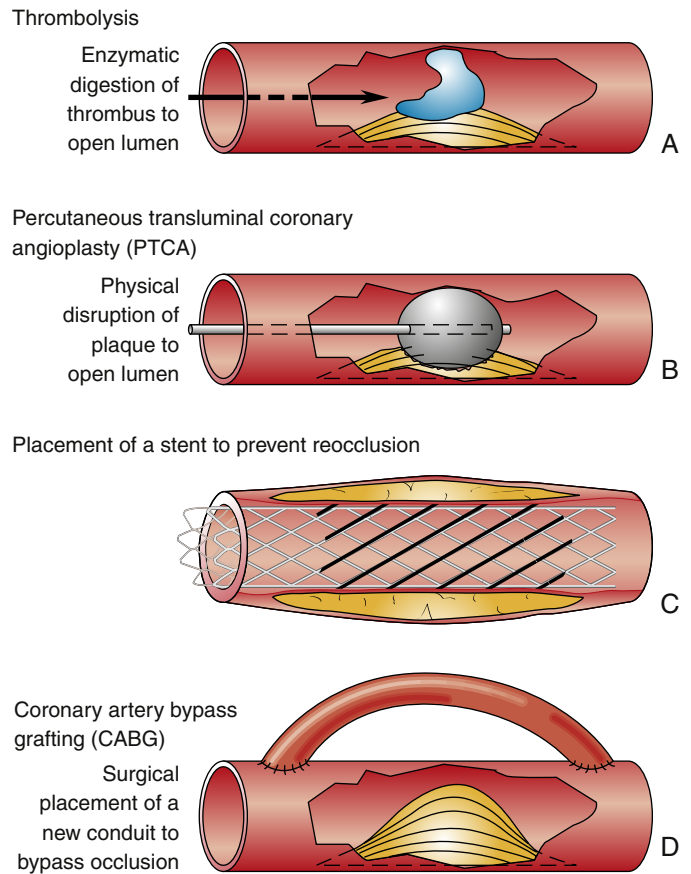

the indicative serum marker proteins (CK-MB, troponins). Partially ischemic cells are potentially salvageable but are unable to maintain normal ion flux across the cell membrane. Abnormal ion flux is responsible for the ST-segment changes in acute ischemia and also predisposes to a variety of cardiac dysrhythmias, including ventricular ectopy and conduction blocks (see Chapter 19).

**FIGURE 18-11** Compensatory responses to increase stroke volume (SV) and maintain cardiac output (CO) after myocardial infarction.

Neither partially ischemic nor totally ischemic cells are able to contract effectively, and poor stroke volume leads to a drop in cardiac output. Decreased stroke volume triggers a number of compensatory actions designed to improve cardiac output. In particular, activation of the sympathetic nervous system increases the heart rate, contractility, blood pressure, and fluid retention by the kidney. Unfortunately, these compensatory efforts impose a greater workload on the heart and may contribute to further ischemic damage. Compensatory mechanisms are shown in Figure 18-11 and include sympathetic nervous system activation, enhanced preload, and hypertrophy of cardiac myocytes.

**Prognosis and treatment.** An overall prognosis for acute MI is difficult to determine because many variables affect the outcome, including the extent and location of the infarct, previous cardiovascular health, age, and the presence of other disease processes. Of particular importance is how quickly treatment is sought. Most deaths from MI occur before the victim reaches the hospital. The in-hospital mortality rate of MI is about 10%.<sup>9</sup> In approximately 25% of cases, an MI is not accompanied by any complications (uncomplicated MI) and the patient recovers rapidly. However, the remaining 75% of MIs are followed by one or more complications.<sup>9</sup> Potential complications include

**FIGURE 18-12** Management of blocked coronary arteries includes (A) thrombolysis with drugs such as streptokinase and tissue plasminogen activator; (B) plaque disruption with percutaneous transluminal coronary angioplasty, followed by anticoagulation or stent placement; (C) placement of a stent to prevent reocclusion; and (D) coronary artery bypass grafting—surgical placement of a new conduit to bypass the occluded area of the artery.

cardiac dysrhythmias, heart failure, cardiogenic shock, ventricular rupture, pericarditis, and thromboembolism.

Treatment for MI is directed at decreasing myocardial oxygen demand and increasing myocardial oxygen supply while monitoring and managing complications as they arise. Measures to reduce myocardial workload frequently include preload and afterload reduction, heart rate control, pain relief, and activity restriction. Sympathetic antagonists, nitrates, and morphine sulfate are the mainstays of drug therapy. Measures to increase oxygen delivery to ischemic areas include oxygen administration, antiplatelet therapy with aspirin and other antiplatelet agents, thrombolytic (fibrinolytic) drugs, anticoagulants, angioplasty, stent placement, and coronary artery bypass grafting (CABG) (Figure 18-12). Therapies aimed at opening the blocked coronary artery are called reperfusion therapies.

Early detection and management of dysrhythmias and conduction disorders are an important part of the immediate care of a patient with MI. Many dysrhythmias are life threatening and, at the very least, lead to decreased cardiac output or increased myocardial workload. Continuous electrocardiographic monitoring is generally the standard of care because of the high incidence of electrical disturbances after MI. Common dysrhythmias and conduction disorders are described in Chapter 19.

### Sudden Cardiac Arrest

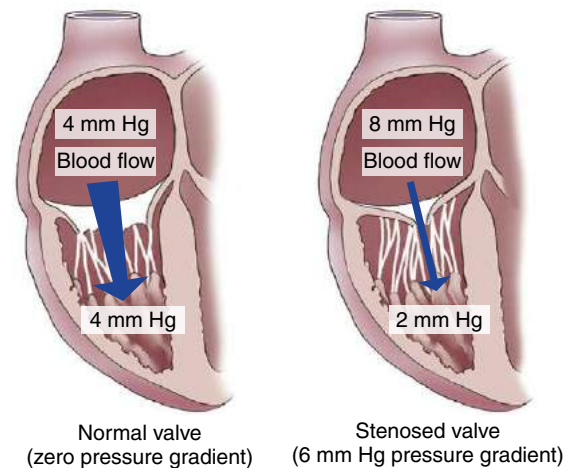

Also called sudden cardiac death (SCD), it is usually defined as unexpected death from cardiac causes within 1 hour of the onset of symptoms.<sup>16</sup> Successful resuscitation efforts by those trained in cardiopulmonary resuscitation (CPR) and use of the external defibrillators found in many public places have resulted in the increased survival of persons who experience SCD. Persons who survive SCD are at high risk for recurrence. Coronary heart disease is the source of the vast majority of cases of sudden cardiac arrest. Rarely, sudden cardiac arrest may be a complication of hereditary or acquired structural or electrical abnormalities, such as long QT syndrome. An estimated 300,000 to 400,000 individuals experience SCD each year in the United States.<sup>1</sup> Most cases are associated with coronary atherosclerosis, and may be the initial manifestation of the disease. Acute MI occurs in a subset of cases of sudden cardiac arrest.<sup>16</sup> A lethal dysrhythmia, such as ventricular fibrillation, is usually the primary cause (see Chapter 19). Ischemia from multivessel atherosclerosis, diffuse myocardial atrophy, scarring and fibrosis of old MI tissue, and electrolyte imbalances are factors that may predispose the heart to the electrical abnormalities that lead to sudden cardiac arrest.

### Chronic Ischemic Cardiomyopathy

Chronic ischemic cardiomyopathy refers to a disorder in which heart failure develops insidiously as a consequence of progressive ischemic myocardial damage. In most cases, individuals affected have a history of angina or MI, often many years before the onset of heart failure. Heart failure appears to be a consequence of slow, progressive apoptotic death of myocytes from chronic ischemia. The disease is usually found in elderly individuals. Atrophic and dead cells are scattered throughout the myocardium rather than being localized, as occurs with MI. The prognosis for patients with chronic ischemic cardiomyopathy is quite poor, with death from heart failure the common outcome. Heart failure is further discussed in Chapter 19.

#### KEY POINTS

- The clinical syndromes of CHD include angina pectoris, ACS (unstable angina, NSTEMI, STEMI), chronic ischemic cardiomyopathy, and sudden cardiac arrest. These conditions are associated with advanced coronary atherosclerosis.
- Angina is characterized by intermittent bouts of chest pain triggered by exertion and generally relieved by rest. No permanent myocardial damage occurs.
- Prolonged or severe ischemia results in MI that is characterized by severe, unrelieved chest pain, nausea and vomiting, diaphoresis, shortness of breath, and inflammation (e.g., fever, increased white blood cell count, increased sedimentation rate).
- Serum protein marker elevations and electrocardiographic changes are diagnostic of MI. The most specific and sensitive serum markers are increased levels of CK-MB and troponins I and T. ECG changes include ST-segment elevation, large Q waves, and inverted T waves.
- A drop in cardiac output as a result of MI triggers a number of compensatory responses, including sympathetic activation. The sympathetic nervous system increases the heart rate, contractility, and blood pressure, all of which increase myocardial workload.
- Treatment of acute ischemia usually includes efforts to decrease myocardial oxygen demand (e.g., sympathetic antagonists, rest, heart rate control, pain relief, afterload reduction) and increase oxygen delivery (e.g., thrombolysis, angioplasty, coronary artery bypass grafting).

