In general, individuals with hypothyroidism have decreased basal metabolic rates as the basis for many of their signs and symptoms. Patients report subjective feelings of weakness, lethargy, cold intolerance, and decreased appetite. Bradycardia, narrowed pulse pressure, and mild to moderate weight gain may occur. Elevated levels of serum cholesterol and triglycerides are common as is an increased incidence of atherosclerosis. The thyroid gland may become enlarged (goitrous), the skin may be cool and dry, and constipation may be present. Depression and difficulties with concentration and memory occur. Women with acquired hypothyroidism may experience menstrual irregularities, with increased flow and clotting.<sup>6</sup> Box 40-2 summarizes the general signs and symptoms of thyroid imbalance.

**Myxedema** occurs in severe or prolonged thyroid deficiency. The term *myxedema* is in reference to the generalized, nonpitting edema that patients with long-term hypothyroidism tend to demonstrate. The edematous-looking skin is from the accumulation of glycosaminoglycans (mucopolysaccharides) in the interstitial spaces, which then retain fluid. Thyroid hormone normally prevents the accumulation of glycosaminoglycans within subcutaneous tissues. Individuals with hypothyroid-induced myxedema usually present in an altered mental state, with alterations in thermoregulation and a history of a precipitating event such as sepsis, trauma, or the use of certain medications.<sup>6</sup> Without medical intervention, patients may lapse into so-called myxedema coma, a medical emergency with significant mortality. Figure 40-5 shows the typical features of patients with myxedema.

The diagnosis of hypothyroidism can be confirmed by measuring serum TSH and thyroid hormone levels. Because the most common

**FIGURE 40-5** Typical facial puffiness and dull expression of patients with myxedema. (From Seidel HM et al: *Mosby's guide to physical examination*, ed 6, St Louis, 2006, Mosby. Courtesy Paul W. Ladenson, MD, The Johns Hopkins University and Hospital, Baltimore, MD.)

cause of hypothyroidism is thyroid failure (primary hypothyroidism), nearly all patients will have elevated TSH levels because of the lack of negative feedback exerted by  $T_3$  and  $T_4$ .<sup>6</sup> The serum TSH level is a sensitive indicator of thyroid hypoactivity, and an increase in TSH level often is detectable long before many symptoms develop. A decline in  $T_4$  and  $T_3$  levels may not occur until later in the course of disease. In the rare case of hypothalamic-pituitary dysfunction, both serum TSH and serum  $T_4$  concentrations will be inappropriately low (Table 40-1).

**Treatment.** The goal of treatment is to return the individual with congenital or acquired hypothyroidism and thyroiditis to a euthyroid state. When serum thyroid levels are replaced too quickly, patients may experience insomnia, anxiety, and mood lability. Once treatment has begun, those individuals with a goiter usually experience a regression in glandular enlargement.

TABLE 40-1 THYROID HORMONE LEVELS IN VARIOUS STATES

STATE	SERUM T <sub>4</sub> (μg/dl), RANGE	SERUM T <sub>3</sub> (ng/dl), RANGE	SERUM TSH (μU/ml), RANGE
Euthyroid	4.5-11.5	60-180	0.5-4.5
Infants (<2 wk)	8.0-15.0	—	0.5-4.5
Children (prepubertal)	6.5-11.5	80-220	0.5-4.5
Hyperthyroid	>11.5	—	<0.15
Hypothyroid	<1.0-5.0	—	>5.0

**FIGURE 40-6** Patients with the usual ophthalmopathy found in Graves disease. **A**, Patient with periorbital swelling, exophthalmos, and chemosis (edema). **B**, Woman with widening of the palpebral fissures owing to lid retraction and proptosis. (From Larsen PR, Ingbar SH: The thyroid gland. In Wilson JD, Foster DW, editors: *Williams textbook of endocrinology*, ed 8, Philadelphia, 1992, Saunders, p 426.)

Oral levothyroxine is used to replace or supplement hormone production from an underactive thyroid. Patients notice an increase in exercise tolerance, decreased fatigue, and improved mentation with therapy. Resolution of symptoms occurs gradually over weeks. As therapy returns the patient to a “euthyroid” state, the serum TSH level should return to the normal range. Overtreatment with thyroid hormone can be detected by a serum TSH level that is below the normal range. Overtreatment should be avoided in part because it contributes to osteoporosis.

### Hyperthyroidism

**Etiology and pathogenesis.** Mechanisms that produce hyperthyroidism include thyroid follicular cell hyperfunction with increased synthesis and secretion of T<sub>4</sub> and T<sub>3</sub> (e.g., Graves disease); thyroid follicular cell destruction with release of preformed T<sub>4</sub> and T<sub>3</sub> (e.g., Hashimoto thyroiditis); and ingestion of excessive thyroid hormone. The increased serum levels of thyroid hormones increase the metabolic rate (see Table 40-1).

Hyperfunction of thyroid follicular cells can be either autonomous (primary) or mediated through stimulation of TSH receptors by TSH (secondary). Primary hyperfunction can be caused by adenomas and, rarely, thyroid carcinoma. Inflammation of thyroid follicular cells, with release of preformed thyroid hormone, can be associated with viral or autoimmune processes. Examples are the toxic thyroiditis of Hashimoto disease and subacute thyroiditis. Hashimoto thyroiditis typically presents first with hyperthyroid symptoms because the injured thyroid gland releases stored hormone and then progresses to a hypothyroid state when the autoimmune process destroys the gland. Acute or chronic ingestion of thyroid hormone preparations can produce excess levels of thyroid hormones.

The most common etiology of hyperthyroidism is from autoantibodies that bind and stimulate TSH receptors on the thyroid gland.<sup>6</sup>

This stimulation leads to a diffuse toxic goiter and a type of primary hyperthyroidism called **Graves disease**. The etiology of Graves disease is autoimmune, and it has been associated with certain genetic markers (e.g., *HLA B8*, *HLA DR3*). There is an increased incidence during the second and third decades of life. In response to the high circulating T<sub>3</sub> and T<sub>4</sub> levels that are stimulated by autoantibodies, the pituitary gland stops producing TSH, and serum TSH falls to very low levels.

**Clinical manifestations.** Symptoms of hyperthyroidism are from an increase in metabolic rate and enhanced sympathetic nervous system activity. Symptoms may be mild to severe and include insomnia, restlessness, tremor, irritability, palpitations, increased heart rate, heat intolerance, diaphoresis, and an inability to concentrate that interferes with work performance (see Box 40-2). Increased basal metabolic rate may result in weight loss, even though appetite and dietary intake increase. In women, amenorrhea or scant menses is a frequent finding. The term thyrotoxicosis is used to describe a hyperthyroid condition that is associated with significant symptoms of the disorder.

Individuals with Graves disease usually present with thyromegaly (diffusely enlarged thyroid), thyrotoxicosis, and, often, **exophthalmos** (enlargement of retro-orbital muscles causing protrusion of the eyes) (Figure 40-6). Spasm and retraction of the eyelids leads to widening of the palpebral fissure, resulting in exposed sclera. Lid lag develops, and severe, progressive exophthalmos may occur. Eye complaints may include vision changes and photophobia. The exophthalmos of Graves disease is not from elevated levels of thyroid hormones but is thought to develop as a result of autoimmune injury to retro-ocular structures. Tissues behind the eye become infiltrated with immune cells, followed by release of inflammatory cytokines that stimulate local cells to secrete excessive glycosaminoglycans. The tissue behind the eye swells and pushes the eyeball forward. Reduction of circulating thyroid hormone levels often does not prevent progression of the exophthalmos.

Undetectable TSH levels are the best indicator of primary hyperthyroidism. Serum  $T_4$  and  $T_3$  levels are elevated. A 24-hour radioactive iodine uptake study can confirm the diagnosis of Graves disease, when the scan shows diffuse homogeneous uptake of tracer, and can exclude the presence of thyroid neoplasms.

**Thyroid storm** (accelerated hyperthyroidism) is a form of life-threatening thyrotoxicosis that occurs when excessive amounts of thyroid hormones are acutely released into the circulation. This may occur under conditions of psychological or physiologic stress or with physical manipulation of the gland during diagnostic or surgical procedures. Thyroid storm presents with the clinical features of elevated temperature, significant tachycardia, cardiac dysrhythmias, and congestive heart failure.<sup>7</sup> Extreme restlessness, agitation, and psychosis may occur. Prompt treatment of thyroid storm is required.

**Treatment.** Depending on the degree of symptoms, hyperthyroidism may be treated with medications, such as  $\beta$ -blockers to block acute symptoms or drugs to inhibit thyroid hormone production, or with radioactive iodine to destroy part of the thyroid gland. Surgical removal of the thyroid gland usually is reserved for hyperthyroidism associated with tumors and may result in acute hypocalcemia from inadvertent resection of one or more parathyroid glands. In the rare case of hyperthyroidism secondary to pituitary adenoma, surgical or laser destruction of the anterior pituitary gland may be undertaken.

Antithyroid drugs called thionamides (e.g., methimazole, propylthiouracil) block the activities of the enzyme thyroid peroxidase and inhibit thyroid hormone production by follicular cells. These drugs do not prevent release of hormone, and because the typical thyroid gland contains a 2- to 3-month supply of previously synthesized hormone, the onset of symptom reduction is slow. Thionamides produce a gradual reduction in the basal metabolic rate and reduction of symptoms. Relapse frequently occurs once medications are stopped.

Radioactive iodine treatment to ablate the gland, thereby curtailing its ability to produce excess thyroid hormones, is the treatment of choice for Graves disease. Hypothyroidism occurs following radioactive iodine therapy in 50% to 80% of patients, so patients should be prepared for the likelihood of lifelong thyroid hormone replacement therapy.

Because thyroid storm is a life-threatening form of thyrotoxicosis, urgent management is needed. Antithyroid drugs such as methimazole may be used, followed by iodine administration to further inhibit release of  $T_3$  and  $T_4$ . High-dose iodine paradoxically inhibits thyroid hormone synthesis.  $\beta$ -Blockers used for their antiadrenergic effects on the heart also inhibit the peripheral conversion of  $T_4$  to  $T_3$ . Antipyretic therapy (e.g., use of cooling blankets or ice packs, administration of acetaminophen) may be started to achieve peripheral cooling. Fluid replacement may be needed and the cardiovascular status should be monitored. Thyroid storm can be fatal if untreated. With treatment, the mortality is between 20% and 30%.<sup>7</sup>

#### KEY POINTS

- Thyroid hormone ( $T_3$ ,  $T_4$ ) is produced in follicular cells of the thyroid gland. The synthesis and secretion of thyroid hormone are stimulated by TSH from the pituitary gland. TSH release from the pituitary gland is stimulated by TRH from the hypothalamus. Thyroid hormone is an important stimulator of growth and cellular metabolism.
- Hypothyroidism may be primary (due to congenital agenesis, autoimmune destruction, irradiation, trauma, surgical removal of the gland, or iodine deficiency) or secondary to pituitary hyposecretion of TSH.
- TSH level is helpful in differentiating between primary (high TSH level) and secondary (low TSH level) causes of hypothyroidism. Low serum  $T_3$  and  $T_4$  levels confirm the diagnosis of hypothyroidism. Hypothyroidism is nearly always from a primary etiology.

- Manifestations of hypothyroidism are attributable to a generalized decrease in metabolism and include nonpitting edema (myxedema), slowed mentation, weight gain, dry skin, constipation, decreased heart rate, decreased pulse pressure, lethargy, and loss of the outer third of the eyebrow. Severe hypothyroidism may lead to myxedema coma, characterized by bradycardia, hypothermia, hypotension, and decreased level of consciousness. Untreated congenital hypothyroidism results in profound mental and physical retardation (cretinism). Treatment centers on hormone replacement therapy.
- Hyperthyroidism may be primary (Graves disease, autoimmune, tumor related, inflammatory) or secondary, attributable to pituitary hypersecretion of TSH. The blood level of TSH is helpful in differentiating primary (low TSH level) from secondary (high TSH level) hyperthyroidism. High levels of  $T_3$  and  $T_4$  confirm the diagnosis of hyperthyroidism.
- The manifestations of hyperthyroidism result from a generalized increase in metabolism. Hyperactivity, irritability, insomnia, weight loss, increased appetite, heat intolerance, diarrhea, and palpitations are common. Most individuals have a detectably enlarged thyroid gland. Exophthalmos is immune mediated and occurs with Graves disease.
- Thyroid storm may be precipitated by stress or manipulation of the gland. It is characterized by tachycardia, hypertension, high temperature, and cardiac dysrhythmias. Treatment includes  $\beta$ -blockers to control cardiovascular symptoms, antithyroid drugs to reduce thyroid production, radioactive iodine to ablate the gland, and surgical removal of tumors.

## ADRENOCORTICAL HORMONE DISORDERS

The adrenal cortex synthesizes three different classes of steroid hormones including glucocorticoids, mineralocorticoids, and androgens. Cortisol is the primary glucocorticoid, and its concentration in the circulation provides negative feedback regulation of the hypothalamus and pituitary gland to suppress corticotropin-releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH) release. Aldosterone secretion is not regulated by the hypothalamic-pituitary system and is instead regulated by the presence of angiotensin II in the circulation. **Androgenic** hormone secretion by the adrenal cortex plays a relatively minor role in the development and maintenance of secondary sex characteristics, except in children with adrenogenital syndromes, which produce virilization in the female and precocious sexual development in the male. Physiologically, adrenal androgens are the main source of androgens in the female. As with mineralocorticoids, there is no known feedback mechanism to suppress ACTH production associated with adrenal sex hormone plasma levels. The details of adrenocortical hormone synthesis, regulation, and activity are discussed in Chapter 39.

### Adrenocortical Insufficiency

**Etiology and pathogenesis.** Hyposecretion of adrenocortical hormones can result from disease of the adrenal cortex (primary adrenocortical insufficiency, **Addison disease**), from the inadequate secretion of ACTH from the anterior pituitary gland (secondary adrenocortical insufficiency), or from a lack of CRH secretion from the hypothalamus attributable to hypothalamic malfunction or injury (tertiary adrenocortical insufficiency). Although hyposecretion of all the adrenocortical hormones may occur, the most severe clinical manifestations of adrenocortical insufficiency occur because of inadequate levels of circulating cortisol.

The syndrome of **congenital adrenal hyperplasia**, a rare cause of adrenal insufficiency in pediatric populations, is due to specific enzymatic defects in the biosynthesis of cortisol by the adrenal glands. The lack of negative feedback results in overproduction of ACTH, leading to hyperplasia of the adrenal glands and excessive androgen secretion.<sup>8</sup>

Congenital adrenal hyperplasia is discussed at the end of the section on adrenal insufficiency.

Primary adrenal insufficiency (Addison disease) is caused by destruction of the adrenal cortex through idiopathic or autoimmune mechanisms, tuberculosis, trauma or hemorrhage of the adrenals (often associated with anticoagulant therapy), fungal disease (e.g., histoplasmosis), and neoplasia. Because of the high functional reserve, symptoms of adrenal insufficiency may not be recognized until 90% of the cortical tissue has been rendered nonfunctional.

Secondary adrenal insufficiency (hypothalamic-pituitary dysfunction) is usually iatrogenic in origin because of the large numbers of patients receiving corticosteroid therapy for chronic illnesses. Prolonged exposure to pharmacologic doses of exogenous corticosteroids suppresses CRH and ACTH stimulation of the adrenal gland through negative feedback. A lack of ACTH results in atrophy of the adrenal cortex. If corticosteroid administration is suddenly halted, or if the individual experiences a sudden stress-induced increase in need for cortisol, the adrenal gland will be unable to respond by increasing

cortisol secretion. Acute and severe manifestations of adrenal insufficiency ensue. Secondary adrenal insufficiency occurs because of damage to the anterior pituitary gland or hypothalamus by tumors, infection, radiation, postpartum necrosis, trauma, or surgery.<sup>8</sup>

Addisonian crisis or acute adrenal insufficiency represents a true medical emergency caused by inadequate levels of glucocorticoids and mineralocorticoids in the circulation. This may result from a slowly developing and unrecognized ACTH or cortisol deficiency in which secretion is adequate for the normal demands of life but inadequate for increased stress or trauma. Diminished vascular tone, reduced cardiac output, and inadequate circulating blood volume all contribute to potentially lethal vascular collapse. Hypotension, tachycardia, and symptoms of shock may occur.

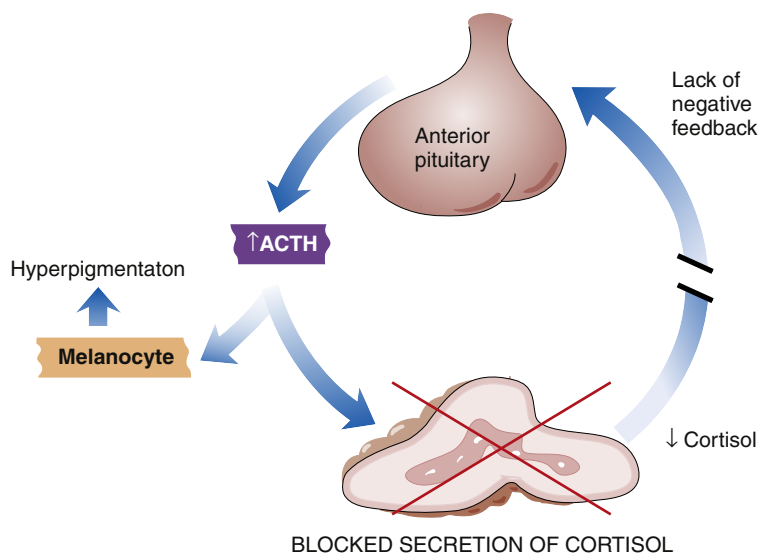

**Clinical manifestations.** The clinical manifestations of adrenal insufficiency (Box 40-3) occur because of inadequate levels of circulating cortisol and aldosterone (Figure 40-7). Clinical manifestations may appear gradually, especially if adrenal destruction is slow and incremental, such as in autoimmune adrenal insufficiency. Symptoms are more dramatic if adrenal destruction is sudden (hemorrhage) or if a stressor, such as trauma, causes sudden decompensation in a patient with chronic adrenal insufficiency.

Early signs of primary adrenal insufficiency include anorexia, weight loss, weakness, malaise, apathy, electrolyte imbalances, and hyperpigmentation of the skin caused by unsuppressed ACTH production (Figure 40-8). ACTH is able to stimulate receptors on melanocytes and promote pigment development in the skin.<sup>2</sup> Salt craving may be present as a result of sodium deficit. If the condition is unrecognized or left untreated, gastrointestinal symptoms can develop, including nausea, vomiting, diarrhea, and dehydration. The patient may be hypotensive or tachycardic. The sudden onset of symptoms suggests acute adrenal insufficiency, which is a medical emergency.

**Diagnosis.** The diagnosis of acute adrenal insufficiency is assisted by the patient's medical history (use of steroids and/or anticoagulant therapy, previous trauma), physical examination, and laboratory findings. Decreased plasma cortisol levels assist in the diagnosis; however, since acute decompensation progresses to death so rapidly, cortisol samples are obtained for lab analysis and therapy is initiated

### BOX 40-3 SIGNS AND SYMPTOMS OF ADRENOCORTICAL HORMONE IMBALANCE

CUSHING SYNDROME	ADRENOCORTICAL INSUFFICIENCY
Truncal obesity	Weakness
Moon face	Hypotension
Dorsocervical fat pad	Hypoglycemia
Hirsutism	Hyperpigmentation (Addison disease)
Muscle wasting	Hyperkalemia
Striae	Weight loss
Petechiae	
Glucose intolerance	
Hypertension	
Hypokalemia	

**FIGURE 40-7** Primary adrenocortical insufficiency (decreased cortisol production) leads to hypersecretion of adrenocorticotrophic hormone (ACTH) because of lack of negative feedback. ACTH binds to receptors on melanocytes and stimulates pigment development in the skin. Even though ACTH levels are high, the adrenal gland is unable to produce adequate levels of cortisol.

**FIGURE 40-8** Altered pigmentation in adrenocortical insufficiency. **A**, Increased pigmentation across the bridge of the nose. **B**, Generalized hyperpigmentation with vitiligo. (From Bondy PK, Rosenberg LE: *Metabolic control and disease*, ed 8, Philadelphia, 1980, Saunders, p 1462.)

presumptively. Resolution of symptoms may be remarkably rapid with administration of intravenous glucocorticoids.

In cases of chronic adrenal insufficiency, an ACTH provocation test can be given. Cosyntropin, synthetic ACTH, is given, and serum samples of cortisol are measured 30 and 60 minutes after administration. Serum cortisol levels should increase following this stimulus if the adrenal cortex is functioning normally. A failure to produce cortisol indicates a primary adrenal insufficiency. Abdominal computerized tomography (CT) or magnetic resonance imaging (MRI) may be performed to determine the size of the adrenal glands. Small adrenal glands occur with autoimmune destruction, whereas tuberculous glands are large and calcified and hemorrhagic glands are large and smooth.

**Treatment.** The treatment for adrenal insufficiency entails replacing the absent or deficient hormones usually produced by the adrenal cortex in a manner that mimics natural production as closely as possible. About two thirds of the daily dosage may be given in the morning and one third in the evening to more closely mimic physiologic adrenal cortical function. In the case of adrenal crisis, intravenous glucocorticoids can be administered intermittently until the symptoms (hypotension, hypoglycemia) resolve; the dose is then titrated downward. In addition, volume replacement is needed to replace the increased urine output associated with lack of mineralocorticoid activity.

Stress situations increase the dose requirements for individuals receiving chronic replacement therapy. Acute illness (increased temperature causes an increase in metabolic rate), injury (e.g., trauma, surgery, burns), and psychological episodes that affect an individual's ability to function normally (death of a significant relative) may double or triple the needed daily corticosteroid dose. If illness or injury restricts the patient's ability to tolerate oral intake, replacement must be given parenterally.

### Congenital Adrenal Hyperplasia

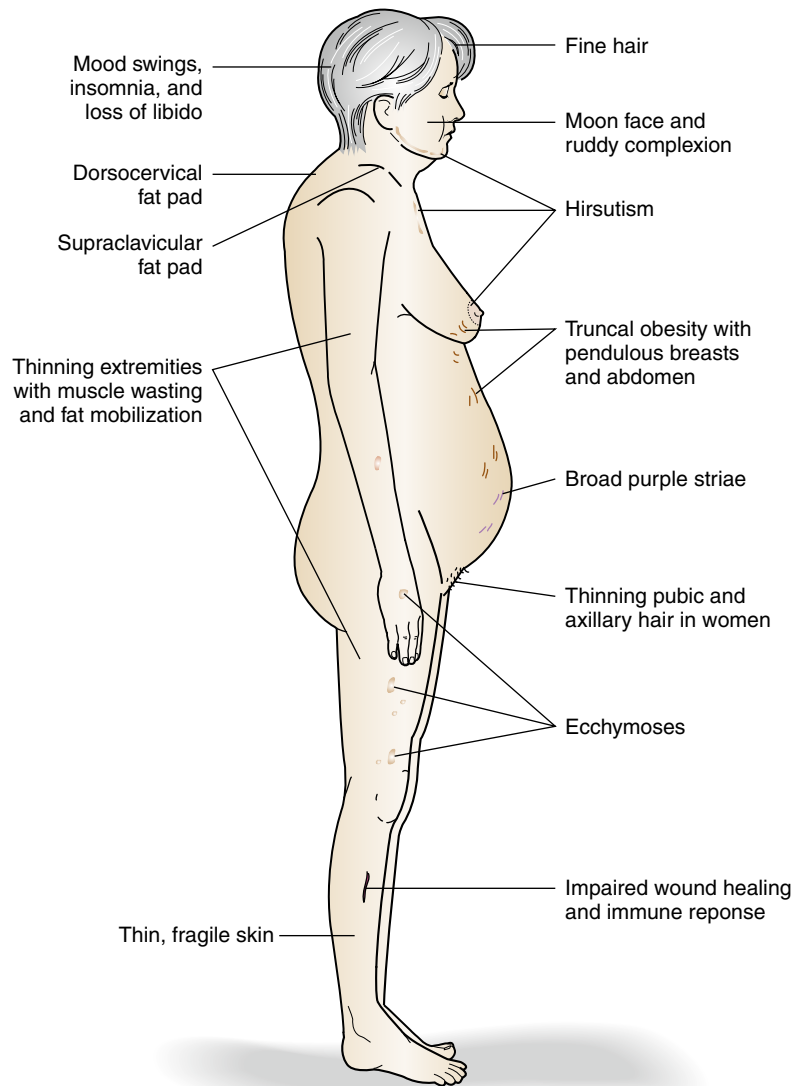

Congenital adrenal hyperplasia is also called *adrenogenital syndrome* and occurs when an enzyme needed for cortisol production is lacking because of a gene defect. The disorder usually follows an autosomal recessive inheritance pattern. Because circulating cortisol levels are inadequate to provide negative feedback to the anterior pituitary

**FIGURE 40-9** Female infant with congenital adrenal hyperplasia demonstrating virilization of the genitalia. Note the enlarged clitoris and the fused labia, which resemble a scrotal sac. (From Hurwitz LS: Nursing implications of selected endocrine disorders, *Nurs Clin North Am* 15:528, 1980.)

gland, ACTH secretion is elevated. This leads to adrenal hypertrophy and overproduction of steroid precursors in the gland, which are shunted into the production of androgens. In the newborn, classic congenital adrenal hyperplasia is a life-threatening condition because of inadequate circulating cortisol.

Infants are frequently diagnosed at birth because of the effects of excessive androgens on the genitals of the newborn. Virilization of the genitalia of a female fetus occurs. The female infant may be born with an enlarged clitoris and fused labia, resembling a scrotal sac (Figure 40-9). Male infants with congenital adrenal hyperplasia may have an enlarged penis and hyperpigmented scrotum, but the examiner may not recognize these subtle signs.

**FIGURE 40-10** Common clinical manifestations of Cushing syndrome.

Depending on the enzymes affected, androgen overproduction may occur at any time from birth to early adult life. If it occurs in an adult female, she may develop such virile characteristics as a beard, a much deeper voice, baldness, masculine distribution of pubic hair, growth of the clitoris to resemble a penis, and deposition of proteins in the skin and muscles to yield typical masculine characteristics.

In adult men, the virilizing characteristics of adrenogenital syndrome are less obvious because masculine characteristics are normal and associated with testosterone secreted by the testes. Therefore, the diagnosis is more difficult. In the prepubertal male, adrenogenital syndrome usually causes precocious puberty.

In all cases, treatment with glucocorticoids is necessary to avoid the complications associated with adrenal insufficiency as previously described. In addition, exogenous glucocorticoid therapy suppresses pituitary secretion of ACTH, allowing the adrenal cortex to atrophy and the overproduction of adrenal androgens to cease.

### Hypercortisolism

**Etiology and pathogenesis.** Hyperfunction of the adrenal cortex results in conditions characterized by hypercortisolism. Primary adrenocortical hyperfunction is caused by disease of the adrenal cortex (adrenal adenoma). Secondary disease is caused by hyperfunction

of the anterior pituitary ACTH-secreting cells, and tertiary disease is caused by hypothalamic dysfunction or injury. The term *Cushing syndrome* is used to describe the clinical features of hypercortisolism, regardless of cause. *Cushing disease* is the diagnosis reserved for pituitary-dependent conditions.

In pediatric and adult populations, hypercortisolism is frequently caused by the excessive production of pituitary ACTH by microadenomas or adenomas. Ectopic ACTH production by nonpituitary tumors can also stimulate the adrenal glands. In the United States, exogenous steroids used in the management of various diseases, such as allergic and autoimmune diseases, are the most common cause of Cushing syndrome.

**Clinical manifestations.** An individual with excess circulating glucocorticoids typically develops a round face with prominent, flushed cheeks, often referred to as “moon face” (see Box 40-3). There is a noticeable weight gain with increasing total body fat, especially in the abdomen. A dorsocervical fat pad, capillary friability, and thinning of the skin with the formation of purple striae and ecchymoses over the abdomen, arms, and thighs develop. Muscle mass decreases and muscle weakness develops. Cortisol increases tissue resistance to the effects of insulin and may contribute to glucose intolerance or hyperglycemia. **Figure 40-10** shows the common clinical manifestations of Cushing syndrome.

Hypertension may develop as a consequence of the salt-retaining activity of cortisol and of the increased blood volume. An associated reduction of serum potassium level is commonly found because of the excessive excretion of potassium by the kidneys. With chronic Cushing syndrome, demineralization of the bones (osteoporosis) and resulting fractures may occur. The cortisol excess may be accompanied by increased androgen production (excessive hair production, acne, menstrual irregularities).

Emotional changes include depression, emotional lability, anxiety, and irritability. Rarely, euphoria or psychosis may develop at higher concentrations of cortisol. Decreases in short-term memory, concentration, and attention span may be present. Appetite is usually increased.

The diagnosis of adrenocortical excess depends on reliable, accurate laboratory measurements. A serum ACTH level may be helpful in differentiating between primary (low ACTH level) and secondary (high ACTH level) hypercortisolism. Urinary free cortisol levels will be elevated in all forms. A 24-hour urine collection is typically done to exclude inappropriate diagnoses attributable to diurnal variations in cortisol production. If the ACTH level is elevated or normal and the 24-hour urinary free cortisol level is found to be elevated, a dexamethasone suppression test may be used to differentiate between pituitary causes and ectopic causes of excessive ACTH production. Most pituitary adenomas (Cushing disease) demonstrate a relative resistance to feedback inhibition by cortisol. When a more potent glucocorticoid is given (dexamethasone), the pituitary gland responds by reducing ACTH production. Sometimes Cushing syndrome is a result of ectopic production of ACTH by cancer cells. In this case, the suppression test will fail to reduce ACTH production because the cancer cells do not respond to feedback control. A negative suppression test will necessitate a diagnostic evaluation to find the ectopic cancer source.

**Treatment.** The choice of treatment for Cushing syndrome is based on its etiology. Patients who have Cushing syndrome as a result of

exogenous glucocorticoid therapy should have doses reduced if possible. Care must be taken to taper doses slowly to avoid acute adrenal insufficiency. For pituitary disease (Cushing disease), transsphenoidal hypophysectomy or laser ablation of the anterior pituitary gland may be done.

Unilateral adrenalectomy is used if the cause of the hypercortisolism is an adrenal tumor. Bilateral removal of the adrenal glands is rarely necessary because most tumors are unilateral. Lifelong steroid replacement is usually necessary following this surgery. Radiation therapy may be an option if surgery is contraindicated.<sup>8</sup> Figure 40-11 shows a woman before and after treatment for Cushing syndrome.

Pharmacologic agents that block cortisol production can also be utilized either alone or in conjunction with surgery and radiation. When any of these therapies is used, the patient should be assessed for treatment-induced adrenal insufficiency.

### Hyperaldosteronism

Excessive aldosterone production may be from primary hyperaldosteronism (Conn syndrome) or secondary to conditions associated with poor kidney perfusion. Conn syndrome usually occurs as a result of aldosterone-secreting tumors. Aldosterone is not under pituitary control and in this case “secondary” refers to disease processes or conditions that stimulate the renin-angiotensin-aldosterone cascade (see Chapter 39). These include heart failure, reduced kidney perfusion, and liver cirrhosis.

Aldosterone facilitates salt and water retention by the kidney. Because aldosterone acts on the distal renal tubule to promote sodium exchange for the potassium lost in the urine, individuals with hyperaldosteronism may have decreased potassium levels. The drug spironolactone is an aldosterone antagonist and therefore is useful in the medical management of aldosterone excess. Spironolactone increases sodium excretion and potassium retention. Sodium restriction and potassium replacement may also be necessary.

**FIGURE 40-11** A woman with Cushing syndrome before (**A** and **C**) and after (**B**) removal of an adrenal adenoma. (From Wyngaarden JB et al: *Cecil textbook of medicine*, ed 19, Philadelphia, 1992, Saunders, p 1285.)

**KEY POINTS**

- The adrenal cortex produces three classes of steroid hormones: (1) glucocorticoids, (2) mineralocorticoids, and (3) androgen steroids. Glucocorticoid synthesis is regulated by the pituitary secretion of ACTH, which is controlled by hypothalamic CRH. Mineralocorticoid synthesis is regulated by the renin-angiotensin system. The glucocorticoid cortisol provides the primary negative feedback mechanism to inhibit CRH and ACTH release.
- Adrenocortical insufficiency may be primary (Addison disease), in which case it is characterized by high ACTH levels in the blood and hyperpigmentation of skin related to excessive pituitary secretion, or it may be secondary, in which case it is characterized by low ACTH levels.
- Primary adrenal insufficiency may follow autoimmune destruction, surgical removal, or trauma of the gland. Exogenous administration of steroids suppresses ACTH, resulting in adrenocortical atrophy. Sudden withdrawal of exogenous steroids may result in adrenal insufficiency.
- Inherited defects in biosynthetic enzymes necessary for cortisol production may affect one or more of the steroid hormone synthesis pathways. Cortisol deficiency results in pituitary release of ACTH, stimulating the adrenal gland to enlarge (congenital adrenal hyperplasia). Excess androgens may be synthesized, leading to masculinization of females and precocious puberty in males.
- Manifestations of primary adrenocortical insufficiency include weight loss, salt wasting, volume depletion, low blood pressure, hypoglycemia, and hyperkalemia. Stress may lead to severe symptoms (addisonian crisis), including circulatory collapse (hypotension). Treatment includes hormone replacement therapy. Dosages are generally increased during periods of stress (e.g., surgery).
- Excess cortisol production attributable to pituitary hyperstimulation of the adrenal cortex is termed *Cushing disease*. Hypercortisolism of any other cause is termed *Cushing syndrome*. ACTH excess may be due to pituitary adenoma or exogenous production by nonpituitary tumors. Cushing syndrome is commonly due to administration of exogenous steroids.
- Clinical manifestations of Cushing disease and Cushing syndrome include moon face, cervical fat pad, central obesity, thin extremities, weight gain, thin skin, striae, hypertension, and hyperglycemia. Plasma cortisol levels and the urinary excretion of cortisol metabolites are increased. Surgical removal of ACTH-producing tumors or removal of the adrenal gland is the usual treatment.
- Primary hyperaldosteronism (Conn syndrome) is usually due to adrenal tumor. Aldosterone enhances sodium and water reabsorption and potassium excretion from the kidney, leading to hypervolemia, hypertension, and hypokalemia.

**ADRENAL MEDULLA DISORDER****Pheochromocytoma**

**Etiology and pathogenesis.** The adrenal medulla secretes two important catecholamine hormones in response to stimulation by the sympathetic nervous system. Epinephrine, or adrenaline, accounts for about 80% of the adrenal medulla's secretion; norepinephrine accounts for the other 20%. Norepinephrine is also the neurotransmitter produced by the postganglionic sympathetic fibers. Sympathetic effectors such as the heart, smooth muscle, and glands have adrenergic receptors for norepinephrine and epinephrine. Both epinephrine and norepinephrine can bind to adrenergic receptors to prolong and enhance the effects of sympathetic stimulation.

**Pheochromocytoma** is a tumor of chromaffin tissue that results in the excessive production and release of catecholamines. It is usually benign, but in about 10% of cases the tumor exhibits malignant behavior. It is usually found in the adrenal medulla, but it may also arise in

other sites where there is chromaffin tissue, such as the sympathetic ganglia. Like adrenal medullary cells, the tumor cells of a pheochromocytoma produce and secrete the catecholamines epinephrine and norepinephrine in response to sympathetic stimulation. Intermittent excessive release of these catecholamines results in periods of hypertension.<sup>9</sup> The hypertension in individuals with pheochromocytoma is influenced by the level of sympathetic nervous system stimulation, the circulating catecholamine levels, and the cardiovascular response to these changes.

**Clinical manifestations.** The most common problem experienced by individuals with pheochromocytomas is intermittent or persistent hypertension. Bouts of the classic triad of headache, tachycardia, and diaphoresis strongly suggest the diagnosis of pheochromocytoma. Sporadic hypertensive episodes may occur with stress, excitement, physical activity, ingestion of certain drugs, and the smoking of tobacco products. Other symptoms may include tremor, nervousness, emotional lability, pallor, fatigue, generalized gastrointestinal complaints, and orthostatic hypotension. Signs of a hypermetabolic state may be present, such as fever and weight loss. CT and MRI are commonly employed diagnostic tools to locate tumors on the adrenal glands.

**Treatment.** Uncontrolled hypertension can lead to end-organ damage and stroke, so prompt diagnosis and aggressive therapy are necessary. The usual treatment for this condition is surgical removal of the tumor. Before surgery, sympathetic blocking medications may be prescribed to manage blood pressure and relieve symptoms.

If surgery is contraindicated, treatment with drugs to block catecholamine production is possible. However, surgery is the only curative therapy. After a period of stabilization, the sympathetic nervous system is able to compensate for the loss of adrenal medullary function and hormone replacement is no longer necessary. Because there is an increased risk of recurrence of the tumor in later years, annual follow-up is recommended.

**KEY POINTS**

- The adrenal medulla releases catecholamines into the bloodstream when stimulated by the sympathetic nervous system. Catecholamines increase heart rate, blood pressure, and glucose release from the liver.
- A pheochromocytoma is a catecholamine-secreting tumor that is usually located in the adrenal medulla. Excessive catecholamine release from the tumor causes intermittent or persistent hypertension, headache, tachycardia, tremor, and irritability. Most tumors are benign, and surgical removal relieves the disorder. Adrenergic blocking agents may be used to manage the hypertension until surgical treatment is accomplished.

**PARATHYROID GLAND DISORDERS****Regulation and Actions of Parathyroid Hormone**

The parathyroid glands are small glands located at the upper and lower poles of the thyroid. There are usually four parathyroid glands, although there are reports of fewer or more than four being found during surgery. The parathyroid glands detect serum calcium concentration and help maintain constant levels through the regulation of calcium absorption and resorption from bone (Figure 40-12). The absorption of calcium from the intestine and renal tubules is dependent on vitamin D and is impaired in conditions such as renal failure, in which active vitamin D is deficient (see Chapter 28).

Serum calcium levels provide the feedback necessary to regulate parathyroid hormone (PTH) secretion. A decrease in serum calcium level causes a release of PTH. An elevated serum calcium level leads

**FIGURE 40-12** Parathyroid hormone (PTH) increases serum calcium level through its effects on bone, renal tubules, and intestine. GI, Gastrointestinal.

to suppression of PTH secretion. PTH is not under control of the hypothalamic-pituitary system. Parathyroid hormone acts on bones, intestine, and renal tubules to increase serum calcium levels. In the bone, PTH increases osteoclastic activity, resulting in the release of calcium (and phosphate) from bone into extracellular fluid. Renal calcium reabsorption increases under the effect of PTH, thus decreasing urinary calcium excretion.

**Calcitonin**, produced by thyroid parafollicular cells (C-cells), also influences the processing of calcium by bone cells. Calcitonin increases bone formation by osteoblasts and inhibits bone breakdown by osteoclasts. Although the role of calcitonin in calcium homeostasis is not entirely clear, calcitonin tends to decrease blood calcium levels and promote conservation of hard bone matrix.

The clinical manifestations of parathyroid hormone dysfunction are those of hypercalcemia and hypocalcemia and related changes in neuromuscular excitability. A discussion of serum calcium regulation and disorders can be found in Chapter 24.

### Hyperparathyroidism

**Etiology and pathogenesis.** The causes of primary hyperparathyroidism remain unclear. Despite an elevated serum calcium level, PTH continues to be secreted. Some forms of hyperparathyroidism can have a genetic origin. Hyperparathyroidism from a single parathyroid adenoma occurs in 80% of surgically proven cases. Hyperplasia of the parathyroid is found in the remainder of the cases.

In hyperparathyroidism, bone resorption and formation rates are increased. Serum calcium levels do not rise uncontrollably; indeed, excessive parathyroid gland secretion rarely causes hypercalcemic crisis. Malignant tumors elsewhere in the body can also release PTH-like hormones and are a more frequent cause of extreme hypercalcemia and hypercalcemic crisis.

A hyperparathyroid state during pregnancy leads to perinatal and neonatal complications. The newborn's PTH production will be

suppressed by maternal hypercalcemia, and neonatal hypocalcemia and tetany can develop. This presentation in a newborn may be the first indication of the need for investigative studies in the mother if the disorder was asymptomatic during pregnancy.<sup>10</sup> In chronic renal failure, hyperparathyroidism may result from reduced production of active vitamin D (which impairs calcium absorption) and from impaired glomerular filtration (which limits excretion of phosphate in the urine). Some drugs, such as lithium and thiazides, may increase serum calcium levels, leading to a misdiagnosis of hyperparathyroidism.

**Clinical manifestations.** The presentation of hyperparathyroidism is related to the level of hypercalcemia and the hyperparathyroid state. Hyperparathyroidism may present as asymptomatic hypercalcemia. Individuals are prone to kidney stones and to bone demineralization (osteoporosis). Severe hypercalcemia causes a wide variety of effects, including polyuria and dehydration. Anorexia, nausea, vomiting, and constipation may develop. Various cardiac problems can arise including bradycardia, heart block, and cardiac arrest.

Often, asymptomatic cases of hyperparathyroidism are found on screening serum chemistry laboratory reports that note mild elevations in serum calcium levels. In primary hyperparathyroidism (not secondary to renal disease), serum calcium levels are elevated and serum phosphorus levels are low to low-normal. Urinary excretion of calcium and phosphate is elevated, as are serum PTH levels.

**Treatment.** Surgical removal of the abnormal parathyroid gland(s) is the treatment of choice. Individuals with asymptomatic hyperparathyroidism may defer surgery. In such cases, medical management may work for a time. Medical management includes hydration (to prevent kidney stone formation) and ambulation to maintain bone density.

For hypercalcemic crisis, rapid volume expansion with normal saline reverses dehydration. Volume replacement also results in improved glomerular filtration rate and increased calcium excretion. Diuretics, other than thiazide diuretics, may be used to increase calcium excretion by the kidney.

### Hypoparathyroidism

**Etiology and pathogenesis.** Hypoparathyroidism most frequently occurs as a consequence of parathyroid or thyroid surgery or radiation in the area. Transient or permanent hypoparathyroidism may develop following thyroidectomy because of damage to parathyroid gland blood supply, postsurgical swelling, or fibrosis.

Hypoparathyroidism can occur following the removal of one hyperfunctioning parathyroid gland. The hyperfunctioning gland had been suppressing the function of the other parathyroid glands, and when removed a temporary state of deficiency may follow until the remaining parathyroid glands resume function. Congenital lack of parathyroid tissue and idiopathic hypoparathyroidism are causes of hypoparathyroidism in infants and children. Autoimmune processes may also target and damage the parathyroid glands.

**Clinical manifestations.** Clinical manifestations of hypoparathyroidism occur as a result of low serum calcium levels. The manifestations of acute hypocalcemia include circumoral numbness, paresthesias of the distal extremities, muscle cramps, fatigue, neuromuscular irritability, anxiety, nonspecific electroencephalographic changes, and prolongation of Q-T intervals on the electrocardiogram. Severe manifestations of hypocalcemia include carpopedal spasm, laryngospasm, and seizures. Neuromuscular irritability can be elicited by a positive Chvostek sign (ipsilateral contraction of the facial muscles that occurs from tapping the facial nerve anterior to the ear) or Trousseau sign (carpal spasm produced by pressure ischemia of the nerves in the upper arm during inflation of a blood pressure cuff for 3 to 5 minutes above the systolic blood pressure).

The serum calcium level is low, and the phosphorous level is elevated. Antibodies to the parathyroid gland are present if an autoimmune mechanism is operant.

**Treatment.** Emergency treatment with intravenous (IV) calcium is needed if an individual presents in acute hypocalcemic crisis (tetany, laryngospasm, and convulsions). Calcitriol, an activated form of vitamin D, may be useful. Long-term treatment includes administration of an oral calcium supplement with vitamin D.

#### KEY POINTS

- PTH is an important regulator of serum calcium levels. Low serum levels of ionized calcium are a potent stimulus for PTH release. PTH increases calcium absorption from the gastrointestinal (GI) tract in concert with vitamin D, resorption of calcium and phosphate from bones, and reabsorption of calcium from the urine filtrate. PTH also increases the excretion of phosphate by the kidney. Disorders of PTH secretion are manifested as alterations in serum  $Ca^{2+}$  levels.
- Hyperparathyroidism may be idiopathic or may be due to a parathyroid adenoma. Its manifestations result from high serum calcium levels and bone demineralization. High serum calcium levels decrease neuromuscular excitability. Treatment entails removing the abnormal glands. Adequate hydration may help prevent the formation of kidney stones.
- Hypoparathyroidism may be idiopathic, autoimmune, or secondary to surgical removal of the parathyroid gland. The manifestations result from low serum calcium levels, which increase neuromuscular excitability. Paresthesias, cramps, spasms, tetany, and seizures may result. Elicitation of Chvostek and Trousseau signs indicates neuromuscular hyperexcitability. Treatment entails calcium (and vitamin D) supplementation rather than PTH replacement.

## ANTIDIURETIC HORMONE DISORDERS

ADH (vasopressin) is secreted from the posterior pituitary gland in response to changes in blood osmolality. The details of ADH synthesis, regulation, and activity are described in Chapter 39. Concepts related to physiologic effects on renal water handling can be found in Chapter 26; Chapter 24 includes details of body fluid regulation and osmolality.

### Diabetes Insipidus

**Etiology and pathogenesis.** Diabetes insipidus (DI) is a disorder of insufficient ADH activity characterized by excessive loss of water in the urine. ADH acts directly on the renal collecting ducts and distal tubules, increasing membrane permeability to and reabsorption of water. Damage to the ADH-producing cells in the hypothalamus can occur with closed head trauma, intracranial tumors, and neurosurgery. Some pharmacologic agents can lead to abnormalities in ADH secretion (Box 40-4). For example, the diuresis that follows alcohol ingestion occurs because of decreased ADH secretion.

Diabetes insipidus (DI) is a term meaning a *large diuresis of inappropriately dilute urine*. In adults with DI, 30% of cases are idiopathic, 20% are caused by the surgical treatment of brain tumors, 16% result from nonsurgical brain trauma, 25% are secondary to brain tumors, and 9% follow a hypophysectomy.<sup>11</sup> ADH deficiency may be accompanied by other hypothalamic-pituitary hormone deficiencies. Damage to the posterior pituitary gland may cause temporary or permanent deficiency of ADH. With insufficient amounts of ADH, urine cannot be concentrated and free water is lost, causing hyperosmolality and hypernatremia. This is called *central DI* because the ability to produce and release ADH from the pituitary gland is lost. *Nephrogenic DI* occurs when the kidney is unable to respond to ADH because of

### BOX 40-4 AGENTS THAT CAUSE ALTERATIONS IN ANTIDIURETIC HORMONE SECRETION

Vincristine	

chronic renal disease, receptor defects, serum electrolyte abnormalities, or drugs (e.g., lithium). The clinical presentation of both forms of DI is similar, and measurement of serum ADH level may be helpful in determining the etiology.

**Clinical manifestations and diagnosis.** The development of **polyuria** (excessive urination) and **polydipsia** (excessive drinking) is the hallmark of DI. The patient may void as much as 15 L of urine daily. The specific gravity of the urine will be greatly decreased. If the thirst center of the hypothalamus is functional, the patient will consume up to 15 L of water to maintain osmolar balance. Symptoms persist at night (**nocturia**), interrupting normal sleep patterns. If the thirst center has been damaged, DI becomes a life-threatening illness because increased water losses from the kidneys (resulting from the absence of ADH) are not counteracted by increased thirst and fluid intake.

DI results in hypernatremia (water deficit) from loss of water without concurrent loss of sodium. Hypernatremia is associated with serum sodium concentrations in excess of 145 mEq/L and indicates a body water deficit relative to sodium. Signs and symptoms include thirst, dry mucous membranes, poor skin turgor, decreased saliva and sweat production, disorientation, lethargy, and seizures. The early neurologic symptoms are thought to be due to shrinkage and dehydration of neuronal cells, which are more sensitive to osmolality changes than other cell types.

Most sudden, critical presentations are straightforward, with documented hypotonic polyuria, hypernatremia, and hypertonicity indicating a defect in secretion of ADH. Individuals presenting with the sudden onset of polyuria and polydipsia should undergo laboratory studies, including tests for glucose, urine and serum electrolytes, serum creatinine, and blood urea nitrogen (BUN) levels. The results of these tests should exclude diabetes mellitus and kidney disease as the basis for the presenting complaints. A comparison of serum and urine osmolality is needed, as is a urine specific gravity measurement. Dilute urine in the presence of water deficit and hypernatremia along with abnormally low serum ADH levels are diagnostic of central DI.

A water deprivation test may be used to confirm the diagnosis. Water intake is restricted, and the urine osmolality is measured hourly. When a plateau in urine osmolality is reached, vasopressin is administered. With central DI, urine concentration increases following vasopressin administration. Polyuria and polydipsia also resolve. In the case of nephrogenic DI, little or no response to vasopressin occurs.

**FIGURE 40-13** Syndrome of inappropriate antidiuretic hormone secretion leads to hyponatremia by two mechanisms: (1) dilution of plasma and (2) increased excretion of sodium by the kidneys. Sodium excretion is increased because of the expanded plasma volume, which enhances sodium filtration and reduces sodium reabsorption. *ADH*, Antidiuretic hormone.

**Treatment.** Daily replacement of ADH is needed for the management of DI. DDAVP (1-deamino-8-D-arginine vasopressin), a synthetic analogue of ADH, can be given to replace vasopressin deficiency. Free access to fluids is necessary, and home testing of urine specific gravity may be useful for some individuals to allow them to adjust their dose independently.

### Syndrome of Inappropriate Antidiuretic Hormone Secretion

**Etiology and pathogenesis.** Inappropriate secretion of excessive amounts of ADH is referred to as *syndrome of inappropriate antidiuretic hormone* (SIADH). The excessive ADH is from ectopic production and has been noted in association with several types of tumors, the most common of which are primary lung malignancies. Nonmalignant lung disorders are also capable of ADH synthesis, or stimulation of central ADH production, especially pulmonary tuberculosis. Drug-induced ADH secretion occurs with the administration of a number of medications, including (but not limited to) chlorpropamide, carbamazepine, morphine, and barbiturates.

SIADH results in hyponatremia when free water is inappropriately conserved and “dilutes” the serum to a sodium concentration below the

normal range ( $<135$  mEq/L). In hyponatremia there is an excess of water relative to solute. Cells swell, and the effects of cellular swelling on neurons can be profound. Adrenal insufficiency and hypothyroidism may also cause increased ADH secretion, and hyponatremia. Both of these hormonal deficiencies must be excluded before SIADH is diagnosed.

**Clinical manifestations.** Clinical manifestations are due to the hypotonicity of body fluids. SIADH is characterized by hyponatremia. Urine osmolality is inappropriately high because of increased water reabsorption in the renal tubules and collecting ducts. Serum osmolality is low because of dilution by the reabsorbed water (Figure 40-13). The symptoms of SIADH include weakness, muscle cramps, nausea and vomiting, postural blood pressure changes, poor skin turgor, fatigue, anorexia, and lethargy. In very severe cases, confusion, hemiparesis (motor weakness on one side of the body), seizures, and coma may occur. Laboratory findings include low serum sodium, hematocrit, and blood urea nitrogen (BUN) levels as a result of dilution of the extracellular fluid.

**Treatment.** Free water restriction is implemented for individuals with SIADH. Water restriction should result in a slow, steady rise in serum sodium levels and osmolality. If severe symptoms develop, intravenous (IV) administration of saline, combined with diuretic therapy, may cause loss of free water. Hyponatremia should be corrected slowly to avoid rapid changes in brain cell volume. If hyponatremia is persistent, drugs such as lithium may be used to block the effects of ADH.

#### KEY POINTS

- ADH secretion is regulated primarily by osmoreceptors in the hypothalamus that respond to changes in extracellular osmolality. An increase in serum osmolality stimulates secretion of ADH. Renal distal and collecting tubules respond to ADH by becoming more permeable to water. In the presence of ADH, water is reabsorbed from the urine filtrate, resulting in a concentrated urine.
- Central DI is due to lack of production of ADH by the hypothalamus or release by the posterior pituitary gland. Central DI may be idiopathic or related to brain surgery, trauma, or tumor.
- Nephrogenic DI is caused by lack of renal collecting tubule responsiveness to ADH. Nephrogenic DI may be caused by receptor abnormalities, renal disease, medications, or electrolyte imbalance.
- Most commonly, DI causes polydipsia accompanied by thirst, polyuria, increased serum sodium level, and increased osmolality. Increased osmolality may cause cellular shrinkage with neurologic signs and symptoms. The diagnosis is confirmed when dilute urine is formed during water deprivation, which is promptly corrected with administration of vasopressin.
- DI is treated with ADH hormone replacement therapy and fluid therapy.
- SIADH is associated with pulmonary tumors, central nervous system disease, and certain drugs. Excess ADH stimulates the renal tubules to reabsorb water despite decreased blood osmolality.
- Clinical manifestations of hyponatremia are associated with cellular swelling and neurologic dysfunction (e.g., confusion, coma). Water restriction and diuretic administration may be used to manage hyponatremia. Detection and management of the underlying cause are paramount.

## SUMMARY

Endocrine disorders present as hyperfunction or hypofunction of hormone actions. An understanding of the usual actions of hormones is useful in predicting the signs and symptoms that will be apparent with excesses and deficits (see Chapter 39). Several important hormone systems are controlled by the hypothalamic-pituitary system and disorders may occur from intrinsic defects in the target gland (primary) or abnormalities in pituitary secretion of trophic hormones (secondary). Diagnosis relies on laboratory evaluation of pituitary gland and target gland hormone levels because the signs and symptoms are similar

regardless of primary or secondary etiology. The etiologies of endocrine disorders are similar regardless of the particular gland involved and include tumors and autoimmune disorders as well as destruction, suppression, removal, or inadequate development of the gland. Treatment strategies are few and for hyperfunction include surgical removal, ablation, or drugs to block hormone synthesis. Replacement therapy is available for most endocrine deficiency disorders and is tailored to mimic normal secretion as much as possible.

The public health impact of diabetes mellitus is enormous. In the United States, nearly 25.8 million persons (8.3% of the population) have diabetes mellitus, although it is estimated that only 72% are aware of their diagnosis. Should this trend continue unabated, worldwide the number of persons with diabetes will rise to 366 million by 2015.<sup>1</sup> The annual cost of diabetes to the U.S. medical care system was estimated to be \$176 billion in 2007, with half of the total cost attributed to inpatient diabetes care.<sup>2</sup> Diabetes mellitus is the seventh leading cause of death and a major cause of disability in the United States. It increases the risk for heart disease, end-stage renal disease, blindness, amputation, and complications of pregnancy. The disease disproportionately affects non-Caucasian and elderly individuals.<sup>3</sup>

## REGULATION OF GLUCOSE METABOLISM

Because diabetes mellitus affects the utilization of all energy nutrients, it is helpful to review energy nutrient metabolism to understand the disease process of diabetes mellitus. The energy requirements of humans are predominantly met by glucose and fats. Produced from endogenous glycogen stores in the muscles and liver or manufactured from such substrates as amino acids and lactate, glucose is supplied to the bloodstream from the gastrointestinal tract and liver. Glucose is typically present in greater quantities in extracellular fluid than within cells.<sup>3</sup>

Cells are variously permeable to glucose, and the diffusion of glucose into them is accomplished by glucose transporters (GLUT 1-4) specific to each tissue. GLUT 1-3 transporters are insulin independent; they remain in the plasma membrane whether or not insulin is present. GLUT 1 is the major glucose transporter at the blood-brain barrier and GLUT 3 is the dominant glucose transport molecule for neurons. GLUT 2 is the primary glucose transporter in the liver and is present in small quantities in the pancreatic  $\beta$  cells.<sup>4</sup> GLUT 1 and GLUT 3 are the predominant glucose transport molecules in the pancreatic  $\beta$  cells.<sup>5</sup>

GLUT 4, found in muscle and adipose cells, is insulin dependent. In the absence of insulin GLUT 4 is sequestered in vesicles located within the cell. When insulin binds to insulin receptors, an intracellular signaling cascade occurs that causes the vesicles with GLUT 4 in their membranes to move (translocate) to the plasma membrane, enabling glucose entry into the muscle cell or adipocyte. When insulin no longer binds to its receptor, GLUT 4 is removed from the plasma membrane.<sup>4,6</sup>

## Hormonal Regulation

Protein and fat metabolism is regulated by the anabolic effects of insulin. Insulin is synthesized in the pancreas by the  $\beta$  cells of the islets of Langerhans. The islets are groups of cells dispersed throughout the pancreas. Within the islets can be found  $\beta$  cells that produce insulin in the form of proinsulin,  $\alpha$  cells that produce glucagon,  $\delta$  cells that produce somatostatin, and F cells that produce pancreatic polypeptide. The primary stimulus for release of insulin from the pancreatic  $\beta$  cells is glucose. Glucose enters the  $\beta$  cells by facilitated diffusion through GLUT 1 and GLUT 3 carriers in the plasma membrane (Figure 41-1). The concentration of glucose in the extracellular fluids determines how much enters the cell. Glucose within the  $\beta$  cell triggers a cascade

of events that results in exocytosis of vesicles containing insulin (see Figure 41-1). Proinsulin is produced and packaged into vesicles along with enzymes that cleave proinsulin into insulin and C-peptide (Figure 41-2). Insulin binds to its receptor on insulin-sensitive cells and triggers glucose uptake through GLUT 4 carriers (Figure 41-3). These carriers are sequestered within the cell when insulin levels are low and then sent to the plasma membrane to transport glucose when insulin levels are higher. Insulin mediates other effects besides glucose uptake. Insulin appears to increase the uptake and to decrease the release of

**FIGURE 41-1** Processes of glucose-stimulated exocytosis of insulin from  $\beta$  cells of the pancreas. Glucose enters the  $\beta$  cells by facilitated diffusion through GLUT 1 in the plasma membrane. Glucose triggers production of ATP, which closes ATP-sensitive K<sup>+</sup> channels and promotes depolarization of the cell. Depolarization triggers opening of voltage-sensitive Ca<sup>2+</sup> channels, allowing calcium ions to enter the cell. Calcium ions interact with release-site proteins and trigger exocytosis of stored insulin and amylin.

**FIGURE 41-2** Structure of proinsulin. The blue-colored amino acids represent the insulin that is released when the C-peptide segment is cleaved.

**FIGURE 41-3** Insulin receptor is a protein kinase receptor that triggers an enzyme cascade within the cell. One of the effects of insulin binding to its receptor is the translocation of sequestered GLUT 4 transporters to the cell surface. The GLUT 4 carriers are passive and transport glucose down its concentration gradient.

amino acids by skeletal muscle, thus inducing protein synthesis and preventing muscle breakdown. The amount of stored fats in the form of triglyceride is potentiated by the action of insulin in preventing fat breakdown and inducing lipid formation. Insulin also appears to have a role in growth by stimulating the secretion of insulin-like growth factor 1 (IGF-1, somatomedin).<sup>7</sup>

Normal glucose metabolism is usually described in reference to the fed and fasting (or absorptive and postabsorptive, respectively) states. The fed state occurs after ingestion of a meal and is characterized by utilization and storage of ingested energy nutrients. The fasting state is characterized by utilization of stored nutrients for the energy needs of the body.<sup>7</sup>

In the fed state, glucose from ingested food provides the primary energy source (Figure 41-4). The postprandial rise in blood glucose level and the presence of certain gastrointestinal hormones stimulate the production of insulin. Initial stimulation produces a brief rise in insulin secretion, termed the *first phase*. The continued presence of increased concentration of glucose produces the second phase of insulin secretion, a state characterized by insulin synthesis. Amylin is a peptide hormone produced by pancreatic  $\beta$  cells and cosecreted with insulin. Amylin acts upon the area postrema (AP) in the brain to inhibit gastric emptying, induce satiety, and prevent postprandial spikes in blood glucose levels.<sup>8-10</sup> Suppression of glucagon release by amylin is from a paracrine effect within the pancreatic islets and does not require any participation by the area postrema.<sup>11</sup>

The ingestion of nutrients stimulates the release of incretin hormones, which include glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1) from cells in the gut. Both hormones stimulate production of insulin in the presence of glucose, promote proliferation of  $\beta$  cells, and inhibit apoptosis. The presence of these hormones and their effect on blood glucose level is known as

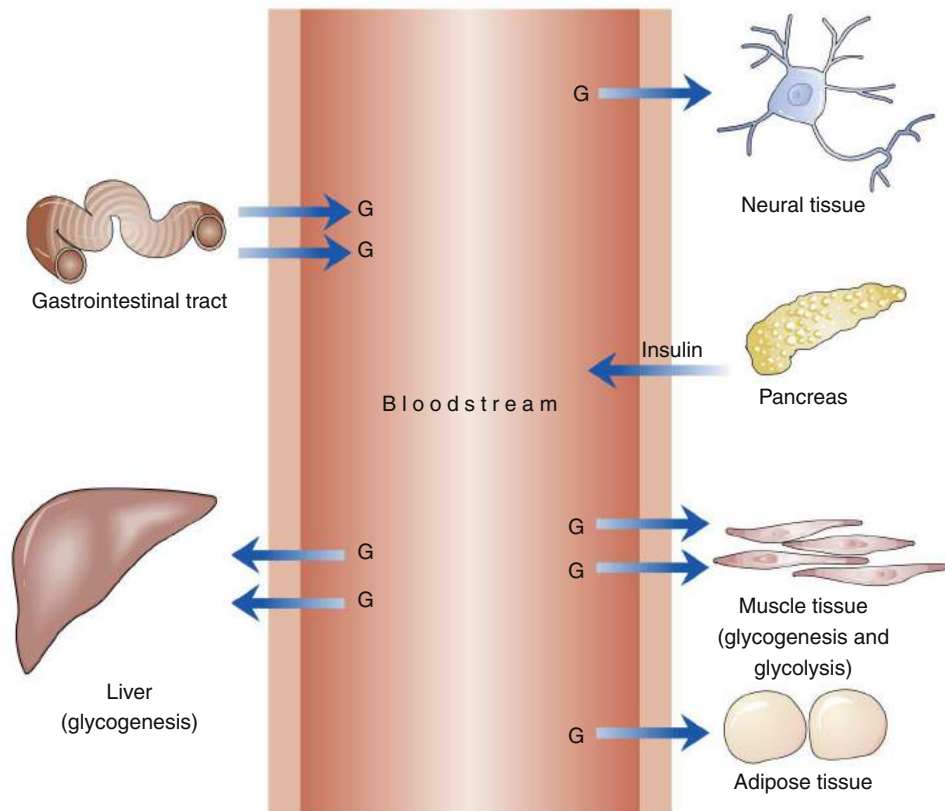

FIGURE 41-4 Energy metabolism in the fed state. G, Glucose.

the *incretin effect*. With parenteral nutrition, the incretin effect is not observed. In addition, GLP-1 delays gastric emptying, inhibits glucagon production, and increases satiety.<sup>12</sup>

The presence of insulin stimulates the diffusion of glucose into adipose and muscle tissue and inhibits the production of glucose by the liver. After diffusion into the cell, glucose may be oxidized for the energy needs of the cell, a process termed *glycolysis*. Most ingested glucose is utilized in *glycogenesis* (production of glycogen in the muscle and the liver) (see Metabolic Syndrome section in Chapter 42).

In the fasting state, glucose is produced by *glycogenolysis* (breakdown of stored glycogen) in the liver and muscles and by *gluconeogenesis* (production of glucose from amino acids and other substrates) in the liver (Figure 41-5). Insulin levels, no longer stimulated by an influx of ingested glucose, fall to a basal level. The catabolic effects of the absence of insulin are evident in the stimulation of glycogenolysis and are accompanied by a rise in glucagon levels. If insulin is the hormone that dominates the fed state, glucagon dominates the fasting state. Glucagon-stimulated glycogenolysis and gluconeogenesis are responsible for up to 75% of glucose production in the fasting state. The primary source of energy to muscle tissue in the fasting state is free fatty acids produced by lipolysis (breakdown of fat from adipose tissue). Lipolysis is stimulated by the decline in plasma insulin levels.<sup>13</sup>

Other hormones referred to as *counter-regulatory hormones* have a role in glucose metabolism in the fasting state. Corticosteroids stimulate gluconeogenesis and counteract the hypoglycemic action of insulin. Growth hormone increases peripheral insulin resistance and prevents insulin from suppressing hepatic glucose production. Catecholamines augment glucose production by prompting hepatic glycogenolysis and gluconeogenesis.<sup>13</sup>

### Neural Regulation

There is a strong connection between the neural regulatory pathways and the enteric function of digestion, motility, secretion, absorption, and defense. Neural influences from the sympathetic and parasympathetic nervous system are directly involved with carbohydrate metabolism and glucose utilization.<sup>14</sup> There are glucose-sensitive receptors in the brain, mouth, and pancreatic  $\beta$  cells and also in the hepatic portal vein. Once food is placed in the mouth, there is stimulation of the parasympathetic nervous system with stimulation of the  $\beta$  cells for insulin release. This is referred to as first-phase insulin release.<sup>14,15</sup> Glucose-sensitive cells are located in many areas of the brain. These are activated by a decline in glucose levels (glucose-inhibited neurons [GI neurons]) or by a rise in glucose concentrations (glucose-excited neurons [GE neurons]). Under the control of the vagus pathway, the parasympathetic nervous system not only stimulates the release of insulin but also can influence the secretion activity and  $\beta$ -cell mass.<sup>15</sup>

Glucagon is predominantly regulated by the sympathetic nervous system in response to hypoglycemia. The hepatoportal vein contains glucose-sensitive nerve fibers; when stimulated they release norepinephrine and, along with epinephrine released from the adrenals, activate  $\alpha$  cells to release glucagon.<sup>15,16</sup>

### Exercise

Increasing activity requires increased fuel for muscle tissue. At the onset of exercise, insulin levels drop and glucagon and catecholamine levels initially rise and increase the production of free fatty acids, the primary energy source of resting muscle (Figure 41-6). Falling insulin levels and increased glucagon levels stimulate glycogenolysis. Under the influence of catecholamines, muscle tissue shifts

**FIGURE 41-5** Energy metabolism in the fasting state. *FFA*, Free fatty acid(s); *G*, glucose.

**FIGURE 41-6** Energy metabolism during exercise. *FFA*, Free fatty acid(s); *G*, glucose.

from using primarily fatty acids for fuel to using stored glycogen. The relative absence of insulin and the increased production of glucagon also stimulate hepatic glycogenolysis. Glucose released by the liver increasingly meets the energy needs of muscle tissue while exercise continues. After 10 to 40 minutes of exercise, blood glucose use by muscle tissue increases 7 to 20 times. The interactions of hormones thus produce the mixture of glucose and free fatty acids used by muscle tissue during exercise.<sup>13</sup>

Muscle tissue is affected not only by the influence of hormones but also by exercise itself. The resulting increase in insulin sensitivity can last as long as 16 hours. Thus in normal metabolism, increased insulin sensitivity allows normal blood glucose values in the presence of lower levels of circulating insulin.

## Stress

During stress such as injury, illness, and pain, stress hormones, including corticosteroids and catecholamines, interact to ensure continuous supplies of glucose. Corticosteroids increase the production of glucose in the liver and elevate the production of glucagon. Glucocorticoids also decrease the utilization of glucose by muscle tissue by diminishing the effect of insulin on glucose transporters and by generating a decline in the number of insulin receptors and their function.

Catecholamines increase plasma glucagon levels, increase glucose production by the liver, and decrease the use of glucose by muscle and fat tissue. The production of fatty acids that is triggered by the action of catecholamines further inhibits glucose uptake in the periphery. The series of events produced by traumatic stress is referred to as *stress hyperglycemia*.<sup>13</sup>

Psychological stress can produce metabolic changes comparable with those of physical stress. Deterioration in metabolic control has been noted in stressed diabetic subjects. However, the response is by no means universal. An increase in blood glucose levels has frequently been observed during acute stress reflecting responses to psychological stress (e.g., disordered eating).<sup>17</sup>

### KEY POINTS

- Plasma membrane permeability to glucose is determined by the type and density of glucose transport proteins in the membrane. In some tissues, particularly muscle and fat, the density of facilitative glucose transporters is regulated by insulin. Insulin binding to receptors on the cell surface results in translocation of glucose transporters to the cell surface. Glucose enters the cell passively by facilitated diffusion. Neurons, endothelial cells and erythrocytes have glucose transporters that do not require insulin.
- The metabolic effects of insulin include enhancing protein synthesis and inhibiting gluconeogenesis, enhancing fat deposition and inhibiting lipolysis, and stimulating cellular growth by enhancing somatomedin secretion. Insulin is synthesized in pancreatic  $\beta$  cells as proinsulin. Proinsulin is stored in granules, where it is cleaved into insulin and C-peptide. A postprandial rise in the levels of glucose and other substrates stimulates the release of insulin into the bloodstream. During fasting, when blood glucose levels fall, the decrease in insulin production and the increase in glucagon secretion lead to lipolysis, glycogenolysis, and gluconeogenesis.
- Exercise has complex effects on glucose metabolism. The decrease in production of insulin and the increase in secretion of glucagon and catecholamines lead to elevated blood glucose levels. However, exercising muscle has increased insulin sensitivity, which facilitates glucose uptake.
- A number of hormones released during stress increase blood glucose levels and oppose the effects of insulin. Catecholamines, glucocorticoids, and glucagon may precipitate stress hyperglycemia.

## GLUCOSE INTOLERANCE DISORDERS

### Classification of Glucose Intolerance Disorders

Diabetes mellitus is not a single disease entity; as many as 30 different disorders may be called diabetes. Criteria for diagnosing the different conditions, all associated with glucose intolerance, were established by the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus in 2011.<sup>18</sup>

Classifications include two pre-diabetes classes and four clinical classes (Box 41-1). Pre-diabetes classes are impaired glucose tolerance and impaired fasting glucose tolerance. The four clinical classes are type 1 diabetes mellitus, type 2 diabetes mellitus, other specific types of diabetes mellitus, and gestational diabetes mellitus.