**FIGURE 18-13** Development of a pressure gradient across a stenosed valve. The chamber behind the narrowed valve opening must work harder to force blood through the valve.

### ENDOCARDIAL AND VALVULAR DISEASES

Endocardial and valvular structures may be damaged by inflammation and scarring, calcification, or congenital malformations. These processes interfere with the normal valvular property of unimpeded, unidirectional flow. Although congenital malformations may affect any valve, acquired valvular disorders generally involve the mitral or aortic valves. Abnormalities in valvular function cause altered hemodynamics in the heart and generally result in increased myocardial workload. Ultimately, heart failure may result from significant valvular dysfunction.

Normally, heart valves open completely, so blood flows through with little or no pressure difference across the valve. Failure of a valve to open completely is termed **stenosis**. Significant hemodynamic consequences generally begin to occur when the valve opening is reduced to half its normal diameter. The severity of stenosis can be estimated by the degree of pressure gradient across the valve (Figure 18-13). Stenosis results in extra pressure work for the heart because blood must be forced through the high resistance of a narrow valve opening. Stenosis generally progresses slowly over years to decades, which allows time for affected heart chambers to compensate through myocardial cell hypertrophy.

**Regurgitation** (insufficiency) refers to the inability of a valve to close completely, thereby allowing blood to flow backward across the valve when no flow should be occurring. Regurgitation may develop suddenly from valvular infection or rupture of a supporting papillary muscle. Sudden regurgitation is poorly tolerated inasmuch as little compensation is possible. Regurgitation results in extra volume work for the heart because more blood must be pumped to maintain adequate forward flow.

Diseased valves may exhibit elements of both stenosis and regurgitation, although one problem usually predominates. Postinflammatory scarring from rheumatic heart disease and valvular calcification with aging are the primary causes of stenosis (Figure 18-14). A wide variety of diseases of the endocardium may lead to valvular regurgitation, including rheumatic heart disease and infective endocarditis, which are discussed later in this chapter. Damaged valves are susceptible to infection, and antibiotic prophylaxis may be indicated for dental, surgical, and diagnostic procedures. The major causes of acquired mitral and aortic valvular diseases are listed in Table 18-6. Valvular disorders are often associated with abnormal turbulence of blood flow that produces heart sounds called *murmurs*. Careful assessment of the location and character of a murmur can help identify the underlying

valvular abnormality. Defining characteristics of common valve disorders are described in Table 18-7.

### Disorders of the Mitral Valve

Three important disorders of the mitral valve are stenosis, regurgitation, and mitral valve prolapse.

#### Mitral Stenosis

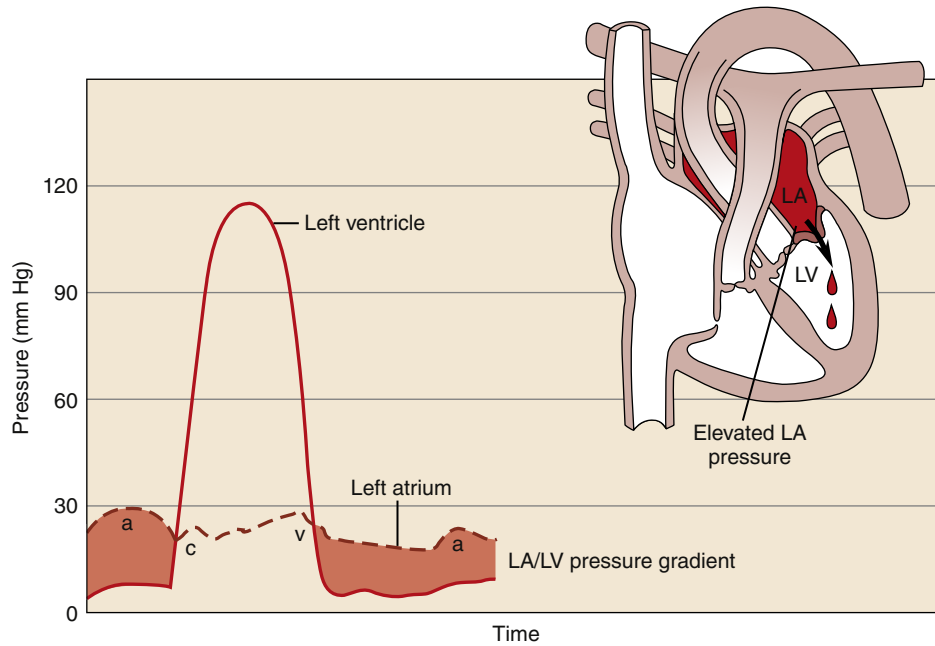

In *mitral stenosis* the flow of blood from the left atrium into the left ventricle is impaired. Mitral stenosis is therefore characterized by an

**TABLE 18-7 DEFINING CHARACTERISTICS OF MURMURS**

VALVE DISORDER	QUALITY	LOCATION, RADIATION
Mitral stenosis	Low-pitched rumble, diastolic	At apex
Mitral regurgitation	Loud, pansystolic, high pitched, blowing	Loudest at apex, transmitted to left axilla
Aortic stenosis	Harsh, midsystolic, crescendo-decrescendo	Right second intercostal space, transmitted to neck
Aortic regurgitation	Faint, blowing, diastolic	Left sternal border, aortic area, apex

abnormal left atrial–left ventricular pressure gradient during ventricular diastole (Figure 18-15). Normally the pressures in the atrium and ventricle are nearly equal during ventricular diastole when the mitral valve is open. Figure 18-15 shows that with mitral valve stenosis, atrial pressure remains higher than ventricular pressure throughout diastole. As the stenosis worsens, the pressure gradient often increases. In normal adults the area of the mitral valve orifice is 4 to 6 cm<sup>2</sup>, and symptoms of stenosis do not appear until the orifice is narrowed to 2 cm<sup>2</sup>. When the mitral valve orifice narrows to 1 cm<sup>2</sup>, a critical stenosis is present and a pressure gradient of 20 mm Hg or more usually develops across the valve.<sup>17</sup> Increased pressure work of the left atrium leads to atrial chamber enlargement and hypertrophy. Progressive narrowing of the mitral valve may lead to markedly elevated left atrial pressures and subsequent increased pulmonary vascular pressure. If uncorrected, mitral stenosis may result in chronic pulmonary hypertension, right ventricular hypertrophy, and right-sided heart failure.

The signs and symptoms of mitral stenosis are due to congestion of blood volume and increased pressure in the left atrium and pulmonary circulation, as well as decreased stroke volume of the left ventricle because of deficient filling. Symptoms are exacerbated by conditions that further decrease left ventricular filling such as an increased heart rate. Atrial dysrhythmias such as atrial fibrillation are common because of excessive atrial volume. Atrial enlargement and fibrillation also predispose to the development of atrial clots, which may dislodge and result in systemic embolization and stroke. Signs and symptoms of mitral stenosis secondary to pulmonary congestion may include orthopnea, cough, dyspnea on exertion, paroxysmal nocturnal dyspnea, abnormal

**FIGURE 18-15** Mitral stenosis is characterized by an abnormal left atrial (LA)-to-left ventricular (LV) pressure gradient during ventricular diastole (shaded area).

**FIGURE 18-16** Mitral regurgitation causes characteristic giant V waves on the left atrial (LA) pressure monitor. LV, left ventricular.

breath sounds, and poor arterial oxygenation. Reduced left ventricular stroke volume may be apparent as fatigue, poor activity tolerance, and weakness. Exertional dyspnea is the most common complaint. Blood rushing through the narrowed mitral valve during ventricular diastole can sometimes be heard as a low-pitched, rumbling diastolic murmur at the heart's apex. In many cases, an opening snap may also be heard.

### Mitral Regurgitation

Mitral regurgitation is characterized by backflow of blood from the left ventricle to the left atrium during ventricular systole. Elevation of left atrial volume and pressure by regurgitant flow leads to characteristic

giant V waves on the atrial pressure monitor (Figure 18-16). The severity of mitral insufficiency is related to the amount of left ventricular stroke volume that is regurgitant and depends, in part, on the aortic resistance to flow (afterload). A high afterload increases the amount of regurgitant flow. The left ventricle must pump a greater volume to compensate for the regurgitant flow and maintain an effective stroke volume. Both the left atrium and the left ventricle generally dilate and hypertrophy to compensate for the extra volume that they are required to pump. In most patients with mitral regurgitation, compensation is maintained for many years before symptoms occur.<sup>17</sup> If severe and uncorrected, mitral regurgitation may eventually lead to left-sided heart

failure. The signs and symptoms of mitral regurgitation are similar to those described for mitral stenosis and result from pulmonary congestion and poor cardiac output. Chronic weakness and fatigue are common complaints. The murmur of mitral regurgitation usually occurs throughout ventricular systole (pansystolic), radiates toward the left axilla, and has a high-pitched blowing character. The arterial pulse may be helpful in distinguishing the systolic murmur of mitral regurgitation from that of aortic stenosis. The upstroke of the pulse is sharp and full in mitral regurgitation, whereas it is weaker and delayed in aortic stenosis.

### Mitral Valve Prolapse

Approximately 2% to 3% of the population have mitral valves that balloon into the left atrium during ventricular systole.<sup>17</sup> This condition is called *mitral valve prolapse* (Figure 18-17). Women are affected twice as often as men. In a great majority of cases, the disorder is asymptomatic and diagnosed only incidentally on routine physical examination. In some cases, the prolapse is sufficient to cause a degree of mitral regurgitation. The cause of this valvular abnormality is uncertain, although it is commonly associated with other connective tissue disorders such as Marfan syndrome or scoliosis.