### Pre-Diabetes

#### Impaired Glucose Tolerance and Impaired Fasting Glucose Tolerance

Guidelines for diagnosing the categories of impaired glucose tolerance (IGT) and impaired fasting glucose tolerance (IFG) are listed in Box 41-2. Impaired glucose tolerance and IFG are intermediate stages between normal glucose metabolism and the onset of diabetes. The pathophysiology of pre-diabetes is complex with a distinct relationship of elevated glucose levels and the development of insulin resistance. Glucose release is stimulated by the mass of metabolically active tissues, including fat free mass and fat mass. The signals to stimulate gluconeogenesis are greater than the counter-regulatory effects, resulting in hepatic insulin resistance.<sup>19</sup>

When glucose levels remain high, the fat-free tissues such as muscle become supersaturated with glucose and start to down-regulate the glucose transporters, accelerating systemic insulin resistance.<sup>19-21</sup>

## Diabetes Mellitus

### Type 1 Diabetes Mellitus

Type 1 diabetes mellitus (type 1 DM) is, by definition, characterized by destruction of the  $\beta$  cells of the pancreas. Type 1 diabetes can occur at any age but peaks at the ages of 2, 4-6, and 10-14 years of age. Type 1 diabetes accounts for 10% of all diabetes and affects 1.4 million people in the United States and approximately 10 to 20 million people globally.<sup>22-24</sup> The incidence is 1 in every 300 to 600 children and adolescents. Caucasian populations are more susceptible to type 1 diabetes mellitus than are African-American, Hispanic, Asian, or Native American populations. Little difference is noted in the incidence of type 1 diabetes mellitus in children younger than age 15.<sup>23,24</sup> However, more men than women are affected in the population.<sup>24</sup>

**Etiology.** The two forms of type 1 diabetes are type 1A immune-mediated diabetes, which is the most common, and type 1B idiopathic, which is rare. Immune-mediated type 1A can be further delineated into three subcategories. Polygenic type 1 diabetes involves two or more genetic loci and accounts for 80% to 90% of type 1 cases. Monogenic causes of type 1 diabetes are rare and associated with IPEX syndrome (*immune dysfunction, polyendocrinopathy, enteropathy, X-linked*). The final subgroup of type 1 diabetes is latent autoimmune diabetes in adults (LADA).<sup>25</sup> LADA is linked to the development of T-cell reactivity to islet antigens and autoantibodies to glutamic acid decarboxylase 65 (GADA65). LADA accounts for 2% to 12% of all cases of diabetes and is typically diagnosed after the age of 35. Often initially misdiagnosed as type 2 diabetes, LADA involves destruction of the pancreatic  $\beta$  cells, resulting in insulinopenia.<sup>25-27</sup>

Type 1A diabetes is the result of an autoimmune attack on the  $\beta$  cells of the pancreas. A strong association with the presence of a gene

### BOX 41-1 CLASSIFICATIONS OF GLUCOSE METABOLISM DISORDERS

#### Pre-Diabetes (Increased Risk for Diabetes Mellitus)

Impaired fasting glucose levels  
Impaired glucose tolerance

#### Type 1 Diabetes Mellitus

Type 1A: Immune mediated

- Polygenic
- Monogenic
- Latent autoimmune diabetes in adults

Type 1B: Idiopathic

#### Type 2 Diabetes Mellitus

##### Other Specific Types of Diabetes

1. Genetic defects of  $\beta$ -cell function
  - a. Chromosome 12, *HNF1A* (formerly *MODY3*)
  - b. Chromosome 7, glucokinase (formerly *MODY2*)
  - c. Chromosome 20, *HNF4A* (formerly *MODY1*)
  - d. Chromosome 13, insulin promoter factor 1 (IPF-1, *MODY4*)
  - e. Chromosome 17, *HNF-1 $\beta$*  (*MODY5*)
  - f. Chromosome 2, *NeuroD1* (*MODY6*)
  - g. Mitochondrial DNA
  - h. Others
2. Genetic defects in insulin action
  - a. Type A insulin resistance
  - b. Leprechaunism
  - c. Rabson-Mendenhall syndrome
  - d. Lipotrophic diabetes
  - e. Others
3. Diseases of the exocrine pancreas
 

Pancreatitis

  - a. Trauma/pancreatectomy
  - b. Neoplasia
  - c. Cystic fibrosis
  - d. Hemochromatosis
  - e. Fibrocalculous pancreatopathy
  - f. Others
4. Endocrinopathies
  - a. Acromegaly
  - b. Cushing syndrome
  - c. Glucagonoma
  - d. Pheochromocytoma
  - e. Hyperthyroidism
  - f. Somatostatinoma
  - g. Aldosteronoma
  - h. Others
5. Drug or chemical induced
  - a. Pyriminil (Vacor)
  - b. Pentamidine
  - c. Nicotinic acid
  - d. Glucocorticoids
  - e. Thyroid hormone
  - f. Diazoxide
  - g.  $\beta$ -Adrenergic agonists
  - h. Thiazides
  - i. Phenytoin (Dilantin)
  - j. Interferon- $\alpha$
  - k. Others
6. Infections
  - a. Congenital rubella
  - b. Cytomegalovirus
  - c. Others
7. Uncommon forms of immune-mediated diabetes
  - a. Stiff-man syndrome
  - b. Anti-insulin receptor antibodies
  - c. Others
8. Other genetic syndromes sometimes associated with diabetes
  - a. Down syndrome
  - b. Klinefelter syndrome
  - c. Turner syndrome
  - d. Friedreich ataxia
  - e. Huntington chorea
  - f. Laurence-Moon-Biedl syndrome
  - g. Myotonic dystrophy
  - h. Porphyria
  - i. Prader-Willi syndrome
  - j. Others

#### Gestational Diabetes Mellitus

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 35(suppl 1):S64-S71, 2012, doi: [org/10.2337/dc12-s064](https://doi.org/10.2337/dc12-s064); Dib S, Gomes M: Etiopathogenesis of type 1 diabetes mellitus: prognostic factors for the evolution of residual beta cell function, *Diabet Metab Syndrome* 1(1):25, 2009.

or genes in the major histocompatibility complex on chromosome 6 has been observed. Genes in the major histocompatibility complex (MHC) are responsible for the creation of cell-surface proteins (human leukocyte antigens, or HLAs) influencing the lymphocytes to stimulate or suppress antibody production. Recent evidence demonstrates that two primary loci (DR and DQ) confer a genetic predisposition whereas other loci may have a protective effect on the development of type 1 diabetes mellitus.<sup>25,28</sup>

Viral infection or exposure to a toxic agent may be the responsible environmental influence for triggering the autoimmune process in susceptible individuals. The immune system activation is a complex process of antigen recognition (please see Chapter 9 for a detailed explanation).

The etiologic progression of type 1B diabetes mellitus is not known. Idiopathic diabetes is associated with  $\beta$ -cell destruction without autoimmune markers or HLA association.

**Pathogenesis and clinical manifestations.** Type 1A diabetes is the result of destruction of the pancreatic  $\beta$  cells. The process is mediated by macrophages and T lymphocytes with detectable autoantibodies to various  $\beta$  cells. The T lymphocytes infiltrate the islets and destroy the  $\beta$  cells through the secretion of cytokines (CD4 cells) and direct cytotoxic action (CD8 cells). The preclinical  $\beta$ -cell autoimmunity is variable and precedes the clinical diagnosis. Specific antibodies that develop against glutamic acid decarboxylase 65 (GADA65), insulinoma-antigen 2 (IA-2), or insulin frequently appear early in the onset of immune-mediated diabetes. Antibodies may be present for as long as 13 years before diagnosis and the order of antibody appearance is not significant; however, the presence of multiple antibodies is highly predictive of type 1A diabetes.<sup>23</sup> The presence of these antibodies results in the destruction of the pancreatic  $\beta$  cells. The presence of hyperglycemia indicates that autoimmune destruction of  $\beta$  cells has reached the point at which insulin secretion is inadequate.<sup>29</sup>

**BOX 41-2**

**Diagnosis of Pre-Diabetes**

Fasting plasma glucose 100-125 mg/dl (IFG)  
 2-hr plasma glucose in the 75-gm oral glucose tolerance test (OGTT) 140-199 mg/dl (IGT)  
 HbA<sub>1c</sub>: 5.7-6.4%

**Diagnosis of Diabetes**

1. FPG  $\geq$ 126 mg/dl. Fasting is defined as no caloric intake for at least 8 hours.\*  
*OR*
2. Symptoms of hyperglycemia and a casual plasma glucose  $\geq$ 200 mg/dl. *Casual* is defined as any time of day without regard to time since last meal. The classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss.  
*OR*
3. 2-hour plasma glucose  $\geq$ 200 mg/dl during an OGTT. The test should be performed as described by the World Health Organization, using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water\*  
*OR*
4. HbA<sub>1c</sub> greater than 6.5%. The test should be performed in a laboratory using a method that is NGSP certified and standardized to the DCCT assay.

From American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 35(suppl 1):S64-S71, 2012, doi: 10.2337/dc12-s064.

DCCT, Diabetes Control and Complications Trial; FPG, Fasting plasma glucose; IFG, impaired fasting glucose; IGT, impaired glucose tolerance; NGSP, National Glycohemoglobin Standardization Program; OGTT, oral glucose tolerance test.

\*In the absence of unequivocal hyperglycemia, criteria 1-3 should be confirmed by repeat testing on a different day.

Type 1A and 1B diabetes mellitus is characterized by an absolute insulin deficiency, and thus glucose cannot enter muscle and adipose tissue (Figure 41-7). Production of glucose by the liver is no longer opposed by insulin. Overproduction of glucagon by pancreatic  $\alpha$  cells stimulates glycogenolysis and gluconeogenesis. Plasma blood glucose levels rise. When the maximal tubular absorptive capacity of the kidney is exceeded, glucose is lost in the urine, and the resulting glycosuria and osmotic fluid loss eventually lead to profound hypovolemia. Tissues dependent on insulin for glucose transport do not have glucose available as a substrate. Neural tissue in the brain responds to this emergency by promoting eating behavior. The increased thirst (polydipsia), increased urination (polyuria), and increased hunger (polyphagia) resulting from the aforementioned processes are the classic symptoms of diabetes.<sup>13</sup>

**Type 2 Diabetes Mellitus**

**Etiology.** Individuals with type 2 diabetes mellitus are resistant to the action of insulin on peripheral tissues. Type 2 diabetes mellitus affects 90% to 95% of individuals with diabetes in the United States. Non-Caucasian and elderly populations are disproportionately affected. The prevalence of diabetes is 7.1% in the non-Hispanic white population, 12.6% in non-Hispanic blacks, and 11.8% in Hispanic/Latino-Americans. The age-adjusted prevalence of diabetes in Native American populations ranges from 5.5% among Alaska Native adults to 33.5% in American Indians in southern Arizona. Overall, close to 26.9% of American individuals older than 65 years have diabetes mellitus. In people under the age of 20, diabetes affects 25.6 million people in the United States or 11.3% of the population. The greatest at-risk population is adolescent Native Americans.<sup>3</sup>

**FIGURE 41-7** Pathophysiology of energy metabolism in type 1 diabetes mellitus. FFA, Free fatty acid(s); G, glucose; KA, ketoacid(s).

**FIGURE 41-8** Pathophysiology of energy metabolism in type 2 diabetes mellitus. G, Glucose.

Risk factors include aging and a sedentary lifestyle, but the most powerful predictor is obesity. Excessive abdominal (visceral) fat introduces a greater threat of diabetes mellitus (and cardiovascular disease) than does lower body obesity. The initial symptoms of polydipsia, polyuria, polyphagia, and weight loss may be subtle or absent in type 2 diabetic patients.<sup>3</sup>

Epidemiologic studies indicate a strong genetic component, but no specific human leukocyte antigen (HLA) type has been identified. Studies indicate that the prevalence of type 2 diabetes mellitus in identical twins when one twin is affected is close to 100%.<sup>30</sup>

**Pathogenesis and clinical manifestations.** Type 2 diabetes is characterized by a relative lack of insulin. The processes instrumental in producing the relative lack of insulin are insulin resistance and  $\beta$ -cell dysfunction (Figure 41-8).<sup>3,30</sup>

The insulin resistance of type 2 diabetes mellitus is defined as a requirement for more insulin for the same biological action, along with lowered glucose utilization at all levels of insulin concentration. A decreased number of insulin receptors and such postreceptor defects as decreased action of glucose transporters are associated with insulin resistance. Impaired glycogen synthesis may also be a factor in the development of type 2 diabetes.<sup>31</sup> Impaired production of insulin by the pancreatic  $\beta$  cells that intensifies as the disease progresses is also present in type 2 diabetes mellitus. Individuals with type 2 diabetes mellitus ultimately have an absent first-phase insulin response and a diminished second-phase response.

Basal insulin secretion may be higher than normal in type 2 diabetes. Glucagon secretion is increased absolutely or relatively (relative to insulin levels). The incretin effect, stimulation of insulin secretion by GLP-1 and GIP, is diminished in type 2 diabetes.<sup>12,30</sup> Individuals with type 2 diabetes may be predominantly insulin resistant or predominantly insulin deficient.

Type 2 diabetes mellitus is a progressive disease characterized by the development of insulin resistance, at first compensated by increased insulin production and hyperinsulinemia. Decompensation occurs as the impaired  $\beta$  cells are unable to produce sufficient insulin to overcome insulin resistance. Insulin levels, however, remain elevated above normal until later in progression of the disease. Relatively decreased insulin levels, continued insulin resistance, and hyperglucagonemia result in the hyperglycemia of diabetes. Hyperglycemia itself may then increase insulin resistance and further diminish insulin secretion. The latter process has been termed *glucose toxicity*.<sup>30</sup>

### Other Specific Types of Diabetes

- **Genetic defects of  $\beta$  cells:** The genetic defects of  $\beta$  cells follow an autosomal dominant pattern of inheritance and are characterized by a defect in the production of insulin. Affected individuals are identified before they reach 25 years of age, respond to oral sulfonylureas, and are nonketotic. The disorder is also referred to as “mature-onset diabetes of the young” (MODY). Latent autoimmune diabetes in adults (LADA) accounts for 2% to 12% of all cases of diabetes. LADA generally affects adults after the age of 35. Initially, LADA has characteristics suggestive of type 2 DM; however, persons with LADA have  $\beta$ -cell antibodies and quickly become insulin dependent.
- **Genetic defects in insulin action:** The disorders listed in Box 41-1 result in relatively rare, genetically determined defects of the insulin receptor.
- **Diseases of the exocrine pancreas:** Diseases of the pancreas can affect the insulin-producing capability of the organ (see Box 41-1).
- **Endocrinopathies:** Excessive production of insulin antagonists (e.g., cortisol, growth hormone, glucagon, and epinephrine) affects glucose metabolism (see Box 41-1).

- **Drug- or chemical-induced diabetes:** Many chemicals can affect the ability of the pancreas to produce insulin (see Box 41-1).
- **Infections:** Destruction of the  $\beta$  cells of the pancreas has been linked to various infectious agents (see Box 41-1).
- **Uncommon forms of immune-mediated diabetes:** Certain autoimmune disorders are linked to glucose intolerance (see Box 41-1).
- **Other genetic syndromes sometimes associated with diabetes:** Certain genetic syndromes are linked to glucose intolerance (see Box 41-1).

**GESTATIONAL DIABETES MELLITUS.** Gestational diabetes mellitus (GDM) is by definition a disorder of glucose intolerance of variable severity with onset or first recognition during pregnancy. Approximately 4% (may range from 1% to 14% depending on population) of pregnancies are affected by gestational diabetes. GDM represents 90% of all pregnancies complicated by diabetes.<sup>18</sup>

**Etiology.** In its pathophysiologic characteristics, gestational diabetes mellitus closely resembles type 2 diabetes mellitus. As in type 2 diabetes, tissue insulin resistance is present during normal pregnancy. Insulin resistance in normal pregnancy is most likely precipitated by the presence of placental hormones: human chorionic somatomammotropin, estrogen, and cortisol. The weight gain of pregnancy is also responsible for an increase in insulin resistance. During pregnancy, women require two to three times as much insulin as they do in the nonpregnant state. Women with gestational diabetes are unable to produce sufficient insulin to meet their needs during pregnancy.<sup>18</sup>

Risk factors for gestational diabetes mellitus include severe obesity, history of gestational diabetes, previous offspring weighing more than 9 lb at birth, presence of glycosuria, or a strong family history of type 2 diabetes. High-risk individuals should be screened as soon as possible after confirmation of pregnancy. Because insulin needs rise sharply in the twenty-fourth to twenty-eighth weeks of pregnancy, it is recommended that all pregnant women older than 25 years be screened for gestational diabetes during the twenty-fourth to twenty-eighth weeks with either 50 or 100 grams (g) of oral glucose. Younger pregnant women who are obese, have a first-degree relative with diabetes, are members of an ethnic/racial group with a high prevalence of diabetes (e.g., African American, Hispanic, Asian, Native American), have a history of abnormal glucose tolerance, or have a history of poor obstetric outcome should also be screened. If the venous plasma glucose concentration is 140 mg/dl or greater with 50 g of glucose, an oral glucose tolerance test is performed using 100-g load (Table 41-1).<sup>32</sup> Untreated gestational diabetes can result in metabolic abnormalities and stillbirth. However, the most common complications of gestational diabetes are macrosomia and neonatal hypoglycemia. Macrosomia (birth weight greater than 4000 g or >90% for gestational age) is a result of increased glucose, free fatty acids, and amino acids delivered to the fetus. Neonatal hypoglycemia is due to increased production of insulin by the fetal pancreas in response to the chronic stimulation of hyperglycemia while in utero.<sup>33,34</sup>

**Treatment.** Management of gestational diabetes mellitus includes education regarding appropriate dietary choices, implementation of an exercise regimen, and observation of blood glucose and urine ketone levels. If hyperglycemia persists, insulin therapy should be initiated. Only glyburide does not cross the placenta to cause fetal hypoglycemia; this sulfonylurea may be used in gestational diabetes mellitus.<sup>32,33</sup>

Glucose tolerance will return to normal after parturition in 97% of women with gestational diabetes mellitus. Women with gestational diabetes mellitus have a markedly increased risk for the development of type 2 diabetes mellitus or impairment in glucose tolerance later in life, especially within the first 5 years postpartum.<sup>34</sup> In subsequent

**TABLE 41-1 DIAGNOSIS OF GDM WITH A 100- OR 75-g GLUCOSE LOAD\***

	100-g GLUCOSE LOAD	75-g GLUCOSE LOAD
Fasting	95 mg/dl	95 mg/dl
1 hour	180 mg/dl	180 mg/dl
2 hours	155 mg/dl	155 mg/dl
3 hours	140 mg/dl	**

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 34(suppl 1):S62-S69, 2011.

\*Two or more blood glucose level determinations must be equal to or greater than these values to establish the diagnosis. The test should be done in the morning after an overnight fast of between 8 and 14 hours and after at least 3 days of unrestricted diet (150 g of carbohydrate per day) and unlimited physical activity. The subject should remain seated and should not smoke throughout the test.

### BOX 41-3 SCREENING FOR DIABETES

Testing should be considered in all adults older than age 30 who are overweight (BMI  $\geq 25$  kg/m<sup>2</sup>) and have additional risk factors:

Physical inactivity

- First-degree relative with diabetes
- Members of a high-risk ethnic population (e.g., African American, Latino, Native American, Asian American, and Pacific Islander)
- Women who delivered a baby weighing >9 lb or were diagnosed with GDM
- Hypertension ( $\geq 140/90$  mm Hg) or receiving therapy for hypertension
- HDL cholesterol level <35 mg/dl and/or triglyceride level >250 mg/dl
- Women with polycystic ovarian syndrome

IGT or IFG on previous testing

Other clinical conditions associated with insulin resistance (e.g., severe obesity and acanthosis nigricans)

History of CVD

In the absence of the above criteria, testing for pre-diabetes and diabetes should begin at age 45 years.

If results are normal, testing should be repeated at least at 3-year intervals, with consideration of more frequent testing depending on initial results and risk status.

Data from American Diabetes Association: Standards of medical care in diabetes, *Diabetes Care* 34(suppl 1):S11-S61, 2011.

CVD, Coronary vascular disease; HDL, high-density lipoprotein; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

pregnancies, recurrence varies between 30% and 84% in women with a history of gestational diabetes mellitus.<sup>35</sup>

### Screening for Diabetes

Because of the high prevalence of undiagnosed type 2 diabetes mellitus, current recommendations are to screen all adults older than age 45 for diabetes at least every 3 years. There is some controversy regarding screening individuals with asymptomatic disease. Individuals with risk factors should be screened at more frequent intervals (Box 41-3).<sup>32</sup>

Screening for gestational diabetes is discussed in the Gestational Diabetes Mellitus section. It is not recommended that routine screening for type 1 diabetes mellitus be performed. No agreement has been reached on the blood level of immune markers that represents a risk for type 1 diabetes or on treatment after identification of the presence of such markers.<sup>32</sup>

**KEY POINTS**

- Diabetes mellitus is an endocrine disorder diagnosed by the presence of chronic hyperglycemia. Diabetes is diagnosed if any two of the following conditions occurs: a random sampling of blood glucose level higher than 200 mg/dl with classic signs and symptoms, a fasting blood glucose level of greater than 126 mg/dl on two occasions, a blood glucose concentration greater than 200 mg/dl 2 hours after a 75-g oral glucose load, or a hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) level greater than 6.5%.
- The classification of diabetes mellitus includes two broad categories: (1) actual glucose intolerance and (2) risk of glucose intolerance. Disorders of actual glucose intolerance include type 1, type 2, other specific types, and gestational diabetes. Pre-diabetes categories include individuals with impaired glucose tolerance and those with impaired fasting glucose tolerance. Individuals at risk for glucose intolerance include those with a history of glucose intolerance and those with a positive family history, obesity, or other risk factors.
- Persons with type 1 diabetes have an absolute insulin deficiency caused by pancreatic  $\beta$ -cell failure. Immune-mediated type 1A diabetes is associated with a specific HLA genetic makeup and is autoimmune. Idiopathic type 1B diabetes is not an autoimmune process. Type 1 diabetes may affect people of any age. Classic manifestations include polyuria, polydipsia, polyphagia, and weight loss.
- Persons with type 2 diabetes have a relative insulin deficiency caused by decreased tissue sensitivity and decreased responsiveness to insulin. A decreased number of insulin receptors or abnormal translocation of glucose transporters is suspected. As the disease progresses, pancreatic insulin production may become impaired. Obesity, female gender, family history, older age, and lack of exercise are risk factors.
- Gestational diabetes is a disorder of glucose intolerance that is diagnosed during pregnancy. Placental hormones and weight gain are contributing factors. High infant birth weight and neonatal hypoglycemia are common complications. Gestational diabetes is a risk factor for the later development of type 2 diabetes.

## CLINICAL MANIFESTATIONS AND COMPLICATIONS

### Acute Hyperglycemia

**Etiology.** Acute hyperglycemia is most commonly caused by alterations in nutrition, inactivity, inadequate use of antidiabetic medications, or any combination of these factors. Persistent fasting hyperglycemia can occasionally be attributed to the dawn phenomenon, which is a rise in blood glucose concentration in the early morning hours attributed to increased growth hormone, cortisol, glucagon, and epinephrine release.<sup>13,30</sup>

**Complications.** A primary concern both of health care providers and of individuals with diabetes is avoiding the acute and chronic complications of diabetes. Acute complications of diabetes include the signs and symptoms of hyperglycemia—polydipsia, polyphagia, and polyuria—and concomitant metabolic and fluid problems. Prolonged insulinopenia can result in ketoacidosis and nonketotic hyperglycemic coma with the accompanying more severe electrolyte and fluid derangements.<sup>32</sup>

Acute complications of diabetes also include infections, most commonly of the skin, urinary tract, and vagina. Infections that particularly affect elderly diabetic patients include malignant otitis externa, necrotizing fasciitis, and persistent candidal infections. Tuberculosis infection and reactivation can be a particular problem in diabetic residents of extended care facilities.<sup>32</sup>

Nausea, fatigue, and a generally decreased sense of well-being frequently accompany hyperglycemia. Blurred vision is a common

**TABLE 41-2 DIABETIC KETOACIDOSIS AND NONKETOTIC HYPERGLYCEMIC HYPEROSMOLAR SYNDROME**

PARAMETER	DIABETIC KETOACIDOSIS	NONKETOTIC HYPERGLYCEMIC HYPEROSMOLAR SYNDROME
Glucose	>300 mg/dl	>600 mg/dl
Urine ketones	Moderate to high	None
pH	6.8-7.3	Normal

BUN, Blood urea nitrogen; Cr, creatinine; Hb, hemoglobin; Hct, hematocrit; WBC, white blood cell.

short-term problem of acute hyperglycemia. These symptoms can be quite distressing and uncomfortable. Acute complications are directly linked to hyperglycemia and recede as euglycemia is approached.<sup>32</sup>

### Diabetic Ketoacidosis

Continued insulin deficiency and other hormonal influences (increased levels of catecholamines, cortisol, glucagon, and growth hormone, in part caused by hypovolemia, physical stress, or insulin deficiency itself) lead to lipolysis in body tissues. As the catabolic process continues, metabolism of fats stored in adipose tissue leads to the production of fatty acids. The resulting fatty acids undergo transformation to ketoacids in the liver. Hepatic gluconeogenesis in response to tissue glucose deprivation is also responsible for the increased production of ketoacids. Under normal circumstances, ketoacids can be used by neural and muscle tissue in energy metabolism. When the normal pathway is saturated, the pH falls (6.8 to 7.3) and ketone bodies are present in the urine, thus sharply increasing osmotic fluid loss. Metabolic acidosis ensues as the bicarbonate concentration decreases, and diabetic ketoacidosis results. In response to the metabolic acidosis, extracellular hydrogen ions are transported intracellularly. Physiologically, potassium is constantly leaking into the vascular space through diffusion and is transported intracellularly via the sodium-potassium pump. This active transport mechanism requires insulin, and in the presence of ketoacidosis, the absence of insulin results in hyperkalemia. Serum potassium levels rise (transient hyperkalemia) and excess potassium is excreted into the urine, eventually leading to a net potassium loss. Losses of sodium, magnesium, and phosphorus also occur as the amount of total body water decreases. Serum levels of the ions may be normal or elevated owing to hypovolemia. Hypovolemia and dehydration also account for increased values of the following: hematocrit, hemoglobin (Hb), protein, white blood cell count, creatinine, and serum osmolality (Table 41-2). Lactic acidosis, or an excessive amount of lactate, a product of glucose metabolism, can also be present because of hypovolemia and possibly reduced uptake of lactate by the liver as a result of acidosis. Hypovolemia and muscle catabolism are present in persons with ketoacidosis and often at diagnosis of type 1 diabetes. Hypovolemic shock can lead to death if the patient is not promptly treated.<sup>13</sup>

Respiratory compensation for the metabolic acidosis in the form of deep, labored respirations that are “fruity” in odor (Kussmaul respirations) results in lowered Pco<sub>2</sub> values (compensatory respiratory alkalosis). Ketoacidosis may be the initial symptom of a new diagnosis of type 1 diabetes. Other factors that may precipitate ketoacidosis are

intercurrent illness and inadequate treatment. The need for hospitalization for diabetic ketoacidosis is greatest for individuals less than 45 years of age (39.7 per 1000 individuals with diabetes).<sup>13</sup>

### Nonketotic Hyperglycemic Hyperosmolar Syndrome

The relative lack of insulin seen in individuals with type 2 diabetes mellitus leads to similar but not identical sequelae as the absolute lack of insulin of type 1 diabetes mellitus. The initial symptoms of polyuria, polydipsia, and polyphagia may be present, possibly in a more subtle form. Ketoacidosis is an uncommon occurrence in type 2 diabetes. The presence of endogenous insulin in type 2 diabetes suppresses the lipolysis that leads to the production of ketone bodies and subsequently ketoacidosis. More common in type 2 diabetes mellitus, especially in older individuals, is nonketotic hyperglycemic hyperosmolar syndrome (NHHS), characterized by severe hyperglycemia with no or slight ketosis and striking dehydration. Nonketotic hyperglycemic hyperosmolar syndrome is more likely to occur in institutionalized patients, especially patients unable to recognize or respond appropriately to thirst. Diabetic ketoacidosis and NHHS can be life-threatening events, especially in the elderly. Seventy percent of all cases of NHHS coma occur in individuals older than 64 years. The mortality rate is approximately 11%.<sup>36</sup>

### Chronic Hyperglycemia

Chronic complications associated with diabetes are extensive and are generally placed into two categories: vascular and neuropathic. The vascular complications are further subdivided into macrovascular and microvascular components. Microvascular complications affect the capillaries, and macrovascular complications involve damage to large vessels.<sup>32</sup>

### Vascular Complications

#### Macrovascular Complications

Macrovascular complications of diabetes mellitus are defined as damage to the large blood vessels providing circulation to the brain, heart, and extremities. Although atherosclerosis is an age-dependent process, the presence of diabetes results in accelerated atherosclerosis. These complications include cardiovascular disease and stroke (38.1% of all individuals with diabetes mellitus over the age of 35), as well as peripheral arterial disease. The presence of heart and blood vessel disease is increased twofold to fourfold in individuals with diabetes and is responsible for more than half of all deaths.<sup>3</sup> Ischemic cerebrovascular accidents (strokes) are more prevalent in individuals with diabetes and are associated with poorer outcomes. Cerebrovascular accidents are responsible for almost 1% of hospitalizations of individuals with diabetes mellitus.<sup>3</sup>

Several studies have investigated whether intensive glycemic control (HbA<sub>1c</sub> <6.5%) would result in a decrease in cerebrovascular events, cardiovascular events, and all-cause mortality. The ACCORD study was the only study to suggest an increase in overall mortality but a significant reduction in nonfatal coronary events.<sup>37</sup> Other studies have demonstrated improved overall mortality with aggressive glycemic control (mean HbA<sub>1c</sub> of 6.5%) and a 14% reduction in cardiovascular events for a 1% decrease in HbA<sub>1c</sub>. Despite the reduced mortality, the risk of severe hypoglycemic events significantly increased.<sup>38-41</sup>

Diabetes is an independent risk factor for coronary artery disease. However, several important risk factors for coronary artery disease—dyslipidemia, hypertension, and impaired fibrinolysis—are present in uncontrolled diabetes and decrease with improved blood glucose level control. The latter risk factor may be linked to the presence of the compensatory hyperinsulinemia of type 2 diabetes mellitus.<sup>30,32</sup> Reduction of insulin resistance by such hygienic measures as caloric restriction

and exercise, and possibly by pharmacologic means, may be of principal importance in reducing the incidence of macrovascular complications. Conventional measures of risk reduction, including measures to control dyslipidemia and hypertension, continue to be considered essential. Improved glycemic control is thought to affect the microvasculature rather than the macrovascular complications.

### Microvascular Complications

The microvascular complications of diabetes—retinopathy and nephropathy—are thought to result from abnormal thickening of the basement membrane in capillaries. Capillary basement membrane thickening has been shown to increase with the length of time after diagnosis and with persistent hyperglycemia.<sup>32</sup>

Hyperglycemia has been shown to disrupt platelet function and growth of the basement membrane. The presence of proteins altered by high glucose levels (advanced glycation end products) is also believed to play a part in the pathogenesis of microvascular complications. Thickening of capillary basement membranes has been shown to decrease with improved glycemic control.<sup>42</sup> Other risk factors for microvascular disease include hypertension and smoking.

Retinopathy is evident in less than 10% of those diagnosed with diabetes for less than 5 years. However, greater than 50% of patients diagnosed with diabetes for more than 20 years are found to be suffering with some degree of retinopathy. Because of the prevalence of long-standing undiagnosed diabetes mellitus, as many as 21% of individuals with newly diagnosed type 2 diabetes are affected by retinopathy.<sup>30</sup>

Retinopathy is the primary cause of new cases of blindness in adults in the United States. The incidence of diabetic retinopathy appears to correlate with the duration of diabetes. Retinopathy is a progressive disease involving three stages: background retinopathy, preproliferative retinopathy, and proliferative retinopathy. Background retinopathy is characterized by microaneurysms and small hemorrhages in the retinal capillaries. Background retinopathy usually does not affect visual acuity. Preproliferative and proliferative retinopathies involve further damage to retinal capillaries, with the latter condition characterized by capillary neovascularization. The small new capillaries are particularly prone to hemorrhage. Proliferative retinopathy is managed with laser photocoagulation.<sup>13,30,43,44</sup>

Nephropathy affects 20% to 40% of individuals with type 1 diabetes. Fewer individuals with type 2 progress to end-stage renal disease.<sup>42</sup> Diabetic nephropathy accounts for 40% of cases of end-stage renal disease. Ethnic origin is a risk factor in the development of diabetic nephropathy, with African-American, Hispanic, and Native American diabetic individuals experiencing an increased rate of end-stage renal disease as compared with Caucasians.<sup>42,44</sup> The characteristic lesion of diabetic nephropathy is glomerulosclerosis, or thickening and hardening of the basement membrane of capillaries in the glomeruli. Filtration, an essential component of kidney function, occurs in the glomerulus. The first stage of diabetic nephropathy is an increase in the glomerular flow rate, or the rate of blood flow through the glomerulus. This increased flow rate leads to hyperfiltration in the glomerulus, or a rise in the rate at which blood is filtered. The mechanisms leading to the increase in glomerular flow rate are unclear but are evidently related to poor glycemic control. As hyperfiltration progresses, the glomeruli become damaged. The resulting glomerulosclerosis leads to blockage and leaking of the capillaries. Protein is characteristically seen in the urine, at first in small amounts (microalbuminuria) and then grossly. As diabetic nephropathy advances, the glomerular filtration rate drops and chronic kidney disease ensues. Hypertension is an important contributing factor to diabetic nephropathy. Management of hypertension with medications that inhibit angiotensin-converting

enzyme has been shown to reduce the rate of chronic kidney disease, end-stage renal disease, and mortality.<sup>43</sup>

### Neuropathic Complications

Diabetic neuropathy produces symptoms in 60% to 70% of individuals with diabetes and is responsible for 6.8 per 1000 diabetic population hospitalizations. Neuropathic complications are divided into autonomic dysfunction and sensory dysfunction. Autonomic complications include gastrointestinal disturbances, bladder dysfunction, tachycardia, postural hypotension, and sexual dysfunction. Approximately 35% to 50% of men with diabetes experience erectile dysfunction. Sensory disturbances include carpal tunnel syndrome and paresthesias or lack of sensation in the feet and lower legs. Neuropathy is largely responsible for the increased risk of serious foot problems in individuals with diabetes. The rate of lower extremity amputation in individuals with diabetes is 15 to 40 times higher than in nondiabetic individuals. More than 60% of all nontraumatic amputations in the United States are performed on individuals with diabetes.<sup>44-46</sup>

Diabetes in humans and experimentally induced diabetes in animals are associated with decreased levels of myoinositol in peripheral nerves. Myoinositol is a cell membrane component normally found in abundance in nerve tissue. Several theoretical explanations have been proposed for the myoinositol link to neuropathy. Glucose appears to compete with myoinositol in transport into the cell. Degradation of glucose to sorbitol and fructose (the polyol pathway) occurs in the nerves in the presence of hyperglycemia and insulinopenia. Increased activity of the polyol pathway also appears to be linked to reduced amounts of myoinositol in the peripheral nerves. Focal ischemic lesions of the nerves may also have a role in diabetic neuropathy. Pathologic findings include degeneration or loss of nerve fibers resulting in decreased nerve function.<sup>13</sup>

Glycemic control has been shown to improve nerve function in animals and in humans and to decrease perceived pain. In addition to hyperglycemia, hypertriglyceridemia, obesity, smoking, and hypertension are modifiable vascular risk factors for the development of neuropathy.<sup>44</sup> Other risk factors associated with neuropathy include male gender, white race, older age, and possibly height >175.5 cm.<sup>45</sup> In addition, the elderly, non-Hispanic blacks, and Mexican Americans are disproportionately affected.<sup>46</sup> Strong evidence linking prolonged hyperglycemia to neuropathy and the microvascular complications of diabetes was provided by the Diabetes Control and Complications Trial, a 9-year multicenter prospective study designed to examine the effect of intensive insulin therapy on the development of retinopathy. Renal and neurologic indices were also examined. Subjects in this trial were individuals with type 1 diabetes and no or mild retinopathy at baseline.<sup>47</sup> The experimental group was intensively treated with three or more insulin injections daily or with insulin delivered by a pump. The incidence of initial retinopathy was reduced by 76%, and progression of existing retinopathy was reduced by 54% in the experimental group. Indices of beginning nephropathy such as microalbuminuria and albuminuria were reduced in the experimental group by 39% and 54%, respectively. Symptomatic neuropathy was reduced by 60% in the experimental group. Dilemmas presented by the Diabetes Control and Complications Trial include the presence of a significant increase in severe hypoglycemia in the experimental group and some question about the validity of extrapolating all results to individuals with type 2 diabetes. A large study on the effect of lowering blood glucose level in type 2 diabetes has also yielded data on decreased morbidity and mortality with improved glycemic control (United Kingdom Prospective Diabetes Study).<sup>48</sup>

### Complications in Pregnancy

Pregnancy in women with type 1 diabetes has been complicated by an increased risk for perinatal infant mortality and congenital anomalies. Metabolic control during pregnancy reduces the risk of perinatal mortality to a rate approximating that of the general population. An increased rate of congenital malformations continues to attend pregnancies in women with type 1 diabetes. Because the affected organs develop early in the first trimester, excellent glycemic control before conception is recommended.<sup>32</sup> Untreated maternal hyperglycemia can result in increased rates of macrosomia, shoulder dystocia, and preeclampsia as well as death, fractures, and nerve palsies.<sup>49,50</sup>

#### KEY POINTS

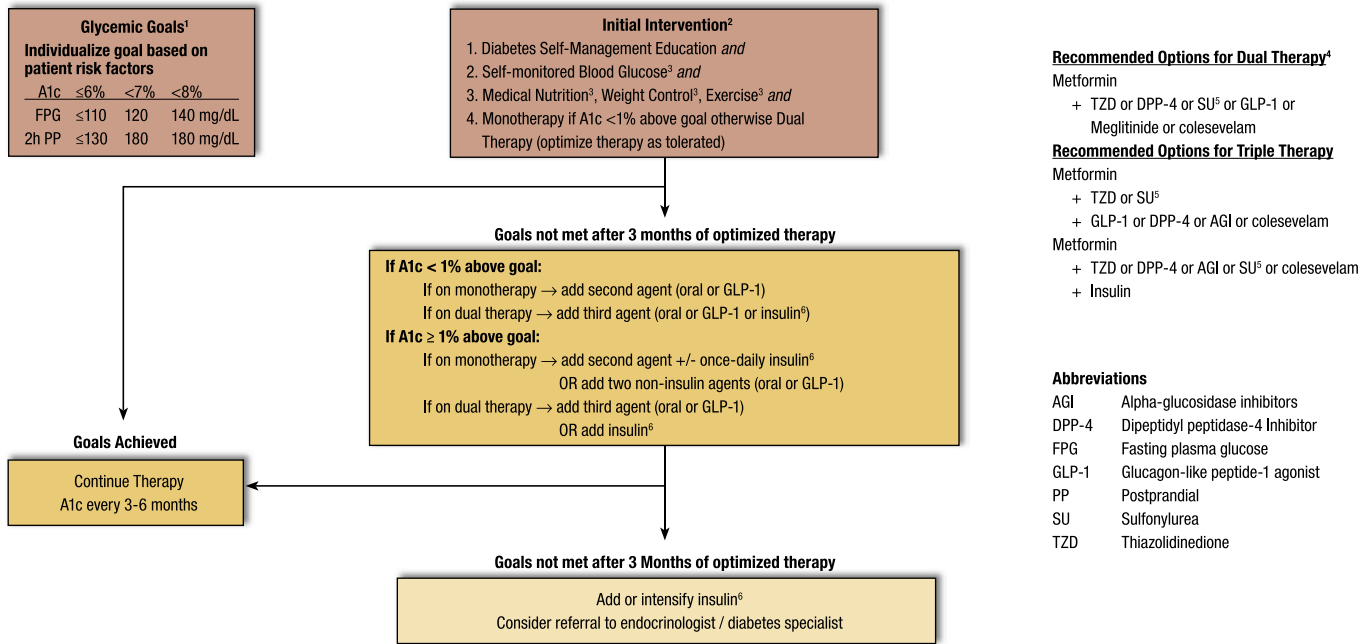

- The acute complications of diabetes are hyperosmolar coma, ketoacidosis, and infection. Hyperglycemia may be associated with nausea, fatigue, and blurred vision.
- Ketoacidosis occurs primarily in type 1 diabetes mellitus as a result of increased lipolysis and conversion to ketone bodies. Excessive ketones result in metabolic acidosis, which is recognized by a fall in pH and bicarbonate levels. Ketoacidosis may occur in patients with type 2 diabetes mellitus under severe stress, such as concomitant sepsis, stroke, or myocardial infarction. Acidosis-induced hyperkalemia and compensatory hyperventilation (Kussmaul respirations) resulting in reduced levels of arterial carbon dioxide are associated findings.
- Nonketotic hyperosmolar syndrome is more common in type 2 diabetes because endogenous insulin suppresses ketone formation and thus prevents ketoacidosis. Hyperglycemia may go untreated for a time and result in persistent glycosuria with osmotic diuresis. Dehydration may be manifested as high osmolality and hemoconcentration of erythrocytes, proteins, and creatinine.
- The chronic complications of hyperglycemia are primarily caused by vascular and neuropathic dysfunction. Individuals with diabetes are prone to vascular complications, including coronary artery disease, stroke, and peripheral arterial disease. These complications are related to dyslipidemia, hypertension, and impaired fibrinolysis. Retinopathy and nephropathy are thought to be due to hyperglycemia-induced thickening of retinal and glomerular basement membranes. Neuropathy is manifested as pain and loss of sensation. Excessive glucose is thought to interfere with myoinositol in neurons.

### TREATMENT AND EDUCATION

The usual treatment goals in diabetes are achieving metabolic control of blood glucose levels and preventing acute and chronic complications. The American Diabetes Association recommends as goals a preprandial blood glucose level between 70 and 130 mg/dl and a postprandial blood glucose level less than 180 mg/dl for adults with diabetes.<sup>32</sup> A glycemic control algorithm to guide treatment is presented in Figure 41-9. The goals of treatment are accomplished by diet, exercise, medication, and such hygiene practices as daily foot care and smoking cessation. Each treatment involves lifestyle changes that are difficult to accomplish initially and challenging to maintain. Treatment must be individualized to the type of diabetes and the unique traits of each patient.<sup>51</sup>

#### Nutrition

Nutrition has often been called the cornerstone of diabetes therapy. Ideas about the optimal dietary prescription have been far from constant throughout recorded history. From wheat, fruit, and beer in ancient Egypt through blood pudding and rancid meats in nineteenth

**Footnotes**

- <sup>1</sup> **Intensify management if:** Absent/stable cardiovascular disease, mild-moderate microvascular complications, intact hypoglycemia awareness, infrequent hypoglycemic episodes, recently diagnosed diabetes. **Less intensive management if:** Evidence of advanced or poorly controlled cardiovascular and/or microvascular complications, hypoglycemia unawareness, vulnerable patient (ie, impaired cognition, dementia, fall history). Refer to TDC "A1c Goal" treatment strategy for further explanation. A1c is referenced to a non-diabetic range of 4-6% using a DCCT-based assay. ADA Clinical Practice Recommendations. *Diabetes Care* 2010;33(suppl 1):S19-20.
- <sup>2</sup> If initial A1c on presentation is  $\ge 10\%$ , consider the use of insulin, with or without oral agents, as the initial intervention (see Insulin Algorithm). Other agents may be introduced as glycemic control improves. If ketoacidosis or recent rapid weight loss, consider Type 1 diagnosis.
- <sup>3</sup> These interventions should be maintained life-long; (refer to Medical Nutrition, Weight Loss, and Exercise Algorithms).
- <sup>4</sup> Refer to the Diabetes Medications Supplement: Working Together to Manage Diabetes found in the Texas Diabetes Council's Diabetes Toolkit.
- <sup>5</sup> If a SU is selected, low dose glipizide ER or glimepiride are recommended because they have a lower incidence of hypoglycemia than glyburide.
- <sup>6</sup> Refer to Insulin Algorithm for Type 2 Diabetes Mellitus in Children and Adults / Initial Insulin Therapy for Type 2 Diabetes Mellitus in Children and Adults: A Simplified Approach

century France to more recent investigations of fiber and fat, nutritional controversies are far from over.

In a position statement, the American Diabetes Association has listed four recommendations for nutritional therapy in patients with diabetes (Box 41-4).<sup>51</sup> Accomplishing the goals can involve changes in composition of the diet, meal patterns and timing, and caloric consumption. All the energy nutrients—carbohydrates, fats, and protein—have an essential role in optimal nutrition. Obesity and eating disorders such as bulimia have an important impact on nutritional status.

**Obesity and Eating Disorders**

Obesity is the strongest risk factor for type 2 diabetes, in addition to being a risk factor for cardiovascular disease in women. Obesity is defined as a body mass index (BMI) of greater than 30 kg/m<sup>2</sup>. BMI is calculated by dividing body weight in kilograms by the square of the height in meters. Increased risk for health problems occurs at a body mass index of equal to or greater than 25.2 kg/m<sup>2</sup>. A body mass index of 18.5 to 24.9 kg/m<sup>2</sup> is considered normal. Weight management is a chronic and difficult problem for many individuals. No single strategy has been shown to be effective for all individuals. Current recommendations for management of obesity include the use of a nutritionally complete diet, a maintenance routine, and an exercise program.<sup>51</sup> Consult Chapter 42 for additional nutritional risk factors related to obesity.

**BOX 41-4 AMERICAN DIABETES ASSOCIATION RECOMMENDATIONS FOR NUTRITIONAL THERAPY**

- Achieve and maintain
- Blood glucose levels in the normal range or as close to normal as is safely possible
  - A lipid and lipoprotein profile that reduces the risk for vascular disease
  - Blood pressure levels in the normal range or as close to normal as is safely possible
- To prevent, or at least slow, the rate of development of the chronic complications of diabetes by modifying nutrient intake and lifestyle
- To address individual nutrition needs, taking into account personal and cultural preferences and willingness to change
- To maintain the pleasure of eating by only limiting food choices when indicated by scientific evidence

Data from American Diabetes Association: Nutrition recommendations and interventions for diabetes, *Diabetes Care* 31(suppl 1):S61-S78, 2008.

Eating disorders such as bulimia and anorexia may be more common in women with type 1 diabetes. Inducing weight loss by reducing insulin levels has also been noted. In order for clinicians to be aware of eating disorders in their patients, careful assessment is necessary.

### Exercise

Exercise, one of the oldest treatments for diabetes, was prescribed in India in 500 BC. Exercise can have a role in both type 1 and type 2 diabetes to lower blood glucose levels and promote health maintenance. Exercise lowers such cardiovascular risk factors as high blood pressure and dyslipidemia, increases work capacity, reduces stress, prevents bone loss, and improves reaction time. Exercise may also be beneficial in weight reduction.<sup>52-54</sup>

The effects of exercise on fuel utilization and insulin sensitivity are comparable to exercise-induced changes in normal metabolism. As glucose production increases and plasma insulin levels drop, the reduction in tissue insulin resistance can result in a net decline in blood glucose levels. Exercise has the potential to decrease insulin requirements in type 1 diabetes, decrease and possibly eliminate the need for pharmacologic agents in type 2 diabetes, and reduce the risk for heart disease in all persons with diabetes. It has been shown to prevent the onset of type 2 diabetes in persons who are genetically at risk.<sup>52-54</sup>

Although the benefits of exercise are numerous, there are associated risks. Individuals with type 1 diabetes are at risk for hypoglycemia and ketoacidosis. Exercise in individuals with type 2 diabetes can be associated with hypoglycemia, cardiac dysfunction, orthopedic injury, and worsening of some complications.

When insulin or an oral hypoglycemic agent is used in the management of diabetes, the usual fuel metabolism of exercise is disturbed. Inappropriately high insulin levels result in decreased hepatic glucose production and increased tissue insulin sensitivity. The latter processes can lead to hypoglycemia. Replacement of expended glycogen and continued insulin sensitivity can result in hypoglycemia as long as 24 hours after activity.<sup>52-54</sup>

Hyperglycemia and ketosis may be a result of exercise under insulinopenic conditions. Safeguards must be built into exercise programs to prevent hypoglycemia, ketoacidosis, injury, cardiac compromise, and exacerbation of diabetic complications.

The exercise prescription is as essential in diabetes management as the medication or nutrition prescription. The Centers for Disease Control and Prevention recommend an exercise program of moderate intensity for at least 30 minutes, 5 or more days per week or vigorous intensity for 20 minutes, 3 or more days per week.<sup>52-54</sup>

Exercise should be avoided if ketosis is present, because it can indicate an acute shortage of insulin. Exercise under the latter conditions can lead to increased hyperglycemia. Exercise when blood glucose values are greater than 250 mg/dl is safe if ketosis is not present.<sup>51</sup>

## Pharmacologic Agents

### Oral Antidiabetic Agents

Along with diet and exercise as initial treatment of type 2 diabetes, numerous medications may be used. Current guidelines call for timely implementation and titration of oral agents as well as insulin to achieve euglycemia.<sup>55</sup> Sulfonylurea drugs have been used in the management of type 2 diabetes for more than 40 years. These drugs have been joined by other agents with different mechanisms of action. Table 41-3 includes a list of common antidiabetic agents.

Sulfonylureas exert their hypoglycemic effect by binding to the ATP-dependent potassium channels on the cell membrane of  $\beta$  cells. This inhibits efflux of potassium, resulting in a rise in intracellular calcium concentration and the secretion of proinsulin. Sulfonylureas are effective in augmenting the action of insulin in glucose disposal,

TABLE 41-3 ORAL ANTIDIABETIC AGENTS

CATEGORY	CLASS	DRUGS
Sensitizers	Biguanides	Metformin
	Thiazolidinediones (TZDs)	Pioglitazone, rosiglitazone
Secretagogues	Sulfonylureas	First generation: carbutamide, chlorpropamide, tolbutamide, tolazamide
		Second generation: glyburide, glipizide, glimepiride
	Meglitinides	Nateglinide, repaglinide, mitiglinide
	DDP-4 inhibitors	Linagliptin, saxagliptin, sitagliptin, vildagliptin
Other	$\alpha$ -Glucosidase inhibitors	Acarbose, miglitol

diminishing insulin clearance by the liver, and reducing hepatic glucose production. Because sulfonylureas are ineffective in the management of type 1 diabetes, stimulation of  $\beta$  cells is known to be a crucial factor in the action of these oral agents. Enhanced insulin secretion appears to be a short-term effect, possibly caused by a reduction in insulin requirements as a result of the other hypoglycemic activities of sulfonylurea agents.<sup>55</sup>

The so-called *first-generation agents* (those formulated earliest) are tolbutamide, chlorpropamide, and tolazamide. Second-generation agents include glyburide, glipizide, and glimepiride. Use of first-generation agents is not recommended unless patients have a well-established history of previous use with good results. Second-generation agents are more potent than first-generation agents, possibly because of increased capacity to bind to the plasma membrane of the  $\beta$  cell. In addition, they are more predictable, have fewer side effects, and represent more convenient dosing.

The side effects of sulfonylureas include hypoglycemia, nausea, dizziness, headache, allergic reactions, and flushing with alcohol use (disulfiram effect). Sulfonylureas that are metabolized to inactive compounds by the liver are considered safer for use in renal disease. Duration of action is another safety issue. After insulin, sulfonylureas are the major cause of severe hypoglycemia caused by a drug. The longer acting sulfonylureas chlorpropamide and glyburide are responsible for the majority of cases of severe hypoglycemia and fatal hypoglycemic coma.

Metformin, classified as a biguanide, suppresses hepatic gluconeogenesis and enhances glucose uptake by peripheral tissues without causing hypoglycemia. Metformin has been used alone and in combination with a sulfonylurea drug and sitagliptin. Metformin is associated with improvement in dyslipidemia and weight loss. Side effects include nausea and diarrhea. Serious side effects of metformin include acute renal injury and metabolic acidosis. In a large review of several thousand patient-years, the incidence of metformin-associated lactic acidosis is rare and most commonly associated with acute kidney injury. Caution should be employed when using metformin in patients with liver disease.<sup>56</sup> Administration of radiographic iodine dyes has potential risk for causing acute renal injury. Patients who are taking metformin have an increased risk of developing metabolic acidosis. Depending on the creatinine clearance value, some patients should hold their metformin for 24 hours before and 48 hours after receiving IV contrast medium.<sup>57</sup>

Acarbose and miglitol,  $\alpha$ -glucosidase inhibitors, diminish postprandial hyperglycemia by delaying carbohydrate absorption. They

can be used alone and in combination with sulfonylurea drugs, metformin, or insulin. Side effects include symptoms related to decreased gastrointestinal absorption (e.g., flatulence and diarrhea). They do not cause hypoglycemia but can complicate management of hypoglycemia if used in combination with a sulfonylurea. Sulfonylurea-induced hypoglycemia cannot be managed with sucrose when acarbose is being used because of drug-induced delayed sucrose absorption.<sup>32,55</sup>

Thiazolidinedione drugs increase tissue sensitivity to insulin and inhibit hepatic gluconeogenesis. Thiazolidinediones are thought to decrease insulin resistance, increase glucose uptake, and redistribute fat. In addition, they are believed to preserve  $\beta$ -cell function, decrease vascular inflammation, and minimally decrease hepatic glucose production. Currently pioglitazone is the only commercially available thiazolidinedione available; rosiglitazone is available only through selective distribution points because of the cardiovascular risks.

When prescribed along with an appropriate meal plan, oral antidiabetic agents can be very effective in the management of type 2 diabetes mellitus. Primary failure of the drug is considered to have occurred when initiation of oral agent therapy does not result in a significant decline in blood glucose levels. Primary failure can be due to misdiagnosis of type 1 diabetes mellitus or inadequate adherence to the diet and exercise regimen. Secondary failure, or hyperglycemia after an effective initial response to the drug, is often due to dietary nonadherence but may also be due to the progressive  $\beta$ -cell dysfunction of type 2 diabetes mellitus.<sup>32,55</sup>

### Incretin Enhancers, Incretins, and Amylins

A newer group of oral agents for management of diabetes are the incretins, incretin enhancers, and amylin.

Dipeptidylpeptidase-4 (DPP-4) is a widely expressed enzyme that is responsible for rapidly degrading glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP). Both of these substances are critical factors in the development and treatment of type 2 diabetes. DPP-4 inhibitors block the secretion of DPP-4, causing sustained action of incretin hormones that results in satiety,<sup>58-60</sup> lower serum glucose levels, and enhanced  $\beta$ -cell mass and function.<sup>61</sup> DPP-4 inhibitors prevent the release of glucagon from  $\alpha$  cells through the release of incretin while increasing insulin secretion. Medications in this class include sitagliptin, saxagliptin, linagliptin, and vildagliptin.

The incretin class of medications focuses on glucagon-like peptide 1 (GLP-1). GLP-1 mimetics delay gastric emptying, inhibit release of glucagon, and increase satiety. GLP-1 mimetics are injectable medications with the common side effects of nausea and hypoglycemia. Exenatide can be used alone or in combination with sulfonylureas, metformin, or thiazolidinediones. Medications in this class include exenatide, liraglutide, and lixisenatide.<sup>61</sup>

Pramlintide is an amylin analogue and can be used in conjunction with insulin for the management of glycemia. It may not be mixed with insulin and should be injected separately. Insulin requirements are usually decreased by 50% with pramlintide; in addition, minimum carbohydrate and caloric intake is required for its use. It is contraindicated in patients with hypoglycemia unawareness or gastroparesis. Both incretin and amylin mimetics have been effective in weight loss and lowering HbA<sub>1c</sub> values when used in conjunction with metformin or a sulfonylurea (both) or insulin (pramlintide only).<sup>62</sup>

### Insulin

Insulin therapy is required in all persons with type 1 diabetes mellitus and in 35% of persons with type 2 diabetes mellitus.<sup>13</sup> Persons with type 1 diabetes mellitus require replacement of the deficient hormone in a manner that most closely resembles normal physiologic mechanisms. The role of insulin in type 2 diabetes mellitus is more complex.<sup>30,32</sup>

Because type 2 diabetes mellitus is a progressive disease, many (if not most) individuals will need insulin at some time, either because of increasing insulin resistance or because of  $\beta$ -cell dysfunction. Glucose toxicity, a phenomenon in which insulin resistance and decreased production of insulin are worsened by hyperglycemia, may respond to insulin therapy. Insulin may be necessary in type 2 diabetes intermittently during times of physiologic stress that increase insulin requirements (e.g., concomitant illness, surgery, inactivity, weight gain). However, with resolution of the stress, the individual may be able to discontinue insulin use.<sup>30,32</sup>

Types of insulin are classified by a variety of features, but from a practical standpoint are grouped according to the duration of action: rapid acting, short acting, intermediate acting, and long acting (Table 41-4). The most commonly used insulins in the rapid-acting category are aspart, glulisine, and lispro. Regular insulin is considered short acting. Intermediate-acting agents include isophane. Gargine and detemir are in the long-acting category.<sup>32</sup> There are novel forms of insulin and incretins being developed, including oral insulin tablets, oral insulin spray, and oral incretins.<sup>55</sup>

Patterns of insulin use vary with the type of diabetes and the degree of desired metabolic control. For patients with type 1 diabetes mellitus, a minimum of two or more daily injections of rapid-acting and long-acting insulins has been used to control postprandial and fasting hyperglycemia. A popular regimen includes use of long-acting gargine with preprandial injections of a rapid-acting insulin.<sup>32</sup>

In the management of type 2 diabetes, insulin is initiated early in the course of the disease to achieve and maintain glycemic control. It can be used concomitantly with other antidiabetic agents. The intensity of the regimen is based on the needs of the patient. Long-acting insulin or rapid-acting insulin can only be used to improve fasting or postprandial glycemia, respectively, depending upon the patient's needs. Normally, fasting glucose is targeted first; if HbA<sub>1c</sub> goals are not met, prandial insulin is initiated. Mixed formulations are beneficial, and require only one to two injections per day, in type 2 diabetes as well.<sup>13,32</sup>

The action of insulin is affected by many elements, including climate, alteration in blood flow, tobacco use, and the injection site. Insulin is absorbed most rapidly from the abdomen, less rapidly from the arm, and most slowly from the legs and buttocks. Insulin is absorbed more rapidly from areas that are exercised or massaged after injection.<sup>13,32</sup>

**Hypoglycemia complications.** Hypoglycemia is the most common complication of hyperglycemic therapy and the most hazardous. Neural tissue depends on a constant supply of glucose for normal function. When insufficient food intake, unplanned activity, or an inappropriate insulin or sulfonylurea dose lowers the blood glucose concentration excessively, counter-regulatory mechanisms are activated to ensure a continued supply of glucose to the brain. The counter-regulatory mechanism that commences with the activation of the sympathetic nervous system is a response to hypoglycemia that results in the release of glucagon, corticosteroids, and growth hormones.<sup>19</sup>

Symptoms of hypoglycemia produced by counter-regulatory mechanisms include pallor, tremor, diaphoresis, palpitation, and anxiety. Neuroglycopenic symptoms noted in hypoglycemia are hunger, visual disturbance, weakness, paresthesias, confusion, agitation, coma, and death. In long-standing diabetes, neuropathy can alter the counter-regulatory mechanisms. Hypoglycemic unawareness, in which the diabetic patient does not experience counter-regulatory symptoms, can be the result.<sup>32</sup>

**Other complications of insulin therapy.** Another typical complication of insulin therapy is lipodystrophy. Lipoatrophy has been linked to the use of insulin from animal and human sources and is manifested as hollows in the surface of the skin caused by the destruction of subcutaneous adipose tissue. The exact mechanism is not clear

TABLE 41-4 INSULIN AND OTHER INJECTABLE ANTIHYPERGLYCEMIC MEDICATIONS

DRUG CLASS	ACTION	BRAND NAME	GENERIC NAME	APPEARANCE	RX OR OTC	DRUG TYPE
Insulin	Rapid	Humalog	Insulin lispro	Clear	Rx	Insulin analogue
		NovoLog	Insulin aspart	Clear	Rx	Insulin analogue

but is suggested to be derived from an immune-mediated response. Lipohypertrophy is characterized by an increase in subcutaneous tissue because of insulin-stimulated growth of adipose tissue at the injection sites. Avoiding repeated injections at the same site is recommended to prevent lipodystrophy.<sup>63</sup>

An acute complication of insulin use can be insulin edema, or a localized or generalized accumulation of fluid. Weight gain can accompany initiation of insulin therapy, especially when glycemic control is improved. A third complicating factor in insulin therapy is insulin resistance. Insulin resistance is exacerbated by obesity and can necessitate the use of large insulin doses. An appropriate diet and exercise program is as important to insulin-treated individuals as it is to other patients with diabetes.<sup>32,51</sup>

### Stress Management

Living with diabetes can be stressful. The tasks of blood glucose monitoring, medication administration, meal planning, and implementing preventive care to avoid complications can be demanding. Fearing the onset of complications and their impact in addition to living with

complications are parts of the psychological impact of diabetes. Depression is more likely to be diagnosed in individuals with diabetes and is correlated with deterioration of glycemic control.<sup>64</sup> Stress management can have an important role in diabetes care by improving quality of life and reducing the possible impact of stress on glycemic control.

### Assessment of Efficacy

Several measures are used by clinicians to determine the adequacy of glycemic control. One indirect but very useful indication of blood glucose levels is the level of glycated hemoglobin. Hemoglobin becomes glycated when glucose is nonenzymatically attached to one of its terminal amino acids. Four glycated hemoglobin products are formed: HbA<sub>1a1</sub>, HbA<sub>1a2</sub>, HbA<sub>1b</sub>, and HbA<sub>1c</sub>. The latter is produced in the largest quantity and is used in most assays.<sup>32</sup>

Because erythrocytes are freely permeable to glucose, the quantities of glycated hemoglobin formed are proportional to the quantity of glucose in the blood plasma. Glycated hemoglobin values will reflect mean blood glucose levels for the life of the average erythrocyte (100 to 120 days).

ONSET (IN HOURS UNLESS NOTED)	PEAK (HOURS)	DURATION (HOURS)	COMPATIBLE MIXED WITH	STORAGE/ EXPIRATION	TYPICAL DOSING/ COMMENTS
15-30 min	1-2	3-4	NPH	Refrigerate/28 days at room temp	15 min before meal or immediately after meal

	20 min	3	None	Refrigerate/28 days at room temp or refrigerated	Immediately before each major meal (≥250 kcal or 30 g of carbohydrate)

Highly significant correlations have been found between HbA<sub>1c</sub> levels and mean blood glucose level.<sup>65,66</sup> The presence of abnormal hemoglobins or hemolytic anemia can skew results. The normal value for HbA<sub>1c</sub> varies with the laboratory technique but is usually less than 7%. Results of the A1C-Derived Average Glucose (ADAG) Trial published in 2008 correlated an HbA<sub>1c</sub> number to average glucose levels rather than a percentage. This change has little impact on clinical management; however, it decreases patient confusion regarding glycemic control.<sup>67,68</sup>

HbA<sub>1c</sub> values are used clinically to estimate long-term control and to establish and evaluate therapeutic goals. Values of less than 7% or as close to normal as possible without adverse effects are considered desirable. Depending upon individual circumstances and life expectancy, less stringent goals may be appropriate. HbA<sub>1c</sub> values cannot be used for daily management of therapy.<sup>32</sup>

Assessment of glycemia on a daily basis was attempted in the past by the use of testing for glycosuria. However, the blood glucose level at which glucose is measurable in the urine, the glycemic threshold, varies from individual to individual, is usually unacceptably high, and cannot be used to establish the presence of hypoglycemia.

The First and Second Consensus Development Conference on Self-Monitoring of Blood Glucose, convened by the American Diabetes Association and other involved agencies, formulated several goals for the use of capillary blood glucose monitoring. The goals included use of capillary blood glucose monitoring to achieve and maintain a specific level of glycemic control, prevent and manage hypoglycemia, avoid severe hypoglycemia, adjust care in response to changes in lifestyle in individuals requiring pharmacologic therapy, and determine the need for initiating insulin therapy in women with gestational diabetes mellitus.<sup>65,66</sup>

Capillary blood glucose monitoring has been shown to be an accurate reflection of venous blood glucose level when performed by health professionals and by individuals with diabetes. Accuracy can be affected by such performance errors as underloading or overloading of the strip, incorrect placement of the sample, and improper handling of the sample. Training improves performance.<sup>65,66,69</sup>

Diabetic individuals using capillary blood glucose monitoring have frequently reported enthusiasm and increased insight into the relationship between blood glucose level and such factors as diet, exercise, and

stress and also have expressed increased feelings of well-being. Capillary blood glucose monitoring has been associated with improved glycemic control. Monitoring of capillary blood glucose levels is simply a feedback mechanism that provides immediate information on the effects of a change in therapy.<sup>65,66,69</sup>

In the replacement of testing for glycosuria with capillary blood glucose monitoring, testing for ketonuria should not be neglected. The presence of ketones in the urine can be an indication of diabetic ketoacidosis and may be harmful to a developing fetus in diabetes complicated by pregnancy. All individuals with diabetes should be tested for ketonuria when blood glucose values are greater than 300 mg/dl, during concomitant illness, during pregnancy, and in the presence of symptoms of diabetic ketoacidosis (nausea, vomiting, abdominal pain).

#### KEY POINTS

- The mainstays of diabetic treatment are diet, exercise, and drug therapy. Education is an integral part of treatment, enabling individuals with diabetes to follow the diabetic regimen and avoid complications. The efficacy of therapy can be assessed by monitoring blood glucose and HbA<sub>1c</sub> levels. Blood glucose monitoring is useful for assessing short-term efficacy. HbA<sub>1c</sub> is a better measure of the long-term efficacy of therapy. A mean blood glucose level less than 170 mg/dl (HbA<sub>1c</sub> level of 7% or less) is desirable.
- Exercise has several benefits for an individual with diabetes. Insulin requirements may be reduced, weight loss facilitated, and the risk of cardiovascular complications decreased. Exercise may precipitate hypoglycemia, so insulin injections or dietary intake may have to be adjusted. Oral antidiabetic agents may be successfully used in type 2 diabetes. The sulfonylureas exert their effects primarily by stimulating the release of endogenous insulin. They also reduce insulin degradation and suppress the release of glucose from the liver. Metformin suppresses hepatic gluconeogenesis and enhances glucose uptake by peripheral tissue; thiazolidinediones enhance glucose uptake by peripheral tissue; and acarbose delays absorption of ingested carbohydrate. Newer agents such as incretin mimetics, incretin enhancers, and amylin analogues will also be impacted by exercise.
- Insulin replacement therapy is required in all patients with type 1 diabetes and in about one third of patients with type 2 diabetes mellitus. Insulin is classified according to its onset, peak, and duration of action. A combination of insulins may be given to produce optimal control. Long-acting insulin (glargine or detemir) and a rapid-acting insulin (aspart, lispro, glulisine) are commonly used to mimic basal and prandial insulin levels, respectively.
- Hypoglycemia is the most common complication of pharmacologic therapy. Symptoms are mediated primarily by activation of the sympathetic nervous system stress response. Secretion of catecholamines, glucagon, corticosteroids, and growth hormone rises in an attempt to increase blood glucose levels. Pallor, tremor, diaphoresis, weakness, and decreased consciousness are the usual manifestations of hypoglycemia.

## PEDIATRIC CONSIDERATIONS

Diabetes has been diagnosed in approximately 176,500 children and adolescents younger than 20 years. One in every 400 to 600 children and adolescents has type 1 diabetes, and 18 new cases per population of 100,000 are diagnosed yearly. The overwhelming majority have type 1 diabetes, with an approximate 5% prevalence of genetic defects in  $\beta$  cells.<sup>1,3,13</sup>

Type 1 diabetes is characterized by destruction of the  $\beta$  cells of the pancreas with resulting insulinopenia. Type 1 diabetes in children is

often manifested acutely as diabetic ketoacidosis when insulin secretion falls below insulin needs. A condition termed the “honeymoon period” can develop if the diagnosis occurs during a time of increased insulin needs, such as during a viral illness. When the illness is resolved, insulin needs can fall below residual insulin production and normoglycemia results without the use of exogenous insulin. The honeymoon period rarely lasts more than 1 year and is usually shorter.<sup>13,18</sup>

### Goals of Therapy

Goals of therapy for children include achieving normal growth and development, avoiding acute and chronic complications of diabetes, addressing psychosocial issues, and educating children regarding self-care.<sup>32</sup>

### Acute Complications

Whenever children with type 1 diabetes mellitus experience hyperglycemia, the resulting glycosuria can precipitate dehydration. The threat of dehydration is especially severe during episodes of diabetic ketoacidosis. Supplemental fluids and insulin may be necessary during these times.<sup>32</sup>

Diabetic ketoacidosis can occur when insulin administration is inadequate for needs. Diabetic ketoacidosis frequently accompanies the diagnosis of type 1 diabetes mellitus. Avoiding diabetic ketoacidosis involves knowledge of appropriate care during times of increased insulin need, such as during concomitant illness. To ensure early detection of incipient diabetic ketoacidosis, children and adolescents should be tested for ketonuria when the blood glucose concentration is greater than 240 mg/dl and during concomitant illness.<sup>13,32</sup>

Hypoglycemia can be difficult to detect in very young children. Caregivers should be alert for behavioral changes such as lethargy, pallor, and sleep disturbances.