The finding of 2 mm or more displacement of the mitral valve leaflets above the annulus on echocardiogram is an important diagnostic criterion.<sup>17</sup> Mitral valve prolapse may be detected by a midsystolic click or systolic murmur. Individuals whose disease is symptomatic may experience palpitations, rhythm abnormalities, dizziness, fatigue, dyspnea, chest pain, or psychiatric manifestations such as depression and anxiety. The large majority of affected persons have no untoward effects and most are unaware of their condition. Complications of mitral valve prolapse are relatively rare and include infective endocarditis, sudden cardiac arrest, cerebral embolic events, and progression to mitral regurgitation.

### Disorders of the Aortic Valve

The primary disorders of the aortic valve are stenosis and regurgitation.

#### Aortic Stenosis

With the decline in incidence of rheumatic fever, the predominant cause of aortic stenosis is age-related calcification. The hallmark of this disorder is the formation of calcium deposits on the aortic cusps (see Figure 18-14). Calcification is particularly common in patients with a congenital bicuspid aortic valve. Aortic calcifications accumulate over several decades and generally become clinically apparent in individuals 70 to 90 years old. Rheumatic heart disease, on the other hand, occurs primarily in children and young adults and now accounts for only a small percentage of cases of acquired aortic stenosis in the United States.

Aortic stenosis results in obstruction to aortic outflow from the left ventricle into the aorta during systole. This condition is characterized by a left ventricular–aortic pressure gradient during ventricular ejection (Figure 18-18). The left ventricle produces high systolic pressure to overcome resistance of the stenotic aortic valve. The slow development of aortic stenosis allows the heart to maintain stroke volume by compensatory left ventricular hypertrophy. The combination of high left ventricular pressure and hypertrophy predisposes the heart to ischemia and attacks of anginal pain. Continued high left ventricular afterload from a stenotic aortic valve may lead to left-sided heart failure.

Critical obstruction is characterized by a mean systolic pressure gradient exceeding 40 mm Hg and an effective aortic valve orifice less than 25% of normal (<1.0 cm<sup>2</sup> in an average-sized adult).<sup>17</sup> The symptoms of aortic stenosis are due to diminished cardiac output, with pulmonary complications occurring later as the left ventricle fails. Syncope, fatigue, low systolic blood pressure, and faint pulses are common signs and symptoms. Angina occurs frequently in patients with

**FIGURE 18-17** Appearance of mitral valve prolapse. Note how the valve balloons up into the left atrium. (From Kumar V et al, editors: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 564. Courtesy William D. Edwards, MD, Mayo Clinic, Rochester, MN.)

critical aortic stenosis and is often initiated by exertion and relieved by rest. Angina is thought to occur because of thickening of the ventricular wall with reduced perfusion and high intraventricular wall tension. Syncope and “graying out” spells may occur when cerebral perfusion is inadequate. The onset of atrial fibrillation or heart block may precipitate worsening of symptoms. A characteristic murmur occurs during ventricular systole and varies in intensity, progressively getting louder and then diminishing (crescendo-decrescendo). The murmur of aortic stenosis generally radiates to the neck. The heart rate is usually slow to allow for a necessarily long ejection phase, and a prominent  $S_4$  is usually present. Surgical correction is indicated for symptomatic aortic stenosis because medical therapy is not effective.

#### Aortic Regurgitation

Aortic regurgitation results from an incompetent aortic valve that allows blood to leak back from the aorta into the left ventricle during diastole. Causes of aortic regurgitation are similar to those of mitral regurgitation (see Table 18-6). Valvular incompetence may be secondary to an abnormal aortic valve or to aortic root dilation with widening of the aorta such that the valve leaflets no longer appose. Aortic root dilation is a more common cause of aortic regurgitation than primary valvular disease.<sup>17</sup> The aorta may dilate because of degenerative changes with aging or as a consequence of connective tissue disease. The left ventricle becomes volume overloaded because it contains its usual preload, received from the atrium, plus regurgitant blood from the aorta. The left ventricle compensates for this extra volume work with hypertrophy and dilation. A larger than normal stroke volume is thus achieved and produces a high systolic blood pressure. Diastolic blood pressure is generally lower than normal because of rapid runoff of blood into the ventricle. The large stroke volume and rapid decline in diastolic blood pressure result in a bounding peripheral pulsation, and the head may bob with each systole (Figure 18-19).

Aortic insufficiency is characterized by a high-pitched blowing murmur during ventricular diastole. Patients may complain of palpitations and a throbbing or pounding heart because of the large ventricular stroke volume. The major complication of aortic regurgitation is left-sided

**FIGURE 18-18** Aortic stenosis is characterized by an abnormal left ventricular (LV)-to-aortic pressure gradient (shaded area). LA, Left atrium.

**FIGURE 18-19** Typical arterial pressure fluctuation in aortic regurgitation showing a high systolic pressure and a low diastolic pressure.

heart failure as a result of the high ventricular workload. However, chronic aortic regurgitation is well tolerated for years, and asymptomatic individuals can delay valve replacement surgery. Acute aortic regurgitation is poorly tolerated and necessitates immediate correction.

## Diseases of the Endocardium

### Rheumatic Heart Disease

Rheumatic heart disease is an uncommon but serious consequence of rheumatic fever. The incidence of rheumatic fever has steadily declined in the United States, but the disease still affects an estimated 15 million people worldwide.<sup>18</sup> Rheumatic fever is an acute inflammatory disease that follows infection with group A  $\beta$ -hemolytic streptococci.

Damage is due to an immune attack on the individual's own tissues. For incompletely understood reasons, antibodies against the streptococcal antigens are also directed against self tissues, possibly because of

an immune hypersensitivity reaction resulting from cross-reactivity between streptococcal antigens and certain tissue molecules. Epitopes on the bacterial surface are similar to proteins on cardiac myosin, valve, skin, joint, and brain tissue. Most individuals with group A  $\beta$ -hemolytic streptococcal infection do not develop rheumatic fever, and a number of genetic factors are associated with development of the disease.<sup>9</sup>

The acute infection occurs primarily in children and is accompanied by fever and a sore throat. In only 3% of children with pharyngeal streptococcal infection does rheumatic fever eventually develop.<sup>9</sup> Prompt initiation of antibiotic therapy is often effective in primary prevention of rheumatic fever. Rheumatic fever diffusely affects connective tissue in joints, the heart, and the skin. The central nervous system and kidney are also frequently involved. Inflammation of the heart usually includes all layers and results in carditis. Endocardial inflammation results in valvular swelling, erosions, and clumping of platelets and fibrin on valve leaflets. Scarring and shortening of valvular structures become progressively more severe. The myocardium and pericardium may show signs of rheumatic inflammation; however, if there is no associated valvular inflammation the diagnosis is unlikely to be rheumatic fever. Other hallmarks of rheumatic fever include joint inflammation, involuntary movements (Sydenham chorea), and a distinctive truncal rash. An elevated antibody titer against streptococcal products (antistreptolysin O, anti-DNase B) may help confirm the diagnosis. Unfortunately, individuals who experience rheumatic fever have a high chance of recurrence if they have another pharyngeal streptococcal infection.<sup>19</sup> Prophylactic antibiotic therapy is recommended for individuals who develop rheumatic fever.

### Infective Endocarditis

Infective endocarditis is caused by invasion and colonization of endocardial structures by microorganisms with resulting inflammation. A variety of organisms are known to have an affinity for the endocardium and for the cardiac valves in particular. Valvular lesions include growths of microorganisms enmeshed in fibrin deposits. These growths are called *vegetations*. They may become quite large, interfering with valvular function and predisposing to embolus formation. The most common bacterial culprits are several strains of *Streptococcus* and *Staphylococcus aureus*. A requisite

**FIGURE 18-20** Mitral valve endocarditis from subacute bacterial infection with *Streptococcus viridans*. The left ventricle contains numerous abscesses formed by seeding from vegetations traveling in the coronary arteries. (From Kumar V et al, editors: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 568.)

for infective endocarditis is invasion of the bloodstream by infective organisms. The portal of entry may be obvious, as with an overt infection, intravenous drug abuse, or invasive surgical or dental procedures. Sometimes the source may be less obvious, such as the gastrointestinal tract or the oral cavity. Once the organism enters the circulation, several factors influence its ability to attack endocardial structures and cause disease.

Acute infective endocarditis may theoretically develop in any individual if host resistance is low, if the organism is highly virulent, and if the bacterial invasion is sufficiently large. Acute infective endocarditis usually affects individuals with previously normal valves and leads to death in a large percentage of patients. The overall mortality rate for infective endocarditis is between 13% and 20%.<sup>20</sup> However, mortality rates vary with the type of infective organism, with *Pseudomonas aeruginosa* endocarditis having greater than 50% mortality. Intravenous drug abusers are particularly susceptible to acute infective endocarditis. Subacute infective endocarditis has a more insidious onset and generally affects individuals with some preexisting propensity for valvular colonization. The offending organisms are less virulent. Rheumatic heart disease, congenital heart abnormalities, mitral valve prolapse, calcified valves, and prosthetic valves are important predisposing factors. Immunosuppression and repeated exposure through intravenous drug abuse are other predisposing influences. *S. aureus*, *Staphylococcus epidermidis*, and *Candida*, which colonize the skin, are common offenders in intravenous drug users. The valves on the right side of the heart commonly are infected in this population.

Organisms associated with subacute infective endocarditis usually are not virulent enough to attack normal healthy endocardium but are able to gain a foothold in hearts with some underlying predisposition. Preexisting cardiac disease may allow the formation of platelet-fibrin deposits on the valves because of abnormal or stagnant blood flow patterns. These deposits become the site of organism attachment. Antibodies against the invader may further assist attachment by causing clustering of organisms.

The diagnostic findings in both acute and subacute infective endocarditis are much the same. Large, bulky, bacteria-laden vegetations hang from the heart valves and adjacent endocardial surfaces (Figure 18-20). In addition to the risk of embolization, vegetations may cause erosion or perforation of the underlying valve leaflet. In acute forms, adjacent myocardium may be eroded and abscessed. With time, valvular vegetations become fibrotic and calcified.

Unfortunately, the clinical features of subacute infective endocarditis are quite nonspecific, with low-grade fever the most consistent sign. Nonspecific fatigue, weight loss, and flulike symptoms may be the only clues. Positive blood cultures may help confirm the diagnosis. In contrast, acute infective endocarditis has a more obvious onset with fever, chills, malaise, and, frequently, a heart murmur. Complications such as valvular insufficiency, myocardial abscess, embolization, and renal disease generally occur early in the course of the disease. The interval between initiation of bacteremia and the onset of symptoms is less than 2 weeks in the majority of cases.<sup>20</sup> Management of the acute and subacute types centers on antibiotic therapy, with surgical replacement of valves when indicated. Prevention through prophylactic antibiotic therapy in individuals at risk is an important consideration.

The endocardium is prey to many other disorders, such as systemic lupus erythematosus (an immunologic disease), calcium deposition secondary to renal disease, and nonbacterial thrombotic endocarditis secondary to hypercoagulable states associated with cancer.

#### KEY POINTS

- Valvular disorders are of two primary types. Failure of stenotic valves to open properly causes an abnormal pressure gradient across the valve and increases the pressure work of the heart. Regurgitant valves allow blood to flow backward across the valve and result in extra volume work for the heart.
- Mitral stenosis is characterized by a large left atrial–to–left ventricular pressure gradient during ventricular diastole. Mitral stenosis leads to left atrial and pulmonary congestion.
- Mitral regurgitation is characterized by large V waves in the left atrial pressure tracing and a loud systolic murmur that radiates to the left axilla. Mitral regurgitation increases the work of the left atrium and ventricle and can lead to left-sided heart failure.
- Aortic stenosis results in obstruction to the outflow of blood from the left ventricle. It is characterized by a large left ventricular–to–aortic pressure gradient and a crescendo-decrescendo murmur during systole that radiates to the neck. The extra pressure work can lead to left ventricular hypertrophy and failure.
- Aortic regurgitation is characterized by a high systolic and low diastolic blood pressure and a bounding pulse. The murmur of aortic regurgitation occurs during diastole. Left ventricular failure may result because of the high-volume work.
- Rheumatic heart disease results from immune-mediated damage to the endocardium after group A  $\beta$ -hemolytic streptococcal infection.
- Acute and subacute infective endocarditis results in the growth of bacteria-laden vegetations on heart valves. In addition to valvular erosion and scarring, embolization may occur.

## MYOCARDIAL DISEASES

In addition to the diseases already discussed, which secondarily affect the myocardium as a consequence of inadequate blood supply or endocardial infection, two additional categories of diseases of heart muscle are *myocarditis* and *cardiomyopathy*. Myocarditis is an inflammatory disorder of the heart muscle characterized by necrosis and degeneration of heart muscle cells. Cardiomyopathy includes several disorders of the heart muscle that may be genetic or acquired but are noninflammatory. The division of these categories is somewhat arbitrary; however, the clinical course of myocarditis is generally acute and stormy, with recovery or death from cardiac failure occurring weeks to months after the onset of symptoms. In contrast, the cardiomyopathies generally evolve more insidiously over years, with few symptoms until the heart slips into failure.

## Myocarditis

Myocarditis is characterized by inflammation, leukocyte infiltration, and necrosis of cardiac muscle cells. Causes of myocarditis are many and include microbial agents, several forms of immune-mediated disease, and several physical agents. The more common causes of myocarditis are listed in **Box 18-2**. The true incidence of myocarditis is unknown because the diagnosis relies largely on circumstantial evidence.

Most cases of myocarditis in the Northern hemisphere are associated with viral infections.<sup>21</sup> Cardiac involvement generally appears days or weeks after a viral infection elsewhere in the body. Documenting a viral cause is often impossible, but a rising antibody titer supports the diagnosis. The mechanism of viral myocarditis is incompletely understood. Direct viral cytotoxicity may occur to some extent, and the virus may evoke an immune response directed against the heart. Most investigators currently believe the second mechanism to be most important. In some countries, nonviral organisms are more commonly associated with myocarditis. For example, the protozoan *Trypanosoma cruzi*, which is endemic in areas of Central and South America, infects about 18 million persons worldwide.<sup>21</sup> A myocarditis called *Chagas disease* eventually develops in a large number of infected individuals and is an important cause of cardiovascular death in endemic countries.

In some cases of myocarditis, the immune system reaction against the myocardium appears to be the primary cause. Antibodies or activated lymphocytes are formed against heart tissue. Several drugs, including penicillin, tend to evoke a hyperactive immune response in some individuals and may cause an allergic-type reaction that affects the myocardium. Myocarditis accompanies some autoimmune disorders, such as systemic lupus erythematosus (SLE) and polymyositis. Toxins

and chemical causes of myocarditis include cocaine, chemotherapeutic agents, snake bite and insect venoms, lead, and numerous others. Regardless of the specific cause, inflammation of cardiac muscle is characteristic.

Acute myocarditis is commonly characterized by left ventricular dysfunction or general dilation of all four heart chambers. The ventricular myocardium is “flabby” with patchy or diffuse necrotic lesions. The heart muscle appears inflamed and edematous with white blood cell infiltrates. Endocardial structures are usually normal. The clinical course of acute myocarditis varies in severity from asymptomatic to rapidly evolving heart failure. Generalized symptoms related to the inflammatory process may be present, as well as electrocardiographic changes caused by myocardial cell death. Common presenting symptoms include fatigue, dyspnea on exertion, and dysrhythmia with associated palpitations. Many persons recover completely, whereas others have progressive disease that is manifested years later as dilated cardiomyopathy. Thus myocarditis and the cardiomyopathic forms of myocardial disease overlap and are difficult to separate. Therapy is supportive and usually includes therapy for heart failure (see Chapter 19). Immunosuppressive therapy may be considered for myocarditis associated with autoimmune disease or hypersensitivity reactions.

## Cardiomyopathy

Cardiomyopathies can be classified by cause or by functional impairments. Those with known causes have been classified as specific cardiomyopathy by the World Health Organization (**Table 18-8**).<sup>22</sup> Those cardiomyopathies with uncertain cause are classified based on their predominant pathophysiologic features. The major functional classes are the dilated, hypertrophic, and restrictive forms (**Figure 18-21**). The terms *primary cardiomyopathy* for dysfunction of unknown cause and *secondary cardiomyopathy* for myocardial dysfunction of known cause are also in clinical use. Definitions of primary cardiomyopathy usually exclude hypertensive, ischemic, congenital, valvular, pericardial, and inflammatory myocardial disorders; however, classification of cardiomyopathy continues to evolve as more is understood about the genetic contributions to the condition.

## Dilated Cardiomyopathy

Dilated or congestive cardiomyopathy (DCM) is characterized by cardiac failure associated with dilation of one or both ventricular chambers. Numerous factors are suspected in the initiation of dilated cardiomyopathy, including alcohol toxicity, genetic abnormality, pregnancy, and postviral myocarditis. Alcohol and its metabolites are toxic to heart muscle cells and are associated with thiamine and other nutritional deficiencies. Peripartum cardiomyopathy is the term applied to cases of dilated cardiomyopathy discovered just before or just after delivery. The etiology is unclear; however, inflammatory factors are implicated and a high incidence of lymphocytic activation has been reported. A risk of recurrence in subsequent pregnancies has been noted.

In some cases, dilated cardiomyopathy runs in families and has a presumed genetic basis. At least 20% of patients with DCM have a first-degree relative with signs of DCM.<sup>23</sup> Inherited genetic defects in the protein structure of the myocardial cytoskeleton appear to be contributory in most genetic forms of DCM.

Postviral myocarditis is an attractive pathogenic mechanism for dilated cardiomyopathy, as previously discussed. Myocardial biopsy specimens often reveal signs of inflammatory injury; however, progression from acute myocarditis to dilated cardiomyopathy is difficult to document. A variety of other causes have been proposed as well. In fact, dilated cardiomyopathy is a bit of a catch-all term invoked to cover cases of dilated congestive failure having no well-defined origin.