### Chronic Complications

Chronic complications of diabetes are rarely manifested during adolescence. Screening for neuropathy and nephropathy and determinations of serum lipid levels should occur on a regular basis. Adolescent girls must be counseled on the importance of excellent metabolic control before initiation of pregnancy.<sup>32,49</sup>

### Treatment

Insulin requirements are approximately 1.0 unit/kg per day. An intensive regimen of at least three injections per day is recommended to prevent chronic complications. The administration of very small doses of insulin in infants and children may necessitate the use of a diluent.<sup>13,32</sup>

Insulin needs increase during times of physiologic stress, such as during concomitant illness or puberty. Children who are inadequately treated with insulin will not grow or mature normally.

Children are usually able to begin administering insulin and performing capillary blood glucose monitoring with supervision when they are of school age. The age may vary with different children. When administering insulin, the abdomen is the least preferred site because of insufficient abdominal subcutaneous fat.

Diabetic teaching of such self-management skills as insulin injection, capillary blood glucose monitoring, and recognition and treatment of hypoglycemia should include all caregivers. Baby-sitters and teachers will need information on prevention, recognition, and management of hypoglycemia. All educational materials used with children should be age appropriate.<sup>32,69</sup>

Children must be provided with a caloric intake adequate to meet needs for energy expenditure, growth, and maturation. Calorie intake is usually calculated as 1000 calories/day plus 100 added calories for

each year until age 11 years. From ages 11 to 18 years, an additional 100 calories is added for girls and an additional 200 calories for boys. Growth should be plotted at each medical appointment to assess adequate nutrition and adequate insulinization. After the age of 2 years, recommended dietary guidelines for percentage of fat, carbohydrate, and protein intake are the same as those for adults.<sup>32,51</sup>

Exercise is encouraged, with careful attention to adequate nutritional intake. Insulin doses may need to be adjusted to plan for unusual levels of activity, such as during long-distance bike riding or hiking.<sup>52-54</sup>

Following a regimen designed to prevent acute and chronic complications of diabetes is difficult under the best of conditions. The goals of treatment are best accomplished when meals, medication, exercise, and blood glucose monitoring are consistent. Achieving consistency while also achieving developmental goals of separation and independence is very difficult. Peer pressure during adolescence can lead to poor adherence to therapeutic regimens. Concern regarding weight can lead to omission of insulin injections or the manifestation of eating disorders.

The child and family need support and counseling to develop effective strategies for achieving desired goals. Disturbed family functioning can have an impact on children and adolescents with diabetes and can lead to an increased frequency of hospitalization for diabetic ketoacidosis.

Genetic defects of the  $\beta$  cell are usually diagnosed in individuals younger than 25 years. These individuals are not likely to become ketotic. Management is identical to that of type 2 diabetes in young adults.

#### KEY POINTS

- Children and adolescents with diabetes overwhelmingly have type 1 diabetes mellitus (5% have genetic defects of the  $\beta$  cell). In type 1 diabetes, insulin is required at diagnosis or shortly thereafter.
- Goals of therapy for children include achieving normal growth and development, avoiding acute and chronic complications of diabetes, addressing psychosocial issues, and educating children regarding self-care.
- Acute complications of diabetes in children and adolescents include hyperglycemia leading to dehydration, possible diabetic ketoacidosis, and hypoglycemia. Hypoglycemia may manifest differently in children than in adults.
- Chronic complications in children and adolescents are rare. Screening for complications should nevertheless be initiated. Adolescent girls should be counseled on issues regarding diabetes and pregnancy.
- Insulin needs will vary according to growth stages, exercise, and concomitant illness. Regular capillary blood glucose monitoring is crucial for determining the efficacy of treatment. The age at which children can perform insulin measurement and administration as well as capillary blood glucose monitoring independently will vary. Nutritional needs are calculated at 1000 calories/day, with 100 added calories per year until age 11 and then an additional 100 calories for girls and an additional 200 calories for boys ages 11 to 18.
- Education in self-care activities should be appropriate for age and include other family members. Support both for the person with diabetes and for the family is important. Counseling may be helpful in some circumstances.

## GERIATRIC CONSIDERATIONS

The prevalence of type 2 diabetes mellitus increases with age. Adults older than 60 years constitute nearly 50% of the diabetic population of the United States. The prevalence of diabetes in the elderly is almost

21% for individuals age 60 or older and more than doubles that of younger adults ages 40 to 59.<sup>1</sup>

The increase in risk for type 2 diabetes in older adults is multifactorial. Aging often involves increased adiposity and a decrease in lean body mass and activity levels. The latter factors contribute to insulin resistance. Insulin secretion also diminishes with age. The risk of diabetes in the elderly is likewise increased by surgery, illness, and the use of such medications as steroids and diuretics.<sup>1</sup>

Diabetes in the elderly can be difficult to diagnose because of fluctuating blood glucose values in response to food intake and activity and because of inconsistent or absent symptoms of hyperglycemia. Chronic complications of diabetes such as neuropathy and retinopathy are frequently present at diagnosis and indicate glucose intolerance of long duration.<sup>32</sup>

### Goals of Therapy

Goals of treatment for the elderly include prevention of acute complications, prevention and management of chronic complications, attention to psychosocial issues, and education regarding self-care.<sup>32,69</sup>

### Acute Complications

Uncontrolled hyperglycemia in the elderly may be asymptomatic or may produce such classic symptoms as polyuria and fatigue. Polydipsia is less common because of decreased thirst perception. Hyperglycemia can result in increased perception of pain and slowing of intellectual processes. The risk of infection is greater when blood glucose values are greater than 200 mg/dl. Such infectious disease processes as malignant otitis externa and reactivation of chronic tuberculosis are linked to hyperglycemia. Elderly individuals with diabetes are two times as likely to be hospitalized for kidney infections as elderly individuals without diabetes.<sup>32,47</sup>

Chronic hyperglycemia can cause mild to moderate dehydration in the elderly that can be exacerbated by age-related changes in kidney function and water conservation. The resulting postural hypotension and electrolyte imbalances can increase the risk of falls.

Elderly people with type 2 diabetes mellitus are not prone to ketosis, but they are at risk for nonketotic hyperglycemic hyperosmolar coma. Particular risk factors include impaired thirst recognition, polypharmacy, dementia, and concurrent illness. Profound dehydration can occur and lead to a significant mortality rate for this complication (10% to 50%).<sup>34</sup>

Older individuals with type 2 diabetes mellitus must be instructed in care during periods of concomitant illness and advised to perform capillary blood glucose monitoring on a regular basis to avoid undetected hyperglycemia.<sup>69</sup>

Hypoglycemia can occur when an elderly individual with diabetes is treated with a sulfonylurea or insulin. Hyperglycemia can occur atypically with symptoms of lethargy or focal neurologic dysfunction. Elderly individuals may have age-related decreases in counter-regulatory function or an inability to report hypoglycemic symptoms. Glycemic targets for these individuals may be higher. The risk of injury during a hypoglycemic episode warrants careful observation of blood glucose values and regular evaluation of treatment of all elderly individuals with diabetes.<sup>32</sup>

### Chronic Complications

The increased prevalence of heart and blood vessel disease, kidney disease, eye disease, and foot disease in patients with diabetes overlaps with the increased prevalence of these conditions in the general elderly population. Diabetes increases the incidence and severity of these diseases.

Aging-related changes can present a particular problem in the performance of diabetic foot care. Orthopedic deformity, loss of

protective subcutaneous fat, and atherosclerotic changes are all common problems of the elderly. Inspection of the feet and nail care can be compromised by changes in visual acuity and joint function. Assistance with foot care is often necessary to minimize the risk of diabetic complications involving the feet.<sup>32,40,42</sup>

### Treatment

Oral antidiabetic agents must be chosen carefully to avoid age-related adverse effects. Oral agents with a shorter duration of action are preferable. Elderly individuals with diabetes should be evaluated for changes in renal and hepatic function. Oral agents metabolized in an impaired system should be avoided. Metformin is not appropriate for individuals with decreased liver and renal function because of the increased risk of lactic acidosis.<sup>32</sup>

Insulin is safe to use with caution in the elderly. Thin elderly individuals can be highly sensitive to insulin and may require very small amounts to control hyperglycemia. Some elderly individuals are quite sensitive to regular insulin. Daily or twice-daily dosing of long-acting insulin may be preferable.

Age- or illness-related changes in vision, manual dexterity, and cognition can diminish the ability to measure and administer insulin. Magnification devices and the use of prefilled syringes can be of assistance.

Exercise is of benefit to individuals of all ages. Exercise plans must often be modified to account for orthopedic or other mobility problems. Armchair exercise can be an excellent way for elderly individuals to stay active.<sup>52-54</sup>

Appropriate food intake can help control hyperglycemia and reduce the risk of chronic complications in the elderly, as in all individuals with diabetes. The quality and quantity of nutrients must be assessed carefully in the elderly. Elderly individuals may be obese, malnourished, or both. Increasing the nutritional value of a meal plan that is low in calories because of choice or a desire to lose weight is an important and difficult goal. Dental and other oral disease or dysfunction can have an impact on nutritional intake.<sup>51</sup>

Education of the elderly in diabetic self-care practices can be challenged by age-related changes in vision, hearing, and cognition.

Simple, clearly written educational materials and less complex therapeutic regimens can be of assistance. Caretakers and family members should be included in education sessions if possible. Family or other assistance can ensure safe performance of diabetic self-care activities while maintaining as much independence as possible.<sup>32</sup>

### KEY POINTS

- The increased prevalence of type 2 diabetes mellitus in the elderly is multifactorial and due to increased adiposity, decreased lean body mass, decreased activity levels, decreased insulin secretion, the hyperglycemic effect of certain medications, concurrent illness, and surgery. Varying blood glucose values can lead to difficulty in diagnosis.
- Goals of treatment for the elderly include prevention of acute complications, prevention and management of chronic complications, attention to psychosocial issues, and education regarding self-care.
- Acute complications of diabetes in the elderly include hyperglycemia, often asymptomatic, which can lead to dehydration; increased risk of infection; and nonketotic hyperglycemic hyperosmolar coma. Hypoglycemia can occur atypically and may lead to injury.
- Heart and blood vessel disease, foot problems, visual disabilities, and kidney disease have a significant presence in the aging population in general, as well as being chronic complications of diabetes. Avoiding foot problems can be particularly challenging given the frequent presence of orthopedic deformity and other common aging-related changes, as well as the decreased ability to perform appropriate foot care.
- Oral antidiabetic agents should be carefully chosen with consideration of renal and hepatic function. Short-acting agents are preferable. When insulin treatment is necessary, visual or orthopedic and other changes may hinder measurement of insulin. Adaptive devices can be helpful. Exercise should be encouraged and may have to be modified for people with limited mobility or other limiting factors. Meal planning for elderly individuals should emphasize appropriate amounts of foods with high nutritional value.
- Simple, clearly written educational material can be helpful for individuals with visual or cognitive impairments. Caretakers or family members should be included in education sessions if necessary.

## SUMMARY

Diabetes mellitus, the most common endocrine disorder, affects millions of Americans.<sup>1</sup> Diabetes is characterized and diagnosed by chronic hyperglycemia, the result of a relative or absolute deficiency of insulin; however, the metabolism of all energy nutrients is altered. Of the four clinical classes of diabetes, the most common are type 2 and type 1 diabetes. Type 2 diabetes is characterized by insulin resistance and a reduction in insulin production leading to a relative insulin deficiency.<sup>30</sup> Type 1 diabetes is the result of destruction of the insulin-producing  $\beta$  cells of the pancreas because of an autoimmune or idiopathic process.<sup>13</sup>

Sequelae of insulin deficiency include the acute and chronic complications of diabetes. Acute complications include diabetic ketoacidosis in type 1 and nonketotic hyperglycemic hyperosmolar coma in type 2 diabetes. Chronic complications include cardiovascular disease, retinopathy, nephropathy, and neuropathy.

The goals of treatment are glycemic control and prevention of complications. Treatment is individualized and encompasses an

individualized diet, regular exercise, and appropriate use of medications such as oral antidiabetic agents, incretin and amylin mimetics, and insulin. The efficacy of treatment and the presence of complications of therapy are evaluated by capillary blood glucose monitoring. Patient education is an essential component in teaching skills associated with treatment.<sup>32</sup>

Special considerations attend the treatment and education of individuals with diabetes in the pediatric and geriatric age groups. Children and adolescents require careful monitoring to adjust insulin levels for variations in maturation, exercise, and concomitant illness. The elderly may have chronic complications of diabetes or other impairments of mobility, vision, or cognition that affect treatment.<sup>32</sup>

Educational materials must be appropriate for age in children and be accessible for elderly individuals with visual or cognitive impairments.<sup>32,41</sup>

Immobility, 854

Throughout its life span, the human body is differentially adjusted and maintained by a complex and connected network of biochemical reactions embedded in pathways that are involved in both energy balance and the interconversion of metabolites to meet ever-changing physiologic needs. This process, known as **metabolism**, uses energy to sustain the body's vital functions.<sup>1</sup> Metabolism utilizes the favorable thermodynamics of biochemical reactions to carry out the physiologic processes of the body in a systematic and tissue-specific manner. These interrelated and dynamic reactions meet the unique requirements of each independent cellular activity.<sup>2</sup> To fuel this system, adequate supplies of digestible foodstuffs with the appropriate organic chemical structure must be acquired on a regular basis or malnutrition and eventual starvation will result. Adequate nutrition is needed for growth and metabolism, organ function, tissue repair, and response to infection. Excess nutrition without a compensatory energy expenditure leads to many diseases and may also make the body more susceptible to pathogens.

Many hospitalized patients enter the care center with a significant degree of physiologic stress and sometimes multiple organ dysfunctions, both of which can alter essential and general nutritional needs. Treatment modalities, altered intake, and restricted mobility may also require nutritional adjustment. In many cases, these problems can be averted, or at least addressed appropriately, if nutritional assessment and therapy are started early.<sup>3,4</sup> This chapter reviews normal nutrient metabolism and nutritional assessment and then progresses to a discussion of physiologic and metabolic dysfunctions.

It is clear that many diseases are fundamentally metabolic, even those typically associated with biological clock mechanisms<sup>5</sup> or ascribed to endocrine hormone dysfunction, such as insulin resistance in metabolic syndrome.<sup>6</sup> Although not discussed here, heritable diseases are almost exclusively inborn errors of metabolism (see Chapter 6).

## METABOLIC PROCESSES

**Metabolism** is the dynamic phenomenon in biological systems involving the physical and chemical processes that produce and maintain (anabolic), and also transform (catabolic), molecules into energy and waste products. Metabolism may be functionally examined along interconnecting biochemical pathways, which fall into three discrete cellular programs:

1. **Intermediary metabolism**, which can be defined as the biochemical process involved with the interconversions of molecules through pathways that are controlled by multiple layers of regulation
2. **Primary metabolism**, which includes biochemical pathways and the cellular machinery of DNA replication, recombination, transcription, RNA processing, translation, and protein processing
3. **Secondary metabolism**, which refers to the synthesis, accumulation, and degradation of molecules that are not specifically essential for normal cellular processes

Nutrition and disease can impact all metabolic programs but the precise nature of this response must be carefully determined using the methods of biomedical screening and interpretation of results. Underlying these medical practices are the basic experimental sciences of biochemistry, genetics, cell physiology, pathology, and microbiology.

The key to metabolism is the control or regulation of the concentrations of metabolites in given cell types such that the system is poised to deal with nutritional and signaling phenomena. Cells must be receptive to membrane-associated signaling so that lipids (or glucose or amino acids) can be transferred or a suite of “messenger” molecules can be recruited and secreted by the activated cell. At the same time, the cell must be in an energetically favorable state; this requires both production and utilization of energy, usually in the form of

adenosine triphosphate (ATP), although many nucleotides take part in this energy transfer (e.g., cyclic AMP [cAMP], guanosine triphosphate [GTP], reduced nicotinamide adenine dinucleotide phosphate [NAD(P)H], flavin adenine dinucleotide [FAD]).

The reactions leading to the assimilation of organic molecules are organized into metabolic pathways. A pathway can be considered a sequential vectorial transfer of substrate to product where the individual catalytic events are carried out by specific enzymatic reactions. The following is a brief account of how metabolic pathways are organized.

- Enzymes in a pathway can be organized in clusters sometimes via simple compartmentalization and sometimes via more specific protein-protein interactions such as multisubunit and polyprotein complexes. Intermediates in a pathway are specifically transferred to the next enzyme active site, even though this process may be nothing more than simple diffusion. The rates of the reactions are such that flux through the pathway is guaranteed and intermediates do not simply diffuse away from the catalysis.
- Soluble and discrete enzymes carry out glycolysis within the cytosol. When this pathway design is utilized, it may be enhanced catalytically by compartmentalization, as the tricarboxylic acid (TCA) cycle is sequestered in the mitochondrial matrix. Another pathway that is utilized in eukaryotic cells is the same as that found in plant fatty acid synthesis (FAS). Here, the proteins are aggregated but not covalently attached. They can be separated as individual catalysts but are believed to exist as protein aggregates in the stroma of the chloroplast. FAS I, as found in mammals and yeast, is a multiprotein or polyprotein covalently linking all of the component proteins in a highly efficient multienzyme complex. Another form of order is that found in the oxidative phosphorylation reactions of the inner mitochondrial membrane leading from the utilization of NADH and the subsequent electrochemical proton pumping coupled to ATP synthesis. These are membrane-bound complexes. Pathways are functionally separated and regulated:
- *Catabolism and degradative metabolism.* Dietary foods are combusted or oxidized to the final end products CO<sub>2</sub> and H<sub>2</sub>O. The electrons from these reactions are largely driven to molecular oxygen, and the production of ATP is coupled to this reduction of oxygen (see Chapter 3). Some of the electrons driven off during the oxidation of carbon are used to make NADPH that in turn provides reducing power for biosynthesis. Glycolysis and the TCA cycle are the major metabolic routes, as well as fatty acid  $\beta$  oxidation, amino acid catabolism to ketogenic (TCA) or glucogenic products, purine degradation to uric acid, and pyrimidine degradation to  $\beta$ -alanine, NH<sub>3</sub>, and CO<sub>2</sub>. Along these degradation pathways, intermediates for biosynthesis are formed and used (e.g., oxidative pentose phosphate pathway, flavin nucleotides).
- *Biosynthesis or anabolism.* This metabolism involves several unique biosynthetic routes each coupled to the energy state of the cell and the specific cell type, age, and degree of stimulation/signaling. NADPH is the preferred bioreductant in biosynthesis. ATP is also usually required to overcome thermodynamic unfavorability of biosynthetic reactions. Thioester intermediates are also commonly used in biosynthesis. During biosynthesis, substrates are replenished from the catabolite pools, as are NADPH and ATP. Examples of biosynthetic pathways include gluconeogenesis, fatty acid synthesis, amino acid and nucleotide biosynthesis, and protein synthesis. DNA replication and transcription are anabolic pathways as is covalent modification of proteins.

## Anabolism and Catabolism

**Anabolism** refers to the constructive phase of metabolism and involves the synthesis of organic molecules by cells. More complex or larger

molecules are built from simple ones, and in the process energy is consumed. Anabolism occurs continuously along with catabolism, but is more prominent during times of rest, healing, pregnancy, lactation, and growth. Hormonal secretions such as insulin and sex hormones may also trigger anabolism. Obesity, with the accumulation of adipose tissue via net synthesis of lipids such as triacylglycerol, is a form of anabolism.<sup>7</sup> Conversely, **catabolism** is the degradative phase of metabolism. Complex molecules are broken down into simpler substances, often with the concurrent release or production of chemical energy. During times of disease, stress, fever, or starvation or during the release of certain hormones such as thyroid hormone and cortisol, catabolism dominates the body's metabolic processes. The resultant tissue wasting may lead to cellular injury or death if excessive catabolism is left unregulated.<sup>8</sup> Anabolism and catabolism occur simultaneously and together create the dynamic, homeostatic balance of chemical substance and energy known as metabolism. In humans, both processes are most efficient in the presence of molecular oxygen although it is not required in active muscle. In some disease states such as cancer, oxygen may be present but is not used in the metabolism found in the tumor (anaerobic glycolysis, *Warburg effect*),<sup>9</sup> although this has recently been challenged and may not be universal in breast cancer.<sup>10</sup>

The metabolic process requires nutrients in the form of carbohydrates, lipids, and proteins. Each of these three nutrients is altered or broken down into simpler substances. Lipids may be directly sequestered into adipose cells after limited lipolysis and synthesis into lipoproteins for transport. Enzymes and coenzymes mediate the metabolism of glucose, fatty acids, amino acids, and nucleic acids. In this fashion, the body's continual cellular energy requirements are met.<sup>8</sup> Energy produced by metabolic processes is used to create the energy currency of the body known as ATP (see Chapter 3).<sup>8</sup>

Cells use energy to perform essential physiologic and biochemical processes. **Energy** can be measured in kilocalories (kcal); 1 kcal represents the amount of energy required to raise the temperature of 1 kg of water from 15° to 16° C. For comparison, a medium-sized baked potato without butter is about 200 kcal whereas a glass of wine is about 100 kcal and a lean filet mignon (8 oz, 227 g) is about 400 kcal.

During catabolism of fuel molecules, approximately 40% of the available energy ultimately is converted to ATP or NADPH (nicotinamide adenine dinucleotide phosphate, reduced form), with the remaining 60% producing heat.<sup>2</sup> The energy released as heat is important for maintaining body temperature.

## Metabolic Rate

Several factors determine the body's energy requirements or metabolic needs, including basal metabolic rate (BMR), growth, stress, activity level, and energy necessary for digestion.<sup>8</sup>

The **basal metabolic rate** refers to the rate of energy consumption by resting tissue. It is a measurement of the energy used in maintenance of the body at rest after a 12-hour fast.<sup>8</sup> It represents the energy used in maintaining basic body processes such as respiration, cellular metabolism, circulation, glandular activity, and the maintenance of body temperature.<sup>8</sup> The body's BMR is determined by calculating oxygen use during a specific period. The normal range for BMR is generally between 0.8 and 1.43 kcal/min.<sup>8</sup> Several factors that affect an individual's BMR are described in Table 42-1. Body stature and size affect BMR by the amount of heat lost from the body surface. BMR also is an important determinant of total daily energy expenditure (TEE).<sup>5</sup> Age is also an important determinant of BMR. A growing child's BMR is significantly higher than an adult's, primarily because of an increased rate of cellular activity, surface-to-volume ratio, and generation of new tissue.<sup>8</sup> Conversely, as one ages, the BMR gradually declines by about 2% per decade. Body composition, determined

**TABLE 42-1** EXAMPLES OF FACTORS AFFECTING BASAL METABOLIC RATE

INCREASING METABOLISM	DECREASING METABOLISM
Childhood growth	Aging process
Exercise	End-stage illness
Sympathetic stimulation	Starvation
Shivering	Sleep
Fever	Tropical climates
Thyroid hormone	Calorie-restricted diets
Muscle tissue	Reduced muscle mass
Pregnancy	
Stress	
Male sex hormone	

by the amount of fat and lean tissue, also affects BMR. Muscle tissue requires more oxygen than adipose tissue, which explains why athletes have an approximately 5% higher BMR than nonathletes.<sup>2</sup> One contribution to this observation among athletes is the enhanced  $\beta$  oxidation of fatty acids in this group.<sup>11</sup> Women typically have a metabolic rate 5% to 10% less than that of men, probably because of differences in body mass. Women also tend to have more adipose tissue than men, and fat is less metabolically active than muscle.<sup>7</sup> Pregnancy increases the BMR by about 20% to 28%, or 300 kcal/day, as a consequence of increased uterine and mammary gland size, fetal development, and additional cardiopulmonary workload.<sup>8</sup> Other factors affecting BMR include nutritional status, muscle tone, sleep, fever, environmental temperature, and stress.<sup>2</sup> Metabolic thermoregulation in newborns is described in the Pediatrics Consideration box.

Almost any alteration in the body's normal homeostatic state will alter its energy requirements and BMR. Many diseases are known to dramatically increase the body's energy requirements, including chronic obstructive and restrictive pulmonary disease, hyperthermia, burns, cancer, diabetes, and Graves disease (hyperthyroidism).

### KEY POINTS

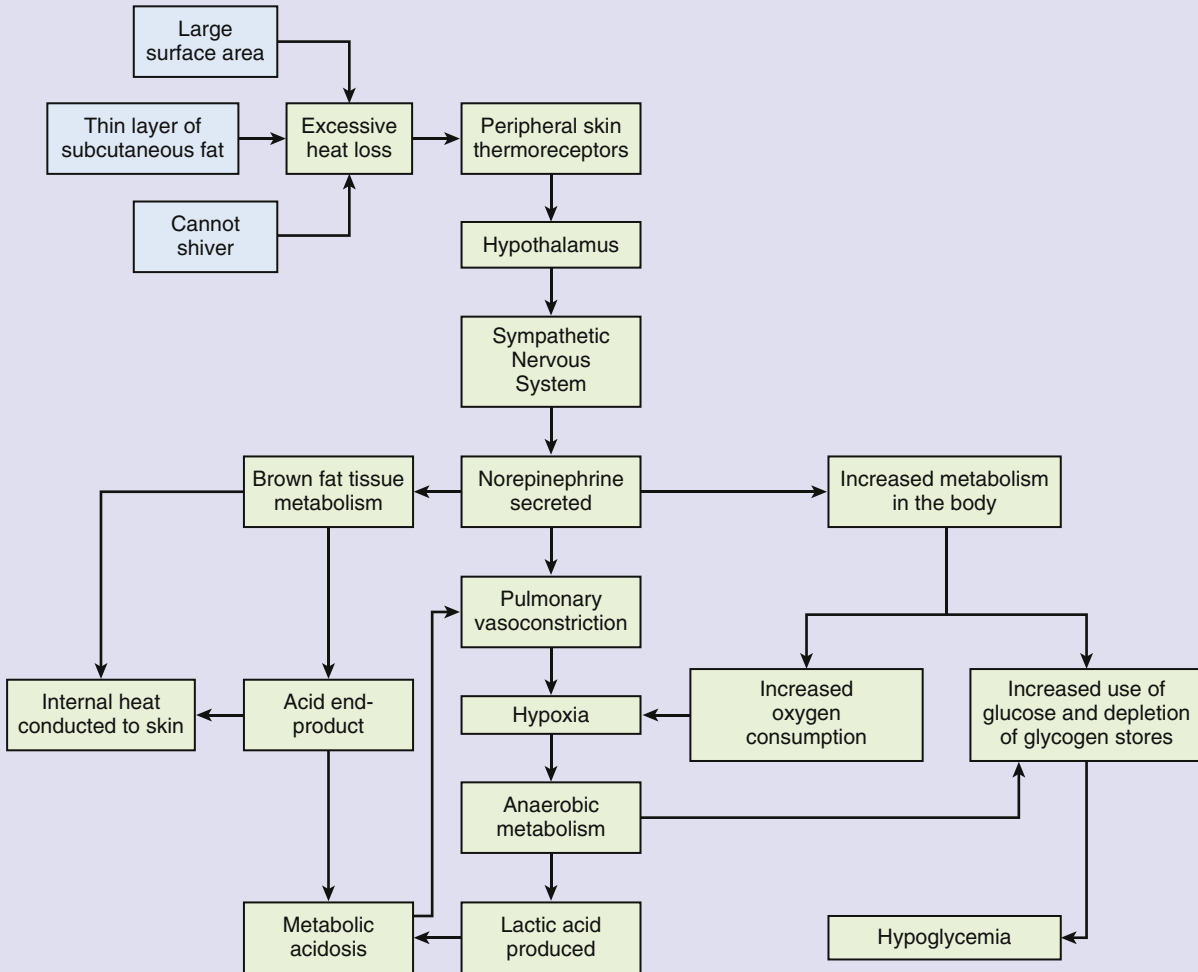

- Anabolism refers to energy-requiring processes involving synthesis of biomolecules. Catabolism refers to energy-producing processes during which biomolecules are broken down into simpler forms. Metabolism refers to the dynamic state of simultaneously occurring anabolism and catabolism.
- The BMR is the rate of energy utilization when the body is at rest. Examples of factors affecting the BMR include body size and composition, age, nutritional status, muscle mass, fever, stress, and pregnancy.

## NUTRIENT METABOLISM

Metabolism is dependent upon energy balance, which is defined as the relationship between nutritional intake and expenditure. In general, metabolism is controlled by both the nervous system and the endocrine system. There are several hormones secreted from these systems that are triggered by the nutritional and energy status of the body, which may become rapidly altered during times of acute stress or chronic disease. Four major hormones involved in nutrient metabolism are insulin, glucagon, catecholamines, and cortisol. The effects of these four hormones on carbohydrate, fat, and protein metabolism are summarized

## PEDIATRIC CONSIDERATIONS

### Thermoregulation in Newborns

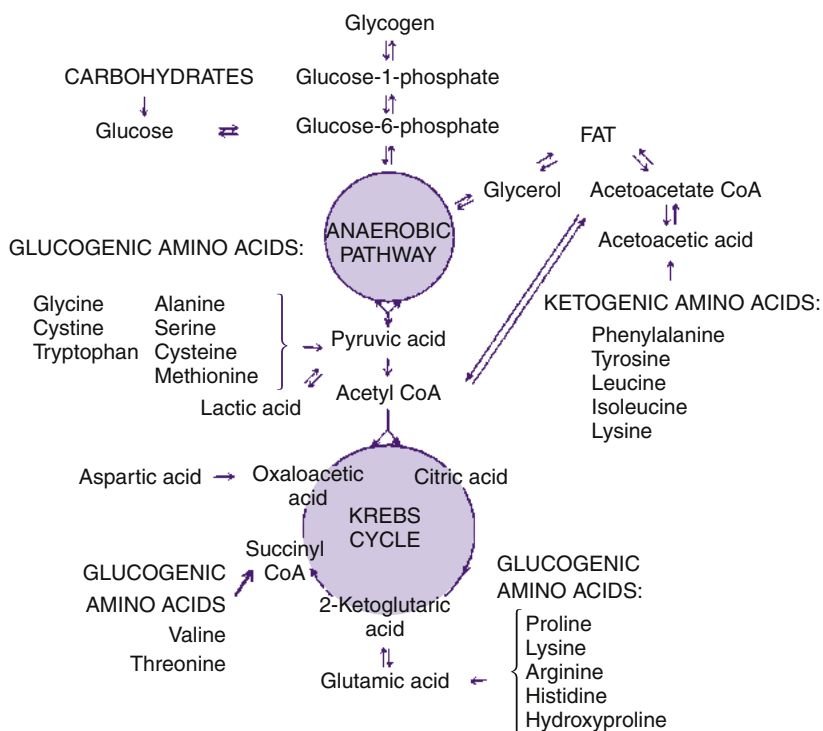

Newborns are more susceptible to excessive heat loss because of several factors. Newborns have a large surface area of skin relative to their weight; they are born with a thin layer of subcutaneous fat, and they cannot shiver. These factors can lead to excessive heat loss if the newborn is not kept warm by other means, such as appropriate clothing.

When heat is lost, the peripheral skin thermoreceptors sense the heat change and signal the hypothalamus. The hypothalamus is responsible for coordinating temperature control in the body. The sympathetic nervous system is signaled by the hypothalamus to secrete norepinephrine. Norepinephrine increases the body's metabolic rate. Metabolism first occurs in the brown fat tissue of the newborn. Brown fat, or adipose, tissue is extremely vascular, has increased glycogen stores, and has more mitochondria within the tissue. As blood passes through the brown fat tissue it absorbs heat from the metabolic process. The

heat is then conducted through the blood to the skin, warming the newborn. Brown fat tissue metabolism creates acidic end-products. Norepinephrine also increases general metabolism in the body, increasing consumption of oxygen, and glucose and glycogen stores. Norepinephrine secretion also results in pulmonary vasoconstriction that can contribute to hypoxia. The lack of oxygen forces the body to use anaerobic metabolism to create energy. Anaerobic metabolism depletes glycogen stores faster than aerobic metabolism, contributing to hypoglycemia. Anaerobic metabolism also produces lactic acid, which combined with the acidic end-products from brown fat metabolism leads to metabolic acidosis. Metabolic acidosis in turn contributes to pulmonary vasoconstriction, which further propagates the cycle. It is critical to keep the newborn warm to minimize cold stress because the newborn is ill equipped for a significant stress response.

in Tables 42-2 to 42-4. Both the nervous system and the endocrine system directly affect metabolism by the release of the catecholamines epinephrine and norepinephrine, which during times of stress inhibit insulin activity. The pancreatic hormones insulin and glucagon have a crucial role in the metabolic processes that govern the body's energy requirements. These hormones function in diametric opposition, with insulin lowering blood glucose levels and glucagon ultimately increasing blood glucose levels.<sup>2</sup> Each of these hormones is controlled by

another hierarchy of regulation. For example, growth hormone (GH) affects metabolism by decreasing cellular uptake and use of glucose. High levels of GH tend to decrease the affinity for insulin at the receptor site such that even increased secretion of insulin by the pancreas has diminutive effects on blood glucose levels. GH, in part, follows a circadian rhythm via stimulation by ghrelin, a gut peptide hormone.<sup>12</sup> Ghrelin concentration is highest after several hours of fasting. Thus, after an extended period of fasting (as during normal sleep) ghrelin is

**FIGURE 42-1** Metabolic integration of carbohydrate, fat, and protein metabolism. Anaerobic pathway: glycolysis moves with downward arrows; gluconeogenesis moves with upward arrows. CoA, Coenzyme A. (From Mahan LK, Arlin MT: *Krause's food, nutrition and diet therapy*, ed 8, Philadelphia, 1992, Saunders, p 345.)

released into the circulation, where it ultimately travels to the hypothalamus and triggers GH release. GH then travels to the periphery (e.g., muscle), where it stimulates lactic acid production for transport to the liver for gluconeogenesis. The release of ghrelin actually starts by catecholamine binding to adrenergic receptors in the gut.<sup>13</sup>

Glucocorticoid hormones, primarily cortisol, stimulate gluconeogenesis by the liver. Blood glucose levels 6 to 10 times normal may occur with significant cortisol secretion. Left uncorrected, diabetes mellitus type 2 may develop (see Chapter 41).<sup>7</sup> Metabolic syndrome, which is well correlated to obesity, may be a precondition for type 2 diabetes (see Metabolic Syndrome section).

## Carbohydrates

Carbohydrates are the main energy source for the body. Approximately 45% to 65% of the recommended diet should consist of carbohydrates.<sup>14</sup> Dietary carbohydrates are starches or sugars. Carbohydrates are classified into the three categories of **monosaccharides** (simple sugars), **oligosaccharides** (2 to 10 joined monosaccharide units), and **polysaccharides** (10 to 10,000 monosaccharide units). They range from very simple sugars consisting of three to seven carbons to incredibly complex polymers made up of repeating units of thousands of monosaccharides.<sup>8</sup>

Dietary monosaccharides are the six-carbon sugars of glucose, mannose, fructose, and galactose. Glucose, the most physiologically important of the group, is the form of sugar normally found in the bloodstream. Glucose is derived from the catabolism of more complex carbohydrates during the process of digestion. Fructose and galactose are also eventually converted to glucose by the liver, although fructose can directly enter the metabolism via phosphorylation.<sup>15</sup> Once in the bloodstream, glucose is transported throughout the body where (depending on the location) it is either oxidized to provide cellular energy and reducing power, metabolized to fatty acids, utilized in

amino acid and nucleotide metabolism, or stored in the liver and muscles as glycogen. Blood sugar levels then reflect the difference between the amount of glucose released into the bloodstream by the liver and the amount of glucose taken up by the cells for energy.<sup>7</sup>

## Intracellular Glucose Metabolism

Once in the cell, glucose undergoes various biochemical transformations including a form of anaerobic oxidation called glycolysis (see Chapter 3). Glycolysis is the metabolic sequence that converts glucose to pyruvate and, depending on several variables including oxygen availability and energy needs, eventually yields the end products of carbon dioxide and water.<sup>8</sup> Catabolism of glucose may occur anaerobically along the Embden-Meyerhof pathway (glycolysis), which is a 10-step process altering the chemical composition of glucose to pyruvic acid and results in a net gain of two ATP molecules for each molecule of glucose that enters the pathway. Pyruvic acid has two important roles in the catabolic process of carbohydrates. It provides the body with acetyl coenzyme A (acetyl CoA), which is required for conversion to fatty acids or to energy, and it is the initial step for the second stage of carbohydrate metabolism, the tricarboxylic acid (TCA) cycle (also called the *citric acid cycle* or the *Krebs cycle*) and oxidative phosphorylation. The TCA cycle occurs in the mitochondrial matrix. Oxidative phosphorylation (see Chapter 3) produces a total of about 30 molecules of ATP for each molecule of glucose. Although other pathways exist, the interrelated glycolytic, TCA cycle, and respiratory chain enzymes can produce nearly all of the energy required for cellular functioning.<sup>8</sup> Figure 42-1 illustrates the metabolism of carbohydrate, fat, and amino acids through the anaerobic glycolytic pathway and the TCA cycle. The TCA cycle and the respiratory chain require molecular oxygen (aerobic) to function.

Depending on needs, glucose is catabolized for the production of energy, synthesized into lipid, stored as polymers of glycogen, or resynthesized. **Gluconeogenesis** refers to the process by which glucose

**TABLE 42-2 HORMONAL ACTIONS ON CARBOHYDRATE METABOLISM**

HORMONE	ACTIONS
Insulin	Stimulates glucose uptake by cells Stimulates glycogenesis Inhibits gluconeogenesis
Glucagon	Stimulates glycogen breakdown Increases gluconeogenesis
Catecholamines	Maintain blood glucose level during stress Diminish glucose uptake by cells Increase glycogen breakdown
Cortisol	Stimulates gluconeogenesis Diminishes glucose uptake by cells

is formed from non-carbohydrate sources, including amino acids or lactic acid supplied by muscle tissue and glycerol supplied from fat breakdown.<sup>14</sup> The glucose made through this mechanism may be either stored in the liver as glycogen or released into the bloodstream. During periods of fasting, gluconeogenesis and glycogenolysis provide the necessary glucose to meet the metabolic requirements of the brain and other glucose-dependent tissues.<sup>7</sup>

### Hormonal Control of Glucose Metabolism

Many hormones affect glucose levels by altering carbohydrate metabolism. The only hormone known to lower blood glucose levels is insulin. Hormones that tend to raise blood glucose levels include glucagon, growth hormone, glucocorticoid hormones, epinephrine and norepinephrine, and thyroid hormone. Table 42-2 describes the major hormonal effects on glucose metabolism.

**Insulin**, a peptide hormone formed from its precursor preproinsulin and synthesized by  $\beta$  cells in the pancreas, is secreted in response to increased blood glucose levels. Minutes after ingestion of a meal, insulin levels in the blood rise significantly, peak in 30 minutes, and plateau in about 3 hours. Between meals, when blood glucose levels tend to drop, insulin levels also remain low. At that time, glucose and amino acid stores are used for cellular energy requirements.<sup>7</sup>

Insulin directly affects glucose metabolism by promoting glucose uptake by the liver, which then favors the synthesis of glycogen. Glucose formation (**gluconeogenesis**) and the breakdown of glycogen to form glucose (**glycogenolysis**) are inhibited by insulin. The transport of glucose across cellular membranes into muscle and adipose tissue is facilitated by insulin and has a direct lowering effect on blood glucose levels.<sup>16</sup>

**Glucagon** is a peptide hormone secreted by  $\alpha$  cells in the pancreas and also by some cells lining the gastrointestinal tract. Acting in a manner opposite that of insulin, glucagon increases blood glucose levels.<sup>17</sup> As blood glucose levels begin to drop, plasma glucagon levels begin to rise. Therefore, the two primary effects of glucagon are to promote the breakdown of liver glycogen with subsequent release of glucose into the bloodstream and to promote liver gluconeogenesis. These actions tend to bring serum glucose levels back to normal. Conversely, as glucose levels rise, glucagon secretion is diminished and serum glucose levels drop toward normal. The diametric actions of insulin and glucagon partially explain why increased glucagon secretion may also have a role in the elevated blood glucose levels seen in people with diabetes mellitus.<sup>2</sup>

**Catecholamines** (i.e., epinephrine and norepinephrine) are derived from the amino acid tyrosine and serve a role in carbohydrate metabolism to maintain blood glucose levels during times of stress. As the stress

response occurs, catecholamines stimulate the conversion of glycogen to glucose in the muscles and liver. Although muscles, unlike the liver, cannot release glucose into the general circulation, mobilization of muscle glycogen makes unused blood glucose available for other tissues such as the brain and the peripheral nervous system. The second primary action of epinephrine during the stress response is to stimulate glucagon secretion and prevent insulin release from the pancreas, thereby preventing glucose movement into muscle cells. Epinephrine also promotes glycogenolysis by the liver and muscles and reduces glucose uptake by muscle tissue. As mentioned previously, catecholamines also control ghrelin signaling. The role of catecholamines in glucose metabolism is very similar to that of glucagon and opposite that of insulin.<sup>2</sup>

Cortisol is derived from cholesterol and is the primary **glucocorticoid** hormone secreted from the adrenal cortex. Cortisol is an insulin antagonist and helps to maintain serum glucose levels. During fasting, cortisol permissively enables other hormonal changes to occur, such as decreased insulin production and increased glucagon and epinephrine secretion. The end result is promotion of gluconeogenesis and lipolysis. If cortisol deficiency occurs simultaneously with fasting, hypoglycemic reactions significant enough to alter brain functioning can occur. A recent study indicated that cortisol deficiency may be a significant cause of morbidity and mortality in critically ill surgical patients, who frequently are poorly nourished.<sup>18</sup>

**Growth hormone** has a role in carbohydrate metabolism, although it may be indirect in comparison with its role in growth regulation and protein anabolism; however, it can have a significant impact on glucose regulation under certain circumstances. Growth hormone's effects parallel those of cortisol: growth hormone increases gluconeogenesis in the liver and inhibits glucose uptake by muscle cells.<sup>2</sup> Growth hormone disinhibits gene expression in the liver in favor of transcription of **phosphoenolpyruvate (PEP)** carboxykinase, a key enzyme in hepatic gluconeogenesis.<sup>12</sup> Elevated serum growth hormone levels tend to increase blood glucose levels. As a result, the insulin-secreting  $\beta$  cells in the pancreas are stimulated. If this process is not corrected, the  $\beta$  cells will eventually be exhausted. It is for this reason that diabetes mellitus eventually develops in individuals with excessive growth hormone, as in acromegaly.<sup>7</sup>

**Thyroid hormone** tends to raise blood glucose levels. In carbohydrate metabolism, the primary mode of action is to increase glucose absorption from the intestines and stimulate the release of epinephrine. Thyroid hormone also promotes the rate of insulin destruction. Ultimately, thyroid hormone causes an increase in cellular oxygen consumption and the basal metabolic rate of tissues. An alteration in thyroid hormone signaling because of activating mutations of its receptor causes a reduction in body weight and decreased amounts of adipose tissue.<sup>19</sup>

### Lipids

Lipids or fats, the most concentrated form of energy, are derived de novo and from animal fats and vegetable oils. Fats supply 9 kcal of energy per gram, as compared with 4 kcal from glucose and 4 kcal from protein. Fats are 98% **triacylglycerol (TAG)**. Like carbohydrates, fats are made up of carbon, hydrogen, and oxygen. The bulk of each TAG molecule in humans consists of fatty acids containing 12 to 22 carbon atoms. Fatty acids are categorized as *saturated* or *unsaturated*. The degree of hydrogen **saturation** refers to the number of double bonds between the carbon atoms in the chain. If a fatty acid chain contains all the hydrogen atoms possible with no double bonds, it is called a **saturated fatty acid**. Those fatty acids with one double bond are termed **monounsaturated**, and those with several double bonds are called **polyunsaturated**.<sup>8</sup>

Fats in the form of TAG supply approximately two thirds of the cell's total energy requirements. Whereas the human body is able to

economically store approximately 140,000 kcal of usable fats in adipose tissue, it can store only 24,000 kcal of protein and a mere 800 kcal of carbohydrate in an adult male.<sup>17</sup> Carbohydrates and amino acids not immediately used by the tissues are converted to fat and stored, along with ingested fat, as adipose tissue. Fat deposits are extremely important in the economical use of metabolites. If intake of calories exceeds expenditure, obesity develops over time. During times of fasting, the body quickly reverts to the breakdown and use of fats as its energy source.<sup>18</sup> All tissues in the body, with the exception of brain cells, can metabolize and use fatty acids as an energy source as effectively as glucose.<sup>17</sup>

Almost all fats are absorbed into the lymph system from the intestinal mucosa. They are then converted to a chylomicron consisting of 80% triglyceride, 9% cholesterol, 7% phospholipid, and 4% lipoprotein coat.<sup>20</sup> Chylomicrons empty into the venous blood at the thoracic duct and are carried to the liver for metabolism or assimilated into adipose tissue. Once in the liver, TAG is stored and eventually mobilized via lipoprotein secretion. TAG can also be hydrolyzed to glycerol and free fatty acid in a process known as **lipolysis**. When released into the circulation, the fatty acids, bound to albumin, are quickly assimilated into tissue. Oxidation in tissue begins when coenzyme A forms a thioester bond with the free carbonyl of the fatty acid. Progressing through a series of reactions known as  $\beta$  oxidation, the fatty acid chain is shortened by two carbon units until all is converted to acetyl CoA. During this process the reduced form of flavin adenine dinucleotide (FADH<sub>2</sub>) and the reduced form of nicotinamide adenine dinucleotide (NADH) are formed, which can be used by the electron-transport chain to make ATP. Acetyl CoA can be used to make ketone bodies or it may enter the TCA cycle and oxidative phosphorylation, with each 2-carbon segment producing 2 molecules of carbon dioxide and 12 molecules of ATP. During prolonged fasting, the ketone bodies can traverse the blood-brain barrier and provide energy to the brain (see following paragraph). The average fatty acid contains approximately 18 carbon atoms, with 146 ATP molecules being produced during catabolism.<sup>2</sup> Unlike fatty acids, glycerol (the other component of triacylglycerol) can be further metabolized (primarily in the liver and in adipose and muscle tissue).<sup>21,22</sup> Free glycerol is generally carried to the liver, where it can be used to form glucose or recycled to generate new triglycerides.

As mentioned, within the liver, fatty acids are generally transformed to acetyl CoA, which is further processed into one of three compounds collectively known as **ketone bodies**. These are acetoacetate,  $\beta$ -hydroxybutyrate, and acetone. Once released into the bloodstream, ketone bodies have a critical role as an energy source for tissues able to oxidize them in the Krebs cycle. During the fasting state, tissues use ketone bodies as a primary energy source, with glucose reserved for brain metabolism. If the fasting state continues, many areas of the brain begin to use ketone bodies as an energy source. As the brain begins to use ketone bodies, less protein is broken down to provide glucose. For this reason, the body is able to withstand periods of fasting with minimal protein breakdown and associated lean body mass degeneration.<sup>2</sup> However, excessive acute ketogenesis is harmful and produces a condition known as ketoacidosis, which is prevalent in type 1 diabetes (Chapter 41).

The liver is the major organ responsible for lipid metabolism and regulation of serum lipid levels. The five primary functions of the hepatic system in regard to lipid metabolism are: (1) synthesis of triacylglycerol from carbohydrates and protein, (2) synthesis of phospholipids and cholesterol from dietary TAG, (3) desaturation and elongation of fatty acids, (4) utilization of TAG as an energy source, and (5) transport of lipids to the periphery, especially to adipose tissue.<sup>8</sup> Liver disease can significantly alter any of these processes and

**TABLE 42-3 HORMONAL ACTIONS ON LIPID METABOLISM**

HORMONE	ACTIONS
Insulin	Increases fatty acid uptake by fat cells Promotes glucose uptake by fat cells
Glucagon	Promotes lipolysis in fat cells
Catecholamines	Increase fat mobilization Increase serum free fatty acid levels
Cortisol	Increases fat cell membrane permeability

cause serious metabolic dysfunction. A fatty liver is characterized by fat deposits in the liver cells caused either by ingestion of hepatotoxic substances such as alcohol or halocarbons or by consumption of diets significantly low in protein for a prolonged period (see Chapter 38). Infections managed with protein synthesis-inhibiting antibiotics, such as tetracycline, and malignancies may also lead to increased fat deposits within the liver by adversely affecting the hepatic cells or biliary tract. Increased mobilization of fatty acids from adipose tissue to the liver occurs in certain conditions, such as metabolic syndrome, diabetes mellitus, starvation, and obesity, where lipogenesis exceeds the ability of the liver to export the fat as lipoproteins.<sup>23</sup> Metabolic studies of critically ill patients indicate that fatty acid breakdown occurs at a much higher rate than required by patient caloric needs. This excess lipolysis may cause fatty liver.<sup>24</sup>

### Hormonal Control of Lipid Metabolism

Carbohydrates can be metabolized along the anaerobic glycolytic pathway and this process can lead to mitochondrial production of citrate (via acetyl CoA and oxaloacetic acid [OAA]; both produced from pyruvate), which may reenter the cytosol for lipid synthesis. Therefore, hormones that affect carbohydrate metabolism also affect lipid metabolism. Table 42-3 describes the hormones considered to have the greatest effect on lipid metabolism. These hormones include insulin, thyroid hormone, glucocorticoids, mineralocorticoids, growth hormone, epinephrine, and norepinephrine. Insulin prevents fat utilization by indirectly causing fatty acids to be taken up by adipose tissue and by decreasing the activity of hormone-sensitive lipase, which promotes the movement of fat out of adipose tissue. Glucocorticoids increase fat cell membrane permeability, whereas mineralocorticoids and glucagon increase the activity of hormone-sensitive lipase. Epinephrine and norepinephrine increase fat mobilization by stimulating the activity of hormone-sensitive lipase, thus increasing the serum free fatty acid level. Growth hormone increases fatty acid mobilization and use by tissues as an energy source.<sup>8</sup>

Lipids also comprise the bulk of cellular membranes and they serve as paracrine and autocrine hormones. Because of their complex structure and elaborate function, including dietary and bioenergetic considerations, lipids are quite possibly the most significant class of organic compounds in metabolism.

### Proteins

Proteins are composed of nitrogen, carbon, hydrogen, oxygen, and, occasionally, sulfur. When hydrolyzed, they yield amino acids. A total of 22 amino acids have been identified in protein, 8 of which are essential—meaning that they must be supplied through the diet.<sup>20</sup> These include phenylalanine, valine, threonine, tryptophan, isoleucine, methionine, leucine, and lysine. The distinction between essential and nonessential amino acids is somewhat unclear, because some amino acids can be produced from others via transamination. Several amino acids are considered to be conditionally essential and must be supplied by the diet

under conditions of reduced ability to synthesize them in the body. For example, tyrosine can be synthesized from phenylalanine, but when a patient is receiving a phenylalanine-restricted diet, then tyrosine cannot be synthesized and must be provided in the diet. Muscle tissue, skin, and hair are composed primarily of protein. Proteins also serve as the major enzymatic catalysts. To function properly, most body processes require an adequate supply of proteins, many of which must be obtained through a balanced diet. Children, because of their rapid growth, require more protein per kilogram of body weight than adults. In addition, when compared with adults, children also need a larger percentage of their dietary intake of protein to contain essential amino acids.

Once ingested, proteins are broken down into amino acids or peptides and are absorbed through the intestinal lumen. They are then carried to the liver through the portal vein. The liver regulates protein metabolism through enzymatic breakdown of amino acids, formation of nonessential amino acids from simple precursors, and detoxification or elimination of ammonia, urea, uric acid, and other catabolic end products. Proteins are rapidly metabolized by the liver, which enables a quick response to changing metabolic demands. Amino acids supplied in excess of metabolic requirements are degraded to by-products such as urea, uric acid, or creatinine, and the remaining carbon skeletons are converted to carbohydrate and fat or oxidized for energy.<sup>25</sup> Of particular importance is the conversion of amino acids to ketoacids, which are carbohydrate-like in structure and created by removal of the amino group during deamination. These ketoacids may then enter the TCA cycle, where they provide energy for liver metabolism, or they may be converted to fatty acids by the liver.

Protein metabolism can be measured in terms of **nitrogen balance**. If nitrogen (protein) intake approximates output, an equal nitrogen balance exists. If dietary intake of proteins exceeds output, a **positive nitrogen balance** occurs. Protein anabolism exceeds catabolism during periods of rapid growth, pregnancy, and the formation of new tissue. Experimentally, positive nitrogen balance has been induced in malnourished patients through the administration of growth hormone.<sup>26</sup> A **negative nitrogen balance** occurs when protein breakdown exceeds daily protein intake and synthesis. If the daily caloric intake is insufficient, the body catabolizes dietary and tissue protein for energy, as is the case after severe burns and during fever, illness, or stress.<sup>2</sup>

### Hormonal Control of Protein Metabolism

Anabolic and catabolic protein metabolism is controlled by various hormones. Table 42-4 lists the major hormonal effects on protein metabolism. Hormones that also promote protein synthesis include growth hormone, especially during growth spurts; testosterone in specific reproductive organs during puberty; and thyroid hormone indirectly, by increasing the metabolic rate. Insulin also promotes the active transport of amino acids across cell membranes and accelerates protein synthesis within the cell. Insulin, in concert with growth hormone, is required for normal growth and development of children

and adolescents. Glucagon, whose actions diametrically oppose those of insulin, promotes gluconeogenesis by stimulating the breakdown of protein into amino acids and increasing their transport into hepatic cells. Glucagon also enables the conversion of amino acids into glucose precursors.

#### KEY POINTS

- Metabolism of carbohydrate, lipid, and protein supplies energy to support the cell's energy-requiring processes and provides building blocks for the synthesis of cellular biomolecules. The primary hormonal regulators of nutrient metabolism are insulin, glucagon, catecholamines (i.e., epinephrine and norepinephrine), cortisol, thyroid hormone, and growth hormone.
- Insulin is secreted from pancreatic  $\beta$  cells in response to elevated serum glucose levels. Binding of insulin to receptors on target cells (muscle, adipose tissue) facilitates the transport of glucose into cells and reduces blood glucose levels. Insulin inhibits lipolysis and gluconeogenesis.
- Glucagon is secreted from pancreatic  $\alpha$  cells in response to low blood glucose levels. Glucagon promotes glycogenolysis and gluconeogenesis (from lactate, amino acids, and glycerol) by the liver, thereby increasing blood glucose levels.
- Catecholamines increase glycogenolysis and gluconeogenesis by the liver, thereby increasing blood glucose levels. Catecholamines also stimulate lipolysis in adipose cells by enhancing the action of hormone-sensitive lipase. Glucagon secretion is enhanced and insulin secretion is inhibited by catecholamines.
- Cortisol enhances the actions of glucagon and catecholamines and promotes glycogenolysis, gluconeogenesis, and lipolysis, thus raising blood levels of glucose and fatty acids.
- Thyroid hormone tends to raise blood glucose levels. In carbohydrate metabolism, the primary mode of action is to increase glucose absorption from the intestines and stimulate the release of epinephrine. Thyroid hormone also enhances the rate of insulin destruction. Ultimately, thyroid hormone causes an increase in cellular oxygen consumption and the general metabolic rate of tissues.
- Growth hormone increases blood glucose levels by inhibiting uptake by muscle cells and by stimulating gluconeogenesis in the liver. Growth hormone enhances the cellular uptake of amino acids and stimulates protein synthesis. Catecholamine stimulation of ghrelin partially controls growth hormone secretion.
- The main sources of cellular energy are glucose and fatty acids. Glucose is the primary energy source for the brain, although the brain can use ketone bodies. Ketone bodies are produced from fatty acids by the liver, particularly under conditions of decreased carbohydrate intake or fasting.

### OBESITY

Obesity is defined as excessive accumulation of adipose tissue and is considered to be one of the leading contributors to preventable death in the United States. The body mass index (BMI) is calculated as weight (kg) divided by height squared ( $m^2$ ). In the United States, estimates suggest 68% of adults have a BMI of 25  $kg/m^2$  or more. Overweight is defined as a BMI of 25 to 29.9  $kg/m^2$ . Obesity is defined as a BMI greater than 30  $kg/m^2$  with morbid obesity 40  $kg/m^2$  or more. Obesity is a major health issue associated with higher rates of heart disease, kidney disease, hypertension, type 2 diabetes, polycystic ovary disease, and stroke. Obesity also creates challenges with activities of daily living from increased risk of osteoarthritis, chronic pain, gallbladder disease, sleep apnea, and psychosocial impairments.

Obesity involves complex interactions among a large number of factors, including lifestyle choices, environment, and genetics. Obesity

TABLE 42-4 HORMONAL ACTIONS ON PROTEIN METABOLISM

HORMONE	ACTIONS
Insulin	Actively transports amino acids into cells Accelerates cellular protein synthesis
Glucagon	Stimulates protein breakdown into amino acids Increases amino acid transport into hepatic cells
Cortisol	Increases protein catabolism

is associated with low-grade chronic inflammation from proinflammatory cytokines and acute-phase reactants affecting adipose tissue, skeletal muscle, and the vascular-renal systems.<sup>27</sup>

Family and twin studies have suggested that genetic heritability can be linked to 30% to 70% of body mass index variations.<sup>28,29</sup> However, most experts agree that genetics contributes only a modest factor to an individual's BMI.<sup>28,29</sup> There is increasing attention being paid to epigenetic control over obesity and related diseases (see Epigenetics in Metabolism and Nutrition).

Health care expenditures related to obesity were estimated to cost \$147 billion in 2008.<sup>27,30</sup> The majority of individuals seek to lose weight through exercise, caloric reduction, or pharmacologic therapies; however, these approaches rarely achieve optimal long-term results.

Another option for weight loss is surgical intervention, known as bariatric surgery. The main focus of surgical interventions is either to reduce the stomach size, thus creating a small pouch for the stomach that severely restricts caloric intake, or to alter the absorptive capacity of the small intestine. In many cases, surgery provides patients with long-term results of weight loss and reduction or remission of chronic illness, including diabetes type 2, hypertension, and improvement with chronic pain issues.

### Metabolic Syndrome

Metabolic syndrome, previously known as “syndrome X,” occurs in 24% of the obese population.<sup>28,31</sup> Clinically, patients with metabolic syndrome have increased amounts of abdominal adiposity, increased levels of plasma free fatty acids, insulin resistance with or without type 2 diabetes, low serum high-density lipoprotein (HDL) concentrations, hypertriglyceridemia, and hypertension. The prevalence of metabolic syndrome has a linear relationship with age, approaching 45% for people in the seventh decade of life.<sup>31</sup>

Abdominal fat accumulation is the most recognized symptom of metabolic syndrome and when combined with hypertension, hyperlipidemia, and insulin resistance can create a “deadly cocktail” of health risk and increased mortality.<sup>28</sup> In most situations, metabolic syndrome is influenced by tissue resistance to hormones, particularly insulin, caused by excess energy intake that disrupts endocrine function.<sup>28</sup>

Numerous hormones are involved in the development of metabolic syndrome and type 2 diabetes including resistin, leptin, ghrelin, and apelin. Resistin is a hormone expressed in response to cellular inflammation and results in insulin resistance and activation of other proinflammatory cytokines linked with obesity. Leptin is produced in adipocytes and normally influences the hypothalamus to inhibit appetite. Resistance to the effects of leptin and hyperleptinemia are associated with the development of obesity.<sup>27,32,33</sup>

Ghrelin is a hormone produced by the epithelial cells of the stomach that appears to regulate appetite.<sup>34</sup> Apelin is expressed by a number of organs including the gastrointestinal tract. Researchers have identified apelin deficiency in type 2 diabetes and insulin resistance.<sup>35</sup> Excessive apelin level is associated with increased serum glucose level, leading to a proinflammatory state resulting from activation of cytokines.

Research suggests that fatty acids released during lipolysis of visceral fat are a key factor of insulin resistance because fatty acids enter the portal vein and are directly deposited in the liver.<sup>31</sup> Data from research suggest that visceral fat metabolism contributes approximately 20% of free fatty acids to the liver and 15% to skeletal muscle.<sup>31</sup> Excessive visceral fat contributes to hepatic insulin resistance.

Obesity and metabolic syndrome are chronic conditions with complex interactions between caloric intake, energy expenditure,

genetics, and hormonal influences. Complications of obesity include type 2 diabetes, cardiovascular disease, and sleep apnea. Metabolic syndrome may precede the diagnosis of diabetes and cardiac disease and if treated early can slow the progression of these diseases.

#### KEY POINTS

- Obesity is a major contributor to several chronic disorders including type 2 diabetes, hypertension, and cardiovascular diseases.
- Obesity rates are increasing with an estimated 68% of adults in the United States having BMIs greater than 25 kg/m<sup>2</sup>.
- Metabolic syndrome is characterized by excess abdominal adipose tissue, insulin resistance, hypertension, hyperglycemia, and dyslipidemia.

### AGING AND METABOLIC FUNCTION

There is no question that the aging process has an effect on normal metabolism. It is sometimes difficult, however, to distinguish the effects of aging from the effects of chronic illness, dementia, drug therapy, or obesity. Essentially all metabolic processes begin a slow decline with increased aging until such morbidity ultimately leads to the end of life. The degree to which metabolism fails in the elderly and the precise targets for these dysfunctions are correlated to genetics, epigenetics (see Epigenetics in Metabolism and Nutrition), and the impact of chronic inflammation and disease.

There seems to be little difference in the ability of healthy people, young or old, to metabolize glucose and little difference in insulin secretion by the  $\beta$  cells in the pancreas. What does appear to occur with the aging process is a change in tissue sensitivity to insulin. Although many possible causes for this phenomenon have been proposed, such as reduced carbohydrate intake, decreased muscle mass, and lowered activity levels, the reason appears to lie in an alteration in the molecular composition of insulin. Compared to younger adults, the elderly population have higher levels of circulating serum proinsulin and there tends to be a decrease in insulin clearance, leading overall to insulinemia.<sup>36</sup> It is also believed that the aging process alters insulin receptor sites and thus renders insulin less effective (insulin resistance).<sup>37</sup>

The aging process may also affect lipid metabolism as proportionate body fat increases. Although caloric intake generally decreases, a concurrent loss of lean body mass and a decline in energy expenditure begin in middle age and continue through life. A decline in the resting metabolic rate also occurs with the aging process. This change is related to several factors, such as reduced lean body mass, reduced lipogenic enzyme response to glucose, and decreased catecholamine secretion after a meal. Although cross-sectional studies demonstrate that cholesterol and triglyceride serum levels tend to increase with age, evidence is increasing that this change may be due more to obesity than to the aging process itself. However, as a risk factor, hyperlipidemia poses less threat for coronary artery disease and atherosclerosis than aging alone.<sup>38</sup>

A decrease in the quantity of skeletal muscle also normally occurs with aging. Although this decrease in muscle is associated with factors such as physical inactivity and a decrease in the number of neurons to muscle cells, endocrine factors also influence the loss of muscle mass. The decreased growth hormone secretion noted in elderly individuals leads to decreased protein synthesis and a decline in insulin-like growth factor 1 (IGF-1), a condition called somatopause.<sup>39</sup>

**KEY POINTS**

- With aging there is a change in tissue sensitivity to insulin because of an alteration in the molecular composition of insulin. Compared to younger adults, elderly persons have higher levels of circulating serum proinsulin. The aging process may also alter insulin receptor sites and thereby render insulin less effective.
- The aging process may affect lipid metabolism as proportionate body fat increases. Although caloric intake generally decreases, a concurrent loss of lean body mass and a decline in energy expenditure begin with adulthood.
- A decline in the resting metabolic rate also occurs with aging. This change is related to several factors, such as reduced lean body mass, reduced lipogenic enzyme response to glucose, and decreased catecholamine secretion after a meal.

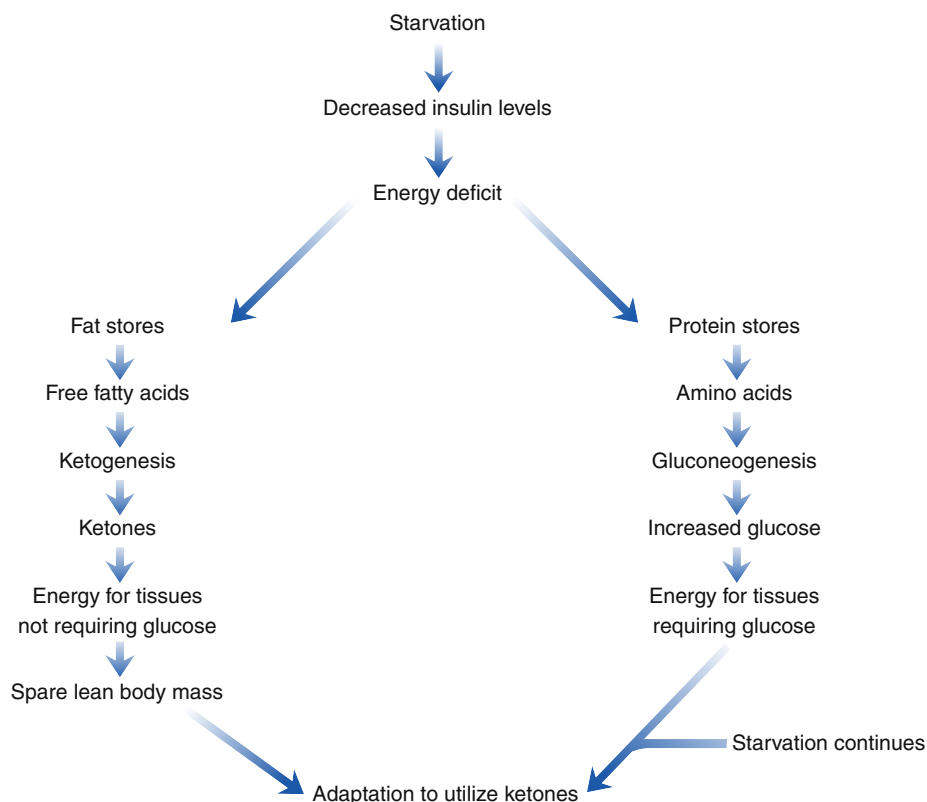

## NUTRITIONAL ALTERATIONS OF PHYSIOLOGIC STRESS

### Metabolic Response

The response of the body to starvation is different from the response to other forms of physiologic stress such as exhaustion from exercise.<sup>40</sup> In a study with healthy young males it was shown that exercise performed in the fasting state enhanced glucose tolerance by increasing the transport of GLUT 4 to the membrane. This was observed even when a diet rich in lipid was provided before fasting.<sup>40</sup> In contrast, a similar group of study participants who were fed and then immediately tested did not show enhanced glucose tolerance. This study suggests that intense physical exercise, which corresponds to a physiologic stress, has a greater impact on glucose and lipid metabolism when the body is fasting and that insulin resistance may be decreased via a regimen of exercise following fasting.<sup>40</sup> Starvation is a gradual process in

which the metabolic rate decreases as storage carbohydrate reserves are metabolized. As insulin levels decline during fasting, free fatty acids are released for energy use. Despite the available free fatty acids, protein is also used for energy by means of gluconeogenesis because certain tissues prefer glucose as an energy source and because oxygen is required for fatty acid  $\beta$  oxidation whereas anaerobic glycolysis can function in the absence of abundant oxygen. This preference creates a negative nitrogen balance. As starvation continues, overall energy needs are reduced and the tissues that usually require glucose for function adapt by using ketone bodies for energy. Then lipolysis provides the source of needed energy, and the use of protein as an energy source decreases. This change is an adaptive response through which the body strives to conserve lean body mass. Overall, the result is minimal depletion of the body's protein. Decreased serum glucose levels and urinary nitrogen excretion, along with elevation in the levels of ketone bodies and free fatty acids, characterize starvation. Fasting (voluntary starving) alone is not associated with a high mortality unless it is prolonged, as it is in anorexia nervosa. Figure 42-2 provides a summary of the physiologic effect of starvation.

With physiologic stress not associated with exercise or starvation, conservation of lean body mass does not occur. The metabolic rate increases rather than decreases, and a high sustained rate of catabolism (breakdown of protein to meet energy needs) results. Protein is used as an energy source via hepatic gluconeogenesis through release of muscle stores of protein-derived amino acids. This adaptation quickly results in a negative nitrogen balance. Cell mass is redistributed in response to the stressor, with an increase in the production of acute-phase proteins.<sup>41</sup> The degree of hypermetabolism, hypercatabolism, and negative nitrogen balance associated with physiologic stress depends on the type, duration, and severity of the stressor present. It has been shown that certain apolipoproteins of the HDL class are specifically targeted for hypermetabolism when levels of very low density

**FIGURE 42-2** Catabolic response to starvation.

lipoprotein (VLDL) apolipoprotein increase and this change is linked to hypertriglyceridemia and insulin resistance in obese males.<sup>42</sup>

### Phases of Catabolic Response

Typically, the catabolic response to stress occurs in two phases: the immediate phase, lasting 5 to 8 days, and the subsequent adaptive phase. The physiologic effects of each phase are summarized in Figures 42-3 and 42-4.

The immediate phase of **catabolism** is characterized by increased sympathetic nervous system stimulation with release of glucagon, glucocorticoids, and catecholamines. The resultant decreased production and circulation of insulin cause a pseudo-diabetic state. Hyperglycemia develops from decreased levels of circulating insulin and decreased utilization of glucose by muscle and other tissues (insulin resistance). An energy deficit is created, and alternative mechanisms of glucose production are then required. The oxidation of branched-chain amino acids occurs for two reasons: to meet energy requirements and to provide the liver with amino acids for the synthesis of acute-phase proteins (C-reactive protein, mannose-binding protein, complement factors, ferritin, ceruloplasmin, amyloid A, and haptoglobin). As the amino acids are mobilized to meet energy needs, alanine is formed and used as a carbon source in hepatic gluconeogenesis. Sodium and water are retained secondary to an increase in aldosterone level, which results in potassium loss. The mineralocorticoid aldosterone is released as a result of stimulation of the sympathetic nervous system. During this phase, adipose is not well used as an energy source because some level of insulin is present and has an antilipolytic action.

The nutritional result of the immediate phase of stress on the body is hyperglycemia, negative nitrogen balance, and retention of fluid and sodium. This protective mechanism uses skeletal muscle to meet

energy requirements and protects the rest of the body's tissue from breaking down during periods of high-energy need. An overall loss of nitrogen and other electrolytes, including magnesium, phosphorus, and zinc, takes place.