Histologic examination of hearts with dilated cardiomyopathy reveals nonspecific changes in the majority of cases.<sup>23</sup> Hypertrophied

### BOX 18-2 ETIOLOGIC AGENTS OF MYOCARDITIS

TABLE 18-8 CLASSIFICATION OF THE CARDIOMYOPATHIES

DISORDER	DESCRIPTION
Dilated cardiomyopathy	Dilatation and impaired contraction of left or both ventricles. Caused by familial/genetic, viral and/or immune, alcoholic/toxic, or unknown factors, or is associated with recognized cardiovascular disease.
Hypertrophic cardiomyopathy	Left and/or right ventricular hypertrophy, often asymmetric, which usually involves interventricular septum. Mutations in sarcolemmal proteins cause disease in many patients.
Restrictive cardiomyopathy	Restricted filling and reduced diastolic size of either or both ventricles with normal or near-normal systolic function. Is idiopathic or associated with other disease (e.g., amyloidosis, endomyocardial disease).
Dysrhythmogenic right ventricular	Progressive fibrofatty replacement of right, and to some degree left, ventricular cardiomyopathy myocardium. Familial disease is common.
Unclassified cardiomyopathy	Diseases that do not fit readily into any category. Examples include systolic dysfunction with minimal dilatation, mitochondrial disease, and fibroelastosis.
<b>Specific Cardiomyopathies</b>	
Ischemic cardiomyopathy	Presents as dilated cardiomyopathy with depressed ventricular function not explained by extent of coronary artery obstructions or ischemic damage.
Valvular cardiomyopathy	Presents as ventricular dysfunction that is out of proportion to abnormal loading conditions produced by valvular stenosis and/or regurgitation.
Hypertensive cardiomyopathy	Presents with left ventricular hypertrophy with features of cardiac failure attributable to systolic or diastolic dysfunction.
Inflammatory cardiomyopathy	Cardiac dysfunction as a consequence of myocarditis.
Metabolic cardiomyopathy	Includes a wide variety of causes, including endocrine abnormalities, glycogen storage disease, deficiencies (such as hypokalemia), and nutritional disorders.
General systemic disease	Includes connective tissue disorders and infiltrative diseases such as sarcoidosis and leukemia.
Muscular dystrophies	Includes Duchenne, Becker-type, and myotonic dystrophies.
Neuromuscular disorders	Includes Friedreich ataxia, Noonan syndrome, and lentiginosis.
Sensitivity and toxic reactions	Includes reactions to alcohol, catecholamines, anthracyclines, irradiation, and others.
Peripartur cardiomyopathy	First becomes manifest in peripartur period, but it is likely a heterogeneous group.

**FIGURE 18-21** The three types of cardiomyopathy. **A**, Normal heart. **B**, Dilated cardiomyopathy demonstrating enlargement of all four chambers. **C**, Hypertrophic cardiomyopathy showing a thickened left ventricle. **D**, Restrictive cardiomyopathy characterized by a small left ventricular volume.

or atrophied myocytes may be apparent, along with mild fibrosis. The clinical picture is one of slowly progressing biventricular heart failure with low ejection fraction (EF). Annual mortality rates vary widely from 10% to 50% depending on the etiology of DCM.

**Hypertrophic Cardiomyopathy**

In contrast to dilated cardiomyopathy, hypertrophic cardiomyopathy (HCM) is characterized by a thickened, hyperkinetic ventricular muscle mass. The hypertrophy is often not uniform throughout the heart, and in about 25% of patients the septum is most affected and causes a dynamic aortic outflow obstruction. The left ventricle is usually more involved than the right.

Substantial evidence suggests that this form of cardiomyopathy is transmitted genetically in an autosomal dominant pattern.<sup>9</sup> Abnormalities of cardiac sarcomere proteins have been identified in several familial forms of the disease. Abnormalities in genes coding for myosin heavy chain, myosin-binding protein C, and troponin T account for 70% to 80% of HCM cases.<sup>9</sup> The remaining third of cases are thought to have mutations in other cytoskeletal proteins. Although the genetic basis of hypertrophic cardiomyopathy is well established, the events leading from cytoskeletal protein mutations to clinical disease are poorly understood.

There is wide variation in the expression of HCM. It may be asymptomatic or may be associated with symptoms of ventricular outflow obstruction or impaired diastolic filling. Outflow obstruction is particularly problematic when the myocardial hypertrophy is localized in the subaortic septal region. Strenuous activity may precipitate profound outflow obstruction, negligible stroke volume, and sudden death. Other factors contributing to reduced stroke volume are the smaller intraventricular chamber size and a noncompliant ventricle characteristic of diastolic dysfunction with preserved EF. The most common symptoms of HCM are dyspnea and angina. Microscopically,

the hypertrophied muscle cells appear disorganized and haphazardly oriented into whorls rather than the usual linear arrangement.

The clinical course of HCM is variable, with most patients experiencing little change in cardiac function over many years. Surgery to thin the septal thickening (myectomy) is rarely performed any longer because this technique has been superseded by drug therapy. In general, drugs that increase myocardial contractility or heart rate are avoided because they further impair diastolic filling and worsen aortic outflow obstruction.  $\beta$ -Adrenergic antagonists and calcium channel-blocking drugs may be used to dampen the hypercontractility. Normal life expectancy is possible. Myocardial ischemia is common, and the risk of sudden cardiac arrest is significant. Patients who die suddenly from HCM usually have fatal dysrhythmias that may occur when sedentary but are frequently associated with vigorous physical exertion.<sup>23</sup>

### Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM) is the rarest form and is characterized by a stiff, fibrotic ventricle with impaired diastolic filling. In about 50% of cases, RCM can be attributed to specific clinical disorders, the most common being amyloidosis—abnormal deposition of amyloid protein in tissues. The mechanisms proposed for development of other cases include sarcoidosis, genetic inheritance (e.g., hemochromatosis), scleroderma, radiation injury, and exposure to agents that promote fibrosis (e.g., serotonin).<sup>23</sup> Regardless of the specific cause, the myocardium becomes fibrosed, rigid, and noncompliant. The major difficulty is restricted diastolic filling with resultant low stroke volume and heart failure. Exercise intolerance, dyspnea, and weakness may be present. RCM is difficult to manage effectively because no specific therapy is available for most types.

### Specific Cardiomyopathy

Cardiomyopathies of presumed known origin constitute the category of specific cardiomyopathy (see Table 18-8). The specific cardiomyopathies present functionally as dilated, hypertrophic, or restrictive disorders, and the symptoms are consistent with the functional categories previously described.

#### KEY POINTS

- Myocarditis is an inflammatory disorder characterized by scattered necrotic and dead heart muscle cells. Most cases are associated with viral infection. The major complication of myocarditis is left ventricular dysfunction and dilation of the heart chambers, with reduced contractility.
- Cardiomyopathies encompass a number of disorders of heart muscle that may be genetic or acquired. In many cases the exact cause is unknown.
- Dilated cardiomyopathy is characterized by enlargement of both ventricular chambers, reduced contractility, and low EF.
- Hypertrophic cardiomyopathy primarily affects the left ventricle and ventricular septum. Genetic mutations in sarcomere proteins are suspected in most cases. Conditions that increase contractility of the heart (exercise, drugs) can result in obstruction of ventricular outflow and reduced cardiac output. EF is preserved, and diastolic dysfunction is predominant. Patients with HCM have a significant risk of sudden cardiac arrest.
- Restrictive cardiomyopathy is characterized by a stiff, fibrotic left ventricle that resists diastolic filling. Decreased cardiac output and left-sided heart failure can result.

## PERICARDIAL DISEASES

Pericardial disorders are rarely isolated processes of primary cause; rather, they are sequelae of other disorders such as systemic infection, trauma, metabolic derangement, or neoplasia. Despite the diversity of

causative factors, pericardial involvement may be asymptomatic, manifested as an accumulation of fluid in the pericardial sac, or as painful inflammation of pericardial structures.

### Pericardial Effusion

An accumulation of noninflammatory fluid in the pericardial sac is called *pericardial effusion*. Normally, the pericardial space contains only 30 to 50 ml of thin, clear fluid. Under pathologic conditions, as much as 500 ml may accumulate. The compositions of the usual types of effusions are as follows:

*Serous*—a transudate secondary to heart failure or hypoproteinemia  
*Serosanguineous*—a mixture of serous fluid and blood that may follow blunt chest trauma, heart surgery, or cardiopulmonary resuscitation

*Chylous*—a collection of lymph from obstruction of lymphatic drainage

*Blood*—hemopericardium usually resulting from penetrating trauma to the heart

### Cardiac Tamponade

The accumulation of pericardial fluid is generally without clinical significance except as an indicator of underlying disease processes. However, if the fluid accumulation is large or occurs suddenly, the life-threatening condition of cardiac tamponade may ensue. *Tamponade* refers to external compression of the heart chambers such that filling is impaired.

Signs and symptoms of cardiac tamponade include reduced stroke volume and compensatory increases in heart rate. Systemic venous congestion occurs because blood is prevented from entering the compressed heart by way of the superior and inferior venae cavae. Venous congestion may be apparent as distended neck veins. Changes in intrathoracic pressure during respiration may have exaggerated effects on cardiac filling. The presence of waxing and waning of blood pressure in synchrony with respiration is called *pulsus paradoxus*. Significant pulsus paradoxus is usually defined as a difference of 10 mm Hg or more in systolic blood pressure between inspiration and expiration. Other manifestations of tamponade include rising filling pressures in the heart chambers, muffled heart sounds, dull chest pain, diminished electrocardiographic amplitude, and a compressed cardiac silhouette on radiographs. The three classic findings in cardiac tamponade—hypotension, distended neck veins, and muffled heart sounds—have been called Beck's triad.

Treatment is aimed at relieving the pericardial pressure by aspirating the offending fluid (*pericardiocentesis*). Failure to manage tamponade may result in drastically reduced diastolic filling, cardiovascular collapse, and death. Pericardial effusions occasionally are detected by chance on chest x-rays being performed for other purposes. Nonsymptomatic pericardial effusions may be aspirated or merely monitored and allowed to resolve spontaneously. Treatment is directed at the underlying cause of the effusion.

### Pericarditis

Inflammation of the pericardium originates from a variety of causes (Box 18-3). Rarely is the pericardium the primary site of disease. Pericarditis is often categorized as acute or chronic; however, these forms are morphologically and etiologically similar.<sup>9</sup> Chronic pericarditis refers to a healed stage of the acute form that results in chronic pericardial dysfunction.

### Acute Pericarditis

It is estimated that 80% of cases of acute pericarditis are idiopathic, and most of these are presumed to be viral.<sup>24</sup> Uncomplicated acute pericarditis typically resolves spontaneously within 2 weeks and nonsteroidal antiinflammatory agents (NSAIDs) may be the only therapy

## BOX 18-3 CATEGORIES OF PERICARDIAL DISEASE AND SELECTED SPECIFIC CAUSES

**Idiopathic\*****Infectious**

Viral\* (echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B, infectious mononucleosis, HIV/AIDS)

Bacterial\* (*Pneumococcus*, *Staphylococcus*, *Streptococcus*, *Mycoplasma*, Lyme disease, *Haemophilus influenzae*, *Neisseria meningitidis*, and others)

Mycobacteria\* (*Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*)

Fungal (histoplasmosis, coccidioidomycosis)

Protozoal

**Immune-Inflammatory**

Connective tissue disease\* (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, mixed)

Arteritis (polyarteritis nodosa, temporal arteritis)

Inflammatory bowel disease

Early post-myocardial infarction

Late post-myocardial infarction (Dressler syndrome),\* late postcardiotomy/thoracotomy\*

Late post-trauma\*

Drug induced\* (procainamide, hydralazine, isoniazid, cyclosporine, others)

**Neoplastic Disease**

Primary: mesothelioma, fibrosarcoma, lipoma, others

Secondary\*: breast and lung carcinoma, lymphomas, Kaposi sarcoma

**Radiation Induced\*****Early Post-Cardiac Surgery and Post-Orthotopic Heart Transplantation****Hemopericardium**

Trauma

Post-myocardial infarction free wall rupture

Device and procedure related: percutaneous coronary procedures, implantable defibrillators, pacemakers, post-dysrhythmia ablation, post-atrial septal defect closure, post-valve repair or replacement

Dissecting aortic aneurysm

**Trauma**

Blunt and penetrating,\* post-cardiopulmonary resuscitation\*

**Congenital**

Cysts, congenital absence

**Miscellaneous**

Cholesterol ("gold paint" pericarditis)

Chronic renal failure, dialysis related

Chylopericardium

Hypothyroidism and hyperthyroidism

Amyloidosis

Aortic dissection

HIV/AIDS, Human immunodeficiency virus/acquired immunodeficiency syndrome.

used. A small number of cases may be complicated by significant pericardial effusion or by persistent or recurrent inflammation, and may require hospitalization for more thorough diagnostic investigation to determine the specific etiology and more intensive therapy.

The symptoms of acute pericarditis are associated with the systemic effects of inflammation and pericardial damage and include fever, leukocytosis, malaise, and tachycardia. Acute pericarditis almost always presents with chest pain and may be confused with anginal pain. Adhesion and friction between the visceral and parietal pericardial layers cause pain that may radiate to the back and be associated with esophageal discomfort and dysphagia (difficulty swallowing). Rubbing of the pericardial layers may be heard as a friction rub. The rub can be transient and intermittent and may sound squeaky or like scratchy sandpaper. Epicardial injury from pericarditis may be apparent on the ECG as ST-segment elevation. Treatment is generally symptom oriented and includes medications to relieve pain and minimize inflammation.

In the past, MI was a common cause of pericarditis, but the incidence of both acute post-MI pericarditis and the delayed pericarditis of Dressler syndrome has decreased with the advent of early reperfusion therapy for MI.<sup>24</sup> Acute post-MI pericarditis occurs within a few days of an MI in which the infarction involves the epicardial surfaces of the heart (transmural MI). The inflammation of the necrotic heart muscle extends to adjacent pericardial structures, causing them to become inflamed as well. The degree of pericardial involvement reflects the size of the MI. In contrast, late pericarditis, occurring 1 week to a few months after the MI (Dressler syndrome), is believed to be an

autoimmune reaction caused by exposure of the immune system to damaged myocardial tissue. The presence of antimyocardial antibodies has been demonstrated, and the pericardial inflammation is diffuse and not localized to the area of myocardial injury.

**Chronic Pericarditis**

Healing of an acute form of pericardial inflammation may result in chronic (healed) pericardial dysfunction of two principal kinds: adhesive mediastinopericarditis and constrictive pericarditis. Adhesive mediastinopericarditis is usually a consequence of suppurative or caseous pericarditis or a complication of previous cardiac surgery. It may also follow significant irradiation of the chest. The pericardial sac is destroyed and the external aspect of the heart adheres to surrounding mediastinal structures. The workload of the heart increases significantly because contraction is opposed by the attached surrounding structures.

Constrictive pericarditis may be a result of previous suppurative or caseous pericarditis, commonly secondary to tuberculosis. However, in many cases the cause of pericardial dysfunction is unknown. The pericardial sac becomes dense, nonelastic, fibrous, and scarred. It encases the heart like a stiff cage and impairs diastolic filling. The constrictive process generally occurs slowly and may be quite advanced by the time symptoms occur.

Symptoms may include exercise intolerance, weakness, fatigue, and systemic venous congestion. Treatment is aimed at relieving the constriction by removal of pericardium (pericardectomy) and administration of inotropic agents to improve cardiac contractility.

**KEY POINTS**

- Large accumulations of pericardial fluid can result in cardiac tamponade. External compression of the heart chambers impairs diastolic filling and results in decreased stroke volume. Distended neck veins, hypotension, muffled heart sounds, pulsus paradoxus, and elevated and equalized intrachamber pressures are indicative.
- Acute pericarditis causes sticking and rubbing of the visceral and parietal pericardial layers. A friction rub, pain radiating to the back, esophageal discomfort, and generalized signs of inflammation are usually present.
- Chronic pericarditis can lead to destruction of the pericardial sac with adhesion of the heart to surrounding mediastinal structures. Cardiac contraction may be impaired.
- Constrictive pericarditis results in a fibrous, scarred pericardium that restricts cardiac filling.

**CONGENITAL HEART DISEASES**

Congenital heart disease is an abnormality of the heart that is present from birth. A wide variety of defects have been described, and only the pathophysiology of the most common defects will be included. A brief description of fetal cardiac development is a necessary prelude to a discussion of congenital heart diseases.

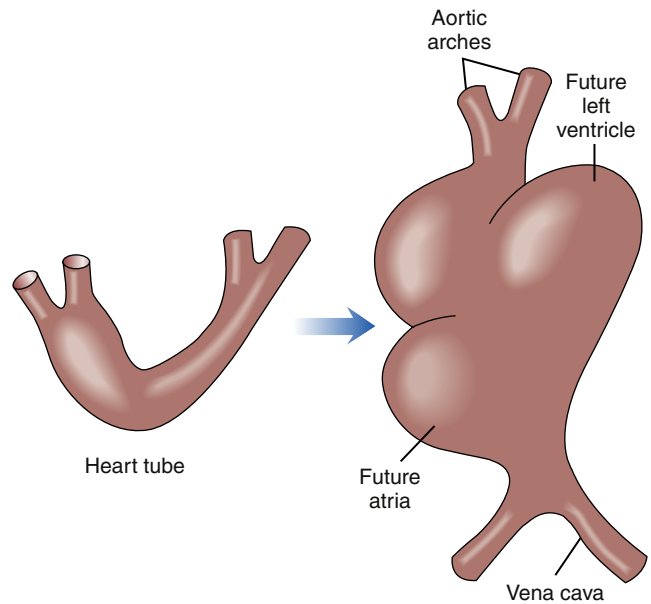

**Embryologic Development**

Development of the heart involves a complex orchestration of formation and resorption of structures. Abnormalities in the development of four important heart structures are at the root of most of the common heart defects: (1) development of the atrial septum, (2) development of the ventricular septum, (3) division of the main outflow tract (truncus arteriosus) into the pulmonary and aortic arteries, and (4) development of the valves. Each of these processes is briefly reviewed.