The adaptive phase occurs if the sympathetic nervous system response can selectively persevere with the stressors present. Hypermetabolism, a condition caused by excessive trauma, helps keep the system active, thus providing essential energy needs and new protein synthesis during severe stress.<sup>43</sup> If the stressors overwhelm the body's response system, the effect on prognosis will be negative. In the adaptive phase, the body begins to use ketone bodies and reducing power from the oxidation of fatty acids, thus limiting protein catabolism. As the sympathetic nervous system response diminishes, insulin resistance decreases and glucose utilization improves. Return of aldosterone levels to normal results in diuresis. The overall result is an improvement in negative nitrogen balance as the serum glucose level improves. This phase is similar to the response of the body during starvation, when fat is used to meet energy requirements. Chronic conditions such as diabetes, liver disease, or renal disease restrict the body's ability to move into the adaptive phase during physiologic stress. Chronic system failure or inadequate treatment of any current disease complicates the course of recovery. Nutritional input is used more efficiently by the body's tissue during the adaptive phase than during the immediate phase. It is in this phase that nutrition can have a vital role in recovery. The combination of starvation and physiologic stress increases the risk for morbidity and mortality. When poor nutritional status coincides with physiologic stress, the body's response is weakened. The ability to mobilize the immune response also decreases with impaired cell-mediated immunity and humoral immunity as well as altered response of the tissue barriers to infection.

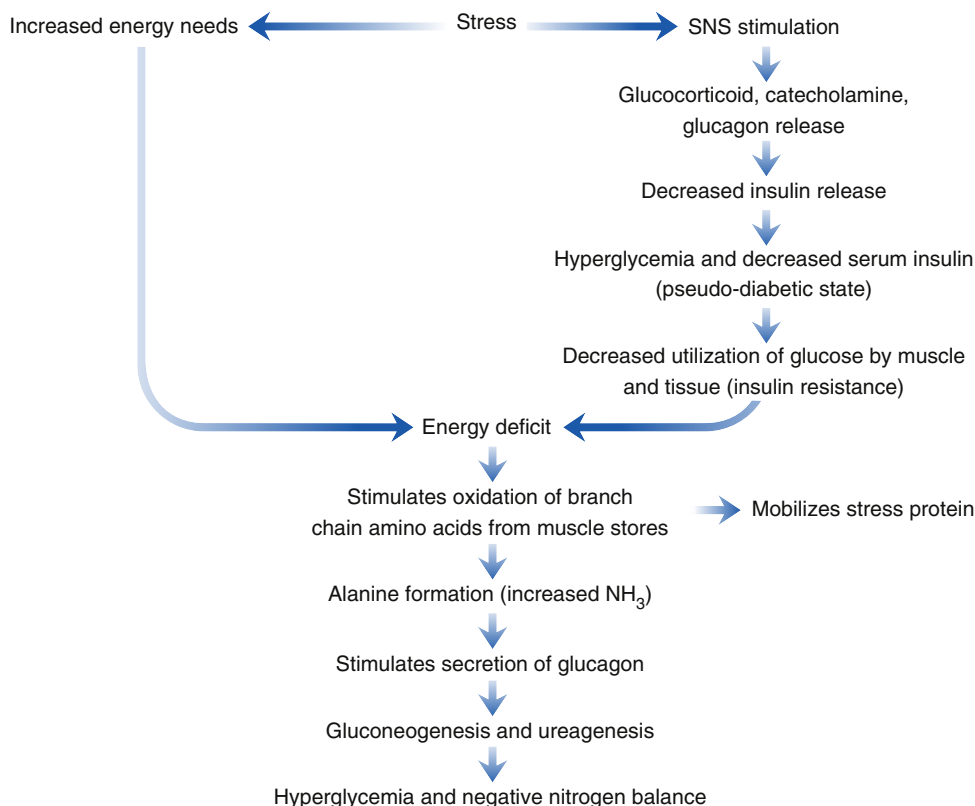

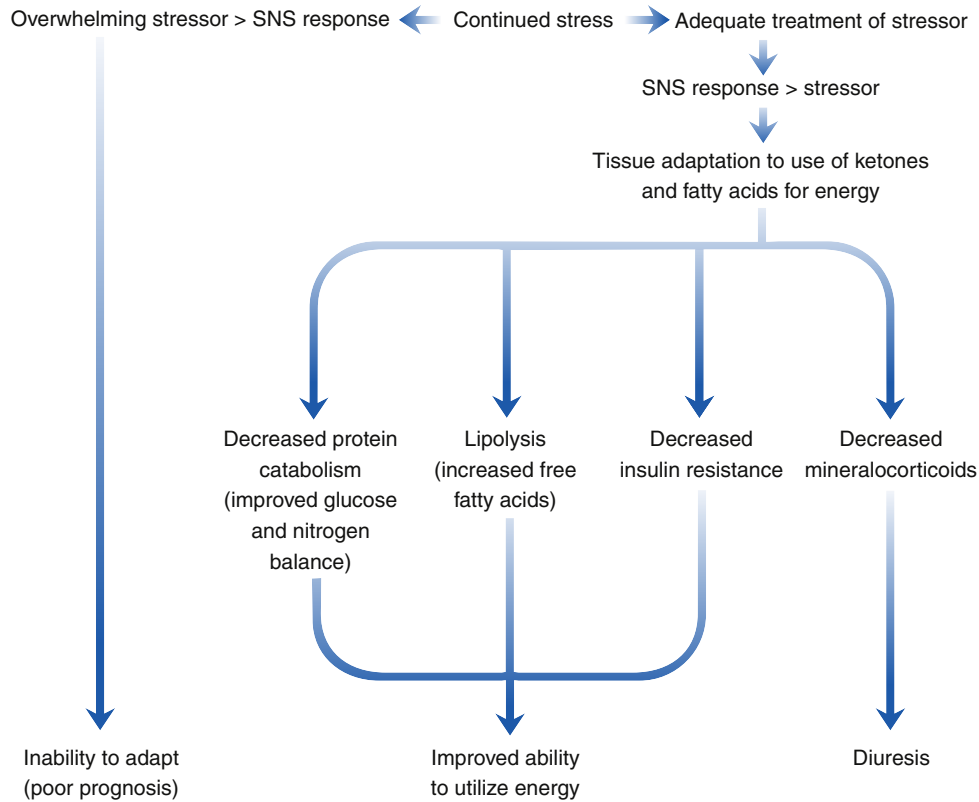

FIGURE 42-3 Immediate catabolic response to stress.  $NH_3$ , Ammonia; SNS, sympathetic nervous system.

**FIGURE 42-4** Adaptive phase of the catabolic response to stress. *SNS*, Sympathetic nervous system.

#### KEY POINTS

- Acute physiologic stress results in activation of the sympathetic nervous system. The immediate phase is characterized by a high metabolic rate, sustained catabolism, hyperglycemia, and salt and water retention. The sympathetic response promotes the use of protein stores for gluconeogenesis, which results in a negative nitrogen balance. Fat stores are poorly utilized.
- After 5 to 7 days of acute physiologic stress, the body may enter an adaptive phase that more closely resembles the normal response to starvation. Ketones and fatty acids from the lipolysis of fat stores are used for energy, and body proteins are conserved. Glucose utilization improves and hyperglycemia resolves. Aldosterone secretion diminishes and edema resolves. During the adaptive phase, nutrients supplied to the body are used more efficiently than during the immediate phase.
- Physiologic stress increases energy and protein requirements. An increase in needed calories of 20% to 50% above baseline is typical. Because glucose is poorly utilized during the immediate phase, carbohydrate intake is controlled to avoid exacerbation of hyperglycemia and excessive carbon dioxide production. Protein should supply about 16% of the total energy needs. Fats are given to fill the remaining caloric requirements. Vitamin and mineral replacement may also be required.

## EFFECTS OF MALNUTRITION

### Cardiovascular System

The cardiovascular system may be injured by malnutrition. Deficiencies in thiamine and selenium can cause primary cardiomyopathy.<sup>44</sup> Protein-energy malnutrition, as seen in an acutely ill patient, can result in visceral protein loss and decreased myocardial function.<sup>45</sup> A decrease in heart size and atrophy of cardiac muscle could result in decreased cardiac output. The increase in extracellular fluid commonly associated with physiologic stress could further compromise

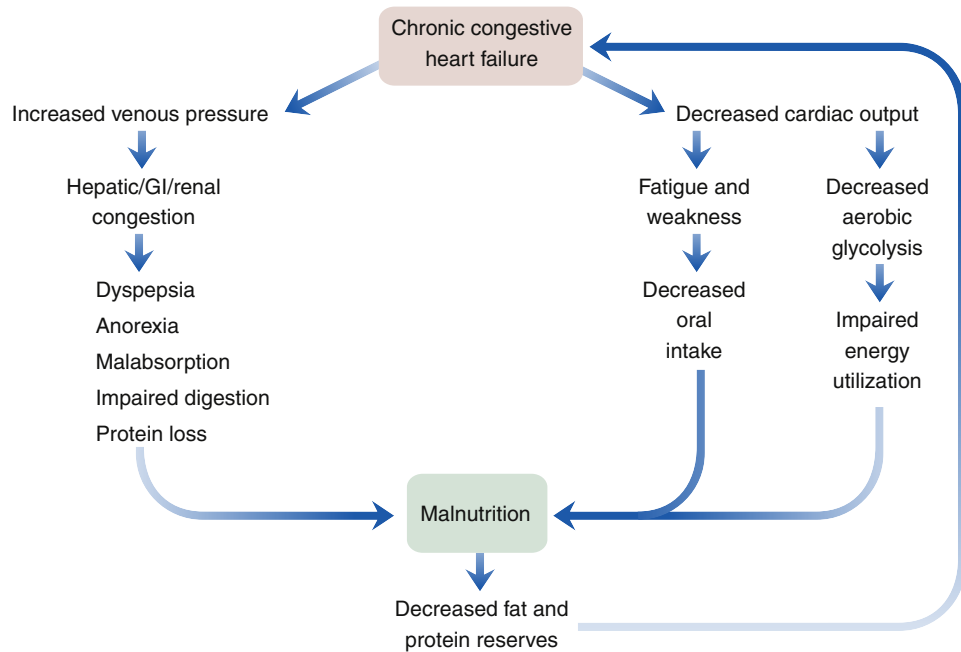

cardiac output. In compensation, the cardiac muscle fibers lengthen in response to increased workload. This compensation, together with a decreased oxygen demand secondary to decreased intake, curtails the development of cardiac failure. However, if the cardiac muscle is diseased, malnutrition will contribute to uncompensated heart failure.

Even though the body compensates to prevent heart failure in a malnourished patient, heart failure is common even in a healthy heart when starvation is corrected by refeeding. Refeeding increases the metabolism of the stressed state, and cardiac output is increased to meet oxygen demands. This added stress could lead to heart failure. In addition, providing a high-carbohydrate diet during the refeeding period would increase carbon dioxide ( $\text{CO}_2$ ) production and result in increased work of breathing, which places further demand on the heart. It is necessary to provide some of the energy needs with fats (which produce less  $\text{CO}_2$  per unit of  $\text{O}_2$  consumed) to decrease the carbon dioxide production, particularly for patients with concurrent respiratory failure. The patient must resume feeding with caution and be carefully monitored for signs and symptoms of cardiac failure. In addition, rapid weight loss secondary to malnutrition has been associated with ventricular dysfunction and dysrhythmias, so cardiac monitoring is an essential component in the care of such patients.

Cardiac cachexia associated with chronic congestive heart failure promotes malnutrition. The mechanisms involved in cardiac cachexia are shown in Figure 42-5. A vicious cycle exists, with congestive heart failure causing malnutrition, and malnutrition further contributing to the congestive heart failure.

### Respiratory System

Malnutrition affects the functioning of the lungs. It decreases the structure of the lung parenchyma because the use of protein for energy reduces protein synthesis. This structural alteration can cause

**FIGURE 42-5** Cyclic effect of malnutrition on chronic congestive heart failure. *GI*, Gastrointestinal.

excessive lung compliance and result in increased work of breathing.<sup>46</sup> Respiratory muscle function is decreased as a result of visceral protein loss, and both endurance and contractility are affected.

Malnourished patients often suffer from decreased vital capacity and respiratory muscle strength. If vital capacity and muscle strength fall below 50% of predicted norms, respiratory failure is probable owing to retention of carbon dioxide. Malnutrition also decreases the immune response in the lung. Surfactant stability is decreased, contributing to decreased lung compliance and microatelectasis. The result of an alteration in immune function and structural changes is an increase in the likelihood of respiratory tract infections. Infections develop easily and are not controlled by the protein-deficient immune system. The consequences of energy deficit in chronic obstructive pulmonary disease (COPD) are summarized in [Figure 42-6](#). When a patient has respiratory distress and must work harder to breathe, the caloric requirement for breathing alone can increase to 10 times normal levels. Inadequate intake and increased utilization further contribute to the effects of malnutrition on the respiratory system.

### Immune System

Increased rates of infection in malnourished patients secondary to depression of the immune system and defense mechanisms are caused by nutrient deficiency. Changes in the immune system vary according to the type of nutrient lacking ([Table 42-5](#)). For example, lack of protein can impair the immune response from lack of amino acids necessary for immunoglobulin and interleukin synthesis.<sup>47</sup> As previously mentioned, cellular immunity (delayed cutaneous hypersensitivity), which is needed for reaction to an antigen in skin testing, is often depressed in undernourished patients. In addition, the total lymphocyte count decreases. Thus the normal reaction that occurs with antigen stimulation is absent or decreased in malnutrition secondary to both a decrease in synthesis of immune system cells and a decrease in antibody response to stimulation (humoral immunity).

Malnutrition also causes a decrease in the amount of lymphoid tissue mass, a decrease in the number of circulating T and B lymphocytes, a depression of phagocytic function, and a decrease in complement activity. The overall result is a decrease in resistance and an increased

infection rate. In the critical care setting, the high number of invasive procedures and indwelling lines increases the potential for infection and complicates the patient's recovery.

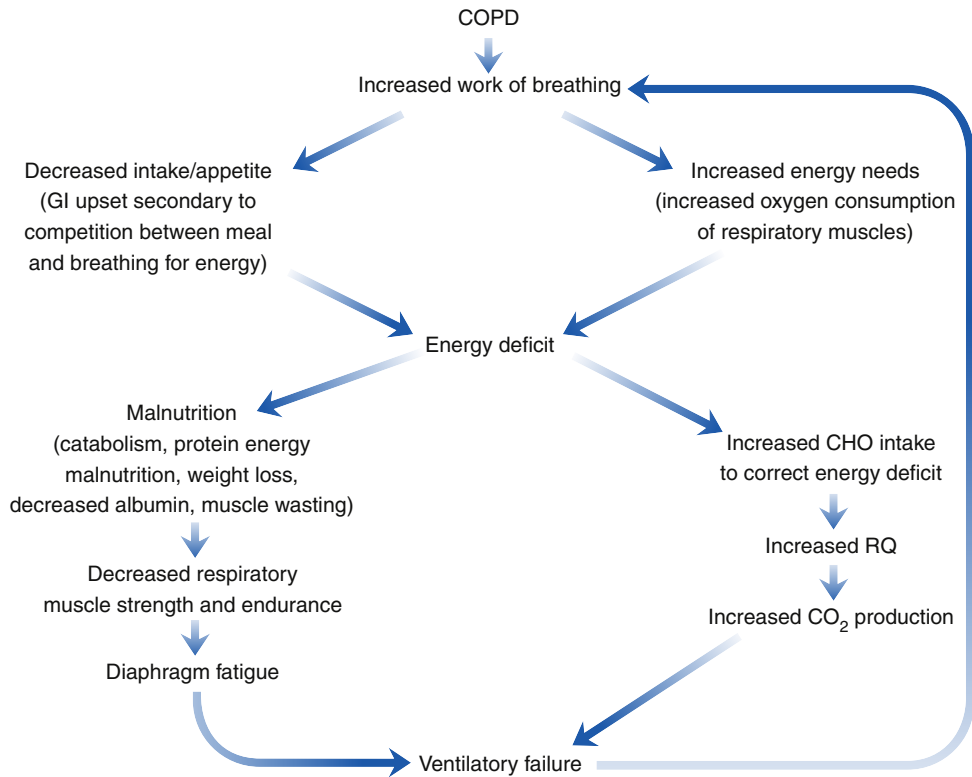

#### KEY POINTS

- The cardiovascular, respiratory, and immune systems are particularly susceptible to the effects of malnutrition.
- Cardiac atrophy and reduced cardiac output may be associated with heart failure, particularly during refeeding, which increases the myocardial workload.
- Respiratory muscle atrophy and fatigue and deficient surfactant production impair effective respiration.
- Immune system depression is associated with an increased risk of infection.

### EPIGENETICS IN METABOLISM AND NUTRITION

Genetic and epigenetic mechanisms shape metabolic activity and can respond negatively to produce the pathophysiologic state. Whereas the genome establishes the template for developmental and metabolic patterns, an adaptational phenomenon helps to produce the final phenotype. This latter epigenetic mechanism has become a key subject of developmental and cell biology, gene expression, and pathology. The biochemistry of epigenetics involves several covalent modifications of nuclear chromatin (DNA and histones) as well as posttranscriptional RNA-based gene silencing. These modifications can be reversibly administered by interactions with the genome caused by, and resulting in, poor nutrition and disease.

Covalent epigenetic modifications have a profound influence over gene expression and the mechanism for this effect requires environmental input and readily available substrates including target DNA and associated histones plus the methylating agent. During fetal development, it has been shown that obese pregnant mothers can transfer a pro-obese phenotype to their offspring.<sup>48</sup> It has been known for some time that maternal metabolism during gestation has an imprinting effect on fetal gene expression. Indeed, this epigenetic regulation controls the divergent expression of paternal over maternal genes, including

**FIGURE 42-6** Increased work of breathing with chronic obstructive pulmonary disease. *CHO*, Carbohydrate; *COPD*, chronic obstructive pulmonary disease; *GI*, gastrointestinal; *RQ*, respiratory quotient.

**TABLE 42-5 EFFECTS OF DEFICIENCY OF SELECTED NUTRIENTS ON IMMUNITY**

DEFICIENT NUTRIENT	IMMUNE SYSTEM CHANGE
Vitamin C	Decreased mobility of neutrophils
Vitamin A	Lymphoid tissue atrophy
Vitamin B group	Lymphoid tissue atrophy
Amino acids	Decreased immunoglobulins, interferons, and acute-phase proteins
Fatty acids	Impaired lymphocyte function
Iron	Decreased bacterial activity of phagocytes
Zinc	Lymphoid tissue atrophy
Selenium	Decreased antibody production

one involved in glucose metabolism and growth—insulin-like growth factor 2 (IGF-2). This fetal imprinting is the result of maternal metabolism, which is indirectly linked to maternal diet. This epigenetic effect is presumably advantageous during a specific stage of gestation.<sup>49</sup> However, if these epigenetic modifications persist into later stages of gestation, they may increase the risk of being a component of “maintenance methylation” that persists after parturition and into infancy, childhood, and even adult development. This may predispose the individual to new environmental pressures leading to chronic disease such as obesity, metabolic syndrome, and cardiovascular and renal dysfunction.

Besides the gestational effects of maternal obesity on subsequent metabolic dysfunction in the offspring, nutritional deficiencies or

excesses can also specifically alter the epigenome. Dietary sources of methylating agents, such as bioavailable folic acid, methionine, choline, betaine, and homocysteine, may have a permanent effect on the epigenetic methylation patterns of CpG islands and the coherence of histones in locus- and temporal-dependent genes. If these gene products are involved in normal development and have been arbitrarily altered, the fetus may not develop correctly or there may be infant diseases linked to these methylation patterns. As the individual matures to adulthood, the maternal exposure to methyl group-containing nutrients may have a lifelong effect on basic physiology, response to nutrition, and, sometimes, the manifestation of pathologic and disease states.<sup>50</sup> Clearly diet plays a major role in both general and specific epigenomic patterns and these can cause significant metabolic disease. Diet (both at the caloric level and at the essential nutrient level) controls metabolic flux in a dynamic way. Excess chronic caloric intake can induce several disease states including obesity and metabolic syndrome. Insufficient caloric intake can also cause disease as can inappropriate nutrition or excessive ingestion of vitamins and certain growth-promoting molecules. Besides a direct effect on metabolic rate and function, diet can also introduce these epigenetic changes to the endocrine hormone system.

Epigenetic changes can arise within a single generation and remain fixed there; alternatively, as in the case of maintenance methylation, the changes can also be preserved and inherited. Therefore, the distinction between the two forms of modification lies more in the degree of alteration in gene expression than in the mechanisms of acquisition or potential for inheritance. Indeed, environment plays a very significant role in epigenesis of the endocrine system and may be the more robust factor in variations around this physiologic axis.

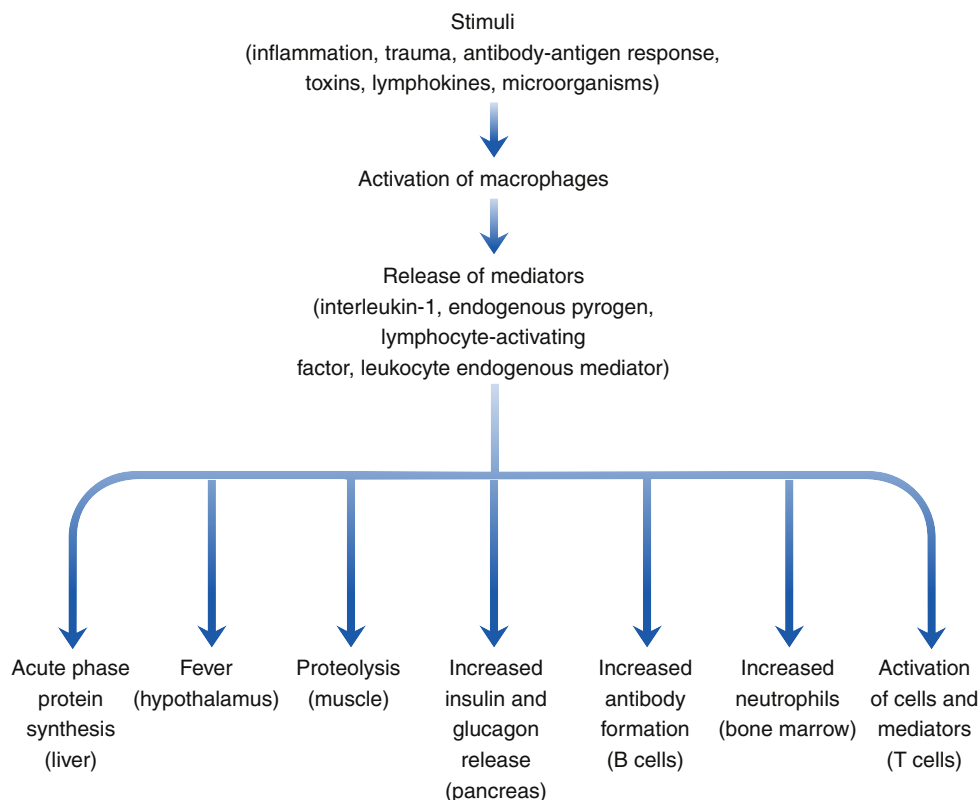

FIGURE 42-7 Mediator-stimulated response.

**KEY POINTS**

- Epigenetic modification of nuclear chromatin can occur throughout life and includes reversible methylation of promoter regions of DNA as well as various covalent modifications of histones and production of interfering RNA.
- Epigenetic modifications can have profound effects on gene expression that may cause nutritional and metabolic dysfunction or conversely may be caused by malnutrition, including that associated with obesity.
- Bioavailability of methyl group-containing nutrients such as folic acid and choline can directly affect DNA methylation patterning that may be acquired in utero and subsequently cause metabolic disease in the adult.

**NUTRITIONAL REQUIREMENTS OF ALTERED HEALTH STATES**

**Infection, Sepsis, and Fever**

A complex interaction exists between the development of infection, the immune system, and nutritional intake.<sup>51</sup> Malnutrition contributes to the infectious process by directly depressing the immune system. This depression impairs the patient’s defense mechanism and opens a pathway for the development of unimpeded infection. Infection then potentiates malnutrition through inhibition of nutrient assimilation and stimulation of metabolic rate (fever).

Fever is a common symptom accompanying infection. Fever increases metabolic needs by 7% for each 1° F increase (13% for each 1° C increase). Energy requirements can increase by 40% when a high fever (above 104° F) is present. The metabolic response to fever is both anabolic and catabolic, which greatly increases nutrient requirements.

It is known that peptide mediators secreted by macrophages and other immune cells initiate the metabolic alterations associated with infection. The mediator-stimulated response is summarized in Figure 42-7. This process is complex, with the need for protein synthesis requiring the

availability of amino acids.<sup>52</sup> Although catabolism may be detrimental in some aspects, it is also a protective mechanism that provides needed substrates for activation of the immune response to infection. Nutritional support is often aimed at decreasing catabolism, but it is also important to provide substrates (amino acids) for the protective mechanisms that catabolism supports.

Infection is a stressor that increases energy expenditure as a result of fever, increased immune cell demand, and catabolism. The body’s metabolic response to the infection is to increase the amount of available glucose. Often the demand is too great for the body to manage; for example, sepsis can increase energy expenditure 20% to 60% above basal energy requirements. Nutritional support is needed to supply additional energy and the necessary substrates so that body stores are not excessively depleted.

**Surgery**

Adequate nutrition before and after surgery promotes wound healing, prevents infection, and decreases complications and mortality. A patient should be in the best nutritional condition possible before surgery.<sup>53</sup> A common cause of protein-energy malnutrition in postoperative patients is starvation. The combination of poor presurgical nutrition and postoperative starvation may increase complications after surgery, such as separation of the layers of the surgical wound. Obesity, malnutrition, and dehydration are among the causes of this serious postoperative problem.

Nutritional needs in the postoperative period depend on the extent and type of surgery, as well as the presurgical nutritional status. The postoperative energy requirement can increase from 10% to 35% above BMR. Frequently, postoperative oral intake is delayed in critically ill patients well beyond the return of bowel function. This combination of increased need with decreased intake can have a major impact on wound healing. The functions of various nutrients in wound healing have long been established and are listed in Table 42-6. In addition,

**TABLE 42-6 ROLE OF NUTRIENTS IN WOUND HEALING**

NUTRIENT	ROLE IN WOUND HEALING
Proteins (amino acids and albumin)	Maintain osmotic pressure to decrease edema; maintain cell-mediated immune responses; cellular proliferation, including neurovascular components, lymphocytes, and fibroblasts
Carbohydrates (glucose)	Meet energy requirements of cells involved in the healing process and prevention of infection
Fats (essential fatty acids)	Components of cellular membranes; building blocks for eicosanoids such as prostaglandins, which regulate cellular function
Vitamins	Roles in cellular function, including capillary function and formation, enzyme cofactors, immune cell function, clotting mechanism, calcium and phosphorus metabolism, collagen synthesis
Minerals	Roles in cellular function, including oxygen transport, immune cell function, collagen synthesis, cellular proliferation

nitrogen loss through wounds can be large and create a greater need for increased protein intake. Protein intake sufficient to replace losses and promote anabolism will be required, together with nonprotein calories for energy requirements. As with every patient, individual assessment and determination of exact needs are required.

### Trauma

The general catabolic response to stress is also seen in trauma patients.<sup>54</sup> Energy expenditure is increased by 15% to 30%. Increased carbohydrate intake will be needed, but patients must be observed for complications of high carbohydrate intake, such as glucose intolerance. Nitrogen loss secondary to catabolism and to cellular damage can be high. Circulating hormones in the immediate phase have an anti-insulin effect that decreases glucose utilization; therefore, gluconeogenesis is increased to meet energy needs. As with other stress states, the catabolism of protein provides a source of amino acids for acute-phase protein synthesis by the liver (see Chapter 9). Because trauma is a sudden stress, catabolism is much greater than anabolism because the body has not had enough time to replenish the proteins lost. This dominance of catabolism results in excessive negative nitrogen balance and significant loss of skeletal muscle, which is a problem in posttrauma rehabilitation.

### Burns

A burn is an extreme physiologic stressor that results in significant hypermetabolism.<sup>55</sup> In addition, the destruction of skin increases energy expenditure through evaporative heat loss. The energy needs of a burn patient increase 50% to 100% from the basal metabolic requirement. Because of individual variations such as preburn nutritional status, the presence of other physiologic stresses, activity level, stage of burn, and patient age, indirect calorimetry is the best method for determination of individual nutrition needs.

As with other stressors, negative nitrogen balance is increased by catabolism and by the use of amino acids to form stress proteins. In addition, burn wounds directly contribute to protein loss because soluble proteins leak from the wound and proteolysis is activated. Fatty acids are also increased in response to the release of stress hormones and breakdown of lipoproteins. The effective utilization of this available energy source in the immediate postburn phase may be impaired.

### Cancer

The nutritional effects of cancer can be severe and result in what is commonly termed **cancer cachexia** (see Chapter 7).<sup>56</sup> Cachexia is associated with the end stage of cancer but can also develop earlier. The cause of cachexia is inadequate nutritional intake relative to energy requirements and increased anaerobic glycolysis. It results in significant weight loss, muscle weakness, and anorexia. A major cause of cachexia is anorexia associated with the malignancy and with the treatment. Sensory alterations such as changes in smell or taste may be associated with cancer treatment and malnutrition. These changes can contribute significantly to the anorexia experienced during cancer treatment. Thus cancer patients often enter the critical care environment with mild to severe malnutrition.

Beyond the anorexia and sensory changes, abnormalities of intermediate metabolism in cancer promote tissue loss. The normal response to decreased intake is a decreased resting metabolic rate; however, abnormalities in substrate metabolism in cancer patients increase total energy expenditure and raise the resting metabolic rate. The tumor also requires energy for growth, often using anaerobic metabolism (because tumor cells may not have sufficient capillary supply), which increases lactic acid production and promotes an increase in gluconeogenesis. The metabolism of vitamins, minerals, and enzymes is also thought to be altered. Because both nutrient intake and substrate metabolism are altered, nutritional support is difficult to achieve and frequently ineffective in reversing the existing cachexia.

### Immobility

The main nutritional effect of immobility is loss of calcium from non-stressed bone, a process that can elevate serum calcium and phosphorus levels. This demineralization is best managed with weight-bearing exercise as early as possible rather than calcium supplementation. Calcium supplementation during immobility may increase the risk of developing renal calculi. A physical therapist should be consulted early to assist in prevention of demineralization. Because negative calcium balance can increase in a catabolic state, serum calcium levels must be monitored and abnormalities treated.

A second effect of immobilization is nitrogen loss while tissue mass is decreased from disuse atrophy. This loss can total 2 to 3 g/kg per day and require up to 10 to 15 g of protein to replenish the daily loss, which further emphasizes the need for early physical therapy and aggressive range-of-motion exercises.

#### KEY POINTS

- Infection is associated with fever and an increased metabolic rate. For each 1° F increase in body temperature, metabolic needs increase 7%. The synthesis of acute-phase proteins and immune factors requires sufficient amino acid substrates.
- A major nutritional problem in postoperative patients is starvation. In addition, nitrogen loss through wounds may be significant.
- Major trauma is associated with a 15% to 30% increase in energy expenditure. Glucose utilization is maintained. Trauma victims are usually in good nutritional health before admission.
- Major burns are extreme physiologic stressors that result in an increase in energy expenditure of 50% to 100% above baseline. Protein loss from burned areas is high.
- Cancer cachexia is a result of several factors, including anorexia, poor intake, and preferential nutrient utilization by tumor cells.
- Immobility is associated with muscle atrophy and bone demineralization.

## SUMMARY

Metabolism is a dynamic and continuous process affecting every organ and physiologic process in the human system. The building phase of anabolic metabolism occurs concurrently with the energy-consuming and destructive phase of catabolic metabolism. Phases of metabolism either release or require energy in the form of ATP. The rate at which metabolism occurs in the resting human system is referred to as the basal metabolic rate, and the process releases both heat and energy. The metabolic fate of carbohydrate, protein, and fat depends on cellular needs and systemic regulatory functions. The endocrine system greatly affects metabolism. Only one hormone, insulin, is known to lower serum glucose levels by decreasing liver glucose production and promoting the transfer of glucose into cells. Although each works in a unique manner, growth hormone, cortisol, epinephrine, thyroid hormone, and glucagon all act in concert to maintain or raise blood glucose levels.

Physiologic stress is accompanied by changes in metabolism that alter nutrient utilization and increase nutrient requirements. The degree to which these changes occur varies with the type and severity of the particular stress. If the patient is not provided with adequate

nutrition when one or more stressors are present, the hypermetabolism, hypercatabolism, and negative nitrogen balance associated with the physiologic stress will have detrimental effects on recovery.

Health care professionals must be aware of the impact of stressors on the nutritional status of the body, as well as the impact of nutrition on the well-being of body systems. If this point is well understood, appropriate interventions can be taken to prevent some of the complications that can develop when nutritional support is inadequate. Most well-nourished patients can tolerate a short period of inadequate intake (about 5 days) without untoward effects. However, critically ill patients require early nutritional support because of the magnitude and intensity of the stressors. Identification of the various risk factors and the nutritional needs of patients is an essential part of nursing care for critically ill patients. Overfeeding of patients should also be avoided because specific complications can develop with inappropriate nutritional support. Nurses must also understand nutritional interventions so that decisions regarding nutritional support for the patient can be based on specific nutritional assessments and knowledge of individual needs.

## KEY QUESTIONS

- How do the central nervous system (CNS), peripheral nervous system, and autonomic nervous system interrelate?
- How is the CNS protected and supported?
- What structures are located in each of the four principal areas of the brain: cerebrum, diencephalon, cerebellum, and brainstem?
- What neurologic functions have been mapped to particular locations in the brain?
- How do the properties of neuronal action potentials and neuronal communication through synapses relate to the functions of the nervous system?
- How is the somatotopic organization of sensory receptors and muscles maintained in the CNS?
- How is voluntary muscle activity initiated and executed?
- How do the properties of the mind, including thought, memory, learning, consciousness, and sleep, relate to the physiologic substance of the nervous system?

The nervous system is a complex network of neurons and supportive cells that enables rapid communication between sensory receptors, central processing neurons, and functional responses. Much has been discovered about the mechanisms of sensory input and motor output, but the physiologic bases of thought, consciousness, emotion, and learning remain elusive. The idea that the mind is within the biological realm has been generally accepted, and the effects of mind-altering drugs on emotions, appetite, sleep, thought, and sensory perception have long been recognized. Research continues to reveal the great complexity of neurologic function. A bewildering array of neurotransmitter signaling molecules and an even greater number of neurotransmitter receptors have been identified. Recently, the long-held notion that neurons cannot regenerate in the mature brain has been disproved, and neuronal stem cells have been identified in certain areas. Each discovery brings us closer to understanding neural physiologic processes and gives hope for finding effective therapies for the devastating diseases that affect them. This chapter provides an overview of neural structure and function and is the basis for understanding the neurologic disorders in the chapters that follow.

## STRUCTURAL ORGANIZATION

The nervous system is traditionally divided into three principal anatomic units: the central nervous system (CNS), the peripheral nervous system (PNS), and the autonomic nervous system (ANS). These systems are not anatomically or functionally distinct, and they work together as an integrated whole. Therefore, when function, rather than anatomy, is the topic of concern, the nervous system is more conveniently divided into the sensory, motor, and higher brain functions. This chapter begins with a review of the major anatomic features of the nervous system, then addresses neurologic function at the cellular and synaptic level, and concludes with a summary of sensory, motor, and cognitive functions.

## CENTRAL NERVOUS SYSTEM

The CNS includes the brain and spinal cord. Its primary functions are receiving and processing sensory information and creating appropriate responses to be relayed to muscles and glands. It is the site of emotion, memory, cognition, and learning. The CNS is bathed in cerebrospinal fluid (CSF) and shielded from the periphery by the blood-brain barrier. The CNS interacts with the neurons of the PNS through synapses in the spinal cord and cranial nerve **ganglia**. The cranial and spinal nerves constitute the PNS.

### Support and Protection of the Central Nervous System

Nervous tissue has the consistency of gelatin, so measures to support and protect its fragile structure are necessary. In addition, the CNS must be shielded from circulating substances that would interfere with neurotransmission. These protective functions are provided by the skull and vertebral column, meninges, CSF, and blood-brain barriers. The bony structures of the skull and vertebral column encase the brain and cord and protect them from external trauma, whereas the CSF and meninges provide buoyancy and shock-absorbing capacity.

The meninges are composed of three layers that serve to suspend and maintain the shape and position of the nervous tissue during head and body movements. The brain is suspended within layers of meninges that are fixed to the skull. In this manner, the brain turns with the movement of the skull. The CSF circulates within the subarachnoid space, giving buoyancy to the brain and making an average 1500-gram brain mass resistant to distortion, which could occur from gravity

alone were it not for the buoyancy effect.<sup>1</sup> The three meningeal layers are the *dura mater*, *arachnoid*, and *pia mater* (Figure 43-1).

The *dura mater*, the outermost meningeal layer, is a thick, tough, collagenous membrane. It is composed of two layers, one contiguous with the periosteum of the skull and the other, which is adherent to the first, covering the surface of the brain. The tough *dura* protects the soft tissue of the brain. Support and stability are also provided by dural septa that invaginate into the cranial cavity. The *falx cerebri* is a thin wall of *dura* that folds down the cortical midline, separating the two hemispheres (see Figure 43-1). The *tentorium cerebelli* is a septum that separates the cerebellum and brainstem from the rest of the cerebrum. The dural septa fix the brain in place by their tentlike structure and limit its movement within the skull. Venous sinuses that collect venous blood from cerebral veins are located between the two layers of the *dura* at the base of the septum.

Beneath and continuous with the *dura* is the *arachnoid* layer. The spaces between the *dura* and the skull and between the *dura mater* and the *arachnoid* are potential spaces. Only in the presence of pathologic processes, notably epidural and subdural hemorrhages, do these spaces become evident (see Chapter 44). Unlike the *dura mater*, the *arachnoid* is a thin, delicate membrane. It is semitransparent and weblike in appearance, hence its name. Strands of collagenous connective tissue called *trabeculae* extend from the *arachnoid* layer down to the *pia mater*, forming a subarachnoid space. The CSF flows in this space.

The *pia mater*, the third meningeal layer, is also very thin. However, unlike the other meningeal layers, the *pia* is attached to the brain and closely follows its contours over every **sulcus** and into every **gyrus**. Consequently, the subarachnoid space between the *arachnoid* and the *pia mater* is not evenly distributed. The *arachnoid* meshes with the *pia* via the *trabeculae* in such a subtle manner that it is often difficult to differentiate one from the other. Consequently, the two layers together are often referred to as the *leptomeninges*.

The meninges that cover and provide protection to the spinal cord are similar to those of the brain, with a few variations (Figure 43-2). The spinal *dura* has no periosteal layer, so it is a single rather than a double layer. It is continuous with the foramen magnum at the base of the skull and is separated from the spinal vertebral periosteum by an epidural space. Thus, in the spinal cord, the epidural space is a true space, unlike its counterpart in the cranium, which is only a potential space. Within this space lie fatty connective tissue and a vertebral venous plexus.

The spinal *arachnoid*, much like that covering the cerebrum, is closely adherent to the spinal *dura*. Between the *arachnoid* layer and the *pial* lining is the CSF-filled subarachnoid space. The spinal meninges end at approximately the second sacral vertebra. However, the spinal cord ends between the first and second lumbar vertebrae (L1 to L2). This results in a large subarachnoid cistern, called the *lumbar cistern*, which is a favored place to obtain CSF samples (see Figure 43-2). The spinal *pia* is much tougher and thicker than the cerebral *pia*. Projecting along the length of each side is the dentate ligament, which anchors the spinal cord to the *arachnoid* and through it to the *dura*. Another *pial* projection connects the tail of the spinal cord (the *cauda equina*) at level L1 to L2 to the **caudal** end of the spinal dural sheath, where it is tethered to the end of the vertebral column. This projection is called the *filum terminale*.

The majority of CSF is produced by the choroid plexus, located in the lateral and third ventricles of the brain, at a rate of approximately 500 ml/day.<sup>2</sup> The composition of normal CSF is compared to plasma in Table 43-1. CSF is absorbed at about the same rate at which it is produced, so that only 150 to 175 ml is in circulation at any time. The large C-shaped lateral ventricles occupy the center of each hemisphere. They communicate with the third ventricle in the

**FIGURE 43-1** Principle membranes of the cranial meninges. Cerebrospinal fluid flows in the subarachnoid space and is reabsorbed by arachnoid villi within the dural sinuses.

diencephalon by way of the intraventricular foramen. The third ventricle is linked to the fourth ventricle by way of the cerebral aqueduct, which lies between the pons and the medulla (Figure 43-3). The CSF flows from the fourth ventricle through the median or lateral aperture and into the subarachnoid space. It flows around the spinal cord and up over the cerebral hemispheres to the arachnoid villi, where it is absorbed into the venous system.

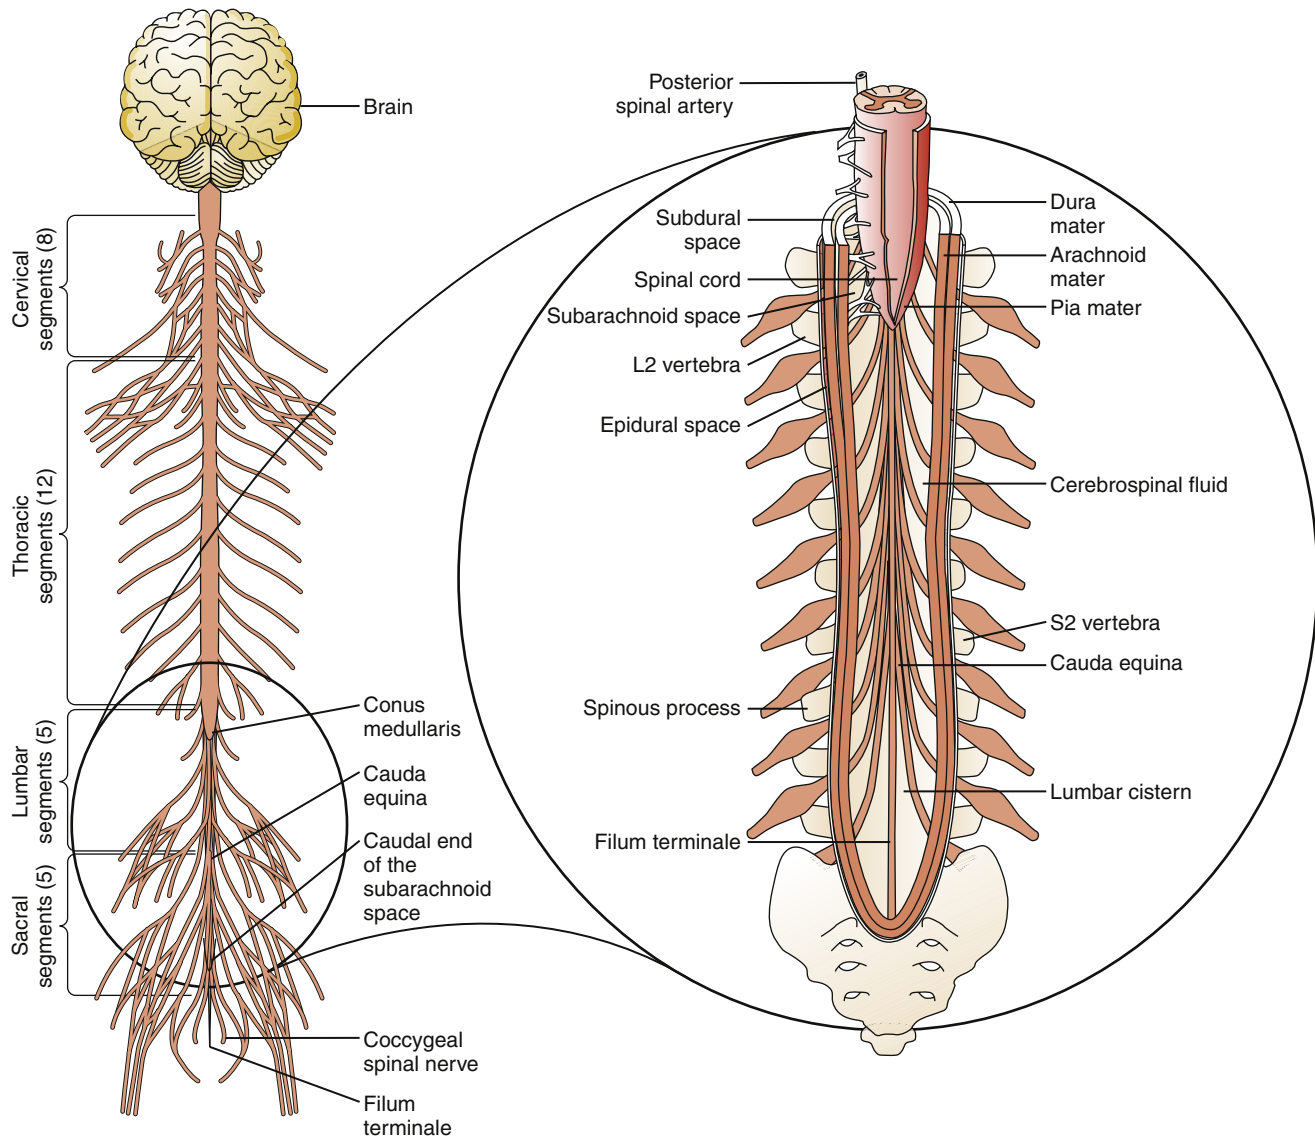

CSF is absorbed by the arachnoid villi, which are small tufts of the arachnoid that invaginate into the dural sinus. These tufts bring CSF into close approximation with venous blood. CSF flows into the venous system through one-way valves because of pressure gradient differences. Although the CSF flows readily into the venous sinus, flow in the opposite direction cannot occur<sup>2</sup>; that is, the fluid in the venous sinus cannot flow into the subarachnoid space. This mechanism is part of a system of barriers between the extracellular space in the nervous system and the rest of the body.

The rate of production of CSF is independent of blood pressure or intraventricular pressure.<sup>2</sup> Thus, CSF will continue to be produced even when its path of circulation or absorption is blocked. If this occurs, the amount of CSF increases, as does the size of the ventricles. This pathologic process is called *hydrocephalus*. Although hydrocephalus is usually caused by blockage of CSF pathways, it can also be caused by overproduction and malabsorption of CSF (see Chapter 45).

Blood supply to the brain is provided by two pairs of arteries; the anterior circulation is supplied by the internal carotid arteries, and

the posterior circulation is supplied by the vertebral arteries (Figure 43-4). The cerebral circulation is discussed in detail in Chapter 44 as it relates to stroke. The internal carotid arteries have three principal branches: the anterior and middle cerebral arteries and the posterior communicating arteries. The vertebral arteries enter the skull at the foramen magnum and join at the level of the pons to form the basilar arteries. The ring of vessels that unites the anterior and posterior circulation at the base of the brain is known as the *circle of Willis* (see Figure 43-4, B). The cerebral veins drain into large vascular channels called *sinuses* that are formed by folds in the dura. From the sinuses, venous blood returns to the heart by way of the jugular veins (see Figure 43-4, C).

The extracellular fluid that bathes the neurons is carefully shielded from elements in the CSF and blood by cellular barriers. Specialized tight junctions between the cells that line the CSF spaces and between the endothelial cells of brain capillaries prevent leakage of molecules through the spaces between the cells (Figure 43-5). Therefore, substances must move through the plasma membranes of these barrier cells to access the CNS. Lipid-soluble molecules move through more easily than water-soluble ones. Thus, the flow of ions, nutrients, drugs, proteins, and other charged or polar substances is highly restricted.<sup>2</sup> The blood-brain barrier (BBB) is a crucial structure for protecting the brain, but it may also restrict access of beneficial molecules, such as antibiotics and cancer drugs, making treatment more difficult.

**FIGURE 43-2** Spinal cord, spinal nerves, and meninges. Spinal meninges are similar to cranial membranes. Spinal meninges end at S2, creating a CSF-filled cistern below the spinal cord. The cauda equina (horse tail) is formed by the lumbar and sacral nerves, which protrude from the end of the spinal cord.

**TABLE 43-1 COMPOSITION OF CEREBROSPINAL FLUID COMPARED TO PLASMA AND SELECTED CEREBROSPINAL FLUID ABNORMALITIES**

SUBSTANCE	NORMAL CSF	ABNORMAL CSF	PLASMA
Na <sup>+</sup> (mEq/L)	148	—	136-145
K <sup>+</sup> (mEq/L)	2.9	—	3.5-5.0
Cl <sup>-</sup> (mEq/L)	120-130	—	100-106
Glucose (mg/dl)	50-75	↓ Infection	70-100
Protein (mg/dl)	15-45	↑ Inflammation	6800
pH	7.3	—	7.4
Red blood cells (high-power field)	None	↑ Trauma, subarachnoid hemorrhage	—
White blood cells (high-power field)	<5	↑ Infection (e.g., meningitis)	—
Pressure (mm H <sub>2</sub> O)	70-180	↑ Mass lesions	—

CSF, Cerebrospinal fluid.

**FIGURE 43-3** Ventricles within the brain from frontal (A) and lateral (B) views.

The integrity of the blood-brain barrier is maintained in part by CNS cells called *astrocytes*. These specialized **glial** cells have foot processes that contact the brain capillaries and are thought to help regulate transport across the capillary endothelium<sup>3</sup> (see Figure 43-5). The blood-brain barrier is less effective in infancy and can also be compromised by ischemia and chemical injury in adults.

A similar barrier exists between the circulating CSF and the interstitial fluid of the CNS—the CSF-brain barrier. The ependymal cells that line the ventricles are tightly joined and regulate the movement of water-soluble elements between the CSF and neurons. In addition, these cells serve the important function of removing unwanted substances from the CNS and secreting them into the CSF for eventual removal by the venous system.

Some areas of the brain need to sample the contents of the blood or CSF more directly to make regulatory adjustments in respiratory, autonomic, or endocrine functions, and these areas therefore have more permeable barriers (leaky BBB). These areas include the hypothalamus, pituitary, and other circumventricular organs (around the ventricles).

## The Brain

Various schemes have been used to subdivide the structures of the brain using embryologic, evolutionary, and anatomic frameworks (Table 43-2). In this section, an anatomic framework is used that includes the cerebrum, diencephalon, cerebellum, and brainstem (Figure 43-6).

## Cerebrum

The cerebrum is divided into left and right hemispheres by the longitudinal fissure and is the largest part of the brain. The cerebral cortex is the outermost layer of the cerebrum and is composed of gray matter arranged in six histologically distinct layers<sup>4</sup> (Figure 43-7). Each layer makes connections with other parts of the brain. The cortex is characterized by its convoluted exterior having ridges (gyri), grooves (sulci), and deeper depressions (fissures). The sulci and fissures are used as landmarks to divide the cerebral cortex into lobes. The central sulcus separates the frontal and parietal lobes, the lateral sulcus separates the temporal lobe from the parietal and frontal lobes, and the parieto-occipital line defines the occipital lobe (Figure 43-8).

Some anatomic locations are particularly associated with certain brain functions. These functions have been characterized through lesion studies in which an area of brain is damaged and then the functional losses studied, and by mapping procedures during which the cerebral cortex is stimulated and responses are recorded. The functional areas of specialization of brain loci are listed in Table 43-3. A partial map of Brodmann areas is shown in Figure 43-9. Although the concept of functional anatomic areas is clinically useful, one should realize that even though an area may be critical for a particular function, it is not wholly responsible for that function, and many brain areas may be involved. A certain degree of reassignment of brain function from one area to another can occur, allowing the brain to adapt to loss of normal neural function (neural plasticity).

Functional areas of the cortex that can be mapped to specific sensory receptors or muscles are called *primary* areas. Primary areas are surrounded by secondary areas that provide greater character to sensations and greater complexity to movements. In addition to primary and secondary cortical areas, there are large areas of association cortex that add interpretive and learned responses. Organization of the primary and secondary cortex is best characterized for the somatosensory cortex and motor cortex (which are discussed later in the Somatosensory Cortex and the Central Control of Motor Function sections, respectively).

Cortical areas involved in visual perception are located in the occipital lobe. Brodmann area 17 is the primary visual cortex, and areas 18

and 19 are the secondary visual cortex. Interpretive association areas for vision are found in the adjacent temporal and parietal lobes. The primary auditory cortex is located on the superior temporal lobe, whereas vestibular information projects to the inferior temporal lobe.

Language expression and interpretation have been mapped to areas in the temporal lobe, particularly the Wernicke area (Brodmann areas 39, 40, and 22). One hemisphere, usually the left, is dominant for language. Lesions in this area lead to difficulty recognizing written words (alexia) and spoken language (receptive aphasia). Another area closely associated with speech is the Broca area (Brodmann area 44) in the frontal lobe. Damage to this region interferes with the ability to use

**FIGURE 43-4** Blood supply to the brain. **A**, The internal carotid and vertebral arteries supply blood to the anterior and posterior aspects of the brain, respectively. **B**, At the base of the brain, the internal carotid and vertebral arteries join to form the circle of Willis. **C**, Major venous drainage from the brain.

language (expressive aphasia). In most cases, receptive and expressive aphasia occur together (see Chapter 44).

The frontal lobe is usually credited with control over emotional responses, ethical behavior, and morality. It is also the site of initiative and motivation. Patients with lesions of the frontal lobe may fail to conform to societal behavioral norms.

Another small cortical lobe, the central lobe or insula, lies deep in the lateral cerebral fissure under the junction of the frontal, parietal, and temporal lobes. Little is known about its specific functions, although it is thought to regulate visceral and intestinal functions.

The limbic lobe and **limbic system** are the parts of the cerebrum most closely associated with memory and emotion. The limbic lobe is a ring of cortex on the medial surface of each hemisphere containing the cingulate gyrus, isthmus, and parahippocampal gyrus (Figure 43-10). Olfaction (the perception of smell) occurs within the limbic cortex. The limbic system is a group of structures that encircle the brainstem. In addition to the limbic lobe, the limbic system includes the amygdala, fornix, hippocampus, and portions of the thalamus (see Figure 43-10). Lesions of the limbic system, particularly the hippocampus, cause impairment of short-term memory.

The **basal ganglia** are large masses of gray matter that lie deep within the cerebral hemispheres. They are intimately involved in the initiation, coordination, and execution of movement.<sup>5,6</sup> The basal ganglia include the caudate nucleus, putamen, globus pallidus, subthalamus, and substantia nigra (Figure 43-11). The caudate nucleus and putamen

together are called the *striatum*. The five basal ganglia structures occur in pairs, with each cerebral hemisphere containing a set.

The basal ganglia are connected by complex neural circuits that incorporate sensory information about the current muscle conditions, cortical input about desired motor activities, and cerebellar signals about timing and coordination. Much of what is known about the function of basal ganglia has been learned from studying Parkinson disease. Parkinson disease is characterized by difficulty initiating voluntary movements (akinesia), stiff muscles (rigidity), and a tremor of the hands when idle (rest tremor). Improvement in symptoms occurs when the patient is given a precursor of dopamine (DA, levodopa), which can cross the blood-brain barrier. Studies of these patients revealed degeneration of DA-secreting neurons that project from the substantia nigra to the striatum. As these neurons slowly degenerate over many years, the amount of DA secreted decreases, downstream  $\gamma$ -aminobutyric acid (GABA) pathways become dysregulated, and the relative activity of acetylcholine-secreting neurons in the basal ganglia is increased.<sup>7</sup> A number of drugs (those that block DA) are known to produce a similar clinical syndrome (see Chapter 45).

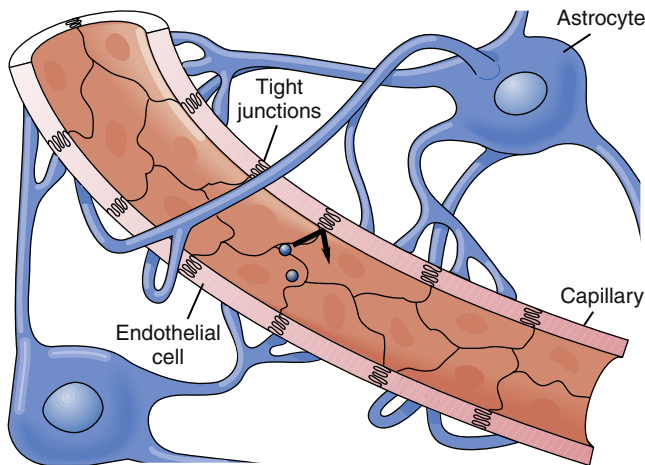

In addition to the gray matter of the cerebral cortex and the basal ganglia, the cerebrum contains thick layers of white matter that consist of myelinated axons. Some of these axons connect the two cerebral hemispheres (commissural fibers), some connect one area of cortex to another within the same hemisphere (association fibers), and others connect the cortex with lower brain centers, including the thalamus, basal ganglia, brainstem, and spinal cord (projection fibers). The corpus callosum and the anterior commissure connect the two hemispheres. The corpus callosum is a massive bundle of fibers crossing the brain just above the lateral ventricles and is the principal means of communication between the hemispheres.

In summary, the cerebrum is the largest brain structure, garnering about 70% of the neurons and supporting cells of the brain to accomplish its diverse and complex functions. Each of the 100 billion neurons in the brain may make hundreds of synaptic connections with other neurons, providing an incomprehensible number of potential interactions. Discovering the ways in which the substance of the cerebrum relates to the workings of the mind is one of the great remaining mysteries of science.

**Diencephalon**

The diencephalon lies deep in the brain, forming a connecting structure between the upper brainstem (midbrain) and the cerebral hemispheres. The principal structures of the diencephalon are the thalamus, hypothalamus, pineal gland, epithalamus, and ventral thalamus (Figure 43-12). The third ventricle also traverses the diencephalon.

The thalamus is the principal receiving site and relay center for impulses traveling to the cerebral cortex from the spinal cord,

**FIGURE 43-5** Tight junctions between brain capillary endothelial cells prevent polar and charged molecules from passing between cells. Astrocytes have foot processes on the capillary that help to maintain integrity of the blood-brain barrier.

**TABLE 43-2 SUBDIVISIONS OF THE BRAIN USING EMBRYOLOGIC, EVOLUTIONARY, AND ANATOMIC FRAMEWORKS**

STRUCTURE	FRAMEWORK		
	EMBRYOLOGIC	EVOLUTIONARY	ANATOMIC
Cerebral hemisphere	Telencephalon	Forebrain (includes diencephalon)	Cerebrum
Thalamus	Diencephalon	—	Diencephalon hypothalamus
Midbrain	Mesencephalon	Midbrain	—
Cerebellum	Metencephalon (includes pons)	Cerebellum	Cerebellum
Medulla	Myelencephalon	Hindbrain	Brainstem (includes midbrain, pons)

**FIGURE 43-6** Four principal anatomic areas of the brain. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 429.)

**FIGURE 43-7** The cortex of the brain is histologically divided into six layers that differ in their connections to other parts of the nervous system. (From Ransom SW, Clark SL [after Brodmann]: *Anatomy of the nervous system*, Philadelphia, 1959, Saunders.)

cerebellum, and basal ganglia. In addition to processing and relaying sensory information, the thalamus is integrally involved in executing motor activities. The thalamus also is involved in propagating the constant background electrical activity of the brain, which can be detected by electroencephalography. Connections between the brainstem reticular activating system and thalamus are necessary to maintain consciousness. Thalamic connections, including the limbic and association cortex, are integral to the expression of those qualities considered to be human: emotion, language, creativity, and complex thought.<sup>8</sup>

The hypothalamus is located just beneath the thalamus on the floor of the diencephalon. The inferior aspect of the hypothalamus extends downward to form the pituitary gland (hypophysis). The posterior pituitary gland is an extension of the neuronal tissue of the hypothalamus, whereas the anterior pituitary gland is derived from glandular tissue (Figure 43-13). Hormones secreted by the pituitary gland enter the systemic circulation and influence target cells at a distance. Neurons in the hypothalamus regulate the secretion of anterior pituitary hormones by releasing and inhibiting hormones (see Chapter 39 for a discussion of the endocrine system).

The hypothalamus is also an important regulatory center for the ANS and for basic functions, such as sleep, body temperature, appetite, and sex drive. Input from sensors of blood pressure, osmolarity, blood oxygen concentration, carbon dioxide level and pH, and temperature is received and integrated into appropriate regulatory responses. The hypothalamus is responsible for homeostasis of life-sustaining functions, including cardiovascular, respiratory, metabolic, fluid and electrolyte, and stress responses.

## CHAPTER 43 Structure and Function of the Nervous System

**FIGURE 43-8** Four principal lobes of the cerebral cortex. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 437.)

**TABLE 43-3 FUNCTIONAL AREAS OF BRAIN SPECIALIZATION**

AREA	SPECIALIZED FUNCTION
Occipital lobe	Visual cortex and association areas
Parietal lobe	Somatosensory cortex and association areas
Temporal lobe	Hearing and equilibrium, emotion, and memory
Frontal lobe	Motor cortex and association areas; prefrontal cortex involved in complex thought, ethical behavior, and morality
Limbic structures	Emotions, short-term memory, olfaction
Basal ganglia	Initiation and planning of learned motor activities
Broca and Wernicke areas	Interpretation and expression of language

The epithalamus contains the pineal gland, thought to be important in regulating circadian rhythms in response to light-dark cycles. The ventral thalamus contains the basal ganglia structure called the *subthalamic nucleus*.

### Cerebellum

The cerebellum is located in the posterior fossa behind the pons. It is separated from the cerebrum by the tentorium cerebelli. The main roles of the cerebellum are to coordinate and smooth movements and to maintain posture and balance. The cerebellum compares the desired motor program with the moment-to-moment execution of the movement and makes instantaneous adjustments to improve the match.<sup>9</sup> The cerebellum receives information from proprioceptors in muscles and joints and from the vestibular apparatus in the inner ear about the

position of the head in space. Some of the fastest-conducting neurons in the nervous system are involved in relaying sensory information to the cerebellum.

The cerebellar cortex is folded much as the cerebral cortex is folded, in a way that significantly increases surface area. Its tightly folded shape gives it a banded appearance. The cortical ridges on the surface of the cerebellum are called *folia*. The white matter beneath is called the *medullary center* and is made up of fibers running to and from the cerebellar cortex.

The cerebellum is divided anatomically, first by the posterolateral fissure, which separates the flocculonodular lobe (the region immediately inferior to the middle cerebellar peduncles) from the main body (Figure 43-14). The midline body is called the *vermis*, and it is straddled on either side by the cerebellar hemispheres.

**FIGURE 43-9** Partial Brodmann map of the cerebral cortex. Note the locations of Broca and Wernicke areas, which are important in the expression and understanding of language. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby, p 441.)

**FIGURE 43-10** The limbic system is composed of a group of structures deep in the brain that are important in memory and emotion. These structures include the limbic lobe, amygdala, fornix, hippocampus, olfactory bulb, and portions of the thalamus.

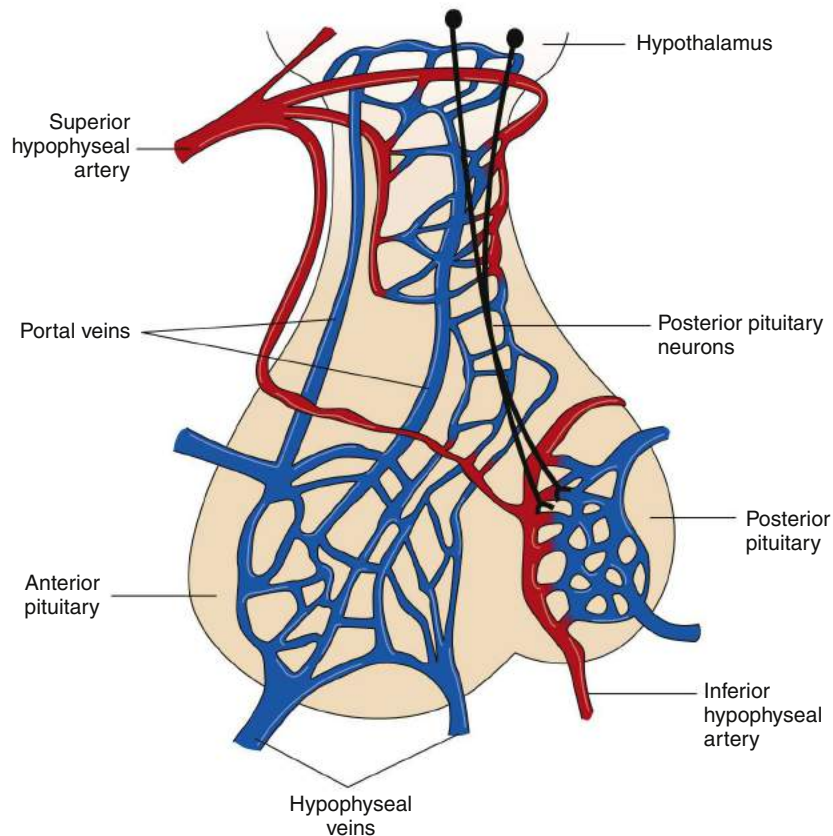

**CHAPTER 43** Structure and Function of the Nervous System

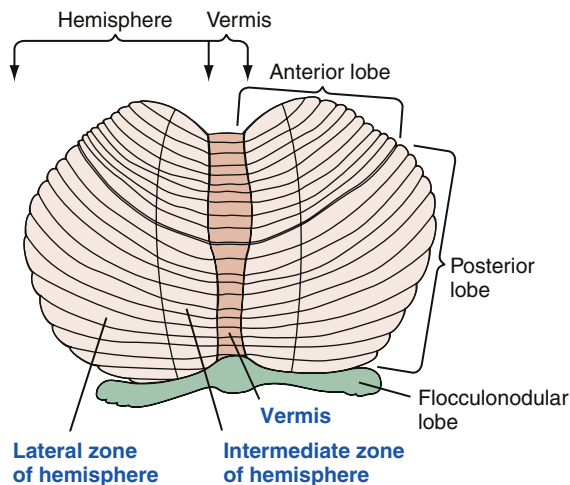

**FIGURE 43-11** The basal ganglia include the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and substantia nigra (labeled in blue).

**FIGURE 43-12** The diencephalon includes the thalamus, hypothalamus, pineal gland, and hypothalamic extension to the pituitary gland.

**FIGURE 43-13** Anatomy of the hypothalamus and pituitary gland. Note that the posterior pituitary gland is connected to the hypothalamus by neuronal axons, whereas the anterior pituitary gland receives signals by way of a portal vein system. The portal veins drain blood from the capillaries of the hypothalamus and take it to the capillaries of the anterior pituitary gland.

**FIGURE 43-14** Lobes of the cerebellum from a posteroinferior view. See text for explanation. (Adapted from Hall JE, editor: *Guyton & Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 682.)

The prominent tracts that attach the cerebellum to the brainstem are called the *inferior*, *middle*, and *superior* cerebellar peduncles. The inferior cerebellar peduncle is composed primarily of afferent fibers coming from the spinal cord and the brainstem. The middle peduncle contains afferent fibers from the contralateral pontine **nuclei**. The superior cerebellar peduncle is composed of major efferent pathways leaving the cerebellum.

Deep within the medullary center in each cerebellar hemisphere are the cerebellar nuclei. These include the dentate nuclei, the interposed nuclei, and the fastigial nuclei. The deep cerebellar nuclei are the final pathway of cerebellar output. Input from several areas of the cerebral cortex is received by the cerebellar hemispheres and dentate nuclei, and then sent back to the motor and premotor cortex. This circuit is believed to influence the planning and programming of voluntary movements, especially learned, skilled movements (those that become more rapid, precise, and automatic with practice).

The major input to the paravermal region, also called the intermediate cortex, consists of somatotopically arranged projections from the motor cortex and spinal cord. The intermediate cerebellum influences spinal cord and motor neurons through the corticospinal tract and the rubrospinal tract, where it is involved in interpreting and responding to the position and velocity of the moving body.

The vermis is most involved with regulation of posture and stereotyped movements that are programmed in the brainstem and spinal cord. The flocculonodular lobe helps maintain equilibrium and mediate the eye movements needed for visual tracking.

Lesions of the cerebellum result in ataxia (impaired balance), intention tremor, past pointing (failure of finger-to-nose test), and dysidochokinesia (failure of rapid movements).

### Brainstem

The brainstem is a stalk of neural tissue that lies between the upper spinal cord and the diencephalon. It has three parts: from top to bottom these are the *midbrain*, *pons*, and *medulla oblongata*. The brainstem is critical for transmission of impulses between the brain and spinal cord. Vital centers for regulating respiratory and cardiovascular function are located in the medulla and pons. In addition, the reticular activating neurons that maintain consciousness and alertness traverse the brainstem to reach the thalamus. Of the 12 pairs of cranial nerves,

10 originate from nuclei in the brainstem; only cranial nerves I (olfactory) and II (optic) originate elsewhere (diencephalon).

The midbrain or mesencephalon contains the cerebral peduncles, consisting of motor tracts to the spinal cord; the superior and inferior colliculi, which control head and eye movements; and the red nucleus, part of a major motor tract. Cranial nerve III (oculomotor) emerges from the midbrain and is prone to compression when pressure in one of the cerebral hemispheres is elevated. Increased intracranial pressure (e.g., from tumor, ischemia, edema, bleeding) is commonly manifested by dysfunction of cranial nerve III resulting in abnormal pupil size and poor reactivity to light (see Chapter 44). Cranial nerve IV (trochlear) also emerges at the level of the midbrain.

The pons (Latin for *bridge*) connects the midbrain above to the medulla below. The dorsal pons consists of reticular formation fibers, ascending sensory tracts, and descending motor tracts. Two respiratory centers (pneumotaxic and apneustic) located in the dorsal pons work in coordination with the principal respiratory centers in the medulla. A major pathway of voluntary motor control, the corticospinal tract, also passes through the ventral pons on its way from the motor cortex to the spinal cord.

The medulla oblongata makes up the lower third of the brainstem and is continuous with the spinal cord. Nuclei within the reticular formation of the medulla form the vital centers that regulate cardiac, vascular, and respiratory function. The medulla also contains centers that coordinate swallowing, vomiting, coughing, and sneezing. The medulla is the site of decussation (crossing over) of the major sensory (dorsal column) and motor (corticospinal) tracts such that innervation of one side of the body is connected to the opposite (contralateral) cerebral hemisphere. The corticospinal tract neurons decussate within ridges on the ventral surface of the medulla called *medullary pyramids*. Motor tracts that do not cross over within the pyramids (e.g., tectospinal, vestibulospinal) are sometimes referred to as extrapyramidal tracts; disorders associated with function of these tracts (balance, posture, gait) may be called *extrapyramidal disorders* (e.g., Parkinson disease). Although the anatomic correlation is not quite accurate, use of the term persists in a clinical context.

All of the remaining cranial nerves (VI, VII, VIII, IX, X, XI, and XII) originate in the medulla. The cranial nerves themselves are part of the PNS and are discussed in that section. The name, origin, and function of the 12 cranial nerves are included in [Table 43-4](#).

### The Spinal Cord

The spinal cord conveys nervous impulses between the brain and 31 pairs of spinal nerves that innervate sensory organs and muscle cells of the body. The spinal cord mediates spinal reflexes involved in maintenance of posture, protective responses to pain, urination, and muscle tone. A great deal of integration and processing occurs in the gray matter of the spinal cord, whereas the white matter contains bundles of myelinated axons forming tracts that run up and down the cord. Tracts in the spinal cord are **somatotopically** organized such that the innervation of a particular body region is connected to a specific region in the cerebral cortex.

The typical adult spinal cord is about 18 inches long, extending from the base of the skull (foramen magnum) to the first or second lumbar vertebra (L1 to L2).<sup>10</sup> The vertebral column extends for several more inches, providing a reservoir for CSF and exit points for the lumbar and sacral spinal nerves. The vertebral column is formed by interlocking sections of bone separated and cushioned by intervertebral disks. At the lateral aspect of the intersection of two vertebrae is an opening (intervertebral foramen) that provides a passageway for spinal nerves to exit the cord. The spinal cord travels in a small lumen (1 cm) in the center of the vertebral column and is itself only slightly larger than the diameter of a pencil<sup>10</sup> ([Figure 43-15](#)).

TABLE 43-4 CRANIAL NERVES

CRANIAL NERVE	ORIGIN	FUNCTION
I (olfactory)	Nasal mucous membrane	Olfaction
II (optic)	Retina	Vision
III (oculomotor)	Midbrain	Movement of eyeball, eyelid, constriction of pupil
IV (trochlear)	Lower midbrain	Lateral eye movements
V (trigeminal)		
Ophthalmic	Forehead, eyes	Sensation from forehead, eye, scalp
Maxillary	Upper jaw, lip	Sensation from cheek, upper lip
Mandibular	Lower jaw area	Sensation from chin and lower jaw, motor chewing
VI (abducens)	Lower pons	Lateral eye movements
VII (facial)	Pons	Taste from anterior tongue, control of muscles of face
VIII (vestibulocochlear)	Cochlea	Hearing
	Inner ear	Equilibrium
IX (glossopharyngeal)	Medulla	Taste from posterior tongue, secretion of saliva, swallowing
X (vagus)	Medulla	Monitors oxygen, carbon dioxide, and pH levels in blood; senses blood pressure; inhibits cardiac action and has extensive gastrointestinal activities
XI (spinal accessory)	Medulla and cervical cord	Voice production, movement of head and shoulders
XII (hypoglossal)	Medulla	Movements of tongue during speech and swallowing

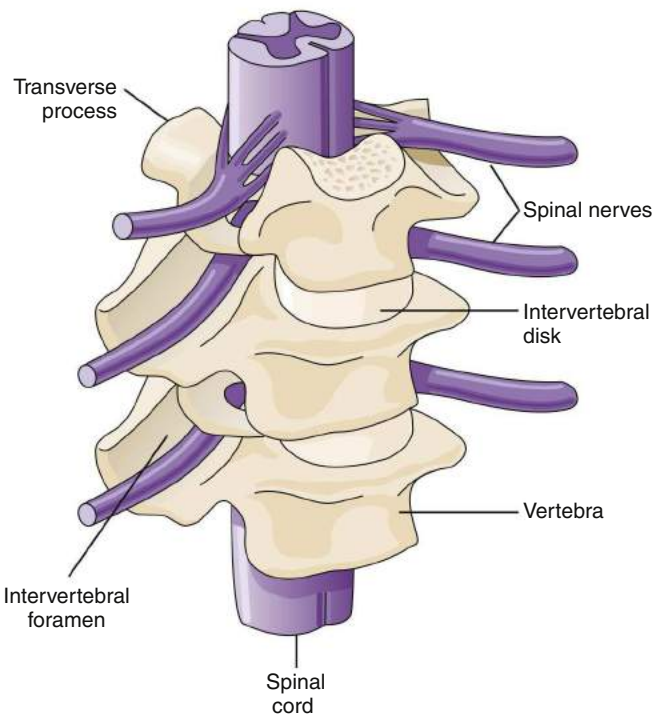

FIGURE 43-15 Spinal cord travels down the center of the vertebral column. A foramen at the intersection of two vertebrae forms an exit point for the spinal nerves.

On cross-section the spinal cord has a butterfly pattern of gray matter surrounded by white matter (Figure 43-16). Three bumps on the butterfly wings are called *horns*: the ventral horn (motor neurons), the dorsal horn (sensory neurons), and the lateral horn (sympathetic neurons). The horns consist of neuron cell bodies, synapses, and small unmyelinated interneurons. The white matter is divided into columns that contain tracts of nerve fibers traveling to and from the brain. These are the posterior (dorsal) columns, anterior columns, and lateral columns. Some of the neurons in the columns convey signals from one level of the cord to another and are important in reflex and postural

adjustments. The principal ascending sensory tracts include the dorsal column–lemniscal and the anterolateral (spinothalamic) tracts, which send **afferent** signals to the brain. The principal descending motor tracts include the corticospinal, rubrospinal, reticulospinal, and vestibulospinal tracts. These tracts are located in specific regions of the cord (Figure 43-17). Sensory and motor pathways are discussed in later sections of this chapter.

Spinal nerves divide into two sections as they make contact with the spinal cord: the ventral and dorsal roots (Figure 43-18). Ventral roots contain motor neurons that originate in the anterior horn and travel in the spinal nerve to skeletal muscles. Dorsal roots carry sensory information from somatic receptors to neurons in the posterior horn. The cell bodies of sensory afferents collect together in the dorsal root ganglion. Autonomic nerves also travel in the spinal cord and exit and enter the cord by way of the ventral and dorsal roots.

The points at which sensory neurons enter the cord and at which motor neurons exit represent the separation of the CNS and PNS.

## PERIPHERAL NERVOUS SYSTEM

The PNS consists of the 31 pairs of spinal nerves and the 12 pairs of cranial nerves. These nerves are myelinated with Schwann cells, which differ somewhat from the oligodendrocytes that form the myelin sheaths of CNS neurons. By convention, groups of cell bodies are called *ganglia* in the PNS and *nuclei* in the CNS. A major exception to this naming rule is the basal ganglia of the CNS. The PNS is not protected by CSF, meninges, or bony coverings as is the CNS; however, a sheath of connective tissue covers the nerves and provides support.

The PNS serves both afferent sensory functions and efferent motor functions of the somatic and autonomic systems. Cranial nerves III, VII, IX, and X and spinal nerves S2 and S3 contain parasympathetic neurons, and spinal nerves T1 to L2 contain sympathetic neurons.<sup>11</sup>

## Cranial Nerves

As previously noted, all of the cranial nerves originate in the brainstem except cranial nerves I and II, which originate in the diencephalon<sup>12</sup> (Figure 43-19). Cranial nerve I is strictly sensory, transmitting olfactory signals from the 10 million to 20 million olfactory neurons in the nasal cavities to the olfactory bulbs. The olfactory bulb neurons then

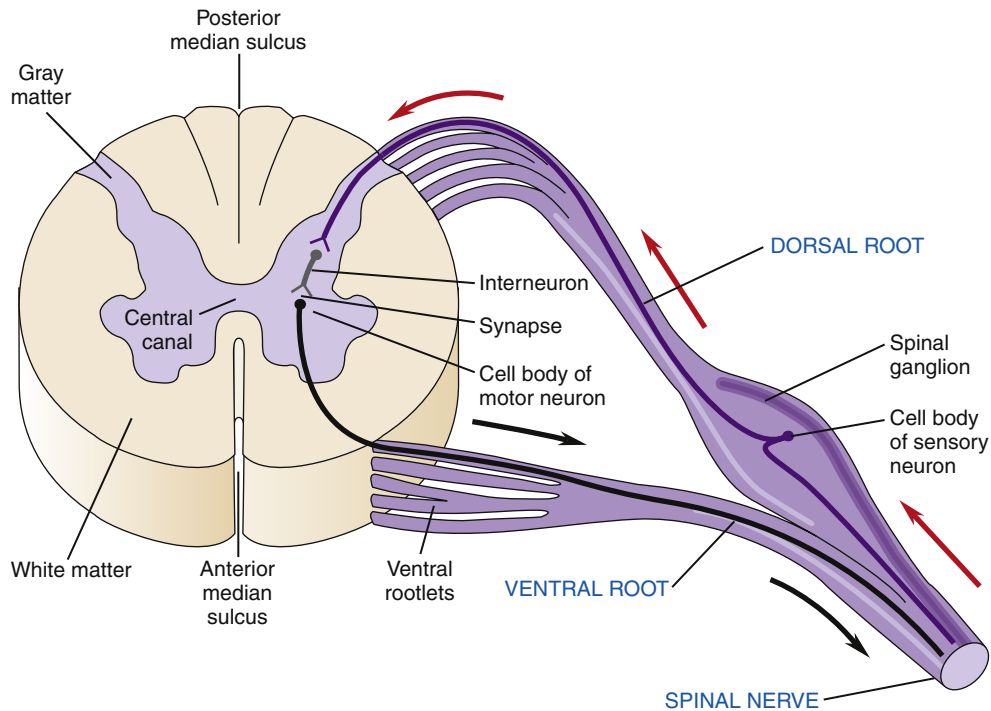

**FIGURE 43-16** Spinal cord in cross-section, showing the butterfly pattern of white and gray matter.

**FIGURE 43-17** Main ascending (*left*) and descending (*right*) tracts of the spinal cord.

**FIGURE 43-18** Spinal nerves split to form dorsal and ventral roots as they emerge from the spinal cord. Ventral roots carry motor efferent neurons, whereas dorsal roots carry sensory afferent neurons. See text for explanation.

project to the olfactory cortex. Cranial nerve II is also sensory, conveying visual information from the retina to the brain. The optic nerve is unusual in that it is an extension of the CNS, myelinated by oligodendrocytes rather than Schwann cells. The neurons from the medial retina decussate in the optic chiasm, whereas the lateral retina neurons do not. Thus, the right visual field projects to the left hemisphere and the left visual field projects to the right hemisphere. Damage to one hemisphere, as occurs in stroke, often interrupts visual signals from the corresponding sides of each retina—a condition known as homonymous hemianopsia (see Chapters 44 and 46).

Cranial nerves III, IV, and VI innervate motor structures in the eyes. Cranial nerve III mediates pupil constriction. The trigeminal nerve (cranial nerve V) is so named because it has three branches, which provide sensory innervation of the forehead and eyes (ophthalmic branch); upper lip, teeth, and palate (maxillary branch); and lower jaw (mandibular branch). The mandibular branch is both sensory and motor. Cranial nerve VII is also mixed sensory and motor, detecting taste in the anterior two thirds of the tongue and innervating muscles of facial expression. Cranial nerve VII also contains autonomic fibers that innervate salivary and lacrimal (tear) glands.

Cranial nerve VIII has two important sensory functions: transmitting auditory information from the cochlea and vestibular information from inner ear structures. The vestibular neurons of cranial nerve VIII interact with the neurons of cranial nerves III and VI to reflexively control eye movements during head rotation such that a visual image can remain fixed on the retina. This reflex, the oculovestibular reflex, is commonly assessed in the unconscious patient to evaluate brainstem function (see Chapter 44).

Cranial nerve IX innervates tongue and pharyngeal muscles, conveying taste from the posterior tongue and controlling pharyngeal

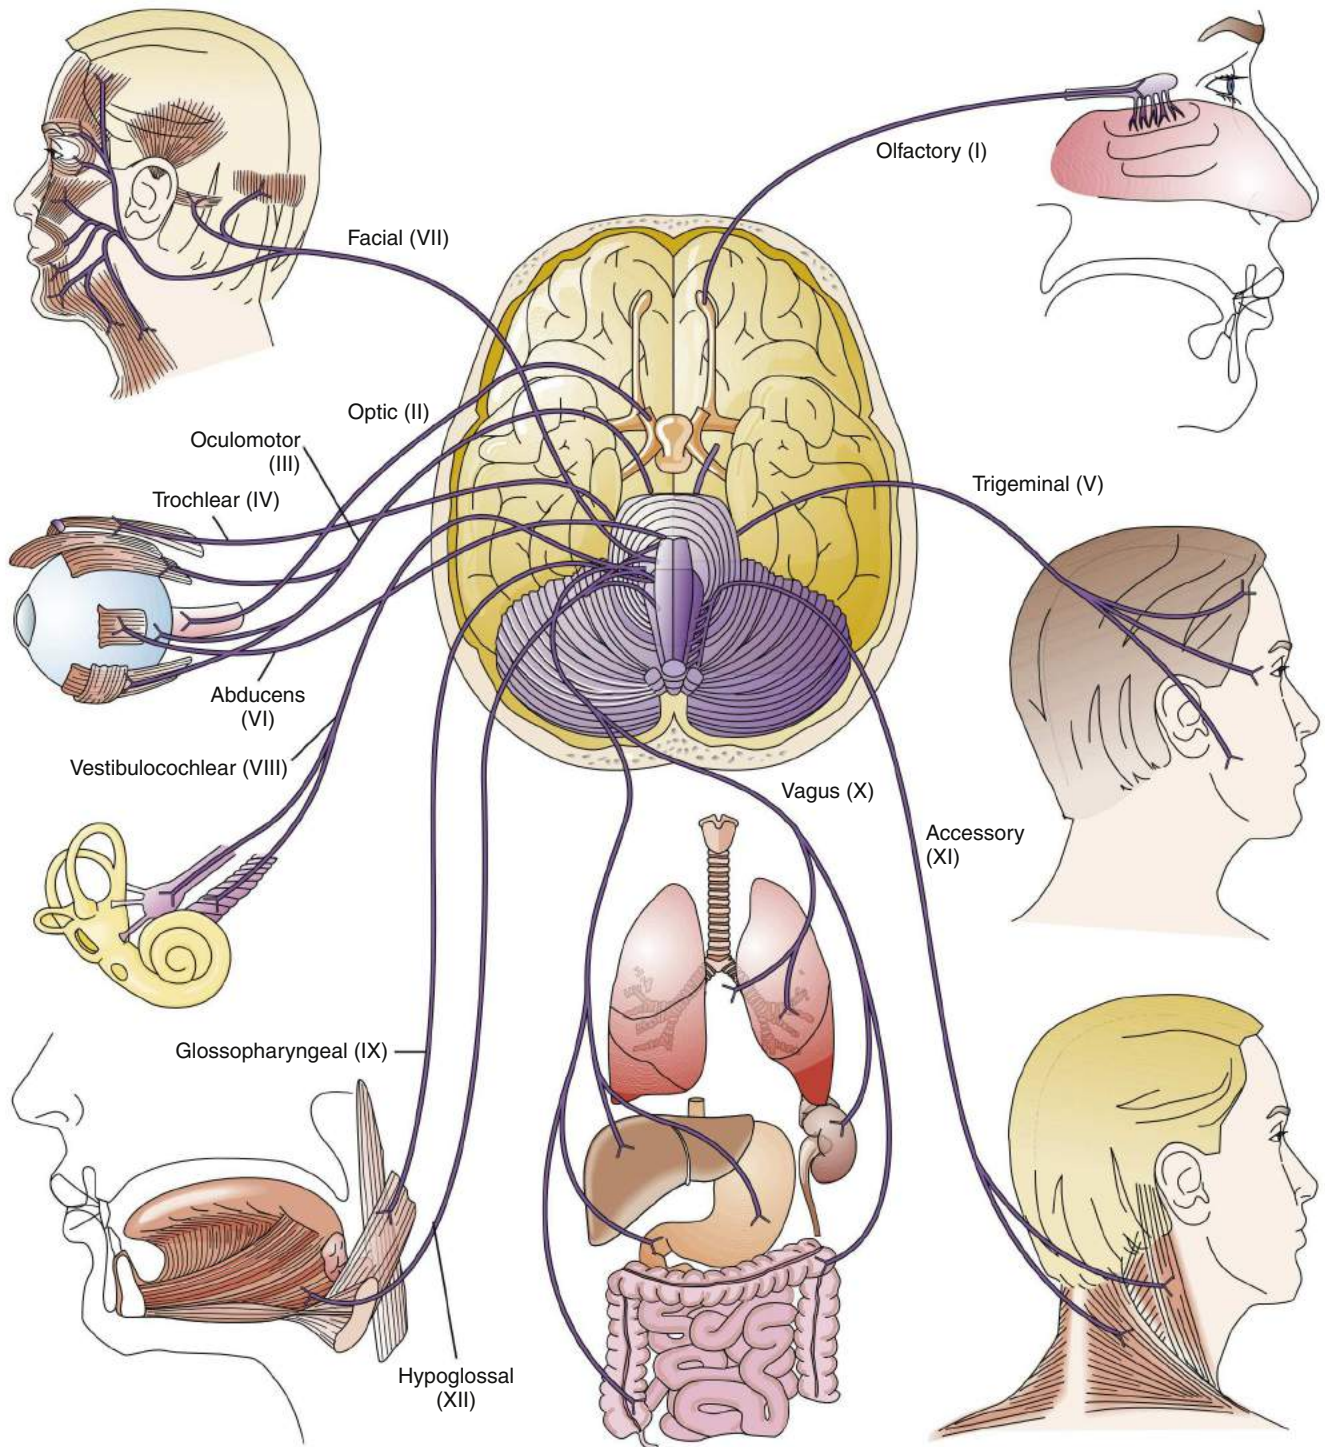

motion during swallowing. Cranial nerve IX also has autonomic functions and transmits sensory information from the carotid baroreceptors and carotid bodies to the brainstem. Cranial nerve X, the vagus nerve, contains parasympathetic afferent and efferent fibers that innervate many visceral structures, including the heart, lungs, and gastrointestinal (GI) tract from pharynx to anus. Sensory information from aortic baroreceptors and aortic bodies is conveyed to the brainstem by the vagus nerve.

Cranial nerve XI innervates muscles of the larynx, neck, and shoulders and mediates voice production and neck and head movements. Cranial nerve XII innervates tongue muscles and controls their action during speech and swallowing.

### Spinal Nerves

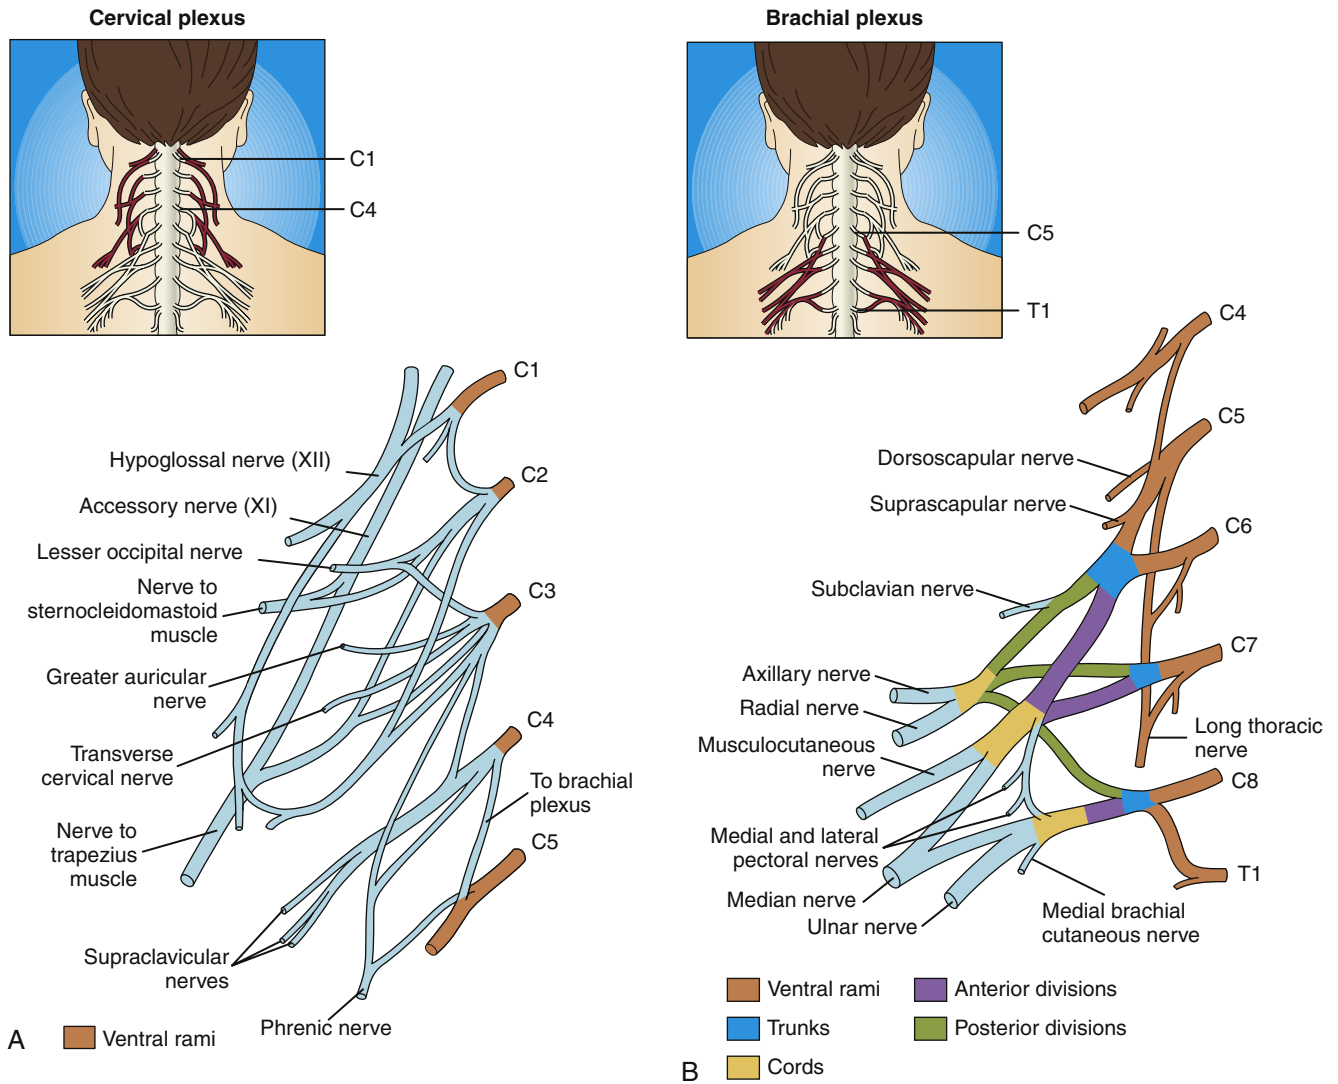

The 31 pairs of spinal nerves are named after the vertebral segments from which they emerge. There are 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal pair of spinal nerves. The first cervical nerve exits above C1, whereas the others all exit below the vertebral segment; thus there is one more pair of cervical spinal nerves (8) than there are cervical vertebrae (7).

Except for spinal nerves T2 to T12, the spinal nerves travel a distance from the cord and then merge into a large group called a *plexus*.<sup>12</sup> In the plexus, nerve fibers are recombined into different groups and emerge as peripheral nerves (Figure 43-20). There are five plexuses: (1) the cervical plexus (C1 to C4), (2) the brachial plexus (C5 to C8, T1), (3) the lumbar plexus (L1 to L4), (4) the sacral plexus (L4 to L5, S1 to S3), and (5) the coccygeal plexus (S4 to S5, coccygeal) (Table 43-5). Because of this recombination of nerve fibers in the plexus, the spinal nerves and peripheral nerves have different somatic distributions. The segment of the body innervated by a spinal nerve is called a *dermatome*, whereas the peripheral nerve innervates a peripheral

nerve field. Knowledge of dermatomes and peripheral nerve distribution can help the clinician differentiate between radiculopathy from spinal nerve compression (dermatomal sensory changes) and peripheral neuropathy. (Dermatomal and peripheral nerve maps are located in Chapter 47.)

The intercostal nerves (T2 to T12) do not form plexuses; they travel in a course parallel to the ribs to innervate intercostal muscles and skin on the trunk and abdomen.

## AUTONOMIC NERVOUS SYSTEM

The ANS is composed of neurons in the CNS and PNS that mediate automatic or involuntary functions. The ANS has both sensory

afferents and motor efferents that primarily innervate visceral organs and blood vessels. As previously described, the hypothalamus and brainstem contain neurons responsible for integrating autonomic sensory information and creating appropriate homeostatic responses. This response is communicated to the effector organs by parasympathetic nervous system (PSNS) efferents located in cranial nerves III, VII, IX, and X, spinal nerves S2 to S3, and by sympathetic nervous system (SNS) neurons in spinal nerves T1 to L2.<sup>11</sup>

The distribution of parasympathetic nerves is shown in Figure 43-21. Note the extensive role that cranial nerve X (vagus) has in cardiovascular, respiratory, and gastrointestinal (GI) function. The distribution of sympathetic nerves is shown in Figure 43-22. Note that after leaving the spinal cord, sympathetic neurons converge on a chain of ganglia that runs parallel to both sides of the spinal cord. Some sympathetic neurons synapse on secondary neurons in the ganglia, and others travel to other plexuses or ganglia before synapsing (see Figure 43-22). The neurons that emerge from the spinal cord are called *preganglionic neurons*, whereas the neurons traveling to the target cell are called *postganglionic neurons*. This terminology is also used for the PSNS; however, the parasympathetic preganglionic neurons are long, traveling all the way to the target organ, and they do not terminate in ganglia.<sup>11</sup> The postganglionic neurons are short and are located within the target organ (see Figure 43-21).

The neurotransmitter secreted by preganglionic neurons is acetylcholine for both the SNS and the PSNS. The postganglionic neurotransmitters differ (Figure 43-23). The SNS secretes norepinephrine (NE) in most cases, although sweat glands and some skeletal muscle vessels are innervated by acetylcholine-secreting SNS neurons. The PSNS secretes acetylcholine as the postganglionic neurotransmitter. Acetylcholine is also the neurotransmitter of the motor neurons that innervate skeletal muscle; however, the target cell receptors differ. Skeletal muscle contains nicotinic acetylcholine receptors, whereas autonomic organs contain muscarinic acetylcholine receptors (see Figure 43-23).

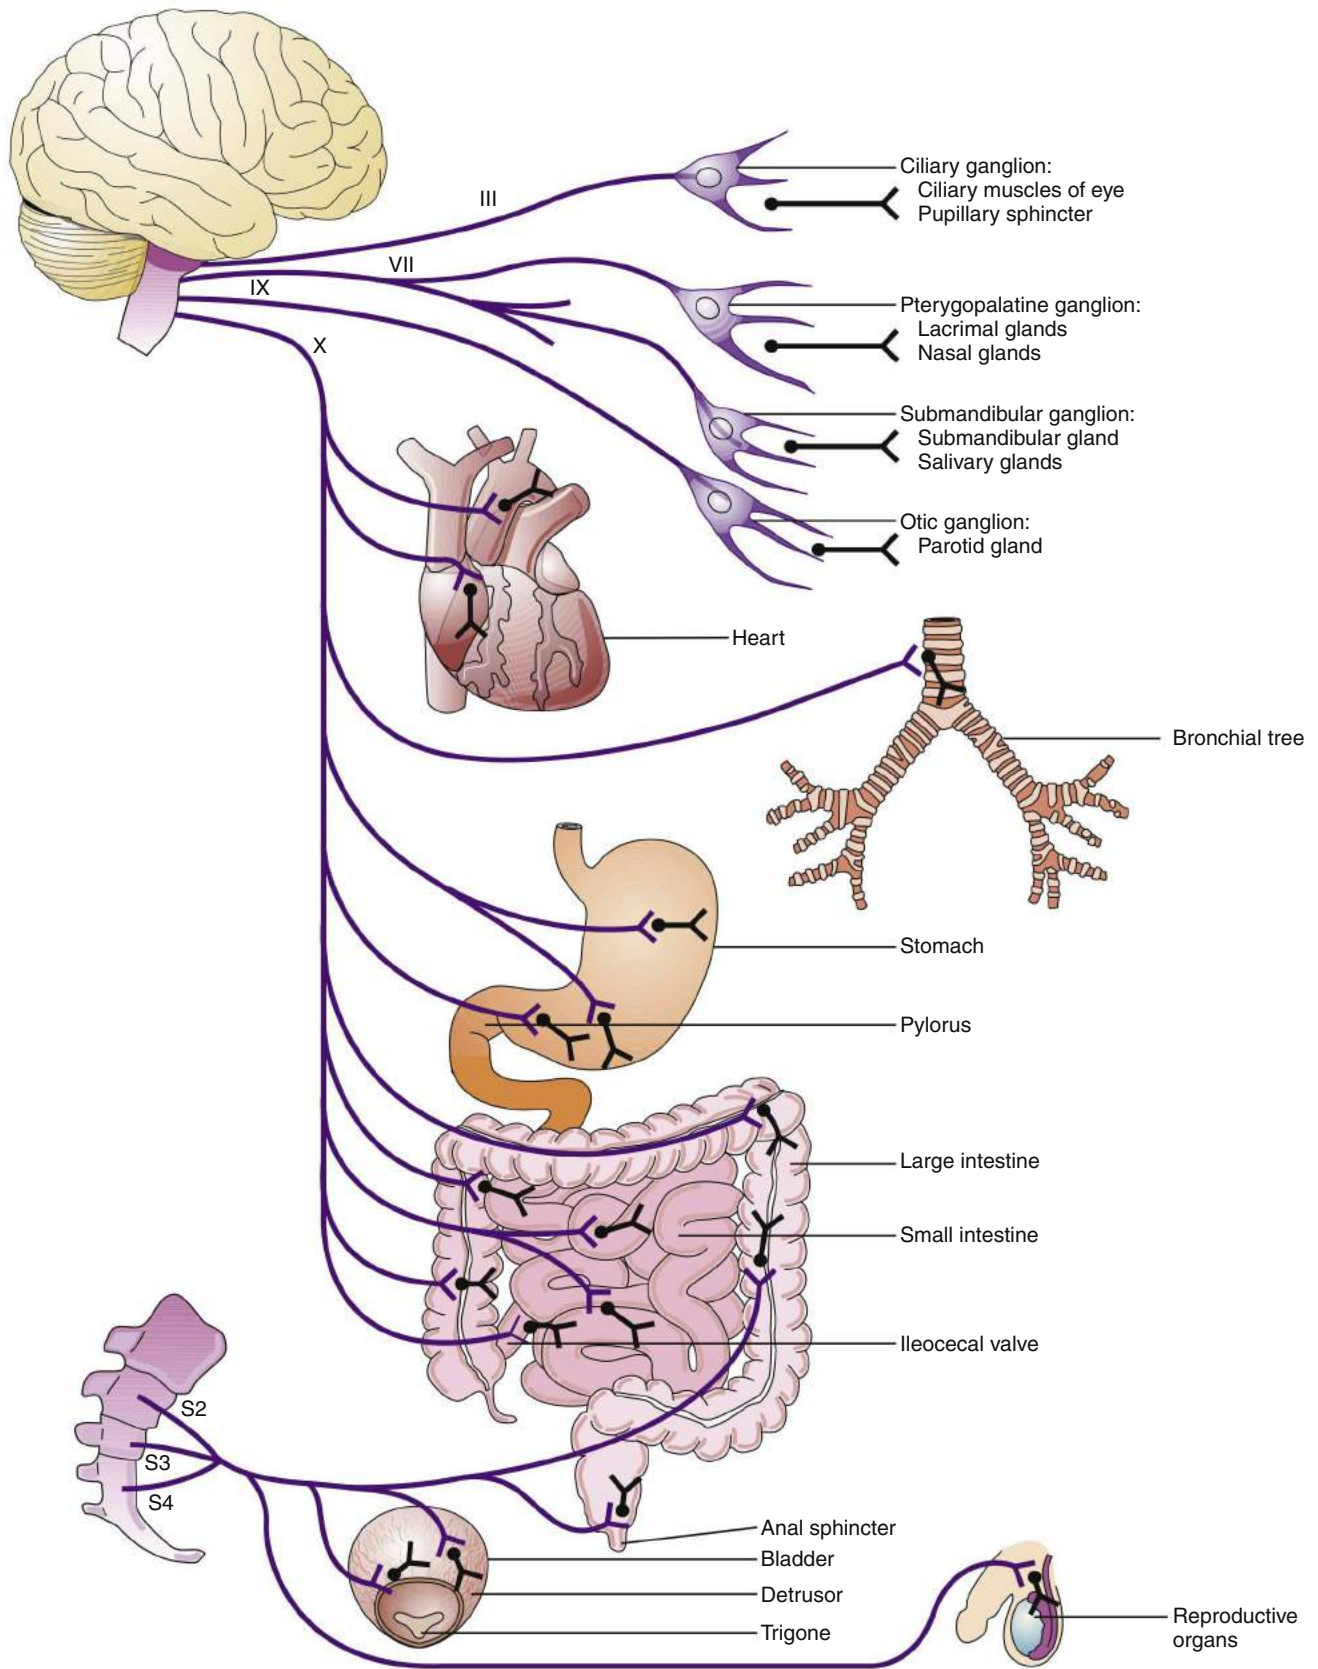

The effect of the SNS and PSNS on target organs is nearly always antagonistic. If one contracts smooth muscle, the other relaxes it; if one stimulates glandular secretion, the other inhibits it; if one speeds up a process, the other slows it down. The effects of SNS and PSNS stimulation on major target organs are shown in Table 43-6.

A specialized extension of the SNS is found in the adrenal gland. The adrenal medulla receives preganglionic neurons from SNS neurons emerging from the spinal cord, which stimulate the gland to secrete epinephrine (and smaller amounts of NE) into the bloodstream. These hormones have effects similar to those of direct SNS stimulation.

The manner in which target cells respond to SNS stimulation depends on the types of receptors they possess. Several subtypes of receptors bind and respond to NE and epinephrine; these include  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ , and several DA receptors (see Table 43-6). (The details of autonomic regulation of cardiac, genitourinary, and GI function can be found in Chapters 17, 29, and 35, respectively.)

The coordination of SNS and PSNS activity within a target organ is accomplished by centers in the brainstem and hypothalamus with input from sensory neurons and cortical neurons. Most of these systems work on a negative feedback principle to achieve homeostasis. Negative feedback requires accurate sensory input about the conditions being regulated. Much of this feedback is provided by the vagus nerves that obtain extensive sensory information from receptors in the GI tract and aorta. This sensory input is processed in lower brain centers and does not reach the level of perception.

Acetylcholine (*ACh*) is the neurotransmitter of the motor neuron, but its receptor differs from that of the parasympathetic terminations. *N*, Nicotinic receptors; *NE*, norepinephrine; *M*, muscarinic receptors.

**KEY POINTS**

- The nervous system can be divided into three principal systems: (1) the central nervous system (CNS), consisting of the brain and spinal cord; (2) the peripheral nervous system (PNS), consisting of 31 pairs of spinal nerves and 12 pairs of cranial nerves; and (3) the autonomic nervous system (ANS), consisting of the sympathetic and parasympathetic branches.
- Meninges affix the brain to the skull so that the brain is suspended and supported. Meninges have three layers: (1) The dura mater is the tough outer layer attached to the periosteum of the skull. (2) The arachnoid is a delicate weblike membrane spanning the space between the dura mater and the pia mater. (3) The pia mater covers the contours of the brain surface. The spinal cord has a similar arrangement of meningeal coverings.
- Cerebrospinal fluid (CSF) is produced in the brain ventricles and circulates in the subarachnoid spaces, providing cushioning and nutritive functions.
- The brain is protected by specialized tight junctions between the cells of the capillary endothelium (blood-brain barrier) and between the ependymal cells that line the ventricles (CSF-brain barrier).
- The brain can be anatomically divided into four principal structures: (1) the cerebrum (cerebral cortex, basal ganglia, limbic cortex, and corpus callosum); (2) the diencephalon (thalamus and hypothalamus); (3) the cerebellum; and (4) the brainstem (midbrain, pons, and medulla).
- Certain cortical areas are closely associated with specific functions: the frontal lobe contains the motor cortex and is involved in complex thought, motivation, and morality; the temporal lobe contains the auditory and vestibular centers and parts of the language center; the occipital lobe contains the visual cortex; the parietal lobe contains the somatosensory cortex; the limbic area is involved in memory and emotion.
- Basal ganglia are located deep within the cerebral hemispheres and are important in the control of skeletal muscles. Parkinson disease is an important example of basal ganglia dysfunction characterized by akinesia, rigidity, and rest tremor.

- The thalamus is a centrally located structure that processes and relays most of the signals traveling to and from the cortex and lower centers. Connections between the thalamus and the brainstem and cortex are needed to maintain consciousness and allow higher brain functions.
- The hypothalamus and brainstem are important structures regulating the ANS. The sympathetic nerves originate in spinal cord segments T1 to L2. The parasympathetic nerves emerge from the sacral segments and also travel in cranial nerves III, VII, IX, and X.

**NEURONAL STRUCTURE AND FUNCTION**

The ways in which the nervous system achieves its rapid communication function can be understood by examining the structure and behavior of neurons and neuronal synapses.

**NEURONS AND SUPPORTIVE CELLS**

The nervous system is composed of two principal cell types: neurons, which generate and transmit nerve impulses; and glial cells, which provide supportive functions to neurons but do not transmit action potentials. There are approximately 10 glial cells per neuron and about 100 billion neurons in the CNS.<sup>13</sup>

**Neurons**

A neuron has three basic components: (1) the cell body containing cellular organelles, (2) the dendrites that receive signals and conduct them to the cell body, and (3) the axon that generates and conducts action potentials. Neurons can be categorized according to their structure or by the neurotransmitters they secrete. Neurons are present in three basic configurations based on the location of the cell body and the relative length and number of dendrites and axons<sup>13</sup> (Figure 43-24).

\*Sympathetic cholinergic neurons.

AV, Atrioventricular; EDRF, endothelial-derived relaxing factor; M, muscarinic receptor; SA, sinoatrial.

Multipolar neurons have a large number of dendrites extending from the cell body and one axon. Most neurons are of this type. Bipolar neurons have only one dendrite and one axon extending from the cell body. These neurons are prevalent in the retina, cochlea, and olfactory structures but are rare elsewhere. Unipolar neurons have a single process protruding from the cell body, which splits to form a dendrite and axon. This arrangement makes the cell body appear to be off-center. Unipolar neurons are prevalent in the somatosensory nerves in which the cell bodies are grouped in the dorsal root ganglia. The dendrites extend to the sensory receptors and the axons enter the spinal cord.

Neurons also can be grouped as excitatory or inhibitory based on the nature of the neurotransmitter they secrete. Each neuron secretes one principal neurotransmitter, which is excitatory if it depolarizes the target neuron or inhibitory if it results in hyperpolarization.

## Glia

Glial cells in the nervous system (neuroglia) serve a number of supportive functions, but they are not capable of generating action potentials. Four major types of neuroglia are recognized: oligodendrocytes, astrocytes, microglia, and ependymal cells (Figure 43-25). The Schwann cells of the PNS are similar to oligodendrocytes. Both of these cell types form the myelin sheath that wraps around nerve axons to insulate and

speed the rate of action potential conduction (Figure 43-26). Myelin gives the white matter its color.

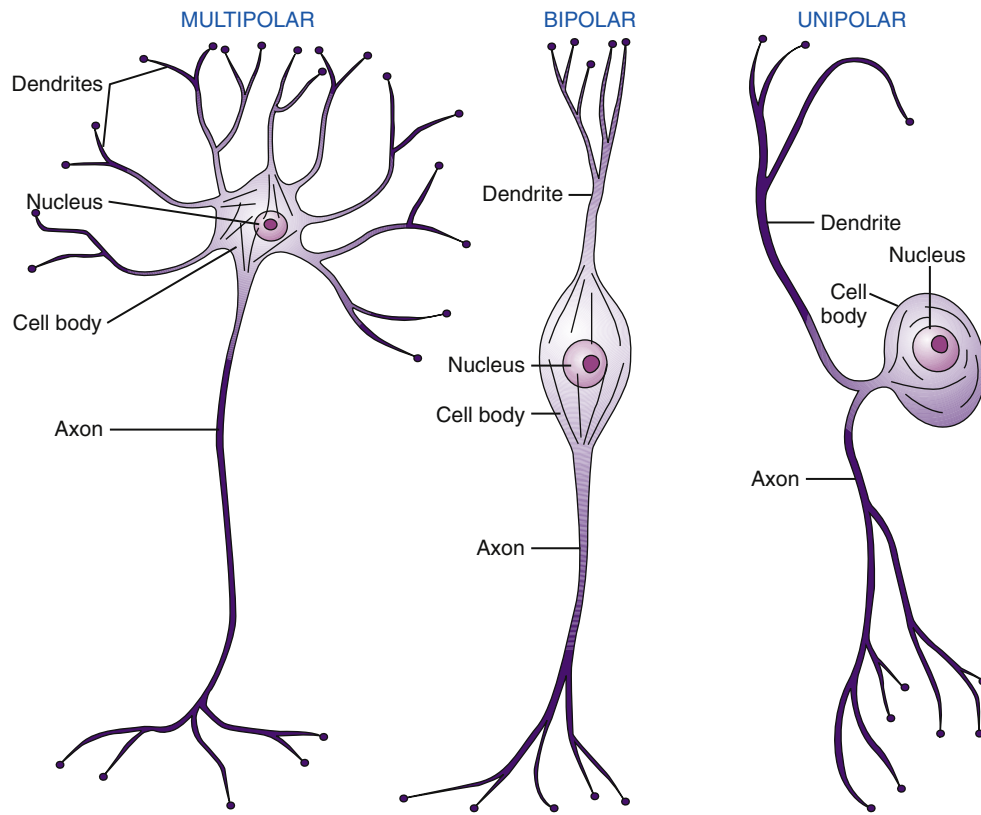

Astrocytes serve many functions in the CNS. Some astrocytes have foot processes that contact the brain capillaries and help maintain the integrity of the blood-brain barrier. Astrocytes regulate ionic balance of the interstitial fluid and may influence the transfer of nutrients from capillaries to neurons. Astrocytes also participate in nervous system signaling and have been shown to take up and release molecules, such as neurotransmitters and cotransmitters that modulate neurotransmission.<sup>3</sup>

Microglia are derived from the monocyte-macrophage cell type and provide phagocytic functions within the CNS.<sup>14</sup> Ependymal cells line the ventricles and central canal of the spinal cord, producing CSF and maintaining the CSF-brain barrier.

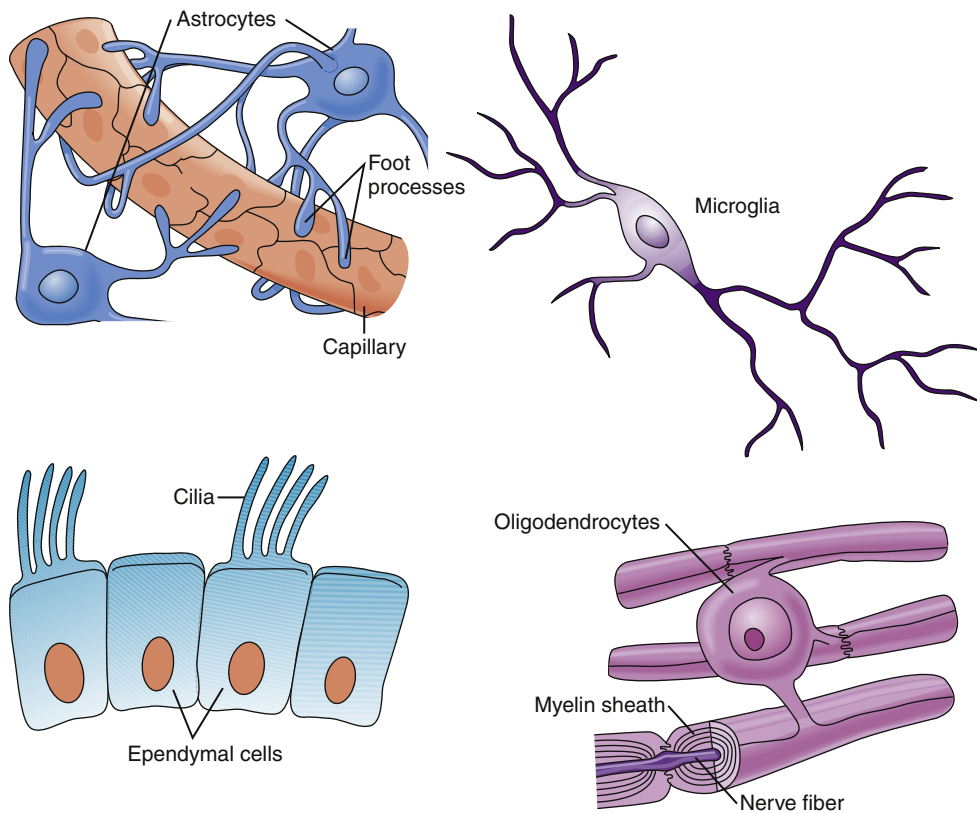

Terminally differentiated neurons are not capable of cell division and cannot replace themselves if they die. However, certain areas of the brain, particularly the hippocampus and ventricles, are populated by neural stem cells. These cells are capable of cell division to produce two daughter cells, one of which retains stem cell characteristics whereas the other may differentiate into a neuron or glial cell (Figure 43-27). Specific signals are thought to guide the new cell as it migrates to the brain tissue and begins differentiation. Approximately half of the newborn cells will not find a suitable place and undergo apoptosis

## CHAPTER 43 Structure and Function of the Nervous System

**FIGURE 43-25** Four types of neuroglial cells: astrocytes, microglia, ependymal cells, and oligodendrocytes.

**FIGURE 43-26** Oligodendrocytes wrap around nerve axons to form a myelin sheath. The nodes of Ranvier are the small spaces between the oligodendrocytes. CF, C-fiber (unmyelinated). (From Kessel RG, Kardon RH: *Tissues and organs: a text-atlas of scanning electron microscopy*, San Francisco, 1979, Freeman, p 80.)

(programmed cell death).<sup>15</sup> The discovery that neural stem cells provide a reservoir for producing new neurons has numerous implications for treating neurodegenerative disorders such as Alzheimer disease and Parkinson disease as well as brain damage after stroke and trauma. However, the methods for stimulating proliferation and coaching the neurons to migrate to the right places to make the correct synaptic connections have not been completely elucidated.

The term *neural plasticity* is used to describe the potential for the brain to change its structure and function. Traditionally, neural plasticity was thought to be a result of recruitment of formed neurons into new functional networks. With the discovery of neural stem cells, plasticity in some regions of the brain is likely to include the addition of new neurons as well as reassignment of the participants in the neuronal circuits. Neural plasticity is used to advantage to train different brain areas to assume new functions. For example, when a person suffers a stroke causing destruction of neurons in the motor cortex, it is possible to train nearby cortical neurons to assume some of the lost motor functions. Persistent attempts to use the muscles in an affected area may recruit cortical neurons into the neuronal circuit and improve motor strength and coordination over time. Neural plasticity is a fundamental process that endows the brain with the potential for memory and learning. Within certain boundaries, it appears that greater exposure to a particular stimulus prompts the brain to dedicate more neurons to that stimulus (and a lack of stimulation allows the brain to reassign neurons to a different function)—and so the old adage “use it or lose it” appears to hold true for the brain. However, with significant effort, it is possible to reclaim at least some of what was lost.

## NEURONAL COMMUNICATION

Neurons communicate primarily through the release of neurotransmitters into the synapses adjacent to target neurons. Postsynaptic neurons

**FIGURE 43-27** Schematic drawing of neural stem cell proliferation. Stem cells can differentiate into glial cells or neurons under the right conditions, but half fail to find a home and undergo apoptosis (programmed cell death).

have receptors for these neurotransmitters and respond by changing the flow of ions through channels in the cell membrane. Some neuronal communication occurs through gap junctions that connect the cytoplasm of one neuron to the next, forming electrical synapses (see Chapter 3).

Sufficient depolarization of the neuronal membrane results in the generation of action potentials, which transmit signals quickly from one end of the neuron to the other. Action potentials reaching the axon terminal open voltage-gated  $\text{Ca}^{2+}$  channels and stimulate the release of neurotransmitter into the synapse. Not all neurotransmitters are excitatory; some are inhibitory and suppress the formation of action potentials in the postsynaptic neuron. Most neurons have many contacts, some inhibitory and some excitatory, such that the response of the postsynaptic neuron is a summation of all the input.

## Membrane Potentials

A detailed discussion of membrane potentials can be found in Chapter 3, and the major points are reviewed here. All cells of the body contain slightly more negatively charged molecules than positively charged ones. These negative ions are trapped intracellularly because they cannot pass through the plasma membrane. Positive ions are attracted to the cell membrane by the negatively charged intracellular ions. Because the cell membrane is permeable at rest to  $\text{K}^+$  ions, but not to  $\text{Ca}^{2+}$  or  $\text{Na}^+$  ions, potassium accumulates in the cell to neutralize the intracellular anions. The unequal distribution of  $\text{K}^+$  across the cell membrane creates a concentration gradient, pulling  $\text{K}^+$  back out of the cell. At equilibrium, the electrical gradient pulling  $\text{K}^+$  into the cell and the chemical gradient pulling it out are balanced. This equilibrium point leaves a few extra negatively charged ions inside the cell with no positive ion to neutralize them. The negative ions line up on the inside of the cell membrane to interact with positive ions on the other side ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{2+}$ ). This separation of charge across the membrane at rest creates a membrane potential that can be measured and is about  $-65$  to  $-90$  mV.<sup>16</sup> The membrane potential changes when the concentration of  $\text{K}^+$  changes and when the permeability of the membrane to other ions changes.

Excitable cell types, like nerve and muscle, have ion channels in their cell membranes that open and close in response to fluctuations in membrane voltage. The most important voltage-gated ion channels in nerves are the fast  $\text{Na}^+$  channels and the  $\text{K}^+$  channels. Fast sodium channels allow  $\text{Na}^+$  influx during the upstroke of the action potential, whereas potassium channels allow  $\text{K}^+$  to leave the cell and help repolarize the membrane (see Chapter 3).

An action potential is initiated when neurotransmitters bind to receptors on the dendrite and cell body and allow cations, especially  $\text{Na}^+$ , to leak in. These channels are not voltage-gated channels; they are ligand-gated channels that open in response to a neurotransmitter binding to their receptor domain. If sufficient  $\text{Na}^+$  leaks into the cell to raise the membrane potential to threshold, the fast voltage-gated  $\text{Na}^+$  channels open and an action potential results. Opening of fast  $\text{Na}^+$  channels in one section of the membrane allows  $\text{Na}^+$  to flow in and bring the next section to threshold, thus opening the fast  $\text{Na}^+$  channels in that section. This pattern repeats over and over again down the length of the axon. Threshold represents the amount of membrane depolarization required to cause fast  $\text{Na}^+$  channels to flip into their open conformation (see Chapter 3). The axon hillock, the point at which the axon emerges from the cell body, is the usual site of action potential initiation because it has a high density of fast  $\text{Na}^+$  channels and, therefore, a lower threshold.

Voltage-gated  $\text{K}^+$  channels assist with repolarization because  $\text{K}^+$  is allowed to flow out of the cell. During an action potential, the electrical gradient holding  $\text{K}^+$  in the cell temporarily disappears as the membrane voltage moves toward zero. Potassium flows out of the cell passively down its concentration gradient. The  $\text{Na}^+$ - $\text{K}^+$  pumps work continuously

to remove  $\text{Na}^+$  from the cell interior and bring  $\text{K}^+$  back in. The majority of a nerve cell's energy expenditure is used to power the  $\text{Na}^+$ - $\text{K}^+$  pumps.

The speed at which an action potential travels is determined by axonal diameter and myelination. Larger and myelinated neurons conduct impulses more quickly (Figure 43-28). In myelinated neurons, action potentials are generated only at the nodes of Ranvier, allowing the impulse to hop quickly from node to node down the axon. This is called *saltatory conduction*.

## Synaptic Transmission

The great majority of synapses responsible for signal transmission in the CNS function by using neurotransmitters. A neurotransmitter is released from the synaptic terminal of one neuron, proceeds across the synaptic cleft, and acts on the receptor proteins in the membrane of the second neuron to excite, inhibit, or modify its activity. The response at the postsynaptic membrane depends on the type of ion channel that is opened or closed when the neurotransmitter binds to the receptor. Once neurotransmitters are released into the synaptic cleft, their potential to activate the postsynaptic receptors is limited by deactivation processes. Neurotransmitters are either actively transported back into the axon terminals for reuse or destroyed by enzyme activity.

An *excitatory postsynaptic potential* (EPSP) results when a neurotransmitter has a depolarizing effect on the postsynaptic membrane. The EPSP may be too small to bring the axon hillock to threshold, and EPSPs from several presynaptic neurons may be required to generate an action potential. Thus postsynaptic potentials are not all-or-none phenomena, as are action potentials. Neurotransmitters that produce EPSPs do so by opening channels in the membrane that allow  $\text{Na}^+$  influx. In some cases, the receptor itself is a channel (*ionotropic receptor*); in others, the receptor is linked to the channel through a second messenger cascade (*metabotropic receptor*) (Figure 43-29). The ion channels regulated by metabotropic receptors may participate in action potential generation, but receptor activation also exerts more long-lasting effects on cell structure and behavior.

Some neurotransmitters inhibit depolarization and may produce hyperpolarization of the postsynaptic membrane by opening  $\text{Cl}^-$  or  $\text{K}^+$  channels. Chloride ions leaking into the cell or potassium ions leaking out of the cell serve to short-circuit the effect of sodium ion influx, thus making it more difficult to reach threshold. This effect is called an *inhibitory postsynaptic potential* (IPSP). Neurotransmitters that result in IPSPs include  $\gamma$ -aminobutyric acid (GABA) and glycine.

Most synapses in the CNS have many presynaptic neurons, some producing EPSPs and some producing IPSPs. The membrane potential of the postsynaptic membrane is an algebraic sum of all the IPSPs and EPSPs occurring at any one moment in time. This is called *summation* and is the basis of neuronal processing and integration (Figure 43-30). The term *spatial summation* is applied when multiple presynaptic neurons release their neurotransmitters onto one postsynaptic neuron at the same time. The IPSPs and EPSPs sum algebraically to produce the overall postsynaptic potential. *Temporal summation* occurs when one presynaptic neuron fires in rapid succession so that it releases more neurotransmitter onto the postsynaptic cell before the postsynaptic neuron has completely recovered from a previous dose.

## Neurotransmitters

Neurotransmitters are grouped according to their chemical structure into six principal categories<sup>16</sup> (Box 43-1). *Acetylcholine* (ACh) is the sole neurotransmitter in its class and is prevalent in numerous areas in the CNS. It is the neurotransmitter in autonomic ganglia, postganglionic parasympathetic synapses, and neuromuscular junctions. There are two major types of acetylcholine receptors: the nicotinic receptors (N) are of the ionotropic variety and the muscarinic receptors (M)

are metabotropic (Table 43-7). When acetylcholine is released into the synapse, it is quickly degraded by acetylcholinesterase to limit the duration of action (Figure 43-31). Choline is actively taken back up into the presynaptic membrane for resynthesis. Acetylcholine receptors located on the presynaptic membrane provide a negative feedback

loop, whereby the presynaptic neuron monitors the amount of acetylcholine in the synapse. Acetylcholinesterase inhibitor drugs are used for treating diseases such as Alzheimer disease and myasthenia gravis in which there is a deficiency of acetylcholine in the synapse and for reversing the effect of neuromuscular blocking drugs.

**FIGURE 43-28** Rate of action potential conduction down an axon depends on the relative degree of internal resistance to current flow. When the diameter is small (**A**), there is higher internal resistance and slower conduction than in large-diameter neurons. A larger diameter (**B**) reduces internal resistance and accelerates the rate of conduction. Myelination (**C**) produces the fastest rate of conduction by increasing membrane resistance and decreasing internal resistance.

**FIGURE 43-29** Neurotransmitter (NT) receptor classes. **A**, Ionotropic receptors are channel proteins that open when a neurotransmitter binds to them. **B**, Metabotropic receptors activate intracellular signaling cascades that generate second messengers in the cell when the neurotransmitter binds.

**FIGURE 43-30** Summation. **A**, Spatial summation occurs when two or more presynaptic neurons release neurotransmitter onto one postsynaptic cell at the same time. The various excitatory postsynaptic potentials and inhibitory postsynaptic potentials add algebraically to determine the overall postsynaptic potential (PSP) reaching the axon hillock. **B**, Temporal summation occurs when one presynaptic neuron fires in rapid succession such that a previous PSP has not fully dissipated before the next PSP is added to it.

**BOX 43-1 SIX MAJOR CLASSES OF NEUROTRANSMITTERS**

<b>Acetylcholine</b>	Enkephalins
<b>Amines</b>	$\beta$ -Endorphin, other derivatives of pro-opiomelanocortin
Dopamine	Cholecystokinin
Norepinephrine	Vasoactive intestinal polypeptide
Epinephrine	Neurotensin
Serotonin	Gastrin-releasing peptide
Histamine	Gastrin
<b>Amino Acids</b>	Glucagon
<b>Excitatory</b>	Motilin
Glutamate	Secretin
Aspartate	Calcitonin gene-related peptide $\alpha$
<b>Inhibitory</b>	Neuropeptide Y
Glycine	Activins
$\gamma$ -Aminobutyric acid (GABA)	Inhibins
	Angiotensin II
	Galanin
<b>Polypeptides</b>	Atrial natriuretic peptide
Substance P, other tachykinins	Brain natriuretic peptide
Vasopressin	
Oxytocin	<b>Purines</b>
Corticotropin-releasing hormone	Adenosine
Thyrotropin-releasing hormone	Adenosine triphosphate
Growth hormone-releasing hormone	
Somatostatin	<b>Gases</b>
Gonadotropin-releasing hormone	Nitric oxide
Endothelins	Carbon monoxide

**FIGURE 43-31** Acetylcholine synapse. Acetylcholine (ACh) released into the synapse binds to nicotinic (N) or muscarinic (M) receptors on the postsynaptic membrane. ACh also can bind to presynaptic receptors that are linked to a decrease in ACh release (negative feedback). Acetylcholinesterase (AChE) quickly degrades the ACh into acetate and choline. Choline is actively taken back into the presynaptic neuron for resynthesis.

The *amines* include dopamine (DA), norepinephrine (NE), epinephrine, serotonin (5-hydroxytryptamine, 5HT), and histamine. Amines are particularly involved in the limbic system, hypothalamus, and basal ganglia. NE is the neurotransmitter released at SNS postganglionic nerve endings. DA, NE, and serotonin are important in regulating thought processes and mood. Antipsychotic and mood-altering drugs change the activity of one or more of these amines in the brain (see Chapters 48 and 49). DA-secreting neurons project to the striatum (basal ganglia), pituitary gland, limbic system, and frontal cortex (Figure 43-32, A). DA can be degraded by enzymes in the extracellular fluid (catechol-O-methyltransferase, COMT) or by enzymes in the presynaptic nerve (monoamine oxidase, MAO). The primary means of clearing DA from the synapse is by active reuptake into the presynaptic membrane (see Figure 43-32, B). There are at least five DA receptor subtypes; all of these subtypes are metabotropic and linked to the production of second messengers (see Table 43-7). Abnormality of DA metabolism is apparent in various diseases, including Parkinson disease and schizophrenia.

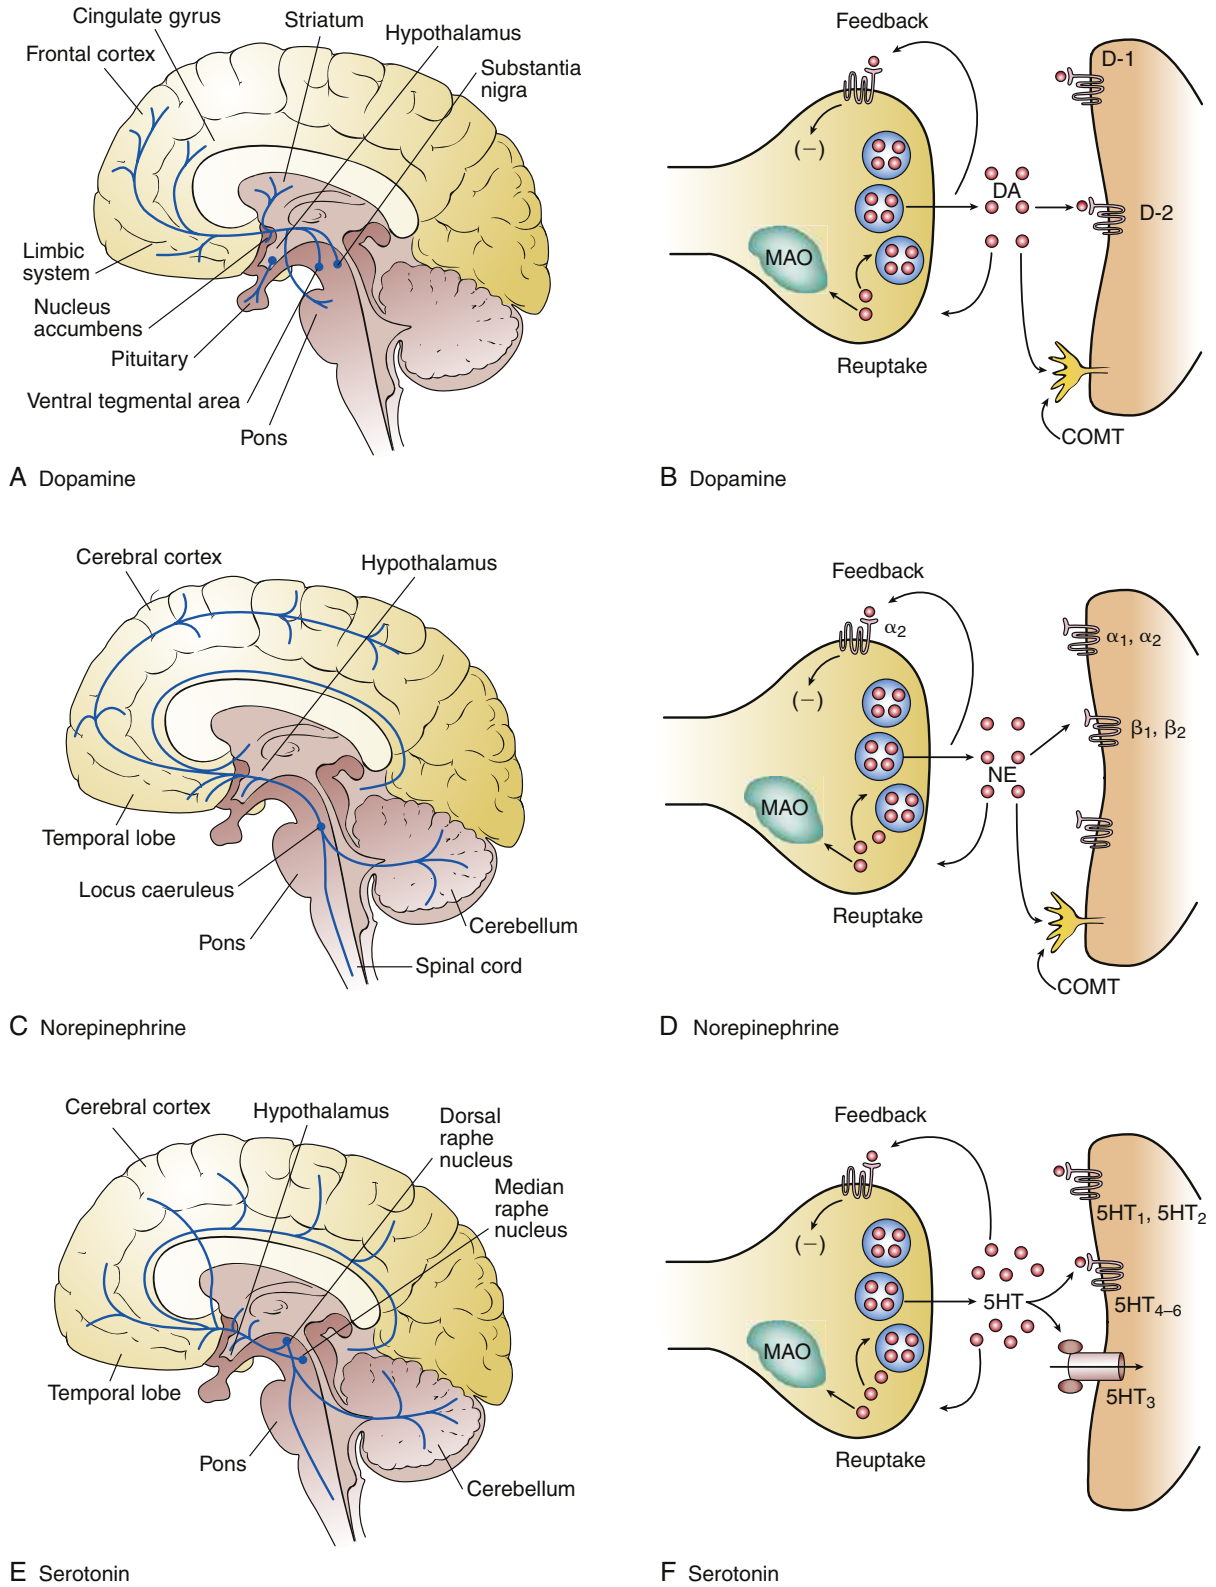

Some neurons have an enzyme for the hydroxylation of DA to form NE. The NE-secreting neurons originate in the brainstem (locus caeruleus) and project widely throughout the brain including the cerebral cortex, cerebellum, limbic structures, brainstem, and spinal cord (see Figure 43-32, C). Most of the NE released into the synapse is cleared by active reuptake into the presynaptic neuron, where it can be repackaged for release or broken down by MAO. A number of receptor subtypes can bind NE in the synapse, and all are of the metabotropic variety and linked to second messenger cascades (see Table 43-7). The receptor subtype  $\alpha_2$  is commonly located on the presynaptic membrane where it provides a negative feedback loop for the presynaptic cell to monitor the amount of NE in the synapse (see Figure 43-32, D). Stimulation of the presynaptic  $\alpha_2$  receptor by NE or by  $\alpha_2$ -agonist drugs reduces the amount of NE released into the synapse by the neuron.

Serotonin is another amine that affects numerous areas of the brain in a pattern similar to that of NE (see Figure 43-32, E). Numerous serotonin receptor subtypes have been identified, including one ionotropic

(5HT<sub>3</sub>) and several metabotropic subtypes (see Table 43-7). Like NE and DA, serotonin is cleared from the synapse by an active reuptake carrier on the presynaptic membrane (see Figure 43-32, F). It is also subject to degradation by MAO in the presynaptic cell. Like other neurotransmitters (NTs), serotonin can bind to presynaptic receptors that regulate its release. Numerous drugs have been developed to manage disorders associated with serotonin pathways, including depression, anxiety, and migraine headache. The class of medications known as selective serotonin reuptake inhibitors blocks the reuptake carrier for serotonin. The tricyclic antidepressants also block reuptake of serotonin, but they are less specific than the selective serotonin reuptake inhibitors and also affect reuptake of other amines.

The category of *amino acids* can be subdivided into excitatory and inhibitory mechanisms of action. Glutamate and aspartate are the principal excitatory amino acids. Glutamate neurons are widely distributed throughout the brain, and it is considered to be the primary excitatory neurotransmitter. Glutamate is involved in memory and has been implicated as a neurotoxin when released in excessive amounts (Chapter 44). Glutamate is removed from the synapse by active reuptake transporters on the presynaptic membrane. When energy stores are low because of interrupted blood supply or hypoxia, the transporters do not function effectively and glutamate remains in the synapse where it can behave as a neurotoxin. Most glutamate receptors are ionotropic; the metabotropic types are poorly understood. The  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) receptors are classic ligand-gated sodium channels that depolarize the postsynaptic membrane. The N-methyl-D-aspartate (NMDA) receptors are interesting because they will not open unless the binding of glutamate is paired with a cotransmitter (such as glycine or D-serine) and concurrent depolarization of the membrane (Figure 43-33).<sup>3</sup> The NMDA receptor is a ligand-gated calcium ion channel, but it is blocked by a magnesium ion when the postsynaptic membrane is polarized. It only opens in response to glutamate binding if a depolarization is produced at the same time by another neurotransmitter-receptor

**CHAPTER 43** Structure and Function of the Nervous System

COMT, Catechol-O-methyltransferase; MAO, monoamine oxidase.