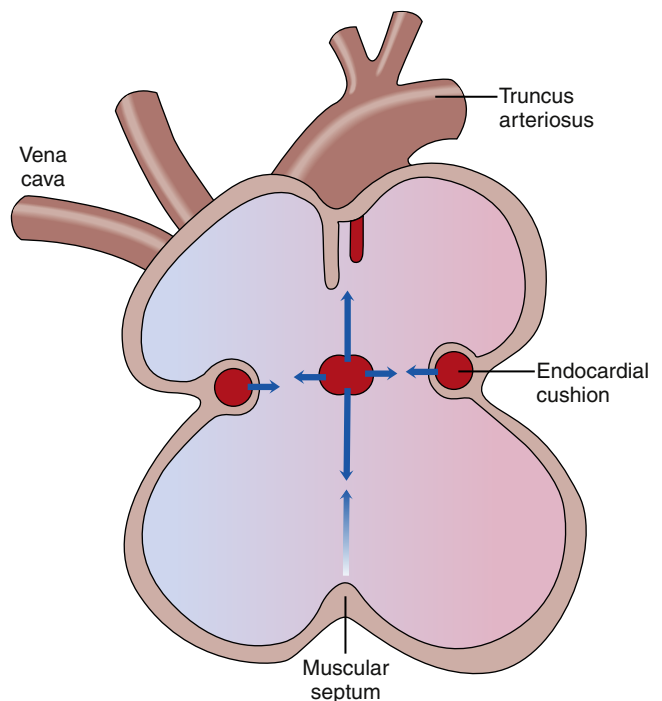

The primitive heart begins as an enlarged tube much like a blood vessel. The tube has three layers. The inner luminal layer is thin and composed of endothelial cells. This layer will eventually line the inner chambers of the heart and valves. The outermost layer is also thin and is called the *myoepicardial mantle*. The outer mantle will form the epicardial and muscular structures of the heart. In between these two thin layers of cells is a thick layer of gelatinous substance called *cardiac jelly*. Cardiac jelly is the precursor to endocardial cushion tissue, which is important in the formation of membranes in the heart, including the septa that separate the four chambers of the heart.

By day 23, the heart tube begins to beat. The tube folds on itself to form an asymmetric loop structure (Figure 18-22). One bulge of the loop forms a primitive single atrium, another forms the future left ventricle, and a third forms the future right ventricle and common ventricular outflow tract (truncus arteriosus). The common atrium is divided into right and left atria by growth of the interatrial septum. Atrial septation occurs in several steps. First, the *septum primum* is formed passively in the superior surface by an indentation caused by the overlying truncus arteriosus (Figure 18-23). Next, the superior and inferior endocardial cushions grow and extend toward each other. These flaps of tissue overlap but do not fuse so that blood can pass through from the right atrium to the left atrium. A reverse in the direction of flow, as occurs at birth, normally would push the flap shut and close the hole (see Pediatrics Considerations box). This flaplike opening, called the *ostium secundum*, remains open throughout fetal life and is later called the *foramen ovale*.

Septal formation between the ventricles follows a similar pattern. The lower portion of the interventricular septum is formed by circular growth and fusing of the muscular ventricular walls. Then the muscular septum proliferates upward toward the atria. The inferior endocardial

**FIGURE 18-22** Asymmetric loop structure in early embryonic development of the heart.

**FIGURE 18-23** Formation of the intracardiac septa.

cushion tissue also grows downward to meet the uplifting muscular septum (see Figure 18-23).

At about the same time that the atrial and ventricular septal structures are being elaborated, the common ventricular outflow tract, the truncus arteriosus, is divided into the pulmonary and aortic channels. This process is accomplished by growth and eventual fusion of mounds of endocardial cushions located in the wall of the truncus arteriosus. The truncal endocardial cushions go on to form the semilunar valves as well (Figure 18-24).

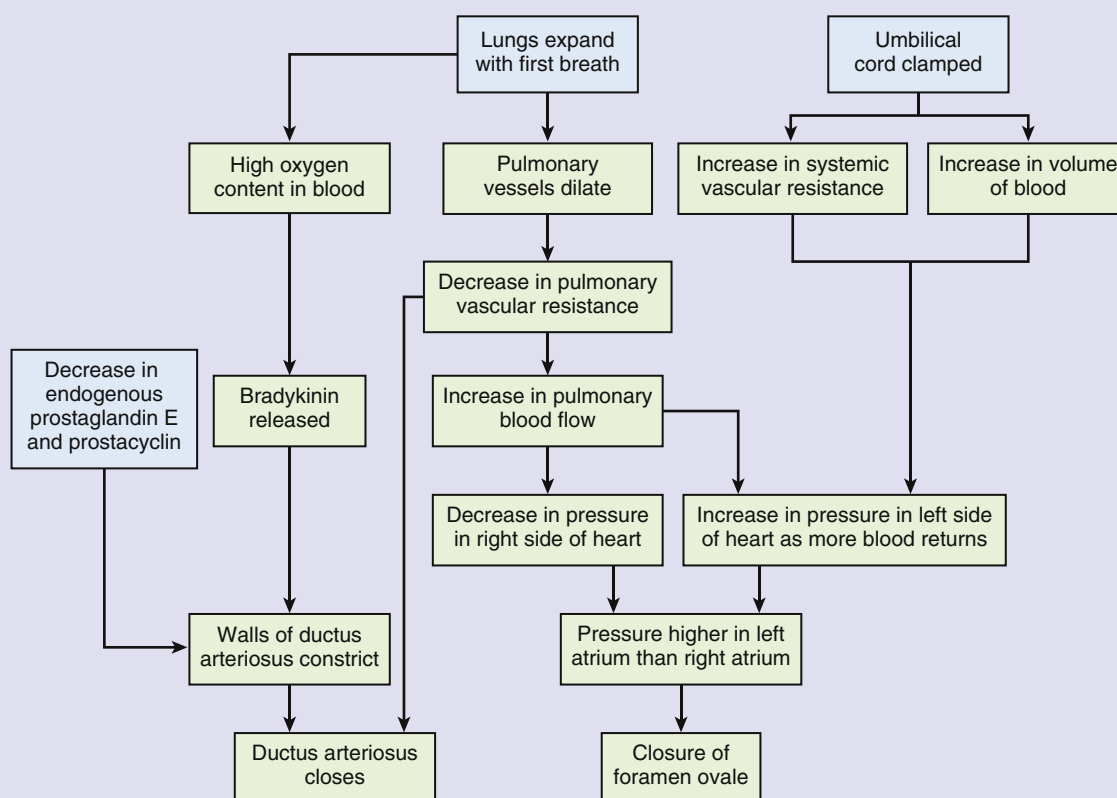

**PEDIATRIC CONSIDERATIONS**
**Changes in Newborn Heart**

When a newborn takes his or her first breath, several changes occur. The alveoli of the lungs expand with the inspired oxygen dilating the pulmonary vessels, which decreases pulmonary vascular resistance. Pulmonary blood flow increases because of this dilation. The increased pulmonary blood flow is from the right side of the heart. Because of this increased flow, the pressures in the right atrium, right ventricle, and pulmonary arteries are decreased. Simultaneously, the umbilical cord is clamped, which increases systemic vascular resistance and increases blood volume. The pressure in the left side of the heart increases as more blood returns to the left atrium from the pulmonary veins related to the clamping. Since the pressure gradient has shifted with higher pressure in the left side of the heart, the circulation of blood through the fetal shunts is reversed.

Foramen ovale closure occurs because of the decreased blood flow from the placenta related to cord clamping. The blood flow from the placenta holds the

foramen ovale open before birth. The change in the pressure gradient closes the foramen ovale at or soon after birth. When this closure occurs blood from the right ventricle flows entirely into the pulmonary circulation.

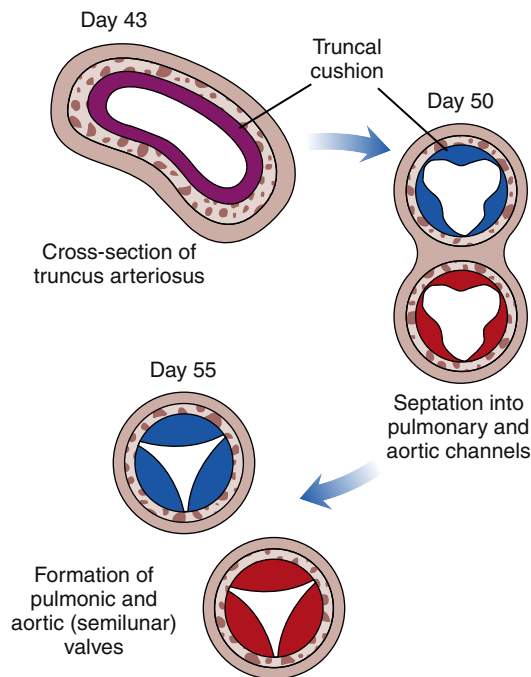

Increased oxygen concentration of the blood is the critical factor in closure of the ductus arteriosus. Bradykinin is signaled to be released by high oxygen concentration in blood from the initial aeration of the lungs. Bradykinin has contractile effects on smooth muscle and forces the ductus arteriosus walls to constrict. The secretion of endogenous prostaglandin E and prostacyclin, which maintain the patency of the ductus arteriosus during gestation, is decreased after birth, which further diminishes the opening of the ductus arteriosus. In addition, decreased pulmonary vascular resistance decreases the blood flow from the ductus arteriosus. Functional closure of the ductus arteriosus occurs 4 days after birth, but may be delayed in preterm or ill infants.