**FIGURE 43-33** Glutamate synapse. Glutamate signaling is complex, having several receptor subtypes and costimulating molecules. The *N*-methyl-D-aspartate (*NMDA*) receptor is of special interest because it requires binding of glutamate and a cotransmitter (glycine or D-serine). In addition, the *NMDA* ion channel is blocked by  $Mg^{2+}$  and cannot open unless the postsynaptic membrane is already depolarized. Glutamate binding to its  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (*AMPA*) receptors can provide this depolarization by allowing sodium influx. When the *NMDA* channel opens, it allows calcium ions to flow in, triggering intracellular signaling cascades that produce nitric oxide (*NO*). Nitric oxide is a gas that can diffuse throughout the synapse. *NMDA* receptor activation has been linked to long-term changes in synaptic efficiency. *NOS*, Nitric oxide synthase.

interaction. The depolarization releases the blocking magnesium ion from the channel, so that when glutamate binds, the channel opens to allow calcium influx. It is also unusual to use calcium ions to produce membrane depolarization because they can trigger signaling cascades within the cell. The *NMDA* receptor is thought to be responsible for long-term changes in the synapse that may relate to long-term memory. Drugs that interfere with *NMDA* receptors block memory; those that activate these receptors produce hallucinations and nightmares.

Glycine and GABA are inhibitory amino acids and are located throughout the spinal cord and brain. A large number of synapses (30%) are inhibitory in nature, and GABA is the principal neurotransmitter in these synapses. GABA is formed by decarboxylation (removal of  $CO_2$ ) of glutamate, which transforms it from an excitatory amino acid to an inhibitory one. The GABA receptors are of two types: the  $GABA_A$  is a classic ligand-gated chloride channel that produces an IPSP when activated. The  $GABA_B$  receptor is a metabotropic receptor that also produces an IPSP and is linked to a reduction of cAMP concentration in the cell. Barbiturates and benzodiazepines are thought to exert their depressive effects by increasing GABA activity.

A long list of neurotransmitters is found in the *neuropeptide* category (see Table 43-7). Neuropeptides may function as the primary neurotransmitter in the synapse, but more often they are released together with another neurotransmitter. Amines and neuropeptides

are commonly released together into synapses.<sup>16</sup> The neuropeptides have long-lasting effects on the postsynaptic cell, mediating changes in receptor number or structure and altering the responses of intracellular signaling pathways. Well-known neuropeptides include substance P, endorphins, and enkephalins, which are involved in the transmission and perception of pain. Neuropeptides are synthesized in the neuronal cell body and not in the nerve terminal like other neurotransmitters. The amount produced depends on the degree of gene activity that produces messenger RNA to direct the synthesis of the neuropeptide. Once synthesized and packaged into vesicles, the neuropeptides must be actively transported along the axon to the nerve terminal. All neuropeptide receptors are linked to second messenger cascades. Neuropeptides are released in very small quantities in comparison to other neurotransmitters, and reuptake mechanisms are not required to turn off their activity. The neuropeptide with its bound receptor may be internalized into the postsynaptic cell, where the receptor is degraded or recycled to the synaptic membrane.

Purines, including adenosine triphosphate (ATP) and adenosine, function as neurotransmitters in various brain regions. Adenosine is thought to be continuously released by most neurons and modulates neurotransmission by blocking neurotransmitter release. Adenosine may be important in preventing seizure activity. The role of ATP as a neurotransmitter continues to be elucidated. There are at least three

**FIGURE 43-34** Convergence of several presynaptic neurons on one postsynaptic neuron is compared with divergence of one presynaptic neuron to several postsynaptic neurons.

ATP receptor subtypes, two that decrease cAMP production and one that increases cAMP production.

Nitric oxide (NO) is a gas that can diffuse through cell membranes and therefore does not require a synaptic receptor for its activity. NO has several different potential targets within cells. For example, NO can bind and stimulate guanylyl cyclase, an enzyme that produces cyclic guanosine monophosphate (cGMP), a second messenger in the cell, or it can alter the activity of ion pumps, metabolic enzymes, and DNA transcription factors.<sup>16</sup> Unlike other neurotransmitters that are produced and released by presynaptic neurons, NO can be synthesized in the postsynaptic neuron and diffuse locally to affect presynaptic neurons and nearby glial cells. The functions of NO are not completely known, but it is thought to be important in memory and pain perception. One trigger known to stimulate NO is activation of the previously described NMDA receptor. The calcium ions that flow in through the open NMDA receptor cause activation of an enzyme called nitric oxide synthase (NOS), which produces NO. NO may be the messenger that alerts the presynaptic membrane that the paired stimuli required to open the NMDA receptor were received.<sup>17</sup>

### Neuronal Circuits

Patterns of neuronal synaptic connections are called *neuronal circuits*. Activity in particular groups of neurons in one or more circuits is the basis of nervous system function: thoughts, memories, sensations, movements, and learning.

*Divergence* is a term used to describe neuronal circuits in which one presynaptic neuron makes contact with more than one postsynaptic neuron (Figure 43-34). Divergence is a strategy used to send sensory input to a large number of receiving neurons. *Convergence* occurs when many presynaptic neurons synapse with one postsynaptic neuron (see Figure 43-34). This arrangement is typical in the motor pathways, in which sensory, reflex, and voluntary inputs must be integrated into a response by the motor neurons that innervate skeletal muscle. Convergence is a mechanism of processing and integration of input.

The efficiency of circuits can be altered by changes in synaptic function. Synaptic transmission can be facilitated or inhibited in various ways. Alteration in the ease of synaptic transmission is the basis of

memory and is discussed in more detail in the Consciousness, Memory, and Sleep section at the end of this chapter.

## NEURAL DEVELOPMENT, AGING, AND INJURY

### Development

The nervous system starts to take shape during the third week of embryonic development. At this time, three primary tissues of the embryo are distinguishable: the ectoderm, endoderm, and mesoderm. A thickened plate of ectoderm, running longitudinally on the dorsal surface of the embryo (neural plate), gives rise to the CNS and PNS. By the end of the third week, the neural plate folds to form a neural tube. Openings at either end of the neural tube are called *neuropores*. The neural tube is the precursor of the future brain and spinal cord.

Fusion of cells and formation of the neural tube start in the cervical region of the future spinal cord and then progress rapidly in a **rostral** direction toward the future brain. Failure of the neural tube to close properly is a cause of congenital malformation of the nervous system. Anencephaly (absent brain) results from failure of the rostral portion to close, whereas failure of closure of the caudal portion results in myelomeningocele. In this defect, the spinal cord and meninges are displaced into a sac on the back (see Chapter 45). A reduction in neural tube defects has been achieved through prenatal maternal supplementation with folic acid.<sup>18</sup>

Neurons grow and divide at an incredible rate during embryological development and make primitive synaptic connections according to a basic architecture that is genetically programmed. The number of neurons and synapses ultimately dedicated to particular functions is determined in large part by their use. For example, if no visual sensory input is relayed to the primary visual cortex (as occurs with congenital cataracts), the cortical neurons will be reassigned to other functions. Similarly, a person born without arms will lack representation of these structures in the primary somatosensory cortex. In contrast, greater stimulation appears to increase the number of neurons dedicated to a particular function. Critical periods in the early neonatal period have been identified when neuronal assignment to specific functions is determined.<sup>19,20</sup> In recent years it has been recognized that a significant

degree of neural plasticity exists throughout life; however, it is much less than that during early childhood. The brain continues to increase in size until puberty and remains stable until middle age.

### Aging

A gradual loss of neurons in later adulthood does not result in significant alteration in brain function during the usual life span. However, the older one becomes, the greater the neurologic impairment. Excessive neuronal degeneration in adulthood is called Alzheimer disease or senile dementia, and is distinguished from the normal changes of aging. The effects of aging on nervous system function are summarized in Geriatric Considerations: Changes in the Nervous System.

### Injury

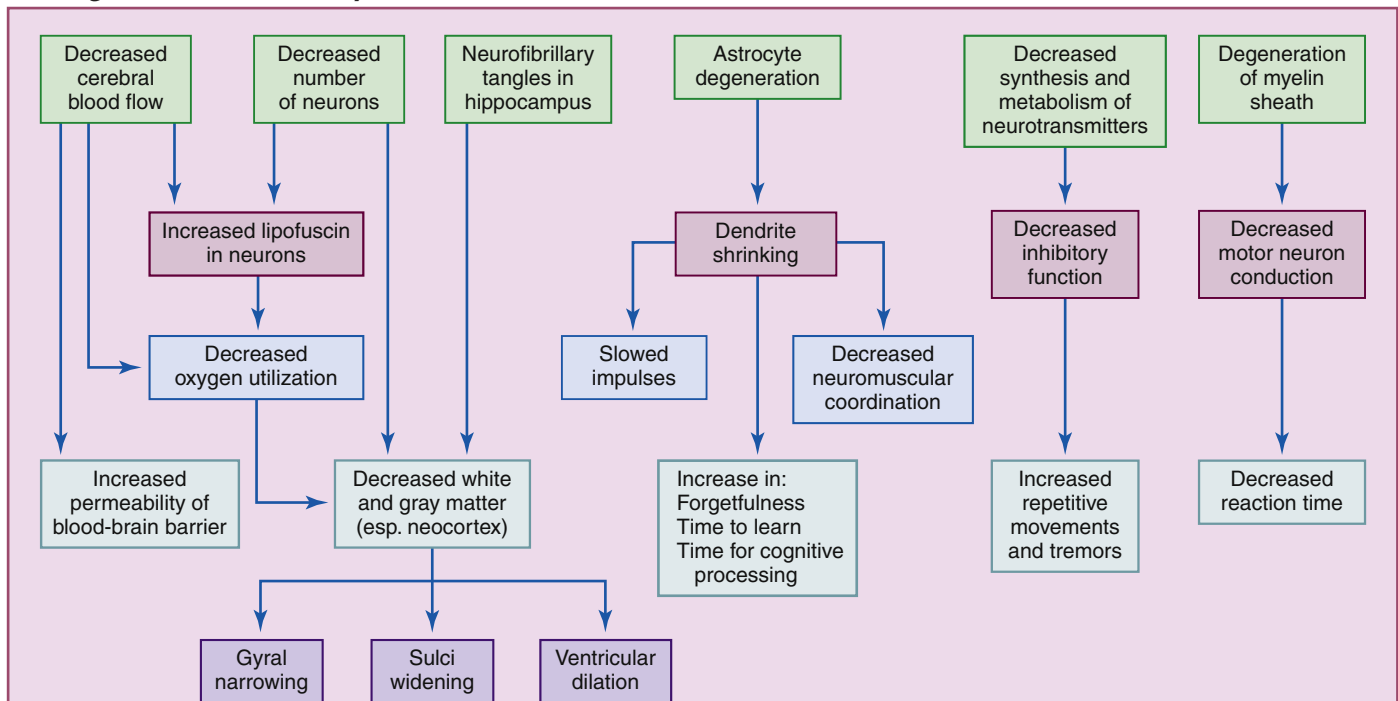

Injury to neurons usually results in neuronal cell death and loss of function; however, some regrowth is possible in peripheral nerves if the

injury is not severe. Stem cells in the brain are capable of producing new, immature neurons; however, the likelihood that they will find and repair a site of injury and make appropriate synaptic connections is uncertain.

Injury to axons of neurons in the PNS results in degeneration of the distal segment (**wallerian degeneration**).<sup>18</sup> Within a few days to a week, the axons break into irregular fragments, and after 3 weeks they disappear completely. In the axonal segment proximal to the injury, a small section also degenerates. If the nerve is myelinated, degeneration usually extends back to the next one or two nodes of Ranvier. As axons and myelin sheaths degrade, Schwann cells of the injured nerve swell and divide. Over the next 2 to 3 weeks, continuous columns of short Schwann cells mark the course of the lost axons. If there is little separation between the ends of a divided nerve, the proliferating Schwann cells bridge the gap. If the divided ends are further apart, the proliferating Schwann cells form bulbous swellings at the end of the nerves and the surviving axons form fine fibrils, which extend into the surrounding

## GERIATRIC CONSIDERATIONS

### Changes in the Nervous System

With aging, brain atrophy and a decrease in brain weight occur. This is evidenced by a decrease in the amount of white matter and gray matter up to 0.5% per year, with gyral narrowing, sulci widening, and ventricular dilation. There is a gradual atrophy and loss of neurons in the brain and spinal cord over time; but neuron loss is not uniform within the brain. Most of the neuron loss is in the neocortex (20%), Purkinje cells of the cerebellum, substantia nigra, and locus caeruleus. Some parts of the brain, such as the vestibular nucleus, have no neuron loss. Blood supply to the brain is decreased because of the decreased metabolic demands and brain atrophy. There is also increased permeability of the blood-brain barrier.

Intracellularly there is an increase in the amount of lipofuscin, which hampers cellular oxygen use, crowds intracellular organelles, and reduces the number of mitochondria. There are also neurofibrillary tangles in the hippocampus and neuritic plaques that are found only in the elderly.

Nerve fibers in the brain decrease in number and show signs of splitting or fragmentation. The cortex, subcortex, and cerebellar astrocytes degenerate. Nerve axons develop swellings near their ends called neuroaxonal dystrophy.

The relevance of these swellings is unknown. Dendrites shrink, decreasing the number of messages received from other cells and synaptic linkages. This causes slowing of impulses and decreases neuromuscular coordination. These changes result in decreased short-term memory, reduced speed of learning, prolonged new information processing, increased reaction time, diminished abstract reasoning, and impaired perception.

Changes in the secretion and metabolism of neurotransmitters also impact the aging brain. There is a decrease in norepinephrine and dopamine secretion with an increase in monoamine oxidase secretion. The reduction of dopamine levels leads to decreased inhibitory motor functions.

In the spinal cord, posterior root fibers and sympathetic nerve fibers of the autonomic nervous system decline in number. Peripherally, there is degeneration of the motor nerve fibers and myelin sheath. Motor neuron axons remain intact. Decreasing motor neuron conduction velocity and prolonged muscle action potentials lead to decreased reaction times. Reflexes may be decreased or absent. There is an increased risk of falls.

Schwann cells at random. Those fibrils that find a column of Schwann cells in the distal part of the nerve grow down the column. There is often good functional return to the nerve secondary to this process. If continuity is not restored, the distal end gradually becomes replaced by collagenous scar tissue.

Damaged axons in the CNS show a pattern of degeneration that is similar to that of peripheral neurons. Damaged axons become irregular and beaded, break up, and disappear, but the process is significantly slower. Methods using stains for  $\beta$ -amyloid precursor protein to identify axonal injury in the CNS have revealed that axonal injury is a common event even in mild concussion.<sup>21</sup> Axonal damage impairs axonal streaming and causes a buildup of  $\beta$ -amyloid precursor protein proximal to the injury. This buildup is taken as evidence of axonal injury. Contrary to previously held notions, a significant degree of axonal repair appears to occur in CNS neurons when the injury is not too severe.<sup>21</sup> If neurons that were the principal source of stimulation to some other group of neurons are damaged and die, that other group of neurons may also degenerate because of the loss of trophic (growth and survival) signals. Researchers continue to discover new nerve growth and survival factors. Eventually they may find ways to minimize neuronal degeneration after injury and encourage repair or replacement.

#### KEY POINTS

- The fundamental unit of the nervous system is the neuron. Neurons have three basic parts: the cell body, dendrites, and axons. The dendrites receive signals and transmit them to the cell body. The axon generates and conducts action potentials. Conduction of action potentials is faster in large and myelinated axons.
- Neuronal communication through chemical synapses can be summarized as follows: Stimulation from other neurons occurs primarily at the dendrite and cell body. Action potentials are initiated at the axon hillock and conducted down the axon to the axon terminal, where neurotransmitter is stored. Depolarization of the terminal opens voltage-gated calcium channels. Calcium influx mediates exocytosis of neurotransmitter into the inter-neuronal synapse. Neurotransmitter binds and activates specific receptors on the postsynaptic cell, changing its ion conductance. With sufficient depolarization of the postsynaptic cell, an action potential is generated.
- There are six categories of neurotransmitters based on their chemical structure: acetylcholine, amines, amino acids, neuropeptides, purines, and gases.
- Excitatory neurotransmitters create excitatory postsynaptic potentials (EPSPs) in the postsynaptic neuron attributable to opening of channels that allow  $\text{Na}^+$  or  $\text{Ca}^{2+}$  influx. Inhibitory neurotransmitters create inhibitory postsynaptic potentials (IPSPs) in the postsynaptic neuron attributable to opening of channels that allow  $\text{Cl}^-$  influx or  $\text{K}^+$  efflux. The summation of EPSPs and IPSPs at the axon hillock determines whether an action potential will be initiated.
- Neuroglial cells are supportive cells in the CNS. Oligodendroglial cells form insulating myelin sheaths, astroglial cells moderate extracellular fluid composition and synaptic conditions, microglial cells are derived from circulating monocytes and destroy foreign materials, and ependymal cells form CSF.
- Development of the nervous system follows a basic architecture that is genetically programmed. However, the brain is quite plastic, especially during infancy, and alters the assignment of neurons to certain functions based on the degree of stimulation.
- Neurons in the CNS that are severely injured generally do not regenerate. Peripheral neurons may regenerate if the Schwann cells provide a pathway for growth. Neural stem cells in the ventricles and hippocampus of the brain can proliferate to produce either glial or neuronal cells depending on specific cues, most of which have yet to be elucidated.

## SENSORY FUNCTION

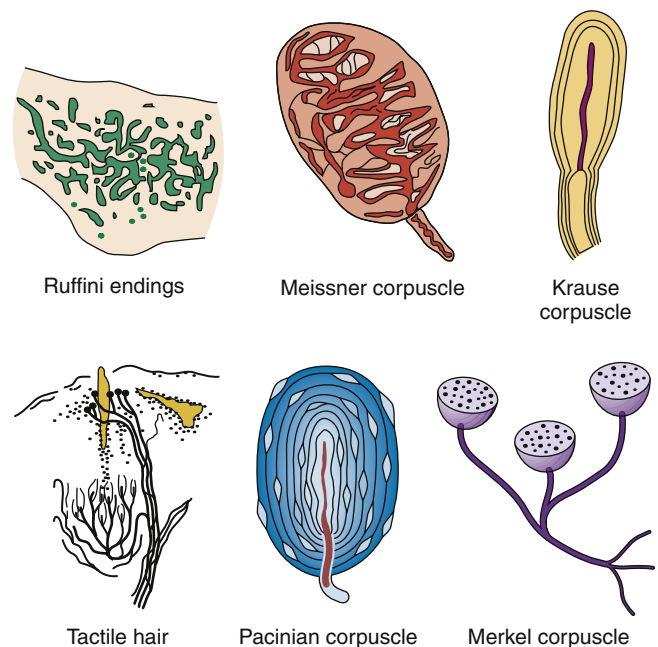

The discussion of sensory function in this chapter is restricted to the somatosensory system. The special senses of hearing, vision, taste, and olfaction are discussed in Chapter 46. Neural pathways related to pain transmission are discussed in detail in Chapter 47.

Transmission of sensory signals begins with activation of specialized dendritic processes, called *sensory receptors*, at the ends of sensory afferents that project to the spinal cord (or brainstem in the case of some cranial nerves). Secondary neurons in the cord are activated and carry the signals up the cord to the brain. The thalamus is the principal receiving site for somatosensory signals, which are then relayed to various brain areas, including the somatosensory cortex in the parietal lobe.

An important principle of sensory transmission is that somatotopic organization is maintained from receptor to somatosensory cortex. This property allows for precise localization of the origin of sensory signals. The somatosensory system conveys a number of different sensory modalities, including fine touch, vibration sense, pressure, temperature, itch, crude touch, and pain. In general, different modalities are sensed by different types of sensory receptors.

## SENSORY RECEPTORS

Sensory receptors are specialized terminations of the dendrites of primary sensory neurons. The receptor may be a free nerve ending or may have various connective tissue elaborations that affect its responsiveness (Figure 43-35). All types of receptors respond to stimuli by altering their membrane permeability to ions, thus creating a change in the membrane voltage. These receptor potentials are similar to the EPSPs generated in postsynaptic neurons, except that the stimulus is not a neurotransmitter. Different receptor types respond to different kinds of stimuli: mechanical stretch, changes in temperature, or the binding of chemicals. When a stimulus depolarizes the receptor sufficiently, voltage-gated fast  $\text{Na}^+$  channels in the membrane open and an action potential is generated. The rate of action potential generation by the receptor depends on the intensity of the stimulus (Figure 43-36).

**FIGURE 43-35** Common types of somatosensory receptors. Sensory receptors are specialized to respond to particular types of stimuli.

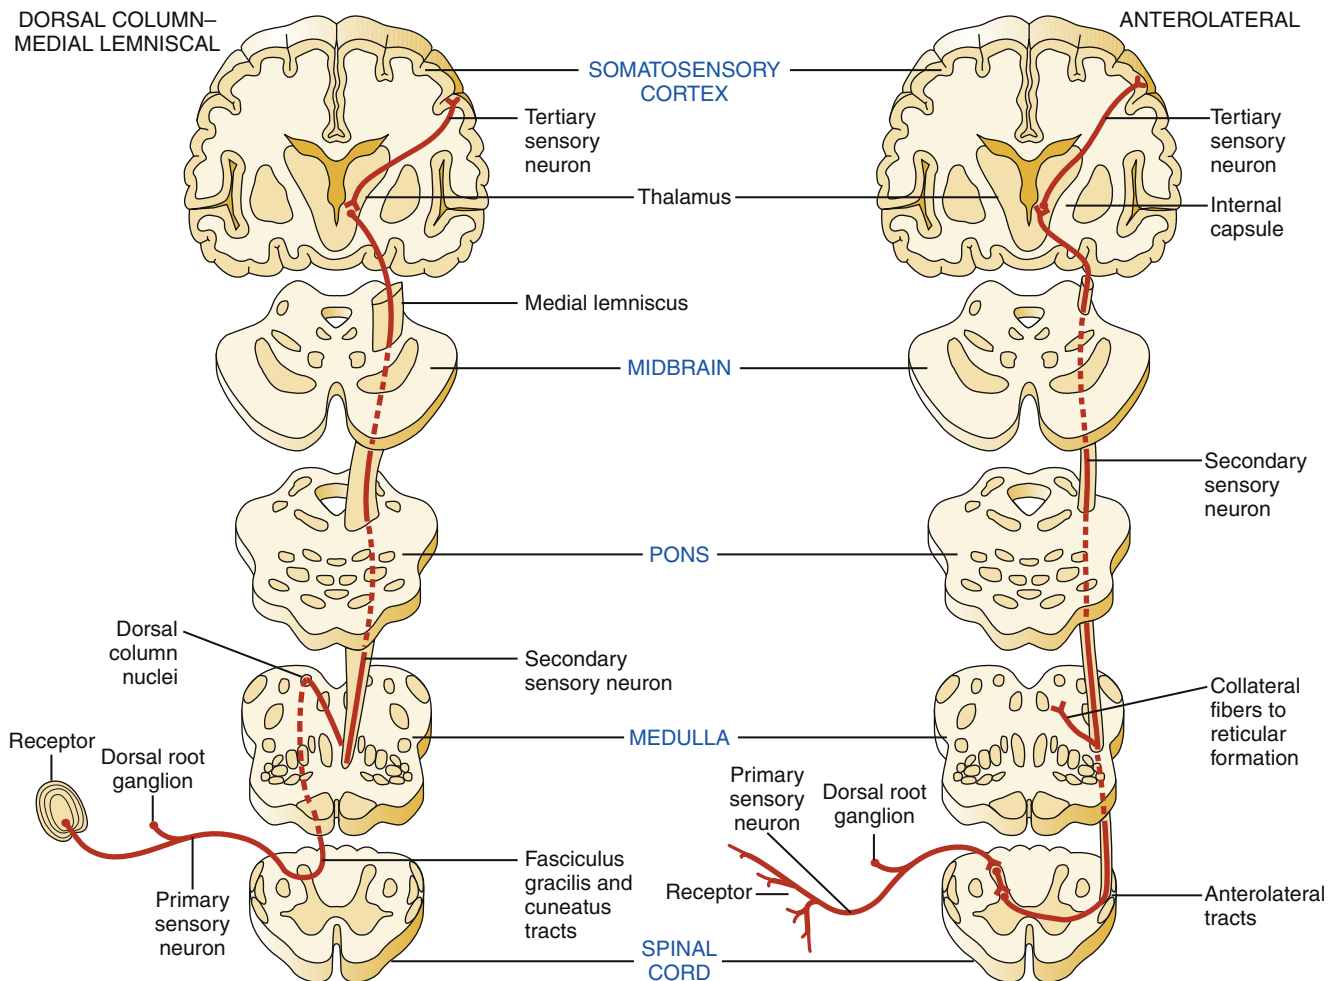

**FIGURE 43-36** Relationship between stimulus intensity and action potential generation. As the stimulus increases, the receptor potential is greater, and action potentials are generated at a faster rate. (From Hall JE, editor: *Guyton & Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 561.)

Some receptors are rapidly adapting and generate action potentials only when a change in the stimulus intensity occurs. The pacinian corpuscle is a classic example of a rapidly adapting receptor that is well suited to transmitting the sense of vibration. Tonic receptors adapt slowly and are good for conveying information about stimulus intensity over time. Free nerve endings, such as pain receptors, are usually tonic receptors.

Impulses generated by receptors are transmitted to the dorsal root of the spinal nerve. Depending on the sensory modality, the nerve impulses may travel up the **ipsilateral** side of the cord or may cross the spinal cord to travel up the **contralateral** side. In general, the well-localized sensations of touch, pressure, and vibration travel up the ipsilateral side of the cord, whereas the sensations of pain, itch, and temperature usually cross over and travel to the brain on the contralateral side. Regardless of pathway taken, somatosensory signals eventually converge on the somatosensory cortex in the hemisphere opposite from the location of the primary receptor.

## SENSORY PATHWAYS

Two major tracts, the dorsal column–medial lemniscal tracts and the anterolateral tracts, carry information from the spinal segments to the brain<sup>22</sup> (Figure 43-37). The dorsal column–medial lemniscal tract

**FIGURE 43-37** Comparison of the two major ascending somatosensory tracts. *Left*, Dorsal column–medial lemniscal tract. *Right*, Anterolateral tract. Note that the dorsal column tracts do not cross the midline until the level of the medulla, whereas the anterolateral tracts cross at the spinal cord level.

carries fine touch, vibration sense, and proprioception and remains ipsilateral until the level of the medulla. As the fibers progress upward, they gradually move toward the midline, so that those corresponding to the lower extremities occupy the medial white column and those representing the arm are more lateral. From the nuclei in the medulla, neurons of the dorsal column pathway cross to the opposite side and travel up the brainstem, where they form the medial lemniscus, and then on to the thalamus. In the thalamus, fibers synapse with tertiary neurons, which in turn pass upward in a great band of fibers known as the *internal capsule*, and then travel on to the primary sensory cortex.

The anterolateral tract (previously called the *spinothalamic tract*) carries impulses for sensations of pain, itch, and temperature from small myelinated (A $\delta$ ) and unmyelinated (C-fiber) neurons. These neurons ascend one or more spinal segments before entering the posterior horn and synapsing with their secondary neuron. A few secondary fibers ascend ipsilaterally in the Lissauer fasciculus all the way to the thalamus. However, the majority of fibers cross the midline and ascend as the anterolateral tract. Fibers from the lower extremities and trunk are pushed laterally as they ascend in the spinal cord by the addition of fibers from the upper extremities and upper body, which enter medially.

On their way to the thalamus, these fibers give off collaterals to the reticular formation of the brainstem and the periaqueductal gray matter in the midbrain, where it is believed that one of their functions is pain inhibition (see Chapter 47). Secondary fibers of the anterolateral tract terminate in several thalamic regions. Tertiary neurons project from the thalamus to the somatosensory cortex. Thus, although the sensations of fine touch and pain are separated in the cord, they reunite in the somatosensory cortex that lies in the cerebral hemisphere opposite the site of sensory receptor origin.

## SOMATOSENSORY CORTEX

The primary somatosensory cortex is organized in columns of gray matter that correspond to specific body locations. All modalities of sensation are grouped together in adjacent sections. The somatotopic representation of the body along a strip of cortex creates a distorted picture of the human body, called a homunculus map<sup>22</sup> (Figure 43-38). Body areas with a greater density of receptors garner a larger part of the homunculus map. The homunculus map was created by stimulating discrete areas of the cortex in awake subjects and recording the sensations that they reported. It is now known that several different cortical areas contain somatotopically organized maps in addition to the well-known one in the primary somatosensory cortex. The *perception* of sensation from the body occurs at the level of the cortex.

### KEY POINTS

- The body is somatotopically represented in the spinal cord and cerebral cortex. Stimulation of points in the primary somatosensory cortex results in discrete sensations in the contralateral side of the body.
- Projections to the somatosensory cortex begin in sensory receptors throughout the body. Receptors send axons to the spinal cord through the dorsal root. Stimulation of receptors by mechanical deformation, temperature, or chemicals alters membrane permeability, resulting in receptor potentials. The intensity of the stimulus is reflected in the rate of action potentials generated.
- Sensations of touch and proprioception (dorsal column–medial lemniscal tract) project up to the medulla on the ipsilateral side, then cross over and project to the thalamus.

**FIGURE 43-38** Topographic organization of the body on the somatosensory cortex, forming a homunculus map.

- Sensations of pain, temperature, and itch (anterolateral tract) usually cross the cord near the level of entry and travel to the brain on the contralateral side.
- Sensory information from both tracts is transmitted from the thalamus to the same areas of the somatosensory cortex by way of the internal capsule.

## MOTOR FUNCTION

The execution of voluntary movement requires interaction among basal ganglia, the cerebellum, and several regions of the cortex. The final program of voluntary muscle activity is transmitted from the brain down the spinal cord by way of the lateral corticospinal tracts. As previously noted, the corticospinal tract decussates in the medullary pyramids and travels down the spinal cord to control muscles on the contralateral side of the body (Figure 43-39). The corticospinal tract primarily controls distal muscles of the arms, wrists, fingers, lower legs, feet, and toes. These are the muscles capable of fine-motor control. Another group of motor tracts innervate large proximal muscle groups and axial muscles that control posture and balance. These tracts include the vestibulospinal, reticulospinal, and tectospinal tracts. Motor tracts descending from the brain synapse on the cell bodies of motor neurons that lie in the anterior horn of the spinal cord and project to skeletal muscles.

## MOTOR NEURONS

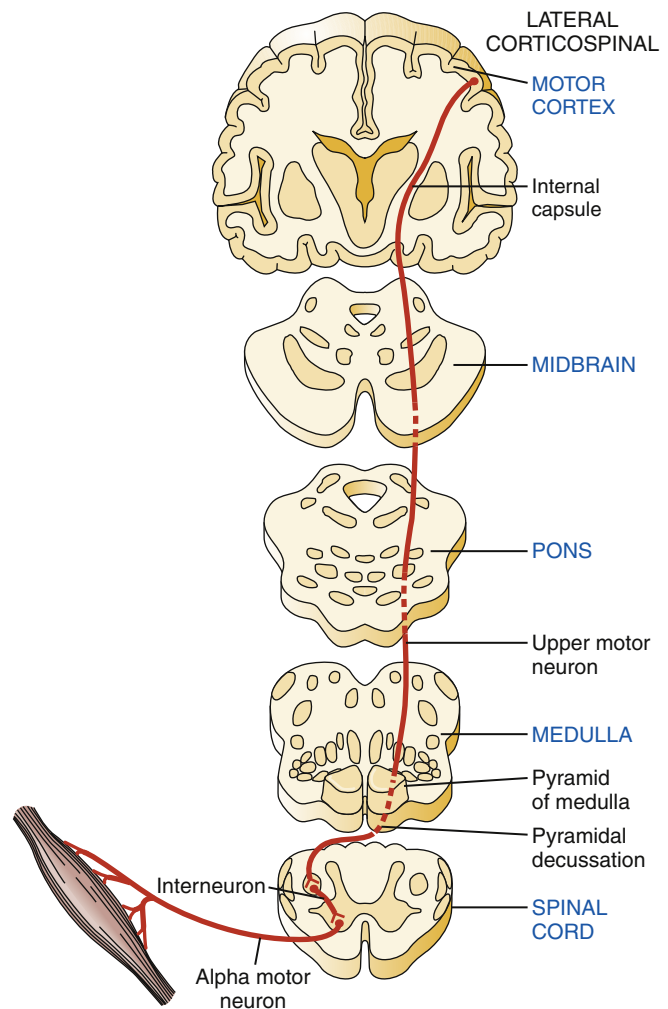

Motor neurons travel from the anterior horn of the spinal cord through the ventral root and within the spinal and peripheral nerves to finally innervate target muscles. The  $\alpha$  motor neurons release acetylcholine into neuromuscular junctions, depolarizing skeletal muscle cells and contracting all the fibers in the *motor unit*. A motor unit consists of a single motor neuron and all of the muscle fibers under its control. Some motor units are large, containing hundreds of muscle cells, whereas others may contain only one muscle cell per motor neuron. Smaller motor units produce finer gradations of muscle control.

A single action potential in the  $\alpha$  motor neuron is sufficient to release enough neurotransmitter to contract the motor unit. Therefore, the point of control of muscle contraction is at the cell body of the  $\alpha$  motor neuron that lies within the anterior horn. A typical motor neuron receives hundreds of synaptic inputs, which summate to control the generation of action potentials. Some presynaptic inputs are from corticospinal neurons; others are sensory inputs from primary sensory afferents and spinal cord interneurons.

The  $\gamma$  motor neurons are small fibers that innervate structures within the body of the muscles, called *muscle spindles*. Muscle spindles are specialized sensory receptors that sense the length or stretch within the muscle and relay the information to the spinal cord. The  $\gamma$  motor neurons contract muscle fibers within the muscle spindle and regulate spindle sensitivity. Excessive  $\gamma$  motor neuron activity occurs in some types of brain coma, making the spindles hypersensitive and the muscles stiff and resistant to stretch (see discussions of decerebrate and decorticate rigidity in Chapter 44).

## SPINAL REFLEXES

A great deal of motor coordination is exerted in the spinal cord through complex reflex pathways. These pathways allow upper motor neurons from the brain to initiate preprogrammed movements, rather than having to excite and inhibit each and every lower motor neuron individually. For example, experiments in lower animals have

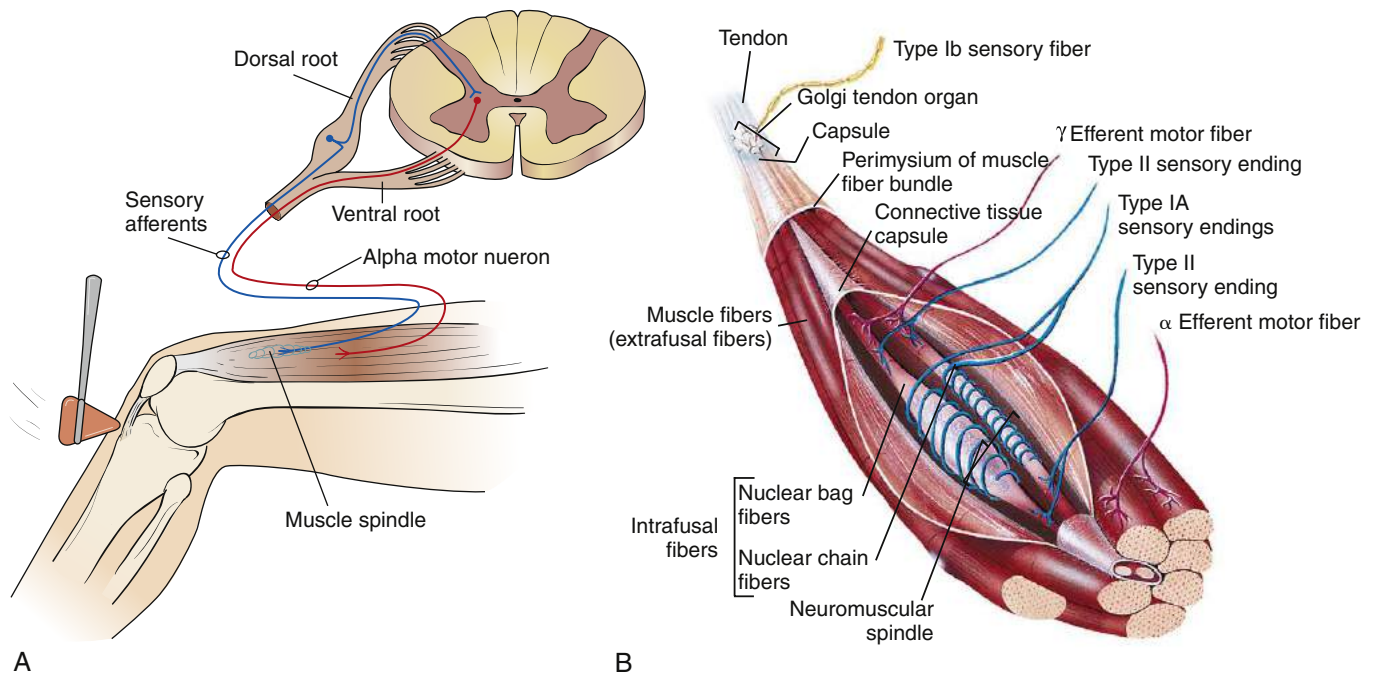

**FIGURE 43-39** Corticospinal tract showing decussation at the level of the medulla.

demonstrated that pressure on the pads of the feet initiates complex walking movements even when the brain is no longer functional.

Spinal reflexes allow sensory information from pain receptors, proprioceptors, and muscle spindles to alter muscle contraction very quickly, even before the information reaches the brain. The stretch reflex and withdrawal reflex are illustrative examples.

The stretch reflex can be demonstrated by tapping the patellar tendon (below the knee) with a rubber hammer, which results in contraction of the quadriceps muscle and elevation of the lower leg. Evaluation of deep tendon reflexes is helpful in localizing a motor abnormality to the PNS or CNS. The deep tendon reflex tests the reflex arc between the sensory muscle spindles and the  $\alpha$  motor neurons. Tapping the tendon produces a quick stretch in the muscle fibers of the quadriceps muscle and stimulates the muscle spindles. The muscle spindle sends action potentials along neurons (group Ia) that enter the dorsal horn of the spinal cord and then synapse directly on  $\alpha$  motor neurons in the anterior horn that activate the muscle in which the spindles lie (Figure 43-40). Other branches of the group Ia neurons make connections with antagonistic muscle groups and inhibit their contraction. The stretch reflex makes only one synapse (monosynaptic) and produces a very quick response in the muscle. The physiologic function of the muscle spindle stretch reflex is to provide feedback to  $\alpha$  and  $\gamma$  motor neurons to adjust the strength of muscle contraction to match the load on the muscle.

**FIGURE 43-40** Diagram of the stretch reflex in which activation of the muscle spindle stimulates contraction of the stretched muscle. **A**, Stretch of the muscle sends action potentials to the cord, which make a monosynaptic connection to motor neurons from the same muscle fibers. **B**, Detailed view of the muscle spindle apparatus showing type 1 and type 2 sensory fibers that are large, myelinated, and rapidly conducting neurons that detect stretch. The  $\gamma$  motor neurons contract the spindle to keep it taut and sensitive to further stretch, while the  $\alpha$  motor neurons contract the muscle fibers. Also shown in this figure is another stretch receptor located at the juncture between the muscle and the tendon called the *Golgi tendon organ*. Muscle shortening during contraction stimulates the Golgi tendon organ, causing it to send signals to the cord that inhibit muscle contraction. This is thought to protect the muscle from excessive contraction that could tear it from its tendon insertion points on the bone.

The withdrawal reflex is an important protective mechanism that allows reflexive withdrawal of a body part from a physical threat while simultaneously making postural adjustments to avoid loss of balance. The withdrawal reflex is polysynaptic, making connections with interneurons in the cord to affect muscles on both sides of the body. A simplified model of the withdrawal reflex is shown in Figure 43-41. Note that a painful stimulus to one extremity results in activation of flexor muscles and inhibition of extensor muscles on the ipsilateral side. This allows quick withdrawal of the extremity from the source of injury. Connections with muscle groups on the opposite side of the cord stimulate extensors and inhibit flexors to stabilize posture.

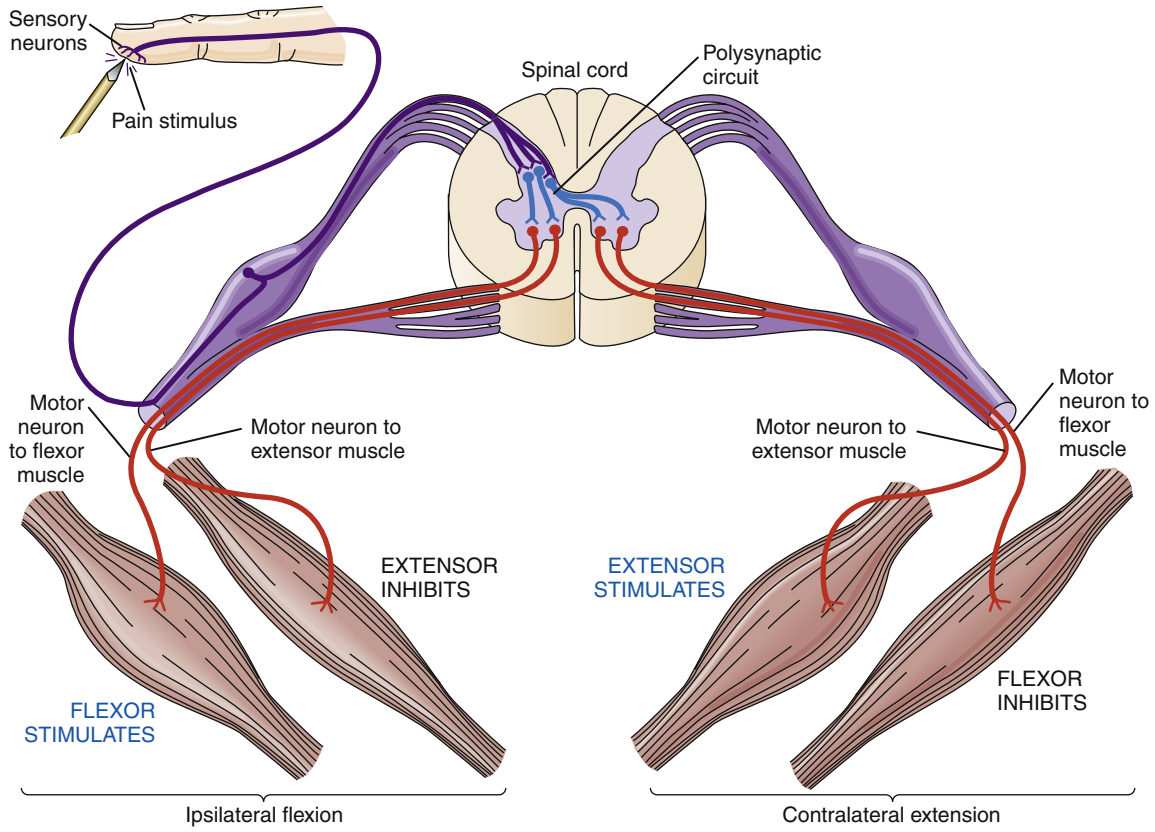

## CENTRAL CONTROL OF MOTOR FUNCTION

Corticospinal tract neurons originate in the primary motor cortex, which is arranged in a similar manner to the somatosensory cortex. The motor homunculus map (Figure 43-42) shows that muscles of the face, lips, tongue, and hands occupy most of the cortical neurons. These areas have small motor units and produce fine-motor control. Corticospinal neurons from the primary motor cortex, in association with neuronal output from the premotor area and the supplemental motor cortex, activate  $\alpha$  motor neurons to execute voluntary motor commands.

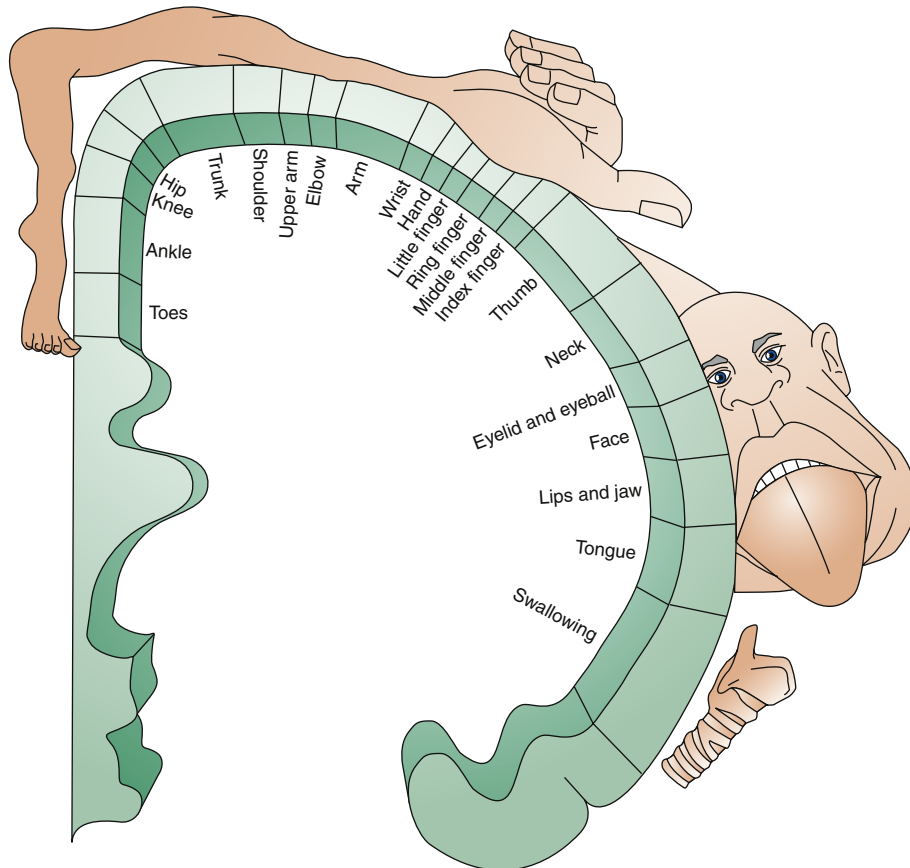

First, a motivation to move is needed to spur an individual to action. Little is known about motivation; however, signals from the

limbic system are thought to be important. Circuits between the basal ganglia and association areas of the cerebral cortex plan the intended movement. Somewhat different circuits are involved in new situations, such as first learning to type, than are involved in the execution of learned, but subconscious, patterns of movement (e.g., typing 100 words per minute).<sup>5</sup> An important part of the planning process involves the somatosensory cortex, which provides information about the spatial coordinates of body parts in relation to the physical surroundings (e.g., placement of the fingers on the keyboard).

The cerebellum serves to adjust the timing and intensity of movements to improve the similarity between the intended and actual movements. Neurons in the cerebellum learn with practice. Visual, proprioceptive, and vestibular information is used by the cerebellum to make adjustments in the execution phase of the movement. In addition, the cerebellum functions with the cerebral cortex to make muscle adjustments in advance of the movement. For example, if a person is asked to lift what appears to be a pile of bricks, but the bricks are made of lightweight Styrofoam, the unsuspecting subject will throw the pile up into the air. Visual cues and past learned experiences are used to gauge the intensity of muscle contraction. The brain learns quickly, however, and if the subject is asked to repeat the maneuver, the intensity of muscle contraction will exactly match that needed to lift the load smoothly. Once a motor activity is well-learned and can be performed “automatically,” the cerebellum participates less and the basal ganglia and cortical neurons are most active.<sup>5</sup>

**FIGURE 43-42** Cortical representation of the muscles of the body. Note the large area devoted to control of the hands and face.

**KEY POINTS**

- The body is somatotopically represented in the motor cortex. Stimulation of points in the primary motor cortex results in discrete movements in the contralateral side of the body.
- Projections from the motor cortex (corticospinal tract) travel by way of the internal capsule, cross over at the medulla, and travel down the contralateral spinal cord to synapse on  $\alpha$  motor neurons in the anterior horn. The  $\alpha$  motor neurons innervate skeletal muscle.
- Extrapyramidal tracts (tectospinal, vestibulospinal, reticulospinal) from subcortical nuclei innervate antigravity muscles and are primarily involved in balance, posture, and movement of large proximal muscle groups.
- A great deal of motor activity is preprogrammed into neuronal connections in the spinal cord. These connections produce reflexive alterations in muscle contraction in response to sensory information about the tension on the muscle or the need to move a body part away from a painful stimulus.
- The planning and execution of movements is accomplished through neuronal circuits between the basal ganglia and the premotor and association areas of the motor cortex. The cerebellum contributes primarily to the learning phase of a motor skill by making instantaneous adjustments in muscle force and timing to improve the match between the intended and the actual movement.

**CONSCIOUSNESS, MEMORY, AND SLEEP**

That the cerebral cortex is integral to the elaboration of complex thought, learning, memory, and so-called higher brain functions is well supported by lesion studies, yet little is known about the ways in which these higher functions are accomplished. Each thought involves neuronal circuits in portions of the cerebral cortex, thalamus, limbic system, and reticular formation of the brainstem. A thought or memory is not stored in any one place; rather, it is the outcome of a pattern or circuit of neuronal activation.<sup>23</sup> Neurons in the limbic system, especially the amygdala, are thought to determine the general emotional value of the thought as being pleasant, painful, or neutral, whereas neurons in the cerebral cortex add the specific details, including remembered sensations and visual and auditory images. Consciousness and memory are prerequisites to thinking.

**CONSCIOUSNESS AND MEMORY**

Consciousness can be defined as awareness of the surroundings and of one's own thoughts and sensations. The neural correlates of consciousness are not known; however, continuous activation of neuronal circuits between the thalamus and cortex and between the thalamus and brainstem are believed to be necessary.<sup>24</sup> Consciousness is assessed by the expression of motor behaviors, such as speech, response to questions, and body movements. However, behavioral responses are not necessarily an outcome of consciousness. A person completely paralyzed with neuromuscular blocking agents is still conscious even though all outward behaviors are suppressed. It is difficult to know the level of brain activity in an individual who cannot move. Brain waves are frequently measured in an attempt to assess brain activity, and a correlation with consciousness is assumed;  $\alpha$  waves are thought to reflect search and retrieval functions and  $\theta$  waves are associated with memory encoding tasks. Groups of neurons firing synchronously produce the regular oscillations of brain waves that seem to underlie consciousness. Much remains to be discovered before the phenomenon of consciousness and its counterpart, unconsciousness, are understood.

To think and learn, one must be able to remember past events and link them to current circumstances. Memory is a synaptic phenomenon

in which neurons in the memory trace or circuit alter the efficiency of synaptic transmission. Greater stimulation of neurons in the memory circuit results in longer-lasting effects. Once the memory trace is established, it can be reactivated by the thinking mind to reproduce the memory. Reactivation by the mind is called *retrieval* and may be enhanced by rehearsal or by strategies to link the memory trace with associated circuits that are already established. Experiences that have important consequences, such as pain or pleasure, are usually enhanced and stored as memory traces, whereas experiences of little consequence may be suppressed. The value of a memory is determined primarily by the limbic system, which helps the brain learn to ignore information of little consequence (which can be construed as a form of negative memory, or remembering to ignore). This is an important function, because it prevents preoccupation and overload of brain circuits with useless stimuli.

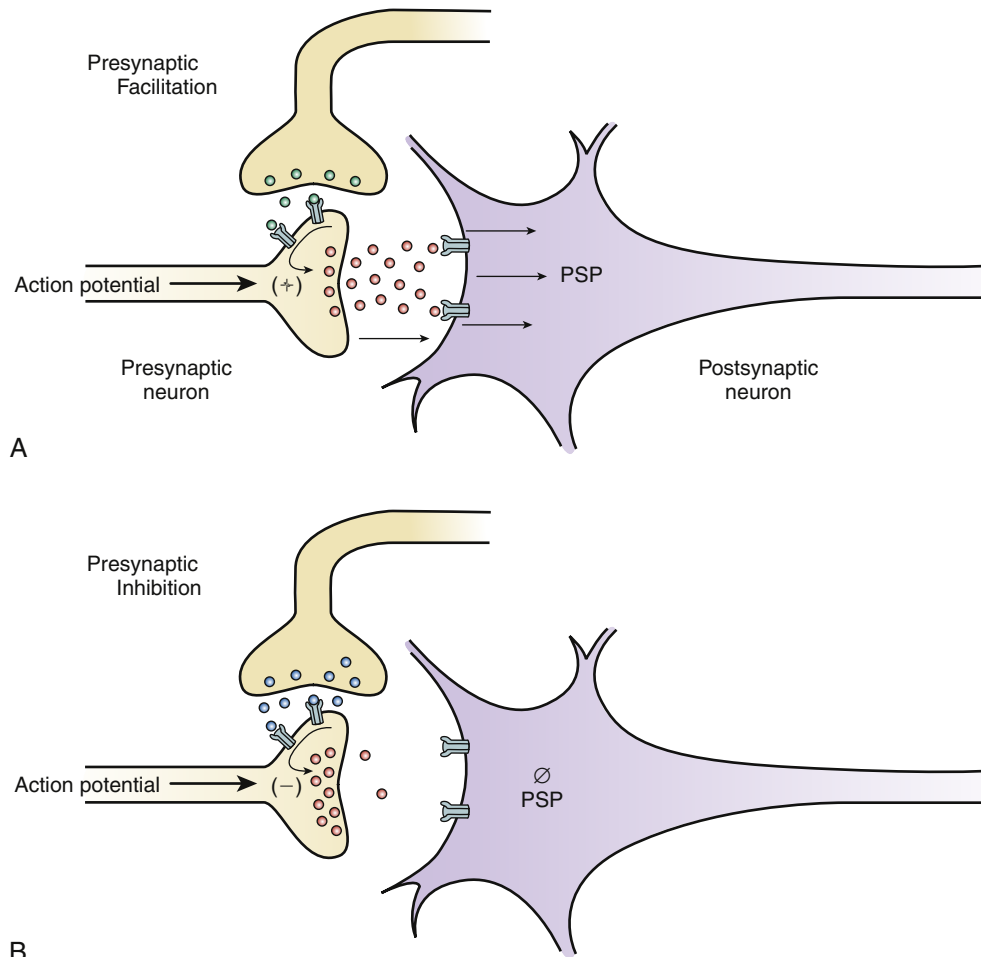

Some memories last for a short time, and others persist for a lifetime. The mechanisms for different types of memory are mostly unknown; however, it is believed that short-term alteration of *presynaptic* neurons in the memory trace is responsible for short-term memory, whereas long-term memory requires more permanent changes in the *postsynaptic* neurons.<sup>23</sup> A certain time period is required for memories to be consolidated into long-term memory. An interruption of the consolidation phase, by head trauma, for example, results in loss of memory for events occurring just before the injury.

Some examples of presynaptic modulation are shown in Figure 43-43. The interaction between the presynaptic and postsynaptic neurons is modified by the activity of the modulating neuron. For example, the modulating neuron could send a signal from the limbic system to indicate that the incoming signal was important. The modulating neuron would then enhance neurotransmitter release from the presynaptic neuron to facilitate transmission to the postsynaptic cell. Presynaptic inhibition could suppress synaptic transmission by preventing or reducing the amount of neurotransmitter released from the presynaptic neuron.

Longer-term memory is thought to occur because of long-term changes in synaptic efficiency. In some cases memory may incorporate new neurons into the memory circuit. The hippocampus is an important limbic structure that must be intact for memory to be consolidated. It is also a site of neural stem cell proliferation, leading some to conclude that memory involves the growth of new neurons.<sup>15</sup> Changes in synaptic efficiency could include alterations in receptor number or structure and changes in the components of second messenger cascades. Protein synthesis in the involved neurons is necessary to consolidate long-term changes in synaptic efficiency.<sup>23</sup> Memories are thought to be stored in the brain in association with memories of similar qualities that share some of the same neuronal circuits. Information is added to the memory circuit that is already in place. This makes it easier to learn information that is connected to previously learned material. Learning something completely new, such as a foreign language, requires a great deal of rehearsal.

**SLEEP**

Sleep is a state of decreased arousal from which a person is easily awakened. Different levels of brain activity from wakefulness to deep sleep are characterized by different electroencephalographic waveforms. Brain waves become progressively slower and more synchronized with deeper levels of sleep. These waveforms are called  $\alpha$ ,  $\beta$ ,  $\theta$ , and  $\delta$  waves (Figure 43-44). The  $\alpha$  and  $\beta$  waves are found in awake individuals:  $\alpha$  waves predominate during a relaxed state with the eyes closed;  $\beta$  waves occur during visual stimulation and with active problem solving.  $\beta$  waves are also apparent during a stage of sleep called *rapid eye movement* (REM) sleep. Both  $\theta$  and  $\delta$  waves occur during deep sleep.

**FIGURE 43-43** Example of a modulating neuron that terminates on the presynaptic cell and alters its response. **A**, Facilitation: The presynaptic neuron releases more neurotransmitter into the synapse when an action potential arrives. **B**, Inhibition: The presynaptic neuron releases less neurotransmitter into the synapse with each action potential. *PSP*, Postsynaptic potential.

**FIGURE 43-44** Brain waves are categorized according to frequency and synchrony as  $\alpha$ ,  $\beta$ ,  $\theta$ , and  $\delta$ .

Most sleep is of the restful, slow-wave type of deep sleep. Interspersed at about 90-minute intervals are episodes of REM sleep, which last 5 to 30 minutes. REM sleep is characterized by irregular breathing and heartbeat, rapid eye movements, depressed muscle tone, and active dreaming.<sup>25</sup> The number and length of REM episodes usually increases over the course of the night. Individuals who have been awake for a prolonged period spend more time in deep sleep at the beginning of sleep and begin to have more REM sleep as the brain becomes more rested.<sup>25</sup> Dreams occur in both types of sleep but are more likely to be remembered when they occur during REM sleep.

The mechanisms of the sleep-wake cycle and the reason the brain needs to sleep are not well understood. Experiments in animals have demonstrated that sleep is an active process initiated by sleep-inducing substances within the brain. CSF removed from sleep-deprived animals promptly produces sleep when injected into another animal. Production of sleep-inducing substances within the brain occurs during wakefulness; they gradually accumulate, producing a desire to sleep. A period of sleep is thought to inhibit production of sleep-inducing chemicals, and they are cleared from the CNS.

The physiologic significance of sleep may be to rebalance synaptic transmission strength and to avoid the behavioral consequences of

sleep deprivation.<sup>25</sup> Prolonged sleep deprivation produces hallucinations, disordered thought processes, and personality changes. It has been noted that the smaller the animal and the higher the metabolic rate, the greater the sleep requirement. Non-REM sleep is associated with lowering of metabolism and body temperature and may provide an opportunity to avoid or repair metabolism-induced brain damage. REM sleep is associated with an active brain; however, certain types of neurons—those that secrete amines—are turned off during REM sleep. The younger and more immature brain spends more time in REM sleep, and some have speculated that the brain is laying down circuits for genetically programmed or instinctive neural pathways.<sup>25</sup>

**KEY POINTS**

- Thoughts and memories are not stored in a particular location in the brain; rather, they are the outcome of activation of neurons in a neuronal circuit.
- Memories are stored by altering the synaptic efficiency of neurons in the memory trace. Short-term memory is thought to result from presynaptic mechanisms, whereas long-term memory is consolidated by more permanent changes in the postsynaptic neurons.
- Sleep is characterized as REM sleep ( $\beta$  waves) and deep sleep ( $\theta$  and  $\delta$  waves). Most sleep is of the deep-sleep variety, interspersed with periods of REM activity at about 90-minute intervals. Sleep is an active process produced by sleep-inducing chemicals in the brain. The reason that the brain requires sleep remains unknown.

**SUMMARY**

The nervous system is a complex network of neurons and supporting cells that provides the body with a rapid means of communication. The anatomy of the nervous system has been extensively studied, but the functional mechanisms of thought, memory, emotion, and sleep are poorly understood. The nervous system can be partially understood by examining the function of individual neurons and their synaptic connections. Neural communication occurs primarily through the secretion of neurotransmitters into synapses between neurons. Neurotransmitters bind to specific receptors to exert their effects on the membrane potential of the target cell.

Activation of groups of neurons in a particular circuit is the basis for neuronal processing of information, thoughts, and memories and for learning. Although certain brain locations have been associated with particular functions, most brain activities require participation by neurons in widespread locations. The ability of the nervous system to learn and adapt is remarkable in the early childhood period, and a significant degree of neural plasticity is maintained throughout life. However, damage to large numbers of neurons in a particular location usually results in significant disability because mature neurons cannot regenerate and neural stem cells may not survive or establish appropriate connections.

### KEY QUESTIONS

- What are the proposed mechanisms and potential consequences of secondary brain injury?
- Which brain components determine intracranial pressure, and under what conditions might each contribute to elevated intracranial pressure?
- How are level of consciousness and cranial nerve reflexes used to assess changes in neurologic status in the brain-injured patient?
- What are the common manifestations of types of traumatic brain injury (focal, polar, diffuse) and hemorrhage (epidural, subdural, subarachnoid)?
- How do the three most common causes of stroke (thrombi, emboli, and hemorrhage) differ with regard to risk factors, prevention strategies, and acute management?
- How do the clinical manifestations of ischemic stroke vary depending on the location of cerebral artery obstruction?
- What are the common long-term sequelae of stroke, and how are they managed?
- What are the causes and usual presentations of cerebral aneurysm and arteriovenous malformation?
- How do meningitis and encephalitis differ with regard to usual infective organisms, cerebrospinal fluid analysis findings, clinical manifestations, and treatment?

Disorders of brain function can result from a wide variety of pathophysiological processes. The focus of this chapter is on primary causes of acute brain injury including brain trauma, cerebrovascular disease, brain hemorrhage, and central nervous system (CNS) infections. These conditions are acute because they generally have a sudden onset and progress rapidly. Thus, early detection and prompt management are necessary to prevent death and minimize morbidity. However, the majority of patients who survive acute injury to brain structures will be left with some degree of permanent neurologic damage and chronic dysfunction. The designation of acute and chronic disorders is, therefore, somewhat arbitrary. The chronic aspects of neurologic diseases, including seizure disorders and dementias, are discussed in Chapter 45. Acute neurologic dysfunction often is a complication of diseases primarily affecting other systems. Hypoglycemia, renal failure, liver failure, human immunodeficiency virus infection, drug overdoses, fluid imbalances, and many other abnormalities may cause acute brain dysfunction. Accurate determination of the source of acute alterations in brain function is an important step in developing an appropriate treatment plan. However, there are many common elements in the pathogenesis of acute brain injuries, regardless of etiologic factors. These cellular aspects are presented as a foundation for understanding the specific disorders that follow.

## MECHANISMS OF BRAIN INJURY

The mechanisms of brain injury are varied, complex, and incompletely understood. Mechanical trauma, ischemia, cellular energy failure, reperfusion injury, excitotoxins, edema, vascular failure, and injury-induced apoptosis (programmed cell death) are all factors thought to be operative in most kinds of acute brain injury. These mechanisms are often separated into two categories: *primary injury* and *secondary injury*.

The primary injury is that which occurs immediately at the onset of brain injury. This definition implies that there is little that can be done to reverse the process once it has occurred. For example, in the case of head trauma, some tissues will be irreversibly damaged at the time of impact owing to mechanical forces. This damage represents the primary injury. Similarly, with the sudden cessation of blood flow to an area of brain tissue, as occurs in stroke, an area of irreversible ischemia in cells may develop quickly, and this constitutes the primary injury. Brain tissue necrosis occurs rapidly as cells lose membrane integrity, rupture, and release their intracellular contents into the extracellular space. Cytotoxic edema quickly follows, which can cause deleterious effects to surrounding brain tissue.

Secondary injury refers to the development of further neurologic damage subsequent to the primary injury, and this may progress over days or weeks. Delayed cell death may involve necrosis from further acute injury or may be a delayed consequence of the primary injury. Cells that die slowly after injury are said to undergo apoptosis or

programmed cell death. Apoptosis requires energy and protein synthesis, and the cells shrink and die in a tidy fashion without releasing their internal contents. Necrosis follows severe ischemic injury, whereas apoptosis is associated with moderate injury. A critical factor in determining the neuronal cell fate after injury is the degree of adenosine triphosphate (ATP) depletion. If ATP levels fall profoundly, increased membrane permeability and necrosis ensue. If the ATP level is partially maintained for a period of time after the injury, apoptosis is the likely consequence. Mild reductions in the amount of ATP are associated with reversible injury and cellular recovery.<sup>1</sup> ATP level reduction is a consequence of ischemia and hypoxia, which accompany many types of acute brain injury including trauma and stroke.

Mechanisms of secondary injury are the subject of much interest because of the potential to effectively intervene to limit brain damage. Unfortunately, effective means of preventing secondary damage have remained elusive, leading to high rates of mortality and morbidity. The effort to elucidate mechanisms of secondary injury and develop effective treatments would seem worthwhile because the degree of primary injury is thought to be small in most cases.<sup>2</sup> Thus, the high rates of mortality and morbidity may be attributed in large part to mechanisms of secondary injury.

### Ischemia and Hypoxia

Ischemia occurs when the delivery of oxygenated blood is below the level needed to meet metabolic demands of the brain tissue. Ischemia is a contributing factor in most forms of acute brain injury, either as the primary insult (e.g., stroke) or as part of the secondary response to injury (e.g., vasospasm, vascular compression, or abnormal autoregulation). Hypoxia is a deficiency of oxygen at the cellular level, which may occur as a result of decreased blood flow (ischemia) or decreased blood oxygenation (hypoxemia). In practice, ischemia and hypoxia usually occur together and are considered together in this discussion. Ischemia results in immediate neurologic dysfunction because of the inability of neurons to generate the ATP needed for energy-requiring processes. In addition, ischemia sets the stage for secondary injury by oxygen free radicals, excitatory amino acids, and inflammatory cells.

### Cellular Energy Failure

Neuronal tissue is highly sensitive to oxygen deprivation because it has great ATP requirements and limited capacity for anaerobic metabolism during ischemia. The normal brain receives about 15% of the total cardiac output and garners 20% of the body's oxygen consumption (750 ml/min), despite contributing only 2% of the body weight.<sup>1</sup> Neurons are dependent on glucose for production of ATP; however, they store little in the form of glycogen. Thus, when oxygen supply is decreased, not only is oxidative phosphorylation impaired, but also the low supply of stored glucose restricts anaerobic production of ATP. Brain cells tolerate loss of ATP for several minutes; about 5 to

10 minutes of complete occlusion is necessary for irreversible brain damage in humans. Complete occlusion of blood flow is rare but even a partial occlusion, if allowed to continue for a sufficient amount of time, may produce irreversible brain damage. Once blood flow to cerebral neurons diminishes, two mechanisms can independently lead to brain cell death: anaerobic metabolism and deterioration of ion gradients.

A general sequence of events following acute brain ischemia has been proposed (Figure 44-1).<sup>3</sup> The critical event is mitochondrial dysfunction owing to lack of cellular oxygen. Recall that oxygen is required to accept electrons from the mitochondrial electron transport chain. In the absence of oxygen, the transport proteins and cytochromes remain reduced and unable to accept any more electrons from the Krebs cycle (tricarboxylic acid cycle). Anaerobic glycolytic pathways are initiated in the affected region to compensate for the loss of oxygen and to provide a source of energy. Glycolysis may continue for a short time, producing pyruvate, which is converted to lactate. However, this conversion releases  $H^+$  and contributes to cellular acidosis, a damaging by-product of glycolysis. Toxicity of hydrogen ions leads to loss of neuronal integrity.

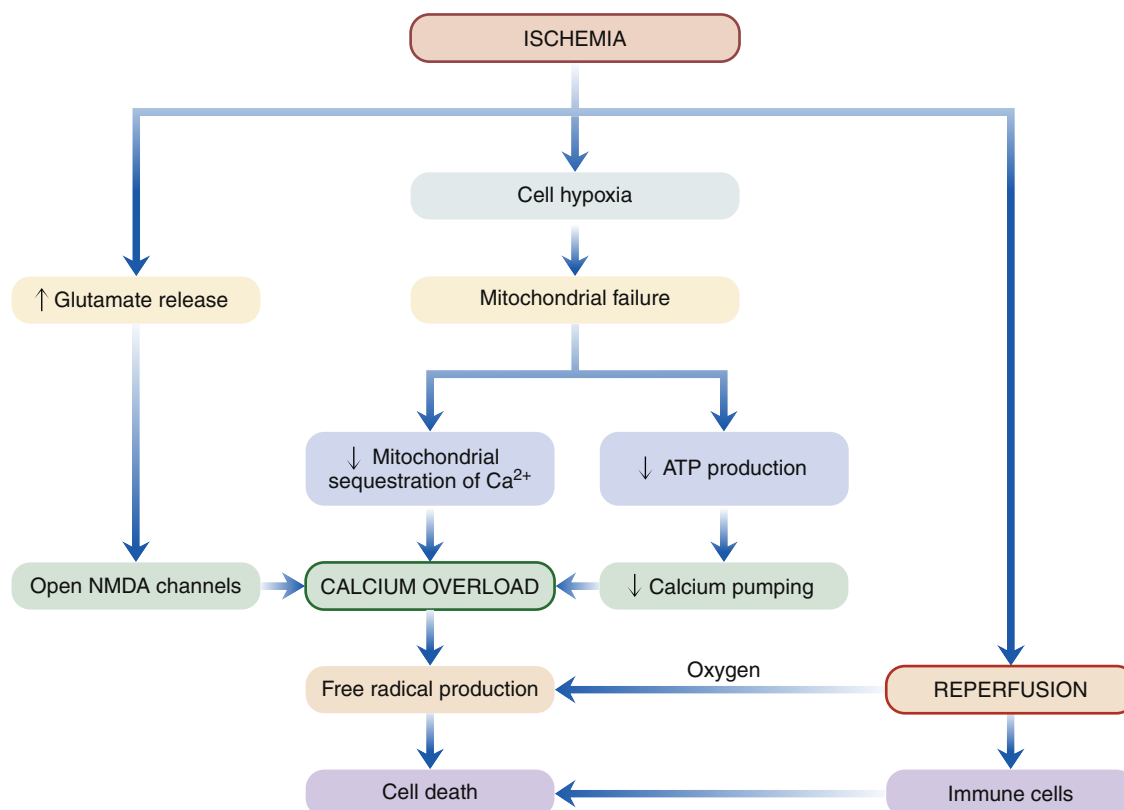

Inadequate energy supply leads to deterioration of ion gradients. Most of the ATP used by neurons is for maintenance of ion gradients across the plasma membrane. The sodium-potassium ( $Na^+$ - $K^+$ ) pump consumes three fourths of the ATP in a typical neuron. Anoxic depolarization causes potassium to leave the cell and sodium, chloride, and calcium ions to enter. Energy also is required to maintain calcium balance and regulate neurotransmitter synthesis and reuptake. Not surprisingly, energy failure results in neuronal dysfunction, injury, and, if severe or prolonged, necrotic cell death. Ischemia also is the probable inciting factor for apoptosis (see Chapter 4).

The mitochondria are also important regulators of calcium ion concentration in the cell. The mitochondrial membrane contains calcium transporters that sequester calcium ions within the mitochondria when cytoplasmic calcium levels are elevated. Mitochondrial energy failure impairs the ability of mitochondria to perform this sequestering function. Thus, the mitochondria become severely overloaded with calcium, which activates enzymes (phospholipases) that damage mitochondrial membrane structures. Ischemic cells are prone to calcium overload because pumps that move calcium out of the cell are energy dependent. Calcium ions have a large electrochemical gradient for diffusion into the neuron and tend to accumulate intracellularly.

Unfortunately, the activity of many intracellular enzymes is regulated by intracellular calcium. Calcium overload is thought to be a critical factor leading to activation of enzyme cascades, which disrupt function and cause irreversible damage to cell membranes (lipid peroxidation). One might speculate that measures to inhibit calcium entry into damaged cells would be of therapeutic benefit. One way to reduce calcium influx is by administration of calcium channel-blocking agents. These drugs block voltage-gated calcium channels. Unfortunately, clinical trials with calcium channel-blocking agents have failed to show benefit.<sup>2</sup> Other avenues for inhibiting calcium overload are being investigated, including those that block the effect of glutamate receptors as described in the following section.

### Excitatory Amino Acids

Calcium may gain entry into cells by portals other than voltage-gated channels. Glutamate is an excitatory amino acid neurotransmitter thought to be important in learning and memory. Overstimulation of neurons by glutamate is associated with cell injury, leading to its designation as an *excitotoxin*. Glutamate binds two kinds of receptors that

**FIGURE 44-1** Sequence of neuronal cell injury following acute ischemia. Calcium overload is a key event in producing cellular damage.

are linked to the opening of ion channels in the plasma membrane of neurons. *N*-methyl-D-aspartate (NMDA) receptors have received the most attention, but  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) channels are also thought to contribute to the neurotoxic effects of glutamate. Activation of AMPA receptors results in opening of  $\text{Na}^+$  channels in the membrane, which leads to depolarization. Depolarization then affects the NMDA channels by removing a  $\text{Mg}^{2+}$  ion that usually blocks the NMDA channel (Figure 44-2). Subsequent binding of glutamate to the NMDA receptor opens it and allows  $\text{Ca}^{2+}$  to enter the cell accompanied by inflow of water, which results in cytotoxic edema, a rapid swelling of neurons. As previously described, calcium overload mediates a cascade of events leading to cell injury.

The amount of glutamate in the synapses is usually tightly regulated by release and reuptake controls. In the presence of neuronal injury, excessive glutamate may be released because of impaired membrane integrity. With concomitant ischemia, reuptake mechanisms fail to

remove excess glutamate from the synapse because they are energy-dependent processes. Excess glutamate stimulates nearby neurons, which then take up large amounts of injurious calcium ions. Small neurons in the cerebral cortex and hippocampus are particularly prone to glutamate excitotoxicity, and selective damage in these areas may occur. In addition to the calcium overload mechanism of injury, NMDA receptor activation stimulates nitric oxide (NO) production in neurons. NO is a neurotransmitter, but in excess it may increase the production of reactive nitrogen species (RNS), which function as free radicals to damage cellular components. The potential neuroprotective effects of controlling glutamate release or activity have been investigated but have not clearly shown efficacy in improving outcomes.<sup>2</sup>

### Reperfusion Injury

Reestablishing perfusion to an area of prior ischemia is a matter of great urgency if neuronal tissue is to be salvaged. The longer and more

**FIGURE 44-2** Mechanism of glutamate-mediated calcium influx. Impaired removal of glutamate from the synapse by energy-requiring reuptake mechanisms on the presynaptic membrane contributes to excessive glutamate in the synapse. Glutamate binds to the *N*-methyl-D-aspartate (NMDA) channel, causing it to open and allow calcium influx. A previous depolarization is necessary to remove the  $\text{Mg}^{2+}$  that normally blocks the channel. Excessive calcium entry impairs mitochondrial function and triggers nitric oxide production. Excessive nitric oxide can increase cell damage through free radical production. AMPA,  $\alpha$ -Amino-3-hydroxy-5-methyl-4-isoxazolepropionate; NO, nitric oxide; NOS, nitric oxide synthase.

severe the period of ischemia, the greater the extent of necrosis. However, previously ischemic cells face new dangers with the return of blood flow. In particular, the return of oxygen brings the potential for oxygen free radical formation, and the flow of blood allows inflammatory cells to invade the area. The secondary injury that occurs after reestablishing blood flow has been termed *reperfusion injury* and has been studied extensively in cardiac tissues. The mechanisms in the brain appear to be similar. During the period of ischemia, brain cells accumulate substrates for oxidative phosphorylation, including the free radical-forming metabolites of adenosine monophosphate (AMP), xanthine, and hypoxanthine. When oxygen reenters the cell, erratic transfer of electrons to oxygen can produce a number of reactive oxygen products that behave as free radicals, damaging cell structures. These include hydroxyl radicals ( $\text{OH}^\cdot$ ), superoxide ( $\text{O}_2^-$ ), and peroxide ( $\text{H}_2\text{O}_2$ ). Cell membranes may undergo lipid peroxidation in response to free radical damage, with subsequent formation of arachidonic acid. The arachidonic acid cascade yields more oxygen free radicals as well as mediators of inflammation.<sup>2</sup>

The role of immune mechanisms in reperfusion injury of brain tissue is only partially understood. Previously, the CNS was thought to be relatively shielded from immune cells because of the low permeability of the blood-brain barrier (BBB). However, the BBB is believed to be compromised with ischemia because the capillary endothelial cells are injured. The amounts of inflammatory cytokines, including interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor (TNF), increase in the brain during ischemic injury and are thought to attract neutrophils to the area and contribute to brain inflammation.<sup>4</sup> The importance of neutrophil recruitment to secondary injury remains controversial, but it may contribute further free radical generation and vascular obstruction by aggregated neutrophils. Trauma and inflammation also promote platelet aggregation in cerebral vessels with subsequent reduction in perfusion and worsening of ischemia.

### Abnormal Autoregulation

Under normal conditions, blood flow through brain tissue is controlled primarily by autoregulation. Cerebral vessels respond to metabolic factors including pH, carbon dioxide concentration, and oxygen levels. Cerebral blood flow is closely matched to metabolic needs despite wide fluctuations in perfusion pressure. Blood flow is maintained at a fairly constant rate over a range of mean arterial pressure (MAP) from about 50 to 150 mm Hg.<sup>1</sup> Above and below these levels, autoregulation fails. Hypotension predisposes to ischemia, whereas severe hypertension may lead to vascular damage and brain edema.

Appropriate autoregulation is necessary to provide a steady supply of oxygen and nutrients to brain cells and to remove metabolic wastes. Cerebral vessels dilate when mean arterial blood pressure falls or when brain metabolism increases. Anything that interferes with the ability of the vessels to dilate can lead to ischemia. Thrombi, emboli, vasospasm, neutrophil aggregation, and tissue edema may inhibit vasodilating autoregulatory mechanisms. Alternatively, vascular injury may impair vasoconstricting mechanisms and allow hyperperfusion and edema formation. Depending on the cause, autoregulation may be impaired locally, as in an area of thrombosis, or globally, as in generalized cerebral edema.

Autoregulation is influenced by the partial pressures of carbon dioxide ( $\text{Paco}_2$ ) and oxygen ( $\text{Pao}_2$ ) in the arterial blood. The response to a change in  $\text{Paco}_2$  is very brisk: as  $\text{Paco}_2$  levels fall, cerebral vessels constrict, and as  $\text{Paco}_2$  levels rise, the cerebral vessels dilate. A rise in  $\text{Paco}_2$  can increase cerebral blood flow significantly. The response to changes in  $\text{Pao}_2$  is much less dramatic.

The autoregulatory response to  $\text{Paco}_2$  remains robust, except in severely brain-injured patients, and can cause detrimental increases in

cerebral blood flow when respiratory compromise leads to hypercapnia. Excessive cerebral blood volume can exacerbate cerebral edema. Conversely, hyperventilation to produce low  $\text{Paco}_2$  results in prompt vasoconstriction and, often, a reduction in intracranial pressure (ICP). Hyperventilation had been used for many years as standard therapy in the treatment of patients with increased ICP. However, prolonged hyperventilation does more harm than good because it critically reduces cerebral blood flow to responsive vessels and triggers tissue ischemia in these areas.

Loss of matching between oxygen supply and demand occurs when autoregulatory mechanisms fail. Cerebral oxygen demand is correlated with the degree of neuronal activity and may vary widely in different regions within the brain. Excessive levels of catecholamines or excitatory amino acids can significantly increase cerebral metabolism. In the context of impaired blood flow, these neurotransmitters may contribute to ischemia by increasing cerebral oxygen demand. Likewise, seizure activity increases neuronal metabolism and leads to worsening neurologic outcomes.<sup>5</sup>

Efforts to reduce release of excitatory neurotransmitters through hypothermia, rest, and pain control may be beneficial. Pharmacologic suppression of brain seizures is imperative in the patient with cerebral ischemia. Drug-induced coma, with agents such as barbiturates, has been advocated to reduce brain metabolism. However, this treatment is not without side effects.<sup>2</sup>

Hypothermia is a strategy for reducing brain metabolism and protecting the brain from ischemic injury. A number of animal and human studies suggest that cerebral injury can be delayed, and possibly avoided, by cooling the brain.<sup>6</sup> Possible mechanisms include inhibition of glutamate release, inhibition of IL-1 release, reduced cerebral metabolic rate, and suppression of inflammation. The effects of hypothermia on patient outcomes and the optimal degree of hypothermia remain controversial. Moderate degrees of cooling ( $28^\circ$  to  $32^\circ$  C) are associated with platelet dysfunction and coagulopathy.<sup>6</sup> Shivering negates the usefulness of hypothermia by increasing oxygen demand, and must be suppressed, usually by pharmacologic means. Further research is ongoing to determine the therapeutic window for effectiveness, appropriate duration, and safe rewarming protocols.<sup>6,7</sup>

Two related concepts important to the discussion of autoregulation are cerebral edema and increased ICP. Swelling and space-occupying lesions (mass lesions), such as tumors or hematomas, may increase the pressure within the cranium such that blood supply is compromised. Measures to reduce cerebral edema, remove mass lesions, and prevent elevations of ICP help to maintain functional autoregulation.

### Increased Intracranial Pressure

ICP is the pressure exerted by the contents of the cranium, and it normally ranges from 0 to 15 mm Hg.<sup>1</sup> Elevated ICP may occur in most types of acute brain injury and is associated with impaired neurologic function attributable to compression of brain structures. In all but very young children, the skull is a rigid, closed system with a set volume and a finite ability to accommodate changes in volume before elevations in ICP occur.

The volume of the cranium is made up of three components: brain tissue, cerebrospinal fluid (CSF), and blood. A relationship known as the Monro-Kellie hypothesis describes the compensatory responses to a change in volume in any of the three components.<sup>8</sup> A slight increase in one component can be offset by a reduction in the volume of the other two. An increase in brain volume, as might occur with cerebral edema, can be offset by a reduction in the CSF space and the space occupied by the cerebral vasculature. The ability to accommodate changes in volume without significant increases in pressure is called *compliance*. Intracranial compliance is limited because of the rigid skull; although

**FIGURE 44-3** A volume-pressure curve showing intracranial compliance. Small increases in volume have little effect on pressure, but larger increases exceed the ability to compensate, and pressure rises dramatically.

small increases in intracranial volume may be absorbed, moderate changes result in significant increases in ICP (Figure 44-3).

Each of the cranial components has a varying capability to compensate for the others. Cerebral blood vessels can reduce their volume through vasoconstriction. The CSF compartment is capable of significant reduction in volume by shunting CSF to the spinal cord or into the venous system via the arachnoid villi. The brain parenchyma has little ability to reduce its volume to compensate for CSF or blood volume expansion. In young children, an increase in ICP may manifest as an increase in head circumference. This occurs because the cranial bones have not yet fused, and the skull can expand to accommodate the increased intracranial volume.

In the healthy brain, transient changes in ICP are common and well tolerated. Sneezing, coughing, straining, and head-dependent positions all cause elevated ICP, but they are without consequence because ICP quickly returns to normal. In the brain-injured person, however, transient elevations in ICP can be very dangerous and poorly tolerated.

**Etiology.** The most common causes of increased ICP include stroke, trauma, and tumors, but many other primary and secondary disorders can cause significant elevations in ICP (Box 44-1). These disorders have common features in that they all affect the volume of CSF, blood, or brain tissue. An increase in brain tissue volume commonly occurs from conditions that cause cerebral edema. Edema of brain tissues is due to accumulation of fluid in interstitial or intracellular spaces.

Interstitial edema is usually secondary to an increase in capillary pressure, damage to the capillary endothelium from a chemical injury, or a sudden increase in vascular pressure beyond autoregulatory limits. This type of edema has been termed *vasogenic*, and it results in extravasation of electrolytes, proteins, and fluid into the intercellular space. Vasogenic edema is a consequence of stroke, ischemia, and severe hypertension, and may occur surrounding brain tumors. The edema is often localized to a particular brain region where the BBB has been disrupted. Thus the swelling may be unilateral, occurring in one brain hemisphere or the other. Unilateral swelling often is poorly tolerated

### BOX 44-1 COMMON CAUSES OF INCREASED INTRACRANIAL PRESSURE

#### Increased Brain Tissue Volume

- Tumor
- Hemorrhage
- Infection
- Cytotoxic edema
- Vasogenic edema
- Ischemia and necrosis

#### Increased Cerebrospinal Fluid Volume

- Obstructive hydrocephalus
- Nonobstructive hydrocephalus
- Pseudotumor cerebri

#### Increased Blood Volume

- Increased right atrial pressure
- Dural sinus thrombosis
- High arterial  $P_{aCO_2}$
- Acidosis

**FIGURE 44-4** Generalized brain edema with increased intracranial pressure. The convolutions of the brain surface (gyri) are flattened, and the space between them is reduced. (From Kumar V, Cotran R, Robbins S: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

because midbrain structures are compressed, and can lead to shifting of cerebral tissue or brain herniation.

Intracellular edema, called *cytotoxic edema*, occurs when ischemic tissue swells because of cellular energy failure. A lack of ATP allows  $Na^+$  to accumulate in the cell, creating an osmotic force to draw in water. Cytotoxic edema predominates in cases of global ischemia. Global ischemia occurs when oxygenation of the whole brain is impaired, as would occur with cardiac arrest or severe hypoxemia. Generalized brain edema flattens the gyri and reduces the spaces between them (Figure 44-4).

In many cases of acute brain injury, vasogenic and cytotoxic edema occur together. Cerebral edema, when severe, can start a cyclic process that promotes further edema of increasing severity and contributes to increased ICP. As edema fluid collects, it compresses local vessels, preventing adequate blood and oxygen from reaching the cells. This results in ischemia, which in turn triggers vasodilation and increased capillary pressure, further fluid leakage into the injured tissue, and increased edema. Vasogenic edema tends to be a delayed process in terms of the secondary effects of brain injury, progressively worsening during the first several days after injury. Clearance of brain edema occurs primarily by absorption into the CSF system.<sup>1</sup>

In addition to edema, a number of space-occupying processes, such as tumors, hematomas, and abscesses, can increase intracranial volume

**FIGURE 44-5** Right subacute subdural hematoma on weighted CT scan. Note the shift in midline structures. (From Yousem DM, Grossman RI: *Neuroradiology*, ed 3, St Louis, 2010, Mosby, p 174.)

and contribute to elevated ICP. These mass lesions are often unilateral and may result in severe compression of vital brain structures. Attempts by the brain to accommodate the expanding mass result in typical findings on computed tomography (CT) scans (Figure 44-5). The ventricles are reduced in size, and midline structures are displaced.

Excessive accumulation of CSF (hydrocephalus) is another important cause of increased ICP. Elevated CSF volume causes the ventricles to enlarge and press on cerebral brain structures (Figure 44-6). Hydrocephalus may be a primary disorder or may develop as a result of obstruction proximal to the arachnoid granulations (obstructive; noncommunicating hydrocephalus) or at the level of the arachnoid granulations (communicating; nonobstructive hydrocephalus). Obstructive hydrocephalus commonly occurs when a lesion blocks the flow of CSF out of the ventricle, whereas nonobstructive hydrocephalus is common following subarachnoid hemorrhage because residual blood clogs the arachnoid villi and prevents the CSF from being reabsorbed.

Increased intravascular cerebral blood volume is unlikely to be a primary cause of high ICP, but it may contribute to pressure elevations initiated by ischemia or trauma. High  $Paco_2$  or loss of autoregulatory controls can lead to vasodilation and increased cerebral blood volume.

**Manifestations.** Manifestations of elevated ICP include headache, vomiting, and altered level of consciousness (drowsiness). The patient may complain of blurry vision, and evaluation of the fundi may reveal edema of the optic disk (papilledema). As ICP rises to higher levels, the level of consciousness decreases, and pupil responsiveness to light becomes impaired. Eventually the patient will exhibit altered respiratory patterns and will become unresponsive to stimulation and unable to move, verbalize, or open the eyes. Prolonged elevations of ICP are thought to damage brain structures by compressing the blood supply and causing ischemia.

Patients exhibiting manifestations of elevated ICP, or those with significant risk for elevated ICP, may be monitored with a pressure device inserted into the brain parenchyma through an opening in the

**FIGURE 44-6** Normal-pressure hydrocephalus. (From Yousem DM, Grossman RI: *Neuroradiology*, ed 3, St Louis, 2010, Mosby, p 255.)

skull (burr hole). The pressure device is connected to an electrical transducer, and the ICP waveforms can be monitored continuously (Figure 44-7). In general, a high ICP is associated with poor outcome. Different ICP waveforms are thought to carry different prognoses. The normal ICP waveform is characterized by three pressure peaks called P1, P2, and P3. These waves are reflections of changes in ICP associated with each arterial pulsation. Normally P1 is higher than P2, and P2 is higher than P3 (see Figure 44-7). As ICP begins to increase, the pattern of waves remains normal, but the peak and mean pressures are higher. Further increases in ICP are characterized by a P2 wave that exceeds P1 and a dampening of the individual waveforms (plateau or rounded waves).<sup>9</sup>

Rounded or monotonous waves reflect severe pathologic increases in ICP attributable to changes in cerebral volume. Plateau waves can reach 50 to 100 mm Hg. After the plateau period the ICP slowly decreases, but it usually remains elevated above baseline. These waves reflect a potentially life-threatening situation, and if the pathologic process is not stopped, a cycle of increased ICP followed by vasodilation to maintain constant blood flow through swollen tissues continues, which in turn further increases ICP. An extreme increase in ICP can precipitate an intense reaction by the sympathetic nervous system as it attempts to maintain cerebral perfusion through the compressed blood vessels. This has been termed an *ischemic response* or *Cushing reflex*. The systolic blood pressure can jump to values exceeding 200 mm Hg, accompanied by bradycardia and a widening pulse pressure. The Cushing reflex generally is viewed as a “last ditch” effort by the brain to reestablish cerebral perfusion.<sup>8</sup>

### Brain Compression and Herniation

A dreaded complication of elevated ICP is brain compression and herniation. Compression of midbrain and brainstem structures is associated with rapid neurologic demise unless corrected quickly. Important midline structures include the reticular activating system (RAS), which is necessary for maintaining consciousness, and vital regulatory centers for cardiovascular and respiratory control. Radiologic examination by computerized tomography (CT) scan or other means (e.g., magnetic resonance imaging [MRI]) is useful in evaluating the patient with increased ICP who exhibits a change in neurologic

**FIGURE 44-7** Intracranial pressure (ICP) monitoring can be used to continuously measure ICP. The ICP tracing shows normal, elevated, and plateau waves. At high ICP the P2 peak is higher than the P1 peak, and the peaks become less distinct and plateau.

status. CT scans may show midline shifts and herniations when ICP is sufficiently elevated.

Herniation refers to the protrusion of brain tissue through an opening in the supporting dura of the brain. Several types of brain herniation have been described according to their anatomic locations. The brain parenchyma is divided into compartments by the supporting structure of the dura. The dura folds into the space between the cerebral hemispheres to form the falx cerebri and folds in from the lateral aspects to form the tentorium, which separates the cerebellum from the cerebral hemispheres (Figure 44-8). The most common herniations occur through openings in these structures (Figure 44-9).

There is a small space between the tip of the falx cerebri and the corpus callosum through which the neurologic lobe of the cerebral cortex can herniate (Figure 44-10). This is called a *subfalcine hernia*. Subfalcine herniation occurs when a lesion in one hemisphere is large enough to cause a lateral shift across the midline of the intracranial cavity, forcing the neurologic gyrus under the falx cerebri. This results in distortion and compression of the internal cerebral vein. Subfalcine herniation can be asymptomatic and generally carries a better prognosis than other types of brain herniation. The greatest danger results from compression of blood vessels, particularly the ipsilateral anterior cerebral artery, which can cause further cerebral ischemia and edema and contribute to the ICP elevation.

The tentorium is a rigid dural fold that separates the cerebellum and cerebral hemispheres. Midbrain structures pass between the

**FIGURE 44-8** Schematic drawing of the normal brain compartments showing the dural folds that form the falx cerebri and the tentorium.

**FIGURE 44-9** Herniations occur when brain tissue is pushed through openings beside the dural folds or the foramen magnum.

infoldings of the dura in a structure called the *incisura*. With transtentorial herniations, a part of the brain protrudes through this space. Tentorial herniations are of two types: (1) bilateral herniations, which cause central transtentorial herniation, and (2) lateral herniations, in which one hemisphere compresses midbrain structures to the side and herniates through the tentorial opening (see Figure 44-9).

Central tentorial herniation results from expanding lesions in the frontal, parietal, and occipital lobes that force a downward displacement of the hemispheres and basal nuclei with compression of the diencephalon and adjoining midbrain. Transtentorial herniation can occur rapidly or slowly, depending on the type of lesion. The speed with which the process is recognized is a critical factor in patient survival. Slowly dilating or odd-shaped pupils is an ominous sign that indicates compression of the third cranial nerve and midbrain. Transtentorial herniations are associated with significant intracranial hypertension and may initiate vascular compression and CSF obstruction, which then contribute to the existing problem of ischemia and hypertension.

Uncal herniation is a type of tentorial herniation that typically occurs with expanding lesions in the temporal lobe. As the lobe shifts, the basal edge of the uncus and the hippocampal gyrus bulge over the edge of the *incisura* (see Figure 44-9). In the process, the third cranial nerve and the posterior cerebral artery are compressed. The pupil on the same side (ipsilateral) as the lesion often becomes dilated and unresponsive to light (fixed). Flattening of the midbrain interferes with the ascending RAS and depresses the level of consciousness. The ipsilateral cerebral peduncle is also compressed, resulting in contralateral motor dysfunction. Compression of the contralateral cerebral peduncle is also common, leading to the confusing symptom of ipsilateral motor dysfunction.

Tonsillar herniation is less common than the other herniation syndromes and involves the shift of the cerebellar tonsils through the foramen magnum and compression of the medulla and upper cervical cord (see Figure 44-9). This typically occurs in patients with cerebellar lesions. Because of the proximity of the cerebellum to the brainstem, tonsillar herniation evolves very rapidly and can result in death in a matter of minutes. Signs usually include precipitous changes in blood

**FIGURE 44-10** CT scan of acute hemorrhage with mass effect and subfalcine herniation and shift of the lateral ventricle. (From Yousem DM, Grossman RI: *Neuroradiology*, ed 3, St Louis, 2010, Mosby, p 185.)

pressure and heart rate, small pupils, disturbances in conjugate gaze, ataxic breathing, and quadriplegia.

### Management

Management of increased ICP is often based on the results of CT or MRI. Processes amenable to surgical intervention can be detected and treated. Removal of excess CSF, tumors, abscesses, and hematomas can dramatically improve ICP. Nonsurgical processes such as cerebral edema, intracerebral bleeding, and infections are managed medically. ICP measurements and determinations of cerebral perfusion pressure (CPP) are used to guide therapy. Controversy regarding the appropriate treatment of increased ICP continues, and the focus of management has shifted from ICP control to management of cerebral oxygenation. The roles of previously established therapies such as hyperventilation, brain dehydration with diuretics, head-up and neutral body positions, and corticosteroid administration have been called into question. Previously discarded therapies, such as hypothermia, hypertonic saline infusion, and drug-induced comas, have been reintroduced. Despite these controversies in medical management, the value of careful observation and assessment of neurologic function is unquestioned. Many times subtle changes in neurologic function are detectable early in the process of evolving brain injury. Several tools have been developed to help standardize neurologic examination and are discussed in the following section.

### KEY POINTS

- Primary brain injury occurs as a direct result of the initial insult. Secondary injury refers to progressive damage resulting from the body's physiologic response to the initial insult.
- Ischemia is an important mechanism of brain injury that occurs when the blood supply is inadequate to meet metabolic needs. A lack of oxygen results in mitochondrial failure, ATP depletion, and accumulation of intracellular calcium ions.

- Excessive release of excitatory amino acids, like glutamate, is thought to contribute to calcium overload during acute brain injury. Calcium overload is a critical event leading to cell dysfunction, membrane damage, and cell necrosis.
- Reperfusion injury occurs when blood flow is reintroduced to previously ischemic but viable cells. Free radicals are generated, which damage cell structures. Inflammatory cells are recruited to the area and may increase edema, block vessels, and contribute to free radical production.
- Autoregulation of cerebral blood flow achieves appropriate flow to meet metabolic needs despite changes in blood pressure and metabolism. Autoregulation is effective over a range of mean arterial blood pressure from 50 to 150 mm Hg. Hypoxia and high  $P_{aCO_2}$  result in dilation of cerebral vessels. Hyperventilation with low  $P_{aCO_2}$  results in cerebral vasoconstriction.
- Pressure in the cranium is a product of the volume of brain tissue, blood, and CSF. Increases in any one component are partially offset by reductions in the others to maintain ICP.
- Brain swelling is a common cause of increased ICP. Edema may result from changes in vascular competency that lead to transudation of fluid into intercellular spaces (vasogenic), or from cellular swelling (cytotoxic) owing to a deficiency in cellular ATP.
- Normal ICP ranges from 0 to 15 mm Hg. Transient increases are well tolerated, but chronically increased ICP results in compression of vessels and brain tissue, leading to cellular ischemia and brain damage. High ICP may precipitate herniation of brain tissue through dural compartments.

## MANIFESTATIONS OF BRAIN INJURY

Depending on the severity and location of brain injury, a wide variety of clinical manifestations may occur. Patients may present with symptoms ranging from minor headache and visual disturbances to complete loss of consciousness. Patients with significant acute injuries require frequent neurologic assessments to detect changes that may evolve rapidly. Level of consciousness (LOC), cranial nerve reflexes, and brain hemodynamics provide important clues to neurologic status.

### Level of Consciousness

A change in level of consciousness is one of the most sensitive indicators of altered brain function. Efforts have been made to standardize the terms used to describe level of consciousness (Table 44-1). In practice, however, it is best to use a full description because of lack of consistency in interpretation of the terms. Consciousness is a state of alertness and attentiveness to one's environment and situation. A fully conscious individual is awake, alert, and oriented to time, person, place, and current circumstances. Consciousness is thought to be dependent on activity in the RAS neurons, which project to the thalamus, and in tracts between the thalamus and cortex.<sup>1</sup> Although consciousness may be suddenly and completely lost, the decline is usually progressive. Cortical neurons are most sensitive, and cognitive and memory functions are impaired early, leading to confusion.

Delirium, a primary disorder of attention, is characterized by an acute onset of severe confusion, motor signs, slurred speech, altered consciousness, and hallucinations. As RAS function is compromised, the patient becomes difficult to arouse and requires increasingly noxious stimuli to produce verbal or motor responses. Eventually complete loss of consciousness may occur, a condition called *coma*. The **Glasgow Coma Scale (GCS)** can be used to assess level of consciousness with greater reliability among different observers (Box 44-2). Sudden or progressive changes in level of consciousness should prompt

**TABLE 44-1 TERMS USED TO DESCRIBE ALTERED LEVEL OF CONSCIOUSNESS**

TERM	DESCRIPTION
Confused	Unable to think clearly or engage in effective problem solving; orientation to time, place, person impaired; easily aroused by verbal stimuli
Delirious	Restless and disoriented, may have hallucinations; easily aroused, but may have difficulty with attention
Lethargic	Uninterested in surroundings or events; sluggish in thought and motor activities; does not engage spontaneously in activities
Obtunded	Falls asleep unless stimulated; arousable with voice or touch, but quickly returns to sleep
Stuporous	In a deep state of sleep; vigorous stimulation is required to arouse, and a wakeful state is not maintained
Comatose	Unable to be aroused, even with vigorous painful stimuli; motor responses, such as withdrawal or posturing, may occur

**BOX 44-2 GLASGOW COMA SCALE**

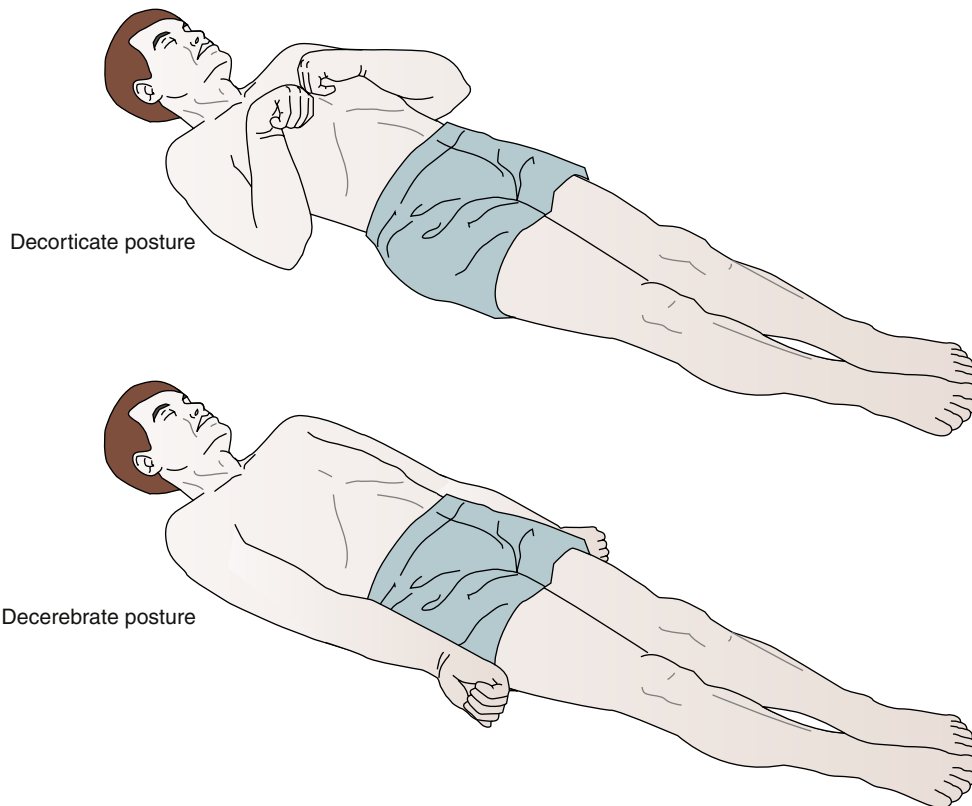

<b>Eye Opening</b>	2. Incomprehensible sounds (moaning, groaning)
4. Spontaneously (eyes open, does not imply awareness)	1. None
3. To speech (any speech, not necessarily a command)	<b>Motor Response</b>
2. To pain	6. Obeys commands
1. Never	5. Localizes pain (deliberate or purposeful movement)
<b>Verbal Response</b>	4. Withdrawal (moves away from stimulus)
5. Oriented (to time, person, place)	3. Abnormal flexion (decortication)
4. Confused speech (disoriented)	2. Extension (decerebration)
3. Inappropriate (swearing, yelling)	1. None (flaccidity)

a thorough neurologic examination to determine the cause and best course of therapy.

### Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is a standardized tool developed for the purpose of assessing the level of consciousness in acutely brain-injured patients. It can also be used to evaluate patients with an altered level of consciousness as a result of other neurologic insults such as hemorrhage or craniotomy. Numeric scores are given to arousal-directed responses of eye opening, verbal utterances, and motor reactions. The best response is scored, bilateral responses are recorded for motor reactions, and consistent application of a painful stimulus is required for accuracy. When used correctly, the GCS has a high degree of interrater reliability.

The eye opening response is a simple measure of alertness. Normally, the eyes open spontaneously in response to verbal stimuli. If the eyes do not open in response to verbal stimuli, noxious stimuli, such as compression of the nail beds, may be applied. It is important to be consistent and vigorous enough to achieve the best response from the patient. In patients with acute space-occupying lesions, eye opening is usually depressed in conjunction with impaired response to pain and motor function. Spontaneous eye opening in the acute phase is

**FIGURE 44-11** Abnormal motor activity with coma. Decorticate posturing is indicated by flexed wrists and arms and extended legs and feet. Decerebrate posturing is indicated by arm and leg extension.

an encouraging sign, as it implies that the arousal mechanism in the brainstem is intact.

The verbal response on the GCS reflects orientation. A full score (i.e., 5) in this category indicates that the patient is alert and fully oriented: the patient knows his or her name, current location, and the time of day. In the next level (score 4), the patient is awake and can pay attention to a certain degree, but is confused about his or her identity and does not know the time or the location. If attention is poor and the verbal responses consist of yelling and swearing, it is scored as an inappropriate response (i.e., score 3). Incomprehensible verbalizations are unintelligible sounds or mumbling (i.e., score 2). Absence of verbalization is given a score of 1. As in the eye opening category, noxious stimuli are applied to achieve the best verbal response from the patient.

Motor response is a powerful predictor of outcome. Motor response is scored as the best level of response the patient is able to perform. Each extremity is evaluated to avoid misinterpretation secondary to muscle paralysis. At the highest level (score 6), the patient can obey a command to move. At the next level down (score 5), the patient does not obey commands, but when a painful stimulus is applied, the patient moves in a purposeful manner to avoid the stimulus; the patient is able to localize the source of pain. As status deteriorates, the patient withdraws only the extremity from the painful stimulus (score 4). This is not considered a purposeful response. Further deterioration results in abnormal posturing movements. *Decorticate* posturing (score 3) is characterized by an abnormal flexor response of the arms and wrists. The legs and feet extend and internally rotate (Figure 44-11). The level below decorticate posturing is called *decerebrate* or *abnormal extension* (score 2). The arms extend with external rotation of the wrists. The legs and feet

extend and rotate internally (see Figure 44-11). The lowest level of motor response is no response to painful stimuli (i.e., flaccidity in all four limbs, score 1). It is important to emphasize that all limbs must be tested separately, because motor responses may be preserved on one side only, and levels of involvement may vary from side to side. Higher initial scores tend to predict better recovery. On the GCS, the level of coma occurs on a continuum from mild (>12), to moderate (9 to 12), to severe (<8). The lowest total score of 3 indicates likely fatal damage, especially if both pupils fail to respond to light and oculovestibular responses are absent; however, the severity and prognosis are predicted more accurately by also considering diagnostic imaging and other factors.

### Cranial Nerve Reflexes

The GCS score alone is not sufficient to accurately determine the status of the patient with an acute insult to the brain. Assessment of the integrity of brainstem function is also important and is indicated by various brainstem reflexes including the pupil light reflex, oculovestibular reflex, and corneal reflex.

### Pupil Reflex

Pupillary assessment provides important information about the function of the brainstem and cranial nerves II and III. The normal pupillary response to light results from an intact afferent cranial nerve II (optic) detecting the light and stimulating the intact efferent cranial nerve III (oculomotor) to constrict the pupils. The response of the pupil to light, in terms of both its shape and the speed of reaction, is a function of cranial nerve III.

The pupillary response is recorded by noting pupil size in millimeters, shape, and reactivity to light. Careful monitoring of the pupillary

response to light during the acute phase is critical, because a failing response may be the first indication of brain compression from increasing ICP. Mild dilation of a pupil with sluggish or absent light response is ominous. This phenomenon results from pressure on the oculomotor nerve (cranial nerve III) by lateral displacement of mid-brain structures. An oval pupil may be an early indicator of dangerously poor compliance and transtentorial herniation. The oval pupil represents a transitional pupil that can return to normal responsiveness if ICP is controlled.

Other pupillary responses indicate damage to the optic nerve. The afferent pupillary defect is a paradoxical response that is detected with the swinging-light test. As the examiner swings a light from the normal eye to the abnormal eye, the abnormal pupil responds by dilating instead of constricting. This occurs because the light signals transmitted to the Edinger-Westphal nucleus in the midbrain through the injured optic nerve are insufficient to maintain constriction triggered by stimulation of the normal eye.

Bilaterally small pupils suggest a destructive lesion in the pons or the presence of certain drugs. Bilaterally fixed and dilated pupils suggest inadequate cerebral perfusion. This could be related to hypotension or increased ICP. If perfusion is not interrupted for too long, a normal pupillary response returns with adequate flow.

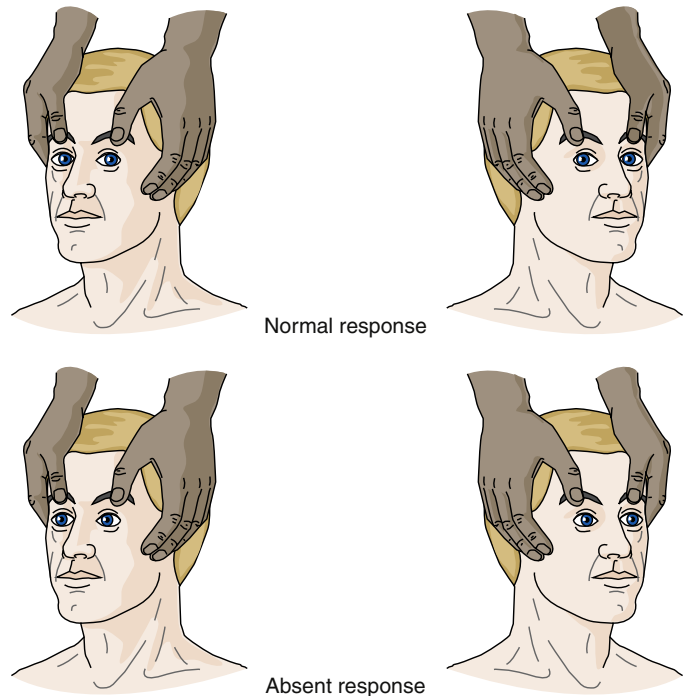

Eye movements are important indicators of brainstem function. Cranial nerves III, IV, and VI are responsible for normal eye movements. Abnormalities of eye movement are useful in localizing the site of brain dysfunction. Abnormal eye movements seen in the brain-injured patient can include nystagmus, dysconjugate eye movements, and ocular palsies. **Nystagmus** is a persistent rhythmic or jerky movement in one or both eyes. **Dysconjugate movements** occur when the eyes do not move together in the same direction. Ocular palsies occur when one or more cranial nerves are dysfunctional such that motor paralysis of the eye muscles impairs movements in one or more directions.

### Oculovestibular Reflex

The oculovestibular reflex normally detects head movements (via receptors in the semicircular canals) and causes appropriate adjustments of eye position such that an object can remain fixed on the retina even though the head is moving. An impaired oculovestibular reflex implies brainstem dysfunction. Two tests can be performed to evaluate this reflex in the unconscious patient: the doll's eyes test and the cold calorics test.

The oculocephalic or doll's eyes test is performed only in patients in whom a lateral spine radiograph has been obtained to rule out spinal injury. The test is performed by holding open the patient's eyelids and rotating the head from one side to the other (Figure 44-12). If the brainstem is intact, the eyes will turn in a direction opposite to the direction of head rotation. If the eyes do not move in conjugate fashion or are asymmetric, the response is abnormal and brainstem function is impaired. If the eyes remain fixed at the midline and do not move, the response is said to be absent. An absent response indicates severe brainstem impairment.

The oculovestibular response, or cold calorics, is a similar test of brainstem function using cold water instillation into the ear. Cold against the tympanic membrane causes action potentials from the vestibular apparatus to change and simulates the neuronal response to head rotation. If the brainstem is intact, the normal response will be a tonic deviation of both eyes toward the side that is irrigated. Dysconjugate or asymmetric eye movement is abnormal. If there is no eye movement, the response is absent. Testing of the oculovestibular response is one of the essential examinations performed in patients thought to be brain dead. Patients with depression of brain

**FIGURE 44-12** Doll's eyes response is indicated by an absent (abnormal) response to the oculocephalic head turning test and indicates brainstem damage. In the normal response, the eyes turn in a direction opposite to head rotation. In the absent response, the eyes stay midline and do not turn when the head is rotated.

function attributable to metabolic abnormalities usually retain an intact oculovestibular response. Certain drugs, such as barbiturates and high doses of phenytoin, can severely depress the oculovestibular response. In the absence of drug effect, an absent response to cold calorics is a poor prognostic sign indicating minimal chance of brain recovery.

### Corneal Reflex

A simple test of cranial nerve function is the corneal reflex. A wisp of cotton is touched to the cornea of the eye to elicit a blink response. Absence of blink is another indicator of severely impaired brain function.

#### KEY POINTS

- A change in level of consciousness often is an early indicator of compromised neurologic status. Normal consciousness is apparent as alertness and orientation to time, person, place, and situation.
- The Glasgow Coma Scale is used to assess level of coma by scoring alertness (eye opening response), orientation (verbal response), and motor control (movements). The highest score is given to demonstrating spontaneous eye opening, showing full orientation, and obeying motor commands.
- Pupillary responses indicate the function of the brainstem and cranial nerves II and III. Changes in size, shape, and reactivity of the pupil may be an early indicator of impending brain herniation. Eye movements controlled by cranial nerves III, IV, and VI may be impaired with increased ICP. Nystagmus, dysconjugate gaze, and ocular palsies may be evident.
- An absent doll's eyes response when the subject's head is turned and an abnormal response to activation of the oculovestibular reflex upon installation of cold water in the ear are very poor prognostic signs.

## TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) refers to injuries of brain tissues sustained as a consequence of trauma. The term is sometimes used interchangeably with head injury; however, injuries to the cranium do not always result in brain injury. Confusion in terms has led to difficulty in determining actual rates of traumatic brain injury, but there is no doubt that it is a major public health concern.

### EPIDEMIOLOGY

Traumatic brain injury is a leading cause of death and disability in the United States. During 1997 to 2007 an annual average of 5014 deaths attributed to TBI were reported.<sup>10</sup> Falls, sports injuries, firearms, and transportation-related trauma are important causes of TBI. The great majority of traumatic brain injuries in the United States are sustained in automobile accidents, whereas other forms of transportation are more significant contributors in other countries.

Certain age, gender, and ethnic groups are at higher risk for sustaining TBI. In the United States, 15 to 24 year olds are at highest risk. Males are twice as likely as females to sustain TBI and are more than three times more likely to die from their injuries. African Americans have a slightly higher risk than white and Hispanic Americans. Individuals at the lowest socioeconomic levels have the highest per capita rates of brain injury.<sup>10</sup>

It is difficult to quantify the social, medical, and economic impact of TBI. The cost of acute hospital care for a moderately to severely brain-injured patient is substantial, and the long-term care, rehabilitation, and loss of productivity for survivors add significantly to the cost. One in five patients who are hospitalized for TBI and survive will have a substantial long-term disability. Prevention of TBI is an important initiative for public health.

Early rescue from the trauma scene and immediate emergency management are important in the effort to reduce morbidity and mortality after TBI. Many TBI fatalities occur within minutes of the traumatic event. Victims who survive until hospitalization require expert monitoring and intervention.

### TYPES OF TRAUMATIC BRAIN INJURY

TBI is often characterized according to severity, location of injury, and mechanism of injury. There are different prognoses and management strategies for the different types of TBI.

Severity of TBI usually is based on the patient's GCS score on admission to the hospital or the lowest score in the first 48 hours following admission. A GCS score of 8 or less is defined as a severe injury; moderate injury is defined by a GCS score of 9 to 12; mild injury is associated with a GCS score greater than 12. Injury severity can also be estimated by the degree of brain injury detected on CT examination.

In general, an increased severity score is thought to be associated with a poorer prognosis; however, the predictive value of these tools is not very high. Some authors have suggested that the duration of postinjury amnesia is a useful predictor of outcome, but this measure often cannot be made early in the course of treatment and may not be timely enough to be helpful.<sup>11</sup>

Injury severity and outcome are somewhat dependent on the physiologic state of the brain before the trauma. Physical factors such as bone thickness, dural stability, brain atrophy, drug effects, previous brain damage, preexisting dementia, and cerebral atherosclerosis have an impact on the outcome of TBI. There is so much individual variation in brain response to injury that making a prognosis statement is often guesswork. After 48 to 72 hours following the injury, a better

estimate of outcome is possible because the degree of secondary injury will be manifested.

### PRIMARY INJURY

Primary injury is the result of the initial trauma on neural tissue. Primary injuries are commonly described as *focal*, *polar*, or *diffuse*. Although such injuries rarely occur in pure form, they are discussed separately for the sake of simplicity.

Focal injuries (coup) are those that are localized to the site of impact to the skull. The extent of the damage is quite variable. They may be superficial or extend deep into the brain matter. Local injury to the brain can result in specific neurologic symptoms, depending on the site. An injury over the motor cortex may result in contralateral weakness of the face and arm, whereas an injury to the frontal lobe can lead to **apraxia**, impulsive behavior, and poor judgment. However, localized hemorrhages or significant edema may act as space-occupying lesions and result in increased ICP, brain shifting, and herniation. In such cases, symptoms may include a decreased level of consciousness, cranial nerve dysfunction, and contralateral muscle weakness.

Polar injuries (coup contrecoup) occur as a consequence of the brain shifting within the skull and meninges during the course of an acceleration-deceleration movement, resulting in local injury at two opposite poles of the brain. This is commonly the case in motor vehicle accidents in which the head, traveling at the same high speed as the motor vehicle, is abruptly stopped by an obstacle such as the windshield. As a result, the frontal and temporal poles are crushed against the anterior and middle cranial fossae, damaging the tips and inferior surface of the temporal and frontal lobes. Damage may cause bruising or bleeding and, in combination with edema, may result in significant intracerebral mass lesions. Most forces to the head have a lateral rotational component; thus, one side of the brain typically is more severely injured than the other. Patients with polar injuries may or may not need significant acute care, depending on the severity of the injury. Polar injuries can, however, be a significant factor in the extent of subsequent cognitive impairment, affecting rehabilitation and long-term recovery.

Diffuse injuries occur when movement of the brain within the cranial cavity causes widespread neuronal damage. The brain is often subject to shifting and rotational forces during injury. The combined force causes stretching and shearing of the axonal white matter, known as *diffuse axonal injury*. Patients with severe diffuse axonal injury frequently are comatose from the time of injury. Coma is a consequence of axonal damage in the cerebral cortex or reticular activating center in the brainstem and can be prolonged. Recovery may be limited to a severely disabled or vegetative state. In addition to falls and motor vehicle accidents, diffuse injury is an unfortunate consequence of vigorous shaking, particularly of babies and the elderly, who have greater mobility of the brain within the skull.

In addition to categorizing primary injuries according to location as focal, polar, or diffuse, they can be differentiated by the mechanism of injury: concussion, contusion, and intracranial hematoma. *Concussion*, otherwise known as mild traumatic brain injury (MTBI), is the most common injury encountered by military personnel and athletes. In this type of injury there is an alteration or loss of consciousness (<30 minutes) but no evidence of brain damage on CT. Symptoms associated with MTBI present immediately and may resolve quickly after the traumatic event. In some instances they may last much longer: headache, nausea, vomiting, dizziness, fatigue, blurred vision. Cognitive and emotional disturbances may also be present. Grades of concussion and management are currently under much debate by the Department of Defense and schools/colleges alike (**Boxes 44-3 and 44-4**).<sup>12</sup> The effects of MTBI may be cumulative with additional

trauma.<sup>13</sup> Long-term behavioral and cognitive changes are seen in individuals with repeated “mild” injuries. Severe intracerebral bleeds have been reported in young athletes returning to practice/play before completely recovering from a MTBI.<sup>13</sup> Contusion is present when CT or MRI reveals an area of brain tissue damage (necrosis, laceration, bruising). An intracranial hematoma is a localized collection of blood within the cranium resulting from vascular damage.

### Intracranial Hematomas

Three types of hematoma can occur after traumatic head injury: epidural (extradural), subdural, and subarachnoid (Figure 44-13). Hematomas may expand slowly or rapidly, progressively compressing brain structures and increasing ICP. The types of hematoma differ in their clinical presentation and significance. Recognition and prompt management of intracranial hematomas can significantly improve outcome in the patient with TBI.

### Epidural Hematoma

Epidural hematomas are collections of blood in the epidural space, which lies between the inner surface of the skull and the dura mater (extradural). Vessels that travel within the dura are susceptible to injury in conjunction with skull fractures. Fracture of the temporal bone commonly disrupts the middle meningeal artery, resulting in an

acute epidural hemorrhage. Because the source of bleeding in most epidural hematomas is arterial, the hematoma can expand rapidly, causing acute deterioration of neurologic function. Often, the severity of the primary injury is minor, and the patient may suffer only a brief period of disturbed consciousness followed by a period of normal cognition (lucid interval). Then consciousness rapidly deteriorates as the epidural hematoma expands and compresses brain structures.

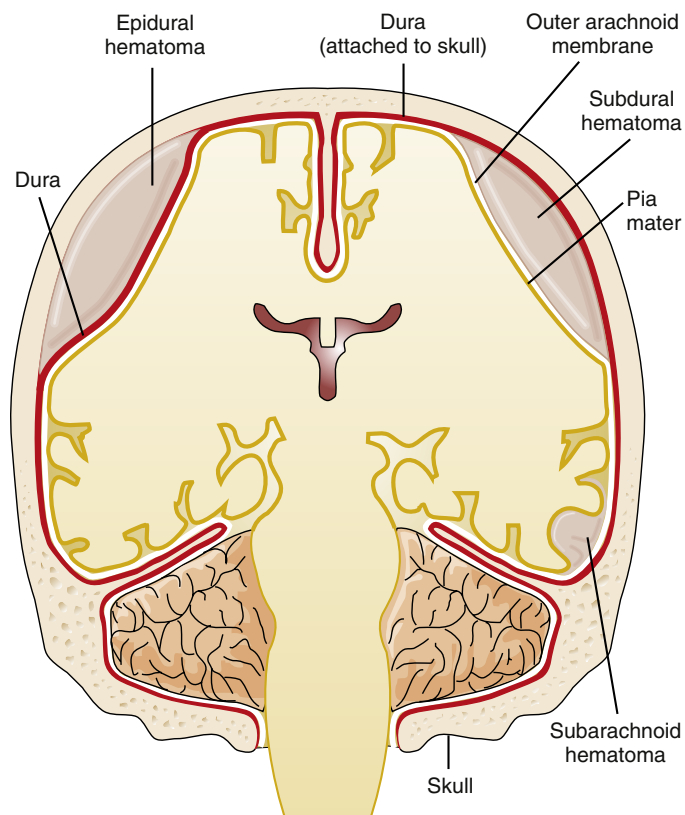

FIGURE 44-13 Locations of epidural, subdural, and subarachnoid hematomas.

### BOX 44-3 GRADES OF CONCUSSION

#### Grade 1

Transient confusion (inattentiveness, inability to maintain a coherent stream of thought and carry out goal-directed movements)  
No loss of consciousness  
Concussion symptoms or mental status abnormalities on examination resolve in less than 15 minutes

#### Grade 2

Transient confusion  
No loss of consciousness  
Concussion symptoms or mental status abnormalities (including amnesia) on examination last more than 15 minutes

#### Grade 3

Any loss of consciousness  
Brief (seconds)  
Prolonged (minutes)

### BOX 44-4 MANAGEMENT RECOMMENDATIONS FOR CONCUSSION

#### Grade 1

Remove from contest.  
Examine immediately and at 5-minute intervals for the development of mental status abnormalities or postconcussive symptoms at rest and with exertion.  
May return to contest if mental status abnormalities or postconcussive symptoms clear within 15 minutes. A second grade 1 concussion eliminates player for 1 week, with return contingent upon normal neurologic assessment at rest and with exertion.

#### Grade 2

Remove from contest and disallow return for at least 1 week.  
Examine on-site frequently for signs of evolving intracranial pathologic process. A trained person should reexamine the athlete the following day.  
A physician should perform a neurologic examination to clear the athlete for return to play after 1 full asymptomatic week at rest and with exertion. If headache or other symptoms persist for 1 week or longer, CT or MRI scan is indicated. A second grade 2 concussion eliminates player for at least 2 weeks following complete resolution of symptoms at rest or with exertion. If imaging shows abnormality, player is removed from play for the season.

#### Grade 3

Transport the athlete from the field to the nearest emergency department by ambulance if still unconscious or if worrisome signs are detected (with cervical spine immobilization, if indicated).  
Perform a thorough neurologic evaluation emergently, including appropriate neuroimaging procedures when indicated.  
Admit to hospital if any signs of pathologic process are detected or if the mental status of the athlete remains abnormal. If findings are normal at time of initial medical evaluation, the athlete may be sent home, but daily exams as an outpatient are indicated. A brief (loss of consciousness for seconds) grade 3 concussion eliminates player for 1 week, and a prolonged (loss of consciousness for minutes) grade 3 concussion for 2 weeks, following complete resolution of symptoms. A second grade 3 concussion should eliminate player from sports for at least 1 month following resolution of symptoms. Any abnormality on CT or MRI should result in termination of the season for the athlete and return to play at any future time should be discouraged.

Rapid evaluation by CT is recommended to detect the hematoma, and surgical intervention to remove the hematoma is necessary in most cases. Patients with promptly managed epidural hematomas usually have an excellent prognosis because the associated primary injury is minimal.

### Subdural Hematoma

Subdural hematomas form in the space between the dura and the outer arachnoid membrane (see Figure 44-5). The vessels traversing this area are called *bridging veins*. Bridging veins drain venous blood from the surface of the brain, crossing the arachnoid and subdural spaces before emptying into the venous sinuses. Venous sinuses are relatively fixed to the dura and are immobile, whereas the brain, which floats in the CSF, is quite mobile. With a sudden change in head velocity, as occurs with falls and vehicular accidents, the brain moves, the venous sinuses remain stationary, and the bridging veins between the two are stretched and sheared apart.

Because venous blood is under low pressure in the head, the rate of hematoma formation is usually slower than that of an epidural bleed. When subdural bleeds do produce an acute deterioration in neurologic status, the severity of the primary injury is likely to be high. Acute subdural hematomas produce symptoms within 24 hours of injury and have a worse prognosis than epidural or subacute subdural bleeds.

Subacute subdural hematomas can present a diagnostic challenge because the symptoms may be so delayed that the patient does not associate them with a head injury event. Venous bleeding is usually self-limited but may slowly progress and produce symptoms of increased ICP (headache, vomiting, blurred vision) 2 to 10 days after the primary event.

When subdural hematomas are large and sufficiently localized, they are amenable to surgical evacuation. If the subdural hematoma has been present for some time, it enters a chronic stage in which fibroblasts infiltrate the area and granulation tissue forms. Hematomas at this chronic stage are prone to rebleeding from thin-walled capillaries in the new granulation tissue. There is a high risk of rebleeding. Chronic subdural hematomas are a common finding at autopsy of elderly individuals. In addition to the increased incidence of falls, the elderly usually have some degree of cerebral atrophy, which makes the brain more mobile within the skull. In the elderly, the likelihood of damage to bridging veins is high even with minor trauma. Alcoholics and those taking anticoagulant medications are also at high risk.

The manifestations of chronic subdural hematoma may be subtle and remain undiagnosed. In the elderly, changes in mentation may be erroneously attributed to dementia. Chronic subdural hematomas are detectable by CT and MRI, and if they are symptomatic they may be managed by surgical removal of the clot and surrounding reactive tissue.

### Subarachnoid Hemorrhage

The space between the outer arachnoid membrane and the pia mater is the subarachnoid space. The pia mater is tightly bound to the surface of the brain. The subarachnoid space is filled with CSF. Traumatic subarachnoid bleeding is due to rupture of the bridging veins that pass through the space, in a manner similar to subdural bleeding. Although trauma is an important cause of subarachnoid hemorrhage, it is more commonly associated with rupture of cerebral aneurysms or arteriovenous malformations (AVMs). In that case, bleeding is arterial in origin.

Blood in the CSF manifests with meningeal irritation and a bloody spinal tap. Blood in the subarachnoid space can spread throughout the CSF spaces and may not organize into a confined hematoma. Blood in the CSF produces severe headache in the conscious person and predisposes to secondary vasospasm and ischemia. It also predisposes to clogging of ventricular drainage, which leads to hydrocephalus.

Further discussion of manifestations and management of subarachnoid hemorrhage is included in the Cerebral Aneurysm section.

## SECONDARY INJURY

TBI often initiates mechanisms of secondary injury, resulting in ischemia, increased ICP, and altered vascular regulation. Most of the research on secondary mechanisms of injury has been conducted in the TBI model. Often the damage done by secondary mechanisms far exceeds that of the primary trauma.

In contrast to other types of brain injury, patients with TBI must be carefully evaluated for skull fractures, epidural and subdural hematomas, and injuries to other body systems. Concomitant trauma may complicate the brain injury. For example, uncontrolled hemorrhage can lead to hypovolemia and hypotension, which contribute to brain ischemia. Injuries to the chest can compromise ventilation and produce hypoxemia and hypercarbia, which contribute to cerebral vessel dilation and increased ICP. Attention to other life-threatening injuries may extend the time until radiologic examination of the head can be accomplished, thus delaying surgical management of lesions.

Once the TBI patient's condition is stabilized, many other sources of secondary injury still loom. Brain swelling from both cytotoxic and vasogenic edema may increase for 48 to 72 hours after injury. Ruptured vessels may rebleed or spasm, and CSF drainage can become clogged. Open skull fractures predispose to CNS infections, as do ICP monitors, burr holes, and surgical incisions. Seizures and fever may develop, significantly increasing the brain's metabolic rate and further contributing to brain ischemia. Inflammation and free radical damage continue to cause injury to cells even after ischemia has resolved. Monitoring and managing a patient's course through the myriad perils of secondary injury requires expert knowledge and skill.

## TREATMENT

After cardiopulmonary stabilization, the first priority in the TBI patient is radiologic screening of the brain for surgically correctable lesions. Hematomas, depressed skull fractures, and bleeding vessels require prompt surgical intervention. Surgical decompression by performing a craniotomy or craniectomy and insertion of ICP monitors and/or CSF drainage devices may be done. Further therapy is individualized, seeking to maintain ICP, cerebral blood flow, and cerebral oxygen utilization within optimal ranges. Treatment recommendations are controversial, but in patients with acceptable cerebral blood flow, maintenance of normal body temperature or mild hypothermia, normal  $Paco_2$ , normal serum glucose levels, and normal intravascular volume is suggested.<sup>2,3</sup> In the acute period of injury, elevated ICP can be managed with administration of mannitol (osmotic diuretic), sedation, hypothermia, and mild hyperventilation. Repeat radiologic examination is indicated to determine if a new surgical lesion has developed. If a new lesion is not present and the patient continues to exhibit high ICP, more aggressive measures may be attempted, including diuretics, hypertonic saline, moderate hyperventilation, and barbiturate coma; however, the outcome is likely to be poor.

Patients with open head injuries may be treated with prophylactic antibiotics to prevent CNS infection. Sometimes fractures at the base of the skull are not visible on the routine CT scan but allow drainage of CSF into the nasal sinuses. Head-injured patients who have drainage of clear fluid from the ears or nose should be evaluated for basilar skull fracture. CSF drainage differs from normal nasal mucus because it has a high glucose content and tends to separate into layers (halo) on tissue paper. Other findings with basilar skull fracture are bilateral periorbital hematomas (black eyes, "raccoon sign") and bruising under

the ear (Battle sign). The presence of basilar skull fracture increases the risk of CNS infection.

Although morbidity and mortality after acute TBI remain high, significant advances in prehospital, hospital, and rehabilitative care continue to occur. The care received during the first hour of injury can dramatically affect outcome. Efforts to improve prehospital management are likely to have the greatest impact on patient outcomes.

#### KEY POINTS

- Most head injuries are incurred in motor vehicle accidents, falls, and sports accidents. Young males ages 15 to 24 years are the most common victims. The seriousness of head injury can be classified according to Glasgow Coma Scale scores as mild (>12), moderate (9 to 12), or severe (<8).
- Injury that is directly due to the initial impact is called *primary injury*. Primary injuries are classified as focal, polar, or diffuse. Focal injuries are localized to the site of skull impact. Polar injuries are due to acceleration-deceleration movement of the brain within the skull, resulting in double injury. Diffuse injury is due to movement of the brain within the skull, resulting in widespread axonal injury.
- Disruption of the vasculature can result in intracranial hemorrhage. Epidural hematomas are associated with skull fracture and progress rapidly because they are arterial in origin. Subdural hematomas are associated with shearing of bridging veins and may develop slowly. Traumatic subarachnoid hemorrhage is also due to trauma to bridging veins.
- Secondary injury is a consequence of the body's response to the primary injury. Mechanisms are similar to those described for nontraumatic brain injury. In addition, concomitant injuries and cardiopulmonary impairment may contribute.
- The management of brain injury is directed primarily to detecting and managing surgical lesions and reducing brain damage from secondary injury. Normovolemia, normothermia (or mild hypothermia), normal glucose level, and normal Pao<sub>2</sub> and Paco<sub>2</sub> values are recommended for most patients. In those with high ICP, diuretics, hyperventilation, and drug-induced coma may be tried. Open head injuries constitute a risk for CNS infections, and prophylactic antibiotics may be used.

## CEREBROVASCULAR DISEASE AND STROKE

Cerebrovascular diseases cause abnormalities of cerebral perfusion including transient ischemic attack (TIA), ischemic stroke, and hemorrhagic stroke. *Stroke* is a term applied to cerebrovascular events that result in a localized area of brain infarction and was previously termed *cerebrovascular accident* (CVA). The term *brain attack* has been popularized to educate the public about the importance of seeking care early, as is recommended for heart attack.

The symptoms of stroke usually are sudden in onset and may include the following: (1) numbness or weakness of the face, arm, or leg, especially affecting only one side of the body; (2) confusion, trouble in speaking or in understanding others; (3) visual disturbances in one or both eyes; (4) dizziness, loss of balance, and difficulty with walking; and (5) severe headache. Persons experiencing any of these symptoms, even temporarily, should seek medical care immediately.

### EPIDEMIOLOGY

More than 700,000 new and recurrent strokes occur each year in the United States, making stroke the third leading cause of death.<sup>14</sup> The majority of these victims survive, with most requiring long-term care and rehabilitation. Currently, there are about 5 million stroke

survivors living in the United States. Stroke is the leading cause of serious disability. Among long-term survivors (>6 months), 50% have **hemiparesis**, 30% cannot walk, 26% are unable to independently perform activities of daily living, 19% are aphasic, 35% are clinically depressed, and 26% are institutionalized in a nursing home. Each year approximately 55,000 more women than men have a stroke.<sup>4</sup> Stroke death rates are significantly higher for black males and females than for their white counterparts.

Risk factors for stroke are similar to those for other atherosclerotic vascular diseases and include hypertension, diabetes, hyperlipidemia, cigarette smoking, advancing age, and family history. A previous stroke significantly increases the risk for suffering a subsequent stroke. Cardiac disease complicated by atrial fibrillation is an important risk factor for embolic types of strokes. Strokes can be categorized according to cause as ischemic and hemorrhagic strokes. Ischemic strokes are by far the most common (87%) and include thrombotic and embolic types.<sup>14</sup>

### ISCHEMIC STROKE

Ischemic strokes result from sudden occlusion of a cerebral artery secondary to thrombus formation or embolization. Thrombotic and embolic strokes are grouped together because the clinical presentation and treatment are similar. However, etiologic risk factors and preventive measures are different and are discussed separately.

Thrombotic strokes are associated with atherosclerosis and hypercoagulable states. Risk reduction strategies for thrombotic stroke are those aimed at reducing atherosclerosis and platelet aggregation. Significant atherosclerotic plaques in the carotid arteries are sometimes evident as carotid bruits. Assessment for the presence of carotid bruits in all individuals older than 50 years may help identify persons at risk so that prevention strategies can be initiated early.

Emboli usually are from a cardiac source, although disruptions in carotid artery plaques may lead to downstream embolization. Cardiac sources include thrombi formed in the cardiac chambers (mural thrombi) and thrombi or vegetations on valve leaflets. Because atrial fibrillation allows stagnation of blood in the left atrium, it is associated with a high risk of mural thrombi, which can dislodge and travel to the cerebral circulation. Patients with chronic atrial fibrillation commonly receive anticoagulant medications to prevent this occurrence.

Sudden blockage of a cerebral artery by a thrombus or embolus produces acute ischemia in the territory served by the artery. Insufficient blood flow to brain tissue results in oxygen deprivation and rapid cerebral deterioration. Neurologic deficits become evident after just 1 minute of insufficient oxygen. If the ischemia continues for several minutes, irreversible cellular damage can occur. With further progression, the local area becomes infarcted and necrotic. Surrounding the infarct is a much larger area of ischemic but viable cells, called the **penumbra**. The penumbra receives some partial or collateral flow and may recover if the ischemia is mild or perfusion is restored in a timely manner. Salvaging the penumbra is the aim of early thrombolytic therapy; however, treatment must be instituted within 3 hours of stroke onset to be maximally effective.

In some cases, the obstructing clot is efficiently lysed by the endogenous fibrinolytic system before permanent tissue damage occurs. If the associated neurologic deficits completely resolve, the episode is called a *transient ischemic attack* (TIA). The neurologic symptoms of a TIA typically last only minutes, but they may last as long as 24 hours. Symptoms resolve completely without evidence of neurologic dysfunction. TIAs are important warning signs of thrombotic disease and carry a significant risk for subsequent stroke. Approximately 15% of strokes are preceded by TIA.<sup>14</sup>

Patients who present with TIAs should undergo evaluation to determine the origin of their symptoms. Unless contraindicated, these patients are started on daily aspirin therapy to prevent thrombus formation. Carotid endarterectomy or angioplasty may prevent stroke in a subset of patients experiencing TIAs who have carotid artery plaques occluding more than 70% of the arterial lumen.<sup>15</sup>

Manifestations of ischemic stroke are related to the cerebral vasculature involved (Figure 44-14) and the area of brain tissue the vessel supplies. The middle cerebral artery is most commonly occluded, resulting in damage to the lateral hemisphere. Contralateral **hemiplegia**, hemisensory loss, and contralateral visual field blindness are usual. If the dominant hemisphere is affected, global aphasia will occur. Occlusions of smaller branches of the middle cerebral artery produce more limited neurologic findings. Occlusions of the other cerebral

arteries have different neurologic manifestations depending on the brain area they normally perfuse (Table 44-2).

Occlusion of the small penetrating arterioles can produce small lesions called *lacunar infarcts*. The basal ganglia, pons, cerebellum, and internal capsule are common sites of lacunar infarcts. These lesions are sometimes not observable on CT scan. The prognosis for recovery from a lacunar infarct is usually good, and neurologic manifestations are more circumscribed, often affecting purely motor or sensory functions.

## HEMORRHAGIC STROKE

Intracerebral hemorrhage is a hemorrhage within the brain parenchyma and usually occurs in the context of severe and often long-standing hypertension. It carries a 38% mortality, with death usually

**FIGURE 44-14** Cerebral vasculature showing fields of perfusion.

**TABLE 44-2 MANIFESTATIONS OF ISCHEMIC STROKE ACCORDING TO LOCATION OF ARTERIAL BLOCKAGE**

CEREBRAL ARTERY	TERRITORY OF PERFUSION	CLINICAL MANIFESTATIONS
Anterior cerebral	Medial aspect of frontal lobes	Contralateral hemiparesis; contralateral sensory loss; impaired cognition and decision making; aphasia (left-sided stroke); incontinence
Middle cerebral	Most of lateral cerebral hemisphere, internal capsule, and basal ganglia	Contralateral hemiplegia; contralateral sensory loss; aphasia (left-sided stroke); homonymous hemianopsia; altered consciousness; neglect syndrome
Posterior cerebral	Occipital lobe and medial aspect of temporal lobe	Visual defects including homonymous central blindness and color blindness; memory impairment
Basilar and vertebral	Thalamus, cerebellum, and brainstem	Sensory loss; mild hemiparesis; disturbances of gait, speech, swallowing, and vision

occurring within minutes to hours.<sup>14,16</sup> In contrast, subarachnoid hemorrhage occurs under the arachnoid membrane and above the pia mater. Two common structural abnormalities that can cause subarachnoid hemorrhage (cerebral aneurysms and arteriovenous malformations) are discussed in the Cerebral Aneurysm and Arteriovenous Malformation sections. Most intracerebral hemorrhagic strokes occur in the basal ganglia or thalamus (see Figure 44-10). If the hemorrhage is large, it may significantly increase ICP, which can lead to herniation and death. The prognosis for hemorrhagic stroke depends on the patient's age, the location and size of the hemorrhage, and the speed at which the hemorrhage produces brain distortion and shift. The degree of secondary injury and associated morbidity and mortality is significantly higher for hemorrhagic stroke than for ischemic stroke.