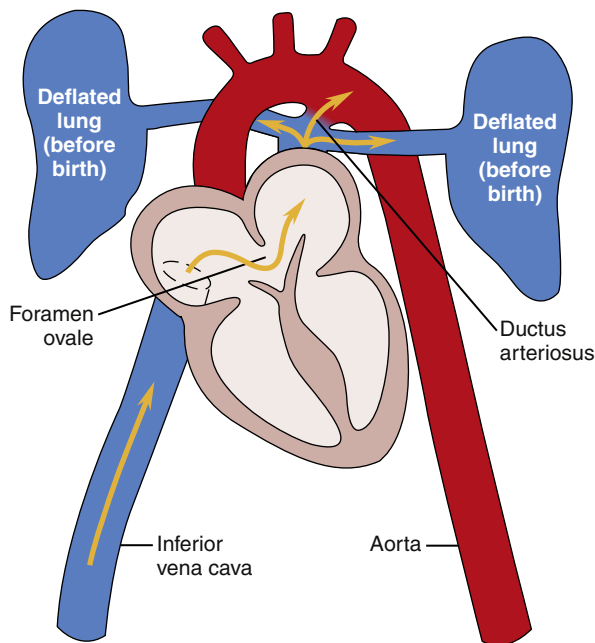

The atrioventricular septum and valves are similarly formed by growth and fusion of the right and left lateral cushions. Superior and inferior cushions also contribute to formation of the septum between the atria and ventricles. Leaflets of the valves are initially formed by lumps of cushion material, which are replaced by muscle tissue from the ventricular wall. The muscle tissue also forms the chordae tendinae and papillary muscle structures. Eventually, the muscle cells of the leaflets and chordae tendinae are replaced by tough, fibrous connective tissue.

When the embryonic heart is fully developed, two important passageways still permit blood flow to bypass the lungs (Figure 18-25).

The foramen ovale lies between the left and right atria and allows blood to bypass the right ventricle. Blood flows right to left through the atrial opening because the pressure in the left atrium is low. High resistance of the deflated lungs also causes right ventricular pressure to be high, which impedes right ventricular filling. The other important structure is the ductus arteriosus, a channel that connects the pulmonary artery and the aorta. Blood flows from the pulmonary artery into the aorta during fetal life because of high vascular resistance in the collapsed lungs. Both these communications generally close after birth when the lungs inflate and the resistance on the right side of the heart falls. Clamping the umbilical cord also serves to increase systemic vascular

**FIGURE 18-24** Septation of the truncus arteriosus and formation of the semilunar valves.

resistance, which further augments the reverse in pressure gradient, with left heart pressures now exceeding those on the right.

### Etiology and Incidence of Congenital Heart Disease

Congenital heart disease is the most common heart disorder in children, with an overall incidence of about 1.0% of all live births.<sup>9</sup> The most common heart defects are listed in Table 18-9, with approximate frequencies of occurrence. In the majority of cases, the cause of the heart defect is unknown. Multifactorial inheritance with both genetic

and environmental influences is probable. Abnormalities in several genes that code for transcription factors increase the risk for congenital anomalies. Very few cases of congenital malformation can be clearly attributed to environmental factors. Maternal rubella during the first trimester of pregnancy is the best documented environmental cause of heart defects. A large number of cardiac teratogens are suspected from animal studies, including hypoxia, ionizing radiation, and heavy alcohol consumption.

Several indications suggest that genetic influence is important in cardiac malformation. A twofold to tenfold increase in the incidence of congenital heart defects is seen in siblings.<sup>25</sup> Several heart defects also occur more frequently in males. Monozygotic twin pregnancies have double the incidence of heart defects compared to singleton pregnancies, but usually only one of the pair is affected even though their genotypes are identical.<sup>25</sup> Thus a complex interplay between genetic and environmental influences is probable and as yet poorly understood.

### Pathophysiology of Congenital Heart Disease

The many forms of congenital heart anomalies result in two primary pathologies: *shunts* and *obstructions*.<sup>26</sup> A shunt denotes an abnormal path of blood flow through the heart or great vessels. The shunt may be further characterized as *right-to-left* or *left-to-right* to indicate the direction of abnormal blood flow. Right-to-left shunts allow unoxygenated blood from the right side of the heart to enter the left side and systemic circulation without first passing through the lungs. Infants with right-to-left shunting of blood generally have some degree of cyanosis because of the decreased oxygen content of the arterial blood (cyanotic defect). Conversely, a left-to-right shunt occurs when oxygenated blood from the left side of the heart or aorta flows back into the right side to be recirculated through the lungs. The blood reaching the systemic circulation is oxygenated and the infant is not cyanotic (acyanotic defect). However, the right side of the heart has an increased workload because of the extra shunt blood. In time, the overload of the right side of the heart can result in right ventricular hypertrophy and high right-sided heart pressures. A left-to-right shunt may then progress to a more dangerous right-to-left shunt when right heart pressures exceed left heart pressures. Congenital disorders causing abnormal

**BOX 18-4 FEATURES OF HEART FAILURE IN INFANTS**

Poor feeding and failure to thrive  
 Respiratory distress (mainly tachypnea)  
 Rapid heart rate (160 to 180 beats/min)  
 Pulmonary rales or wheezing  
 Cardiomegaly and pulmonary edema on radiogram  
 Hepatomegaly (peripheral edema unusual)  
 Gallop sounds  
 Color (ashen pale or faintly cyanotic)  
 Excessive perspiration  
 Diminished urine output

blood flow through the heart include atrial septal defect, ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot, transposition of the great arteries, truncus arteriosus, and tricuspid atresia.

Some heart anomalies produce obstructions to blood flow because of abnormal narrowings. Stenosis or atresia (failure to develop) of valves and coarctation of the aorta are the most common obstructive defects. Obstructions do not result in cyanosis but generally increase the workload of the affected chamber. Heart failure is a potential consequence of congenital heart defects and presents differently in infants and children than in adults (Box 18-4).

In addition to being classified according to pathologic features as obstructions or shunts, heart defects are also classified according to the clinical manifestation of cyanosis. Acyanotic disorders include the obstructive disorders and left-to-right shunts. The cyanotic category includes abnormalities causing right-to-left shunts. Specific heart defects are described further and follow this categorization.

**Acyanotic Congenital Defects****Atrial Septal Defect**

During the third to fifth week of fetal development, the left and right atria are separated by flaps of tissue that become the atrial septum. The foramen ovale remains patent during intrauterine life such that blood may pass from the right to the left atrium and bypass the uninflated and non-functional lungs. The foramen ovale normally remains open in utero because pressure on the right side of the heart is higher than that on the left. With birth, however, the pressure gradient reverses as the lungs inflate and greatly reduce pulmonary vascular resistance. The higher left-sided pressure forces the flap shut, and fusion of the foramen ovale membrane normally occurs. The majority of atrial septal defects occur at the location of the foramen ovale. The abnormal septal opening may be of variable size. Small defects (1 cm) are well tolerated. Even larger atrial septal defects may be asymptomatic for many years as long as the shunt flow is left to right and therefore acyanotic (Figure 18-26).

The long-term increase in pulmonary blood flow may eventually lead to pulmonary hypertension, right ventricular hypertrophy, and a reversal of the shunt to a right-to-left pattern. Cyanosis, respiratory difficulty, and right-sided heart failure may ensue. Large or symptomatic atrial septal defects are commonly repaired surgically early in life, before pulmonary complications occur.

**Ventricular Septal Defect**

A ventricular septal defect is the most common congenital cardiac anomaly.<sup>9</sup> It is frequently associated with other cardiac defects such as tetralogy of Fallot, transposition of the great arteries, and atrial septal defects. The ventricular septum develops between the fifth and sixth weeks of fetal life as the membrane derived from the endocardial cushion fuses with the muscular septum.

**FIGURE 18-26** Atrial septal defect. Blood flow through the defect is usually left to right and produces an acyanotic shunt.

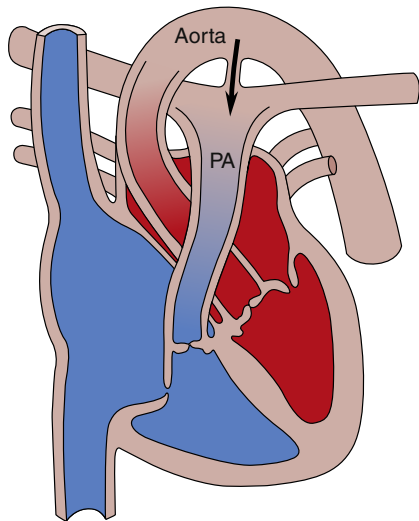

**FIGURE 18-27** Ventricular septal defect. Blood flow through the defect is usually left to right and produces an acyanotic shunt.

The majority of ventricular septal defects are located in the membranous septum, very close to the bundle of His. As with atrial septal defects, the functional significance depends largely on the size of the defect. The shunt is initially left to right because left-sided heart pressures are higher (Figure 18-27). With the increase in pulmonary blood flow, pulmonary hypertension and right ventricular hypertrophy may result and cause a reversal of the shunt.

Large ventricular septal defects may be apparent at birth because of rapidly developing right-sided heart failure and a loud systolic murmur. Large, symptomatic defects in infants or moderate defects in older children are repaired surgically to avoid progression to pulmonary vascular disease. Small ventricular septal defects in infants are generally not immediately repaired because of the tendency of such defects to close spontaneously.

**Patent Ductus Arteriosus**

The ductus arteriosus is a normal channel between the pulmonary artery and the aorta that remains open during intrauterine life (Figure 18-28). Within 1 to 2 days after birth, the ductus arteriosus closes