## TREATMENT

Initially, after the patient's airway, respiratory status, and cardiovascular function are assured, an assessment of stroke severity and associated neurologic deficits is made. An initial CT scan is used to determine the type of stroke and treatment, because treatment pathways differ between ischemic and hemorrhagic stroke. Patients who have experienced a hemorrhagic stroke secondary to hypertensive disease often have extremely high blood pressure. Returning their blood pressure into normotensive ranges could result in ischemia. In these circumstances it is best to keep the patient mildly hypertensive with the goal of normalizing the blood pressure once the patient is medically stable.<sup>16,17</sup> Patients who have experienced a hemorrhagic stroke are at risk for increased intracranial pressure and are assessed and treated similar to patients with a traumatic brain injury. Thus, the remaining discussion will focus on treatment of ischemic stroke.

The goals of therapy for acute ischemic stroke are to minimize infarct size and preserve neurologic function. Aspirin may be administered following negative findings of hemorrhagic stroke on CT scan. The administration of 325 mg of aspirin immediately affects platelet aggregation and may help inhibit thrombus size. Thrombolytic therapy is most effective in limiting infarct size if it is initiated early.

It is critical to prevent further cerebral hypoxia or ischemia after ischemic stroke. Thus, volume depletion, hemoconcentration, hypotension, and arterial obstruction must be avoided. As with the hemorrhagic stroke patient, careful blood pressure management is critical. Overhydration can result in cerebral edema in the ischemic area of the brain and raise ICP. Patients should have their ability to swallow evaluated *before* they take any food or liquids orally. Injury to cranial nerves V, VII, IX, X, or XII can place a patient at risk for respiratory aspiration and further compromise the individual's health and potential for recovery.

Anticoagulation therapy may be used in ischemic stroke, especially if the event is progressive. A stroke is termed *progressive* if an initial focal deficit worsened or fluctuated before hospital admission or deteriorated on serial examinations after admission. Patients who receive thrombolytic therapy should not receive anticoagulation therapy because the risk of bleeding is high. Throughout the course of therapy, it is essential to monitor clotting parameters and recognize the potential for hemorrhage into the ischemic area. Even in the absence of thrombolytic or anticoagulant therapy, a significant number of ischemic strokes convert to hemorrhagic lesions. A sudden change in neurologic function should prompt reevaluation by CT. Trials of medications called free radical scavengers appear promising for reducing lesion size for certain CVA types.<sup>18</sup>

Management of the stroke patient also must include efforts to prevent stroke recurrence. Evaluation and management of risk factors is an essential part of prevention. The survivor of a stroke is at high risk

for a subsequent stroke if precipitating factors are still present. Patients who have experienced thrombotic strokes are also at significant risk for other vascular events, such as myocardial infarctions. Secondary prevention varies according to the cause of the stroke. For hemorrhagic strokes, careful monitoring and control of blood pressure is essential. For ischemic strokes of embolic origin, identifying and removing the source of emboli is crucial. Usually the source is the heart, and therapy includes control of dysrhythmias, implementation of anticoagulation therapy, and administration of antiplatelet drugs such as aspirin. The most common cause of embolic stroke is atrial fibrillation. Conversion of this dysrhythmia to normal sinus rhythm can sometimes be accomplished with antidysrhythmic agents or electrical cardioversion. Measures to improve left ventricular function may help to reduce atrial pressure and correct atrial fibrillation. Patients with long-standing atrial fibrillation require anticoagulation therapy. When abnormal valves are suspected to be the source of emboli, evaluation for surgical replacement may be indicated.

Secondary prevention for thrombotic stroke includes lifestyle modifications to address modifiable risk factors, including smoking cessation and lowering of serum lipid levels. In addition, the long-term daily use of aspirin or other antiplatelet agents (e.g., clopidogrel bisulfate) has been recommended. Some patients may benefit from surgical removal of carotid artery plaque by endarterectomy or angioplasty. Placement of rigid tubes, called *stents*, in the area of plaque removal may be helpful in preventing reocclusion.

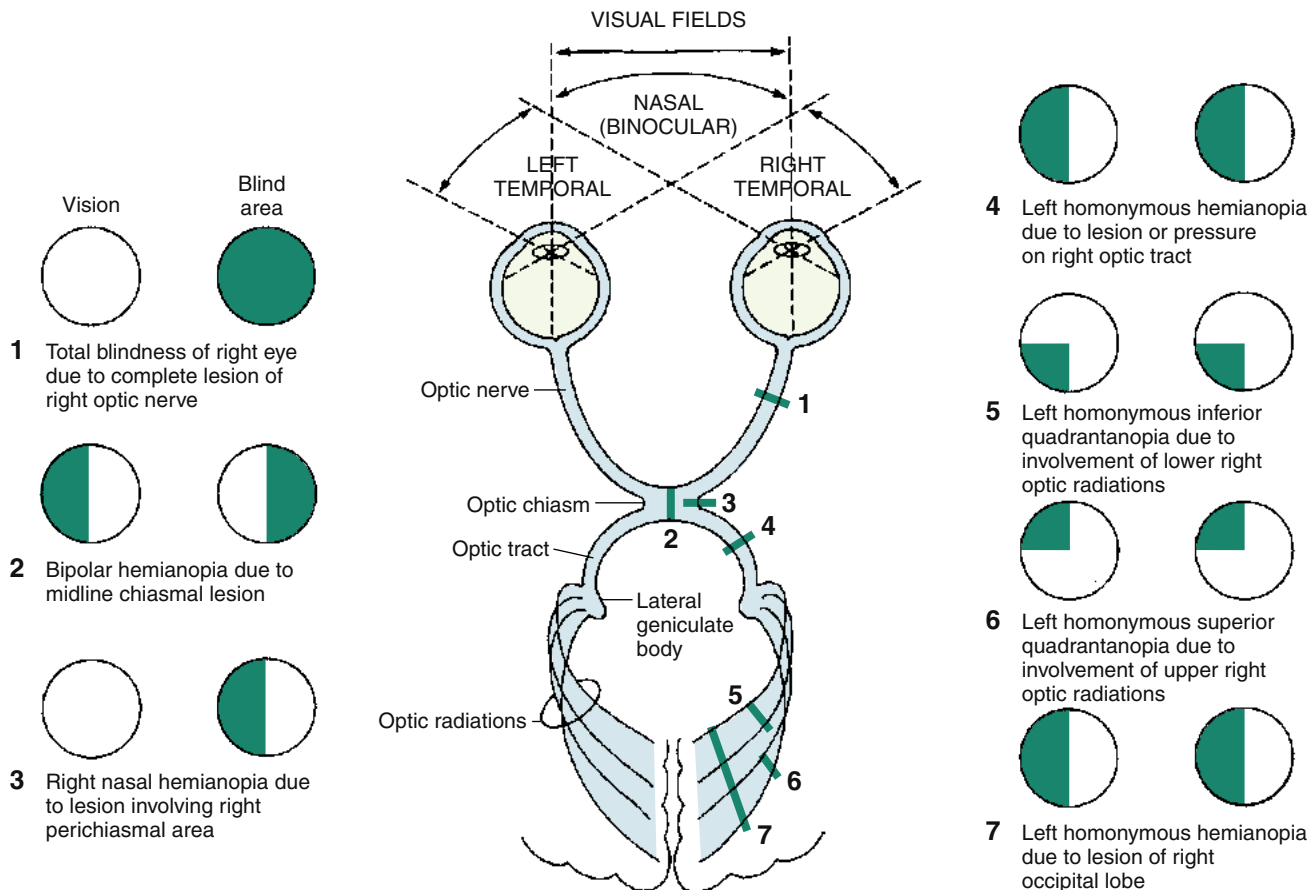

## STROKE SEQUELAE

Recovery after stroke depends on the size and location of the cerebral infarct, comorbid conditions, and rehabilitative efforts. Stroke rehabilitation begins during the acute hospitalization phase and continues after the patient has returned to the community. Many patients have residual or permanent deficits in motor, sensory, language, and cognitive functions that necessitate intensive strategies to maximize the likelihood of return to a productive life.

### Motor and Sensory Deficits

Motor impairment from a stroke is initially characterized by flaccidity, which is a decrease in or absence of muscle tone in the affected extremities. Most commonly, motor paralysis is contralateral to the side of the brain in which the stroke occurs. Thus a stroke on the right side of the brain results in left-sided body paralysis, whereas left brain strokes result in right-sided body paralysis. Footdrop, outward rotation of the leg, and dependent edema are common features in the lower extremity. In the upper extremity, the arm may separate from the shoulder if not supported. Muscles in the affected limbs tend to atrophy from lack of tone and use. Many of the complications can be limited with therapeutic interventions, including performing frequent range-of-motion exercises, elevating edematous limbs, wearing elastic stockings, and maintaining body alignment.

Starting at about 6 weeks after the stroke, recovery of motor function is evident by the onset of spasticity. Spasticity is the resistance of muscle groups to passive stretch with an increase in tone. Increased flexor tone is usually seen in the upper extremities and increased extensor tone in the lower extremities. Performing passive or active range-of-motion exercises and maintaining proper body position are critical to maintenance of function, because uncontrolled spasticity can result in contractures of the limbs, including adduction of the shoulder, pronation of the forearm, and flexion of the fingers. In the lower extremity, the patient may have problems with hip and knee extension. If spasticity in a paretic extremity is not evident within 3 months, motor function is not likely to return to the affected limb.

**FIGURE 44-15** Homonymous hemianopia (also called hemianopia). A right-sided brain stroke may cause lesions that disturb visual fibers and result in blindness in the left visual field. The optic pathway from the other side remains intact. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1850.)

Sensory impairment occurs in the same locations as the motor paralysis. A lack of sensory information from the paralyzed side contributes to the phenomenon of *neglect* (also called *hemiattention*). The patient seems unaware that the affected body parts belong to him or her. Loss of the visual field on the paralyzed side also contributes to neglect. Contralateral field blindness is called *homonymous hemianopsia* (also called hemianopia) because the same side of the retina in each eye is blinded (Figure 44-15). Patients with neglect may crush, burn, or otherwise injure the neglected body parts without realizing it. Poor hygiene of affected extremities may be apparent. Neuropsychological studies have shown that objects in the field of neglect are usually ignored. For example, when asked to draw the numbers on the face of a clock, all 12 are drawn on one side. Self-portraits may be conspicuous for the distortion or omission of structures on the neglected side. Neglect is associated with a high risk for falls and other injuries.

### Language Deficits

**Aphasia** is an integrative language disorder that occurs with brain damage to the dominant cerebral hemisphere (usually left) and involves all language modalities. Characteristics of aphasia include a reduced vocabulary, reduced verbal attention span, and reduced ability to use learned linguistic rules. Aphasia is associated with lesions in the primary language centers (Broca and/or Wernicke areas) as well as in adjacent cortical areas. Aphasia is categorized according to the location of the lesion and the linguistic deficit. The following is a brief description of those categories.

Broca aphasia, also known as verbal motor or expressive aphasia, results from a lesion in the third frontal convolution of the left hemisphere in most persons. Patients speak with poorly articulated and sparse vocabulary and in the simplest grammatical constructions.

Wernicke aphasia, also known as sensory, acoustic, or receptive aphasia, is characterized by impaired auditory comprehension and speech that is fluent but empty of content. This form of aphasia is caused by lesions in the posterior portion of the first temporal gyrus of the left hemisphere. Speech is frequently circumlocutory or tangential and contains paraphasic errors and jargon. Word finding and naming difficulties are a prominent feature of this disorder. Patients with Wernicke aphasia are unable to monitor their own language production and cannot comprehend or monitor the language production of others.

Anomic aphasia results from lesions in the parietotemporal area in proximity to the angular gyrus. This is a fluent aphasia with intact grammatical structure. Patients have greater word finding difficulties than those with Wernicke aphasia but do not make paraphasic errors and have intact comprehension. However, their speech is typically constructed of simple words.

Conduction or central aphasia is associated with increased paraphasic errors and a reduced ability to repeat words. It is associated with a lesion in the arcuate fasciculus in the left hemisphere. Patients are well aware that they are making language errors. However, the more they struggle to find the correct words, the more likely they are to repeat paraphasic errors.

## Cognitive Deficits

Patients experience impairments of cognition attributable to diffuse cortical or subcortical injuries that affect the ability to be alert, to concentrate or attend to stimuli, to remember, and to reason. Cognitive impairment varies according to the area of brain affected and the severity of the injury. Injuries that disturb an individual's ability to maintain an alert status are the most severe. Increasing cognitive skill is necessary for the function of memory and the ability to learn and associate, to discriminate, to separate, and to categorize various stimuli. The highest levels of cognitive function include analysis, synthesis, and reasoning abilities.

Cognitive impairment is commonly evidenced as language deficit, impaired spatial relationship skills, short-term memory impairment, and poor judgment. Patients who do not retain the ability to learn are unlikely to benefit from rehabilitative services.

### KEY POINTS

- Stroke is the sudden onset of neurologic dysfunction attributable to cerebrovascular disease. The most common cause of stroke is thrombosis, followed by embolization and intracranial hemorrhage.
- Thrombi form at atherosclerotic plaques, causing sudden occlusion of an already narrowed vessel. If the clot is quickly lysed, the deficits may completely disappear, a phenomenon associated with a TIA. Emboli are usually a consequence of clots from within the heart chambers caused by disease or dysrhythmia. Hemorrhagic stroke is usually associated with uncontrolled hypertension.
- Stroke symptoms depend on the area of brain affected, which in turn depends on the vessel occluded: internal carotid, anterior cerebral, middle cerebral, or posterior cerebral artery. Common manifestations include contralateral motor and sensory loss, aphasia, and contralateral visual field loss.
- Treatment is aimed at limiting the size of the brain infarction, supporting bodily functions, and initiating aggressive rehabilitation strategies. Acute therapy with thrombolytic agents may limit infarct size in patients with ischemic stroke.
- Stroke is associated with long-term deficits in motor, sensory, language, and cognitive abilities. Initially, affected muscles are flaccid, with spasticity occurring after about 6 weeks. Prevention of contractures is a major concern. Aphasia may be described as expressive or receptive. Most individuals with aphasia have impaired integrative ability involving all language modalities. Concentration, memory, and reasoning may be impaired.

## CEREBRAL ANEURYSM AND ARTERIOVENOUS MALFORMATION

Structural abnormalities of the cerebral arteries predispose individuals to intracerebral bleeding and hemorrhagic stroke. Cerebral aneurysms and arteriovenous malformations (AVMs) are the two most common causes of subarachnoid hemorrhage. Early recognition and surgical management of these conditions are necessary to prevent significant mortality and morbidity associated with rupture.

### Cerebral Aneurysm

**Etiology.** An aneurysm is a lesion of an artery that results in dilation and ballooning of a segment of the vessel. Aneurysm rupture occurs in about 30,000 Americans each year; 60% of these individuals will either die or suffer permanent disability.<sup>19</sup> The prevalence is higher in women than in men, and rupture most often occurs between the ages of 30 and 60 years. Intracerebral aneurysms are found in about 6% of the general population, and more than half remain unruptured

**FIGURE 44-16** Saccular (berry) aneurysms are most commonly found in the circle of Willis, particularly at arterial bifurcations. (From Kumar V et al: *Robbins and Cotran pathologic basis of disease*, ed 8, Philadelphia, 2010, Saunders, p 1297.)

and undiagnosed.<sup>19,20</sup> Thus, other factors are likely to be important in precipitating aneurysm rupture. High blood pressure, acute alcohol intoxication, and recreational drug use (especially cocaine) have been implicated. The annual risk of rupture in persons with aneurysms is 1% to 2%. Larger aneurysms and those located in the posterior circulation are more prone to rupture.

**Pathogenesis and manifestations.** Although the exact pathogenesis is not understood, saccular aneurysms are believed to result from congenital defects of the medial layer of the artery. This structural weakness permits gradual ballooning at the site as a consequence of arterial pressure effects over years. A common location for saccular aneurysms is arterial bifurcations, where turbulent blood flow might have a greater impact on a weakened vessel wall. Ninety-five percent of cerebral aneurysms are located in the circle of Willis; 10% to 20% of affected individuals have more than one aneurysm.

Saccular aneurysms (berry aneurysms) are round and are the most common (Figure 44-16). The aneurysmal sac is composed of thickened intima and adventitia layers, with the medial layer having abruptly ended at the sac edge (Figure 44-17). Rupture of the aneurysm generally occurs from the dome of the sac or at the edge of the atheromatous plaque.

The development of aneurysms is a multifactorial interaction of acquired factors, such as atherosclerosis or hypertension, and congenital predisposition, and aneurysm development is associated with various vascular abnormalities. Multiple conditions have been associated with cerebral aneurysms including autosomal dominant inherited polycystic kidney disease, Marfan syndrome, Ehler-Danlos syndrome, lupus, and bacterial endocarditis, among others.<sup>19</sup>

Warning leaks may occur before an aneurysm ruptures and often produce severe headache, which is typically described by the patient as “the worst headache I have ever had.” The frequency of true “warning leaks” is unknown, but rapid evaluation of patients presenting with new onset of severe generalized headache is warranted.<sup>20</sup> Patients may also complain of photophobia (visual sensitivity to light), nausea/vomiting, and stiff neck. A stiff and painful neck results from meningismus caused by the irritating properties of blood in the CSF. After rupture, the onset of symptoms is very rapid. Sudden injection of blood into

**FIGURE 44-17** Gross view of a massive saccular aneurysm in the circle of Willis. (From Kumar V et al: *Robbins basic pathology*, ed 8, Philadelphia, 2007, Saunders, p 867.)

the subarachnoid space raises ICP and distorts intracranial structures. Secondary cerebral vasospasm, a pathologic narrowing of the major vessels around the area of rupture, typically occurs from day 4 to day 14. This process significantly reduces cerebral blood flow and results in increased cerebral ischemia and possibly infarction. Vasospasm is due to the presence of blood in the CSF. The next most serious consequence of the initial rupture is rebleeding. The risk for rebleeding is highest in the first 14 days. Patients are also at risk for developing hydrocephalus from clogging and obstruction of CSF flow through the ventricular system.

Diagnostic procedures for detecting a ruptured aneurysm include CT or MRI to confirm a subarachnoid hemorrhage. If the scan is negative but suspicion of subarachnoid hemorrhage is high, a lumbar puncture for CSF analysis can be done. Blood in the CSF is indicative of subarachnoid hemorrhage. A cerebral angiogram is obtained to demonstrate the location of aneurysms in preparation for surgical management.

**Treatment.** The primary treatments for aneurysms are surgical stabilization by clipping or placement of endovascular coils for embolization. Prognosis is favorable if the aneurysm is detected and managed before significant rupture occurs. In most cases, the aneurysm is not diagnosed until after subarachnoid or intracerebral hemorrhage has occurred, and mortality is higher. Early surgery in stable patients with subarachnoid hemorrhage is associated with a lower overall mortality. Aneurysm clipping is accomplished by placement of a permanent vascular clip at the neck of the aneurysm. Coil devices may be inserted under radiographic guidance to thrombose or sclerose the area.

In patients experiencing subarachnoid hemorrhage as a consequence of a ruptured aneurysm, the complications of cerebral vasospasm and hydrocephalus must be monitored and managed. Vasospasm can be managed by keeping blood volume and blood pressure at normal to high levels. Calcium channel blockers may be used to reduce vasospasm. In addition to hemodynamic monitoring, careful and frequent neurologic assessments are essential to monitor stability and indicate the first signs of deterioration so that rapid intervention can be undertaken.

### Arteriovenous Malformation

**Etiology.** AVMs are the second most common cause of spontaneous subarachnoid hemorrhage, but can also cause intracerebral hemorrhage. The majority of AVMs are diagnosed in patients between 10 and 30 years, and are located in the cerebral hemispheres.<sup>20,21</sup> AVMs are vascular lesions thought to be congenital; however, they are rarely

diagnosed in the pediatric population. AVMs are more frequent in men and rarely follow a familial pattern.<sup>21</sup>

The risk of clinically recognizable hemorrhage from an AVM is 2% to 4% per year.<sup>21</sup> The risk of rebleeding within the first year after an initial hemorrhage is approximately 2% to 4%.<sup>21</sup>

**Pathogenesis and manifestations.** In the normal vascular system, the capillaries are situated between the arterioles and the venules. In an AVM, the capillary system fails to develop appropriately, and arterial blood is shunted directly into the venous system. Exposure of the high-capacitance venous system to the high pressure of the arteries causes the vessels to progressively enlarge, as do the arteries and veins that feed and drain the lesion. The blood vessels that comprise the AVM proliferate and enlarge over time. AVMs were once considered purely a congenital abnormality, however, numerous endothelial growth factors and vascular substances have been identified that continue to affect the structure and function of these abnormal vessels and contribute to the risk of rupture and hemorrhage.<sup>22</sup>

Because of their abnormal structure and the high vascular pressure, AVMs are vulnerable to hemorrhage. Hemorrhage is the initial manifestation in 50% of cases of AVM; 30% are manifested by seizures and the rest by varying degrees of vascular steal syndrome. The abnormal shunting of blood into the AVM, called *vascular steal syndrome*, causes progressive neurologic dysfunction as a result of ischemia in normal tissue.

**Treatment.** Once the AVM and vascular bed are evaluated, the AVM may be surgically removed. Alternatively, gamma knife or stereotactic radiosurgery can be used to deliver precisely aligned beams of gamma radiation to shrink the abnormal vascular tissue. For deep or very large AVMs, other approaches (e.g., irradiation and glue embolization) may be used.<sup>20</sup> Supportive therapy for AVMs that rupture and cause subarachnoid hemorrhage is similar to that described for ruptured cerebral aneurysms.

#### KEY POINTS

- Cerebral aneurysms and arteriovenous malformations are the two most common causes of subarachnoid hemorrhage. Aneurysm is most common and has a higher mortality rate.
- Blood in the subarachnoid space is associated with headache, stiff neck, and secondary cerebral vasospasm. Vasospasm, which leads to cerebral ischemia, is an important cause of morbidity and mortality.
- Aneurysms are congenital weaknesses in the arterial walls that lead to dilation and ballooning of the wall. Treatment includes surgical stabilization by clip ligation and aggressive management of secondary vasospasm.
- AVMs are congenital malformations in which arterial blood is shunted directly into the venous system, causing high venous pressure. The AVM enlarges and may compress adjacent structures or rupture. Surgical management, radiation, or glue embolization to occlude the AVM may be done to prevent bleeding.

## CENTRAL NERVOUS SYSTEM INFECTIONS

Infections of the CNS include meningitis, encephalitis, and abscesses. Organisms gain access to the CNS by various portals of entry. These include via the bloodstream, by direct extension from a primary site (e.g., sinuses), by extension along peripheral and cranial nerves, and through maternal-fetal exchange. Factors contributing to infections include such conditions as immunocompromised status, debilitation, poor nutrition, radiation therapy, steroid therapy, and contact with vectors. Meningitis and cerebral abscess are most commonly associated with bacterial infections, whereas encephalitis is usually viral.

## Meningitis

Meningitis is the most common sequela to microbial invasion of the CNS. Most frequently, meningitis is bacterial in origin, but it can also be viral or fungal. Persons with acquired immunodeficiency syndrome (AIDS) have an increased susceptibility to infection and have an increased prevalence of meningitis of viral, fungal, or parasitic origin.

**Etiology.** The bacterium most frequently involved in causing meningitis in adults is *Streptococcus pneumoniae*. *Haemophilus influenzae* type B (HIB) incidence has fallen dramatically since the introduction of the HIB vaccines.<sup>23</sup> The bacteria that cause meningitis usually reach the CNS by way of the bloodstream or by extension from cranial structures, such as the paranasal sinuses or ears. Some of the organisms responsible for causing meningitis may be normal inhabitants of the nasopharynx. Pathogens can also gain access to the CNS through breaks in the barrier system, as occur with penetrating head wounds or skull fractures or following neurosurgery in which the dura is penetrated. The overall mortality rate for meningitis is highest for individuals 65 years of age and older (23%) whereas that for infants is 7%. Survivors of meningococcal disease have an 11% to 19% chance of ongoing neurologic deficits.<sup>24</sup>

**Pathogenesis and clinical manifestations.** Bacterial meningitis is a **pyogenic** infection that invades the **leptomeninges** and the subarachnoid space. Because of its involvement in the subarachnoid space, the infection travels readily around the brain and spinal cord. The accumulation of inflammatory exudate frequently results in obstructive hydrocephalus and exudative invasion into the sheaths of the blood vessels and spinal and cranial nerves.

The combination of headache, fever, stiff neck (meningismus), and signs of cerebral dysfunction (confusion, delirium) is the classic presentation of meningitis. Deterioration in level of consciousness is progressive and often rapid. Patients who deteriorate rapidly often demonstrate dramatic tachypnea. About one third of patients experience seizures. Cranial nerve involvement is also common and is most often seen as ocular palsies, facial weakness and/or deafness, and vertigo.

The diagnosis of meningitis is usually made by lumbar puncture. Typical CSF findings are shown in Table 44-3. Gram stain of the CSF will reveal the causative organism in most patients. In addition to the causative organism, classic CSF findings include white blood cell counts between 1000 and 10,000/mm<sup>3</sup> with a predominance of neutrophils. The CSF glucose level is reduced and often extremely low, and patients with bacterial or fungal meningitis have increased protein levels.

**Treatment.** Recovery from bacterial meningitis depends largely on how quickly effective treatment is started. Treatment includes general supportive care, intravenous antibacterial drug therapy targeting the specific pathogen, and management of any complications. Complications from meningitis can include visual impairment, optic neuritis, deafness, headache, seizures, personality changes, motor weakness, hydrocephalus, endocarditis, and pneumonia. Much of the damage to CNS structures is not a direct result of the pathogen; rather, it is the immune response that is injurious. Antibiotic therapy, with resultant bacterial cell wall lysis, can increase the immune-mediated injury. This has led some investigators to recommend the use of corticosteroids during the antibiotic treatment phase. However, treatment with dexamethasone remains controversial.<sup>23,24</sup>

Prevention strategies include public education promoting prompt and appropriate management of sinusitis, mastoiditis, ear infections, and pneumonia. Strict aseptic techniques for all procedures involving a break in the CNS barrier system may help prevent nosocomial CNS infections. Vaccination against *Neisseria meningitidis* provides short-term protection (a few years) and may be useful before situations in which exposure is more likely, such as during the college years.

**TABLE 44-3 TYPICAL CEREBROSPINAL FLUID FINDINGS IN BACTERIAL MENINGITIS**

CSF VARIABLE	TYPICAL FINDINGS	NORMAL
White blood cell count	1000-5000 cells/mm <sup>3</sup> (up to 10,000) (high)	<5 cells/mm <sup>3</sup>
Neutrophils	≥90% (high)	60-80%
Protein	80-500 mg/dl (high)	30 mg/dl
Glucose	≤40 mg/dl (low)	50-80 mg/dl
Gram stain	Positive (60-90% of cases)	Negative
Culture	Positive (70-85% of cases)	Negative
CSF opening pressure	>20 cm H <sub>2</sub> O (high)	<15 cm H <sub>2</sub> O

CSF, Cerebrospinal fluid.

## Encephalitis

**Etiology.** Encephalitis, an inflammation of the brain, can be caused by a variety of agents including viruses, bacteria, fungi, and parasites. Viral causes account for the vast majority of encephalitis cases. According to the Centers for Disease Control and Prevention (CDC), approximately 20,000 cases of acute viral encephalitis are reported annually in the United States.<sup>25</sup> Death occurs in 5% to 20% of affected individuals and another 20% are left with residual neurologic deficits of varying severity. In herpes simplex encephalitis, approximately 50% of patients die or are left with impairment. Western/eastern equine and West Nile infections only cause death or neurologic deficit in 5% to 15% of patients.<sup>25</sup> Herpesviruses are by far the most common viral cause. It is almost always associated with herpes simplex virus type 1 (HSV-1), which is also the cause of herpetic lesions of the oral mucosa; however, it can also be caused by HSV-2. Western equine and West Nile viruses are arthropod-borne viruses transmitted to humans primarily through the bites of infected mosquitoes or insects.<sup>25,26</sup>

**Pathogenesis and manifestations.** HSV-1 encephalitis occurs sporadically in healthy and immunocompromised adults. The HSV-1 virus lies dormant in the trigeminal nerve and is reactivated, or infects the nose and travels along the olfactory tracts. HSV-2 can be transmitted to neonates during vaginal delivery. Once across the blood-brain barrier, the virus enters the neurons and disrupts cellular functioning, causing bleeding and inflammation. HSV forms intense hemorrhagic necrosis of the inferior and medial temporal lobes and mediobasal parts of the frontal lobe.<sup>25</sup>

Clinical manifestations of HSV encephalitis typically evolve over several days and commonly include fever, headache, seizure, confusion, stupor, and coma. Hallucinations, personality changes, and psychotic behavior also may occur. Lumbar puncture shows increased opening pressure with elevated numbers of white blood cells (WBCs). Rarely do red blood cells (RBCs) appear in the CSF despite the hemorrhagic nature of the lesions. CSF protein level may be elevated and glucose level will likely be normal. CT and MRI may show characteristic scattered hemorrhages with surrounding edema.

Western/eastern equine virus is transmitted by mosquitoes—birds serve as a host as well as humans. It is primarily a disease of summer months. It most often infects the very young and those older than 50. Once inside the CNS these viruses infect neurons and cause severe immunopathology and apoptosis. The mechanism used by these viruses to cross the blood-brain barrier and invade the CNS is unclear. However, case studies show that underlying hypertension and vascular disease may predispose individuals to neuroinvasive disease.<sup>26</sup>

Onset of symptoms is generally rapid and includes malaise, mild headache, and often nausea and vomiting. A moderately elevated

temperature develops and the headache usually becomes more severe. In an uncomplicated infection, symptoms persist about 10 days and gradually resolve. In severe cases, lethargy progresses to stupor alternating with extreme restlessness. In fatal cases the progression of the disease is rapid, culminating in coma and death.

**Treatment.** In general, the management of encephalitis is supportive and symptomatic. As with all severe illnesses, respiratory and cardiovascular support is imperative. Patients with encephalitis must be carefully hydrated because they frequently show signs and symptoms of excessive antidiuretic hormone secretion and water retention. Those with moderate to severe disease require careful and ongoing neurologic assessment. Seizures are a common complication in encephalitis secondary to hypoxia, tissue destruction, toxic encephalopathy, inflammatory vasculitis, and hyponatremia. All patients with moderate to severe illness should be monitored for intracranial hypertension. Although there is no definitive drug treatment, steroids may be given to control edema, anticonvulsants to prevent seizures, analgesics to relieve headaches, and antipyretics to control hyperthermia. Patients in whom herpes simplex encephalitis has been diagnosed should be treated with antiviral medications such as acyclovir.

### Brain Abscess

**Etiology.** A brain abscess is a localized collection of pus within the brain parenchyma. **Pyogenic** (pus-producing) pathogens reach the brain by a number of routes, including (1) penetrating wounds, (2) direct extension or retrograde thrombophlebitis of an infected neighboring structure (e.g., mastoiditis, sinusitis), or (3) bloodborne dissemination from a distant infected site (e.g., the lungs). Most brain abscesses are bacterial. The most common infective organisms are streptococci, staphylococci, and anaerobes.<sup>27</sup>

**Pathogenesis and manifestations.** Brain abscess presents as a space-occupying lesion in the brain. Most patients experience symptoms 1 to 4 weeks after the initial infection. The abscess has a focal infected core in which the central portion contains an abundance of neutrophils and tissue debris (pus). The peripheral portion of the abscess consists of inflammatory granulation tissue. Around the abscess is perifocal edema with proliferation of surviving astrocytes. In the chronic phase, the core of the abscess is liquefied and the peripheral portion forms a collagenous capsule that in turn is surrounded by fibrous gliosis. A CT scan typically shows an outer ring surrounding a low-density core (Figure 44-18).

**Treatment.** Management of a brain abscess depends on its location and accessibility, and usually involves drainage or excision. A critical feature in management is the administration of intravenous antibiotics, which is required for several weeks. Recently, the treatment of patients with brain abscess has become increasingly challenging because of the increase in unusual bacterial, fungal, and parasitic infections, particularly in immunosuppressed patients. Postinfection care must address residual neurologic deficits of cognitive, motor, or sensory function.

**FIGURE 44-18** CT scan of a cerebral abscess showing typical ring with decreased core density and an edematous area surrounding the abscess. (From Yousem DM, Grossman RI: *Neuroradiology*, ed 3, St Louis, 2010, Mosby, p 199.)

#### KEY POINTS

- Meningitis is usually a consequence of bacterial infection in the CNS. Infection may be introduced through the bloodstream or by invasion from infected sinuses or ears. Fever, stiff neck, and headache are common. Seizures may occur. The diagnosis is based on an elevated CSF white blood cell count and the presence of bacteria in the CSF.
- Obstructive hydrocephalus is a serious complication of meningitis that leads to increased ICP. Antibiotics are used for treatment.
- Encephalitis is inflammation of the brain that is most commonly due to viral infection. Common causes of viral encephalitis in the United States include West Nile virus, Western equine encephalitis, and herpes simplex virus. Management is based on symptoms and may include steroids, anticonvulsants, analgesics, and antipyretics. Antiviral agents (e.g., acyclovir) are helpful in the treatment of herpes simplex encephalitis.
- Brain abscesses are usually due to pus-forming bacteria. Abscesses may be asymptomatic at first, later showing manifestations of a progressive space-occupying lesion. Drainage or excision and antibiotics are indicated.

### SUMMARY

Acute disorders of brain function are characterized by rapidly progressing neurologic deficits and life-threatening complications. The cellular pathophysiologic process is similar for most types of brain injury and includes mechanisms of ischemia, cellular calcium overload, and free radical and immune-mediated damage. The development of increased ICP with compression of vital brain structures is a potential complication of all types of brain injury.

Efforts to minimize brain damage focus on recognizing and managing secondary brain damage. Careful monitoring and management of body temperature, blood pressure, volume status, and respiratory function are essential. Efforts to reduce brain ischemia are important because it is thought to be a critical factor in acute brain injury.

The acute brain injury disorders presented in this chapter, including TBI, stroke, vascular rupture, and CNS infections, are all largely preventable. Efforts at prevention are paramount because often the outcome of acute brain injury is poor.

### KEY QUESTIONS

- How are the various types of seizures recognized, classified, and treated?
- How is Alzheimer dementia diagnosed and managed?
- What are the similarities between Alzheimer dementia and vascular dementia?
- What are the proposed neurotransmitter alterations in Parkinson disease, and how are drugs used to restore balance?
- What are the similarities and differences between multiple sclerosis and amyotrophic lateral sclerosis?
- How are congenital disorders, such as cerebral palsy, hydrocephalus, and spina bifida, manifested in the newborn?
- How does the level of spinal cord injury relate to expected functional losses and clinical manifestations?
- What are the roles of immune mechanisms in Guillain-Barré syndrome, amyotrophic lateral sclerosis, and multiple sclerosis?
- What are the causes of facial paralysis in Bell palsy, and how is this condition different from other chronic disorders of neurologic function?

### CHAPTER OUTLINE

*Guillain-Barré Syndrome, 938*  
*Bell Palsy, 939*

Patients experiencing neurologic dysfunction from chronic disease states present a challenge to health care professionals, who must strive to maximize the patient's function and quality of life. This chapter focuses on common chronic disabilities of neurologic function including those primarily affecting the brain such as seizures, dementia, Parkinson disease, cerebral palsy, and hydrocephalus. Disorders of the spinal cord or peripheral nervous system include multiple sclerosis (MS), spina bifida, and spinal cord injury. Guillain-Barré syndrome

and Bell palsy are examples of disorders affecting the peripheral nervous system.

### BRAIN AND CEREBELLAR DISORDERS

#### Seizure Disorder

**Seizures** are a transient neurologic event of paroxysmal abnormal or excessive cortical electrical discharges that are manifested by

disturbances of skeletal motor function, sensation, autonomic visceral function, behavior, or consciousness. Symptoms are not constant, and the length of time between seizure episodes is extremely variable. A seizure may only occur once in a person's lifetime. Epilepsy or seizure disorder refers to recurrent seizures. Seizures are a component of many diseases. Epilepsy affects 2 million Americans. It is predicted that 44 per 100,000 new cases will be diagnosed each year.<sup>1</sup>

**Etiology.** Seizures have many causes, and under the right circumstances anyone can experience a seizure. A seizure disorder can be acquired as a consequence of cerebral injury or other pathologic process, including structural lesions such as tumors, blood clots, or infection. Other causes include metabolic and nutritional disorders such as electrolyte and water imbalance, hypoxia, acidosis, pyridoxine deficiency, acute withdrawal from alcohol, therapeutic medication overdose or medication adverse effect, and exposure to toxins such as heavy metals or street drugs. If seizures develop as a result of a structural change such as head injury or stroke, the onset is not predictable. In some cases, seizures may not develop for months or years after the structural change has occurred. In some cases, no explanation for the seizure disorder can be found. These individuals are classified as having **idiopathic** seizures.

A seizure event is often triggered by specific stimuli, usually unique for each individual. Physical inducements include specific sensory stimuli such as flashing lights, loud noises, and rhythmic music. Fever, physical exhaustion, sleep deprivation, fatigue, inadequate nutrition, hormonal changes of the menstrual cycle, hyperventilation, injury, and drugs can also prompt seizure activity. Psychosocial factors include family and environmental stress, shock, and emotional stress.

**Pathogenesis.** Seizures are due to an alteration in membrane potential that makes certain neurons abnormally hyperactive and hypersensitive to changes in their environment. These physiologically abnormal neurons form an **epileptogenic focus** (i.e., an area of the brain from which the seizure emanates). The epileptogenic focus functions autonomously, emitting excessively large numbers of paroxysmal electrical discharges. Results from animal studies suggest that neuroinflammation may be a cause or consequence of these electrical abnormalities.<sup>2</sup> Nerve cells in this area can recruit neurons in adjacent areas as well as synaptically related neurons in distant areas of the brain, greatly increasing the number of neurons involved in the seizure activity. Recruitment can also incorporate neurons in the opposite hemisphere. Clinical symptoms become evident when a sufficient number of neurons have been excited. Seizures are classified according to clinical symptoms and the electroencephalographic (EEG) features. Clinical manifestations depend on the area of the brain involved, the area of origin, and the areas to which the seizure spreads.

**Clinical manifestations.** Seizures may be classified as partial, in which only part of the brain surface is affected (also known as focal seizures), or generalized, in which the whole brain surface is affected during the seizure (Box 45-1).

**Generalized seizures.** Episodes in which the entire brain is involved from the onset of the seizure are referred to as **generalized seizures**. Involvement of the thalamus and reticular activating system results in loss of consciousness. Metabolic or toxin-induced seizures tend to be generalized. This category includes the following: absence (petite mal), atypical absence, myoclonic, atonic (drop attack), or tonic-clonic (grand mal) seizures.

Absence or petite mal seizures usually occur only in children and are sometimes identified in children manifesting poor academic performance. They are very brief (2 to 10 seconds), and episodes are characterized by staring spells that last only seconds. Onset and termination of attacks are abrupt. During the spell, the individual is unaware of the surrounding environment and is usually motionless; however,

it is not unusual for the person to continue walking or performing a routine motor task. If the seizure activity occurs during conversation, the individual may pause or miss a few words. Absence seizures almost always occur during childhood and resolve by age 20 years, although another seizure type may occur later in life.<sup>3</sup> Atypical absence seizures have accompanying myoclonic jerks and automatisms (such as lip smacking or repetitive semi-purposeful movements) with the staring spell. The electroencephalographic patterns are unique to each syndrome. Myoclonic seizures are extremely brief and are characterized by a single jerk or multiple jerks of one or more muscle groups. Atonic seizures or drop attacks are characterized by a sudden and complete loss of muscle tone. Falls and injuries are common with this type of seizure activity. Myoclonic episodes may also be associated with atonic seizures. Tonic-clonic seizures involve stiffening and repetitive jerking of muscle groups.

Tonic-clonic or grand mal seizures are characterized by a sudden loss of consciousness followed by muscle rigidity (tonic phase). The individual falls, and initial motor signs include opening of the mouth and eyes, extension of the legs, and adduction of the arms. There may be tongue biting or a high-pitched cry while the whole musculature is in spasm and air is forced out of the lungs through closed vocal cords. Respiration is arrested, and cyanosis may occur. Bowel and bladder incontinence frequently occurs. The tonic phase may last 10 to 15 seconds and is followed by clonic activity, in which there is often violent but rhythmic muscular contractions. During this phase the eyes roll, the face grimaces, and the pulse rate accelerates. Salivation increases and the patient may become diaphoretic. The clonic phase usually lasts 1 to 2 minutes with a gradual decline in the amplitude of the clonic jerks. The individual remains apneic until the end of the clonic phase that is marked by a deep inspiration.

During the terminal or postictal phase, the individual may regain consciousness or drift into a deep coma-like state. Disorientation and confusion are common. If allowed, the individual may sleep for several hours. Other findings include headache, drowsiness, nausea, muscle soreness, no memory of the seizure event, and retrograde amnesia. During the seizure, the person is at risk for injury from the initial fall as well as from the muscle contractions of the clonic phase.

A potentially life-threatening situation known as **status epilepticus** occurs in some seizure disorders. Status epilepticus is a continuing series of seizures without a period of recovery between seizure episodes. It can occur with all types of seizures but is of greatest concern in tonic-clonic seizures. Irreversible brain damage and possible death from hypoxia, cardiac dysrhythmias, or lactic acidosis can occur if the airway is not maintained and seizure activity is not halted. Whether nonconvulsive status epilepticus causes neuronal damage is still a

### BOX 45-1 CLASSIFICATIONS OF SEIZURES

#### Generalized Seizures: Entire Brain Surface Is Affected During Seizure

Absence (petit mal)  
Atypical absence  
Myoclonic  
Atonic (drop attack)  
Clonic  
Tonic  
Generalized tonic-clonic (grand mal)

#### Partial Seizures: Part of Brain Surface Is Affected During Seizure

Simple partial: There is no impairment of consciousness during the seizure.  
Complex partial: There is impairment of consciousness during the seizure.  
With secondary generalization: Onset begins as simple partial, and then progresses to impairment of consciousness.

matter of debate. Studies of elderly patients with nonconvulsive status epilepticus show very high mortality rates and ongoing research is suggesting that EEG be part of the evaluation for patients with altered levels of consciousness that cannot be otherwise explained.<sup>3,4</sup>

**Partial seizures.** Partial seizures are those in which activity is restricted to one brain hemisphere. They are further divided into three categories: simple partial, complex partial, and partial seizures that are secondarily generalized.

In simple partial seizures, the individual does not have a change in level of consciousness. The symptoms may be motor, sensory, or autonomic, or any combination of the three. Motor symptoms may be limited to one part of the body. Sensory seizures may result in tingling or numbness that spreads or “marches” to different parts of the limb or body (depending on the location of the seizure activity in the brain) or may involve the special senses, producing auditory (buzzing sounds), olfactory, or visual manifestations (flashing lights). Autonomic symptoms may include pupillary (pupil dilation), skin (diaphoresis, flushing), or respiratory changes.

Complex partial seizures have many different combinations of cognitive, affective, and psychomotor symptoms. Either loss or alteration of consciousness may occur when the seizure begins. After the attack, the individual may feel drowsy or confused. At the onset of impairment of consciousness, the individual often displays automatism. Aggressive behavior may be displayed as well, especially if bystanders attempt to restrain the individual. Complex partial seizures often last several minutes and may be followed by a postictal state.

Partial seizures that are secondarily generalized are the third subtype of partial seizures. This category comprises seizures that begin as simple partial seizures and then progress to involve both brain hemispheres. Once generalized, these seizures are clinically similar to primary generalized seizures.

**Aura/prodrome.** Some people may have a subjective sense of an impending seizure. This **prodromal period** may be characterized by any one of several phenomena such as a type of myoclonic jerking, headache, lethargy, mood alterations, palpitations, or epigastric sensations, which may precede the actual seizure by several hours. In about half of cases there is some type of movement or odd sensory experience (visual, auditory, olfactory, or gustatory) that occurs seconds before consciousness is lost and that is remembered by the individual after recovery from the seizure. This experience is known as an *aura*. Although the individual may interpret the aura as an indication that a seizure is about to occur, in fact it is the beginning of the seizure episode. Auras can be significant, because they may be a clue to the location of the epileptogenic focus.

**Diagnosis and treatment.** The diagnosis and management of seizure disorders are based on the patient’s history, physical, and neurologic examination results as well as the results of electroencephalographic studies. Electroencephalograms (EEGs) may be normal between seizures, so activation techniques (sleep deprivation, hyperventilation) may be used to elicit the pathologic mechanism. Laboratory studies are frequently used to investigate possible metabolic abnormalities as well as therapeutic serum levels in those already using anticonvulsant drugs. Lumbar puncture may be utilized when there is a suspicion of a central nervous system (CNS) infection.<sup>3</sup> Initial studies ruling out structural causes may include computed tomography (CT) or magnetic resonance imaging (MRI).

Treatment of an individual experiencing a seizure is concentrated on maintaining an airway and protecting the individual from injury. Recording the course of the seizure episode is useful for identifying the location of the epileptogenic focus and for noting any change in the patient’s seizure pattern. These data are useful in treatment planning. The information recorded should include the time of onset and

duration of the seizure, precipitating factors, presence of a prodrome or aura, sequence of seizure activity, autonomic signs, level of consciousness, and postictal state.

Long-term treatment depends on the cause of the seizure disorder. In seizures resulting from a metabolic abnormality, infection, or tumor, the precipitating source is removed. If the seizures are due to irreversible or unidentifiable factors, anticonvulsant medications specific to the type of seizure are the best management. The decision to treat after one seizure is controversial when an identifiable cause has not been found.<sup>5</sup> The objective of therapy is to achieve seizure control with a minimum of side effects. Medication is continued until there have been no seizures for at least 2 years and is then gradually withdrawn.<sup>3</sup> If seizures continue despite treatment at a maximal dose of a single medication, a second agent is added and the dosage is increased depending on patient tolerance. The first drug is then gradually discontinued. Anticonvulsant medication is a form of control, not a cure.

Treatment also includes patient education in the avoidance of activating factors (e.g., stress, loud noise, alcohol). Patients should be advised to avoid situations that could be dangerous or life threatening if seizures should reoccur (e.g., driving or swimming). State laws defining when patients with seizure disorders are allowed to resume driving vary widely.<sup>5</sup> Compliance to the treatment plan is sometimes difficult because of side effects of pharmacologic interventions. However, most patients are able to achieve optimal seizure control and lead active and productive lives. For some patients with seizure disorder uncontrolled by medications, surgical excision of the seizure focus may be an option. Neurostimulation is an appropriate therapy for certain patients with refractory seizures.<sup>6</sup>

#### KEY POINTS

- Seizure disorder is characterized by recurrent episodes of abnormal electrical impulses in the brain. Some individuals appear to have a lower-than-normal threshold for seizure activity. Seizure activity may occur in anyone, given the right conditions. Head injury, meningitis, brain tumors, and metabolic disorders (electrolyte imbalance, fever, acidosis) may predispose an individual to having seizures.
- Initiation of seizure activity may occur in a particular brain area (the epileptogenic focus). Nearby and distant neurons may then be recruited into the seizure. When sufficient neurons are involved, the seizure becomes clinically evident as involuntary movement or unusual sensations.
- Seizures are classified as partial or generalized. Partial seizures involve a part of the brain; generalized seizures involve the entire brain at the onset. Partial seizures are further classified as simple, in which consciousness is retained, and complex, in which consciousness is impaired. Seizures may begin as partial and then generalize to affect the entire brain. Generalized seizures include absence, myoclonic, atonic, and tonic-clonic types. Consciousness is always impaired in generalized seizures.
- Status epilepticus is a serious condition in which seizures occur continuously, resulting in intense brain metabolism. Ischemic brain damage may result. Management of a seizure in progress is aimed at maintaining the individual’s airway and protecting the person from trauma. Close attention is given to the quality and progression of seizure activity. Anticonvulsant medications are used to suppress seizure activity.

#### Dementia

**Dementia** is not a specific disease but rather a syndrome associated with many pathologic processes. It is characterized by progressive deterioration and continuing decline of memory and other cognitive changes. Personality and behavior changes accompany the cognitive

deterioration. Judgment, abstract thinking, and complex task performance are all affected. The onset of dementia may be insidious, and the affected individual may initially appear uninterested or lacking initiative. Many demented patients have **agnosia** or lack of insight into their cognitive deficiencies.

Alzheimer disease accounts for 60% to 80% of all dementias, whereas vascular dementia is the second most common cause. An estimated 1 in 8 people older than 65 have Alzheimer disease. It affects nearly half of those 85 years of age and older.<sup>7</sup>

**Etiology.** Multiple causes/types of dementia exist, and a full discussion of each is beyond the scope of this chapter. Some examples of dementia-causing illness include alcoholism, intracranial tumor, normal-pressure hydrocephalus, Parkinson disease, Lewy body disease, Huntington disease, multiple sclerosis, Pick disease, Creutzfeldt-Jakob disease, and bovine spongiform encephalopathy (mad cow disease). Unfortunately, these also can occur in combination, causing severe disease. Because Alzheimer- and vascular-type dementias are the first and second most common causes of dementia, they will be discussed in detail. The subsequent discussion of treatment of individuals with dementia will be more general because the care issues are similar regardless of type of dementia.

It is important to consider all potential causes of cognitive change when dealing with patients with mental status change. Both delirium and depression in the elderly can cause signs and symptoms that resemble those of dementia. Delirium is a global mental dysfunction that includes disturbed consciousness, decreased awareness of the environment, inability to maintain attention, disrupted sleep-wake cycles, drowsiness, restlessness, emotional lability, incoherence, and hallucinations.<sup>8</sup> Symptoms of delirium tend to have an abrupt onset and may fluctuate often, becoming worse at night. Delirium can result from numerous causes such as medication/polypharmacy, metabolic abnormalities, nutritional deficiencies, and infection, among others. Delirium may occur more frequently in individuals with an underlying dementing illness.

**Pathogenesis.** The hallmark pathophysiologic changes associated with Alzheimer disease include intracellular neurofibrillary tangles and extracellular amyloid (senile) plaques (Figure 45-1). As a result of these changes, diffuse neuronal damage and brain atrophy occur. The brain of a patient with advanced Alzheimer disease often weighs up to 20% less than a normal brain.<sup>9</sup> The temporoparietal and anterior frontal regions of the brain are chiefly affected, exhibiting enlarged sulci and ventricles and atrophic gyri (Figure 45-2). Neurofibrillary tangles are composed of helical filaments formed from hyperphosphorylated

Plaque surrounding amyloid deposit

protein tau, also known as neural thread protein.<sup>9</sup> In the central nervous system, neural thread proteins bind and help stabilize microtubules (the cell's internal support structure or skeleton). Inflammatory changes, lipid abnormalities, and aging are among the processes thought to be responsible for activating the phosphorylating enzymes altering the structure of the tau proteins.<sup>10</sup> The presence of neurofibrillary tangles is well correlated with dementia; however, neurofibrillary tangles are not specific just to Alzheimer disease and are found in other neurodegenerative disease processes.<sup>11</sup> The second, but most specific, change in the brain of patients with Alzheimer disease is the deposition of extracellular amyloid plaques.

It is not known whether amyloid plaques cause Alzheimer disease or result from it. The number of senile plaques seems to correlate with the severity of disease. In plaques,  $\beta$ -amyloid is a protein fragment snipped from a larger protein—**amyloid precursor protein (APP)**—during metabolism. APP is a member of a large family of proteins that are associated with cell membranes. During metabolism, APP becomes embedded in the membrane of the nerve cell, partly inside and partly outside the cell. While APP is embedded in the cell membrane, proteases cleave APP apart.  $\beta$ -Amyloid is produced only when the cleavage happens at the wrong place in APP.

After  $\beta$ -amyloid is formed, it is not known how it moves through or around the nerve cells. In the final stages of its journey, it joins with other  $\beta$ -amyloid filaments and fragments of dead and dying neurons to form the dense, insoluble plaques that are a hallmark of Alzheimer disease in brain tissue. Inflammatory processes including acute-phase response, complement activation, and accumulation of activated microglia and astrocytes accompany the amyloid deposition and neurofibrillary tangle formation.<sup>10,11</sup> The accumulation of  $\beta$ -amyloid also causes oxidation of lipids, activation of apoptotic genes, disruption of cell membranes, and excitotoxicity from the neurotransmitter glutamate.<sup>10</sup>

Much interest exists in the neurotransmitter systems in relation to Alzheimer disease. Damage in Alzheimer disease involves changes in three mechanisms: nerve cell communication, metabolism, and repair. Several studies have found abnormalities in the cholinergic system, including reduced activity of choline acetyltransferase (the enzyme necessary for acetylcholine synthesis) and decreased acetylcholine synthesis (Figure 45-3). Some researchers believe that  $\beta$ -amyloid may be responsible for lower choline levels in nerve cells and decreased acetylcholine levels. The degeneration of cells in the nucleus basalis, a band of gray matter in the ventral portion of the medulla oblongata, has also been linked to diminished levels of acetylcholine in the cerebral cortex, a finding that provides further evidence for the significant role of the cholinergic system in Alzheimer disease.<sup>9</sup> Along with alterations in acetylcholine, other neurotransmitters are also affected. Imbalances in the activity of glutamate, dopamine, and serotonin contribute to the behavioral signs and symptoms of Alzheimer disease.<sup>12</sup>

Vascular dementia results from single cerebrovascular insults (such as cerebral infarction), from multiple lacunar infarcts, or from microvascular pathology. Microvascular insults may not show any localizing clinical symptoms and may be found incidentally on brain imaging. However, the presence of these also does not automatically mean a diagnosis of vascular dementia.<sup>13</sup> The symptoms of vascular dementia may be similar to those of Alzheimer dementia as entirely separate entities; however, there is increasing evidence that particularly in elderly patients the brain lesions associated with both often coexist. There is emerging evidence that the cascade of events leading to the development of Alzheimer disease plaques and tangles may be due to ischemic and inflammatory insults of cerebrovascular disease.<sup>10,13</sup>

The primary risk factors for the development of Alzheimer disease include age and family history. Epidemiologic studies show that individuals who have an affected first-degree relative with Alzheimer disease have a fourfold greater risk of developing the disease. The risk is greater if there are individuals in more than one generation with the disease.<sup>7</sup> Three main genes have been identified and are thought to be responsible for autosomal dominant familial Alzheimer disease. *Presenilin 1*, *presenilin 2*, and *APP* are believed to increase the amount of  $\beta$ -amyloid protein.<sup>11</sup> These genes are rare, accounting for only 3% of Alzheimer disease cases, usually the early-onset variant.<sup>11</sup> The major gene associated with late-onset Alzheimer disease is apolipoprotein  $\epsilon 4$  (*APOe4*). By age 85, those who are homozygous for the *APOe4* allele have a 50% to 90% chance of developing Alzheimer disease. Those who are heterozygous have a 45% chance of developing the disease. Carrying the *APOe4* gene has also been associated with increased risk of atherosclerosis and cerebrovascular disease, strengthening the link between Alzheimer disease and vascular dementia.<sup>10,13</sup> Lifestyle has also been linked to the risk of Alzheimer disease. Head trauma, diabetes, and depression have been linked to an increased incidence of the disease as well as marital status, urban living, and inactive mental and physical lifestyle.<sup>13</sup> Risk factors for vascular dementia include those for stroke, hypertension, and diabetes.<sup>13,14</sup> Clearly, both vascular dementia and Alzheimer disease include a complex interplay of genetic, environmental, and lifestyle factors.

**Clinical manifestations.** Regardless of when patients first present with dementia, it is likely that brain disease has been present for quite some time. Most patients experience a gradual onset with a chronic progressive decline in cognitive functioning. There is memory loss, especially in short-term memory, whereas long-term memory may be preserved. Thinking ability declines, and there is a decreasing ability to function at work and in social settings. Anxiety and agitation are common. As the disease progresses, individuals have increasing difficulty with judgment, problem solving, and communication. Assistance may be necessary for completing activities of daily living (ADLs). Difficulty with eating and swallowing, and weight loss are common. Loss

FIGURE 45-3 Cholinergic synapse.

of bladder and bowel control and eventual complete loss of the ability to ambulate occur in the late stages. Accidents and infection are common causes of death.<sup>7</sup>

**Diagnosis and treatment.** The initial evaluation of a patient thought to have dementia of any type begins with a complete history and physical examination. This should address the patient's overall general health and any coexisting medical conditions. All manageable causes for dementia or delirium should be ruled out. It is recommended that the evaluation should include a complete blood cell count, chemistry panel, thyroid function, vitamin B<sub>12</sub> levels, and syphilis serology. Other testing such as Lyme serology, human immunodeficiency virus (HIV), urinalysis with culture/sensitivity, heavy-metal assays, sedimentation rate, and other vitamin levels may be warranted in certain patient situations. Other evaluations such as a chest x-ray and lumbar puncture may also be helpful. Neuroimaging may include computerized tomography (CT) and magnetic resonance imaging/magnetic resonance angiography (MRI/MRA), which may identify vascular disease, normal-pressure hydrocephalus, tumors, abscesses, or subdural hematoma. PET (positron emission tomography) scans are not routinely recommended at this point, but show promise in identifying Alzheimer disease when combined with a history of genetic risk. Mental status examinations, the clock drawing test, and tests of functional status are recommended.<sup>9,11,14</sup> A current list of the patient's medications, including over-the-counter medications, must also be reviewed. Medications with anticholinergic actions/side effects are a common cause of changes in cognitive functioning in the elderly.

Early diagnosis and intervention are key in the management of dementia. The financial and legal ramifications of dementia can be devastating to patients and their families and caregivers. If the diagnosis is made before the onset of severe cognitive disability, the patient can be involved in decisions regarding long-term care, power of attorney, and living will issues. Early diagnosis is also vital to initiating therapy as early as possible.

Currently, two classes of drugs are approved by the Food and Drug Administration for the treatment of Alzheimer disease. The first class is the acetylcholinesterase inhibitors: tacrine (Cognex), donepezil (Ari-cept), rivastigmine (Exelon), and galantamine (Reminyl). These agents are indicated for use in patients with mild to moderate Alzheimer disease. Although not a cure, the acetylcholinesterase inhibitors have been shown to stabilize cognitive function and slow progression of the illness.<sup>14,15</sup> Acetylcholinesterase inhibitors have also been shown to improve cognitive functioning in patients with vascular dementia.<sup>15</sup>

The second class of drugs used in the treatment of Alzheimer disease is known as the *N*-methyl-D-aspartate (NMDA) receptor antagonists. Currently only one drug in this class is available in the United States. Memantine (Namenda) is indicated for the treatment of moderate to severe Alzheimer-type dementia. This drug blocks stimulation by the neuroexcitatory transmitter glutamate. Again, this medication is not a cure, but slows progression of the disease.<sup>16</sup> Studies using combination therapy of acetylcholinesterase inhibitors and NMDA antagonists are showing modest improvement in cognitive functioning.<sup>15,16</sup> Studies using NMDA antagonists for vascular dementia have not shown conclusive benefit.<sup>17</sup>

Many other medications, although not approved for use in treating Alzheimer disease, are used to manage the symptoms, such as depression, sleep disturbance, agitation, and psychosis. These medications include antidepressants, anxiolytics, antipsychotics, and mood stabilizers.<sup>16</sup>

A variety of medications and nutritional supplements have been used in the prevention and management of Alzheimer disease, including ginkgo biloba; antioxidants such as vitamin E,  $\alpha$ -lipoic acid, omega-3 fatty acids, and coenzyme Q<sub>10</sub>; and nonsteroidal antiinflammatory

drugs (NSAIDs). The blood pressure drugs angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are showing slowed progression of disease beyond just lowering blood pressure. However, all the research has been completed on hypertensive individuals.<sup>18-20</sup> Research findings regarding nutritional supplements are inconsistent and therefore ongoing.<sup>18</sup>

Other treatments for dementia include optimal management of other coexisting illnesses, interventions aimed at wellness, regulation of optimal nutritional intake, and protection from injury. In early stages of the disease, most patients are cared for at home, often by family members. It is important that the home environment be safe and that there be measures in place to control wandering. Consistent routines and familiar surroundings allow the patient to feel more comfortable and experience less confusion. As the disease progresses, the individual with dementia may have to be placed in an alternative living situation such as a nursing home or assisted-living program. Caring for the caregivers of patients with dementia is important.

#### KEY POINTS

- Dementia refers to progressive degeneration of cognitive function attributable to organic causes. In many instances the cause is unknown. There are limited definitive treatments for dementia, none of which is a cure. It is important to first rule out manageable causes of mental impairment.
- The dementia of Alzheimer disease is characterized by degeneration of neurons in the temporal and frontal lobes, atrophy of the brain, and the formation of amyloid plaques and neurofibrillary tangles. The synthesis of brain acetylcholine is deficient. The cause of Alzheimer disease remains unknown, although genetic factors and environmental triggers are suspected.
- The behavioral problems of individuals with Alzheimer disease progress from forgetfulness to total inability for self-care. Depression and psychosis may be significant.

### Parkinson Disease

Parkinson disease is a disorder of mobility that affects 1 million Americans. It is estimated that 60,000 new cases are diagnosed each year. Although it usually develops after age 65, 4% of those diagnosed are younger than age 50.<sup>21</sup>

**Etiology.** Parkinson disease may be idiopathic or acquired. Idiopathic Parkinson disease is that in which no demonstrable cause is identified. Common causes of acquired **parkinsonism** include infection, intoxication, and trauma.<sup>3</sup> Typically, parkinsonism attributable to drug toxicity evolves rapidly, unlike the slow, insidious onset of the idiopathic form of the disease. Side effects of drugs of the phenothiazine class (e.g., chlorpromazine, prochlorperazine, and thioridazine) and butyrophenone class (e.g., haloperidol) may manifest in a parkinsonian syndrome at toxic levels. Discontinuing the medication generally results in improvement in the symptoms. However, the additional use of the anticholinergic antiparkinsonian drugs may aid in more rapid recovery. The rest of this discussion of Parkinson disease refers to the most common idiopathic type.

**Pathogenesis.** Parkinson disease results from degeneration of the pigmented dopaminergic neurons found in the substantia nigra (Figure 45-4) and, to a lesser extent, neurons elsewhere in the brain. Eosinophilic cytoplasmic inclusions known as Lewy bodies may be found in the surviving neurons. Incidentally, Lewy bodies are found along with amyloid plaques at autopsy in the brains of some patients with a severe form of dementia. This suggests a possible link with Alzheimer disease. The exact cause of this degeneration is unknown,

**FIGURE 45-4** Dopaminergic neurons and their pathways in the human brain.

but mitochondrial dysfunction from oxidative stress, genetics, and environmental toxins has been implicated.<sup>22</sup> Adaptive immunity may play a part in the progression of Parkinson disease by reacting to the abnormal proteins and causing neuroinflammation.<sup>23</sup>

At least 13 different gene groups have been identified as having a role in the development of Parkinson disease. In particular, identification of a mutation in the *α-synuclein* gene has become the focus of much interest. Although mutations of the gene are a rare cause of Parkinson disease, *α-synuclein* is abundant in neurons, specifically in presynaptic terminals, and is a major component of Lewy bodies.<sup>22</sup> Another gene identified in the development of Parkinson disease is *parkin*. Mitochondrial quality control is mediated by *parkin*. When functioning normally, it selectively recognizes and eliminates damaged mitochondria from the cell by autophagy. *Parkin* mutations are associated with monogenic forms of Parkinson disease.<sup>24</sup> Although genes have received much attention in Parkinson disease research, environmental factors have also been studied. High caffeine intake has been found to have an inverse relationship to the risk of developing the disorder.<sup>22,25</sup> Long-term exposure to the pesticide rotenone and the herbicide paraquat have been linked to increasing risk for Parkinson disease.<sup>26</sup> Whatever the cause of the degeneration of the dopaminergic cells, 75% to 80% of the neurons have died before any symptoms of the disease become apparent.

**Clinical manifestations and treatment.** Because of the insidious onset, earlier evidence of Parkinson disease may be discovered in a thorough health history. Frequently, the very early signs of the disorder (loss of flexibility, aching, and fatigue) are overlooked by the patient or are attributed to the aging process. Initially, symptoms are usually worse on one side of the body and then progress to involve both sides. Tremor is often the first symptom recognized that prompts patients to seek treatment. The tremor is generally at rest, unilaterally affecting distal extremities. Hand tremors may be described as pill-rolling movements. Attempts to passively move the extremities are met with cogwheel rigidity. As Parkinson disease progresses, the tremor will

**FIGURE 45-5** Clinical manifestations of Parkinson disease. (From Monahan FD, Neighbors M: *Phipps' medical-surgical nursing: health and illness perspectives*, ed 8, Philadelphia, 2007, Saunders, p 1446.)

often become bilateral/more generalized. Additional early signs of the disease include bradykinesia, rigidity, hypokinesia, loss of facial expression, and infrequent eye blinking (Figure 45-5). Again, these symptoms may be overlooked by patients but are usually apparent to observant family members.

As the disease progresses, additional functional changes are noted. The patient's handwriting may become small (micrographia) and cramped, with evidence of tremor. Speech may become low in volume, monotonous, and dysarthric. There may be a mumbling quality to the speech. The effects of bradykinesia are evident in the patient's swallowing function, ability to initiate activity, and level of mobility. Swallowing becomes delayed so much so that the individual may drool, and patients are at risk for aspiration. The effect of the disease on the ability to initiate activity is evident when the individual rises from a chair or begins to walk from a standing-still position. However, many people with Parkinson disease are able to act quickly in times of emergency, such as fire. This phenomenon is known as paradoxical kinesia.

Additional difficulties in mobility are evident from the lack of spontaneous position changes while the individual is sitting in one

position, from the decreased or absent arm swing while the individual is walking, and from the shuffling gait. Impairment of postural reflexes presents particular safety problems for the individual with Parkinson disease in maintaining balance, as evidenced by propulsive or retropulsive gaits. Involvement of the autonomic nervous system may result in orthostatic hypotension, which adds yet another risk to the individual's health. Because of these various impairments, falls are a common problem. Depression is present in many patients with Parkinson disease. Daytime sleepiness is also common as well as sleep disturbances and restless leg syndrome.<sup>27</sup> Dementia is prevalent in patients with Parkinson disease.

There is no known cure for Parkinson disease. Treatments are aimed at slowing the progression of the disease and managing symptoms. The mainstay of Parkinson therapy has been aimed at increasing the level of dopamine in the CNS. Dopamine precursors such as levodopa are one approach to increasing dopamine levels. Dopamine itself cannot be used because it does not cross the blood-brain barrier efficiently. Outside the CNS, levodopa is metabolized to dopamine and then to adrenaline and noradrenaline, which can cause altered blood pressure. To minimize these side effects, levodopa is combined with carbidopa. This agent blocks the conversion of levodopa to dopamine in the periphery, allowing it to cross the blood-brain barrier.<sup>27,28</sup> Long-term use of levodopa has been associated with “on-off” phenomena (in which the action of the drug suddenly stops, leaving the patient with sudden onset of symptoms) or abnormal movements called *dyskinesias*. Other medications aimed at increasing the level of dopamine in the CNS include dopamine agonists (pramipexole, ropinirole); medications to slow the metabolism of dopamine (monoamine oxidase inhibitors such as selegiline, catechol-*O*-methyltransferase inhibitors); and medications shown to be helpful with akinesia and dyskinesia (such as amantadine).<sup>27,28</sup> Anticholinergic medications may help with tremor, rigidity, or drooling. The Alzheimer drug rivastigmine (Exelon) may be used to slow the progression of Parkinson-induced dementia.<sup>28</sup>

Surgical options for the management of Parkinson disease have received much recent attention. Tissue transplantation of embryonic stem cells in an attempt to increase the level of dopamine in the CNS is very controversial and has not been consistently shown to improve the symptoms of Parkinson disease.<sup>29</sup> Deep brain stimulation involves the surgical implantation of a high-frequency thalamic electrical stimulator that interrupts the tremor-causing nerve impulses, minimizing dystonia. This can decrease the need for Parkinson medication.<sup>28,30</sup>

Ablative surgical techniques of thalamotomy and pallidotomy create small lesions in the thalamus or pallidum; these can improve rigidity, tremor, and bradykinesia.<sup>31</sup> Symptoms are better controlled with medication following the surgery. These surgical techniques are considered for patients who have been unresponsive to the medical treatments or who are unable to tolerate the side effects. These surgical techniques have high morbidity associated with them and are rarely used. Genetic research on Parkinson disease continues.

### KEY POINTS

- Parkinson disease may be idiopathic or a consequence of the use of certain drugs. Dopamine deficiency in the basal ganglia (substantia nigra, caudate, and putamen) is associated with symptoms of motor impairment. Difficulty initiating and controlling movements results in akinesia, tremor, and rigidity. Tremor occurs at rest, and hand tremors may be described as pill-rolling movements. Attempts to passively move the extremities are met with cogwheel rigidity. There is a general lack of movement, loss of facial expression, drooling, propulsive gait, and absent arm swing.

- Treatment is aimed at restoring brain dopamine levels or activity by administration of dopamine precursors, dopamine agonists, monoamine oxidase inhibitors, and anticholinergics. Antidepressant therapy may also help alleviate depression, and surgical procedures may be helpful for motor symptoms.

## Cerebral Palsy

**Etiology and pathogenesis.** Cerebral palsy refers to a diverse group of crippling syndromes that appears during childhood and involves permanent, nonprogressive damage to the developing brain. Such damage occurs during fetal development; before, during, or shortly after birth; or during early infancy. Damage occurs in the upper motor neurons that control voluntary and involuntary muscle movement. The symptoms of this damage remain for life. The majority of these children will survive until at least early adulthood. Although cerebral palsy is not considered a progressive disorder, these adolescents and adults are challenged by a variety of health problems and functional decline including chronic pain, scoliosis, and respiratory dysfunction along with a host of other symptoms.<sup>32</sup>

Cerebral palsy is classified on the basis of neurologic signs and symptoms, with the major types involving spasticity, ataxia, or dyskinesia, or a combination of these symptoms. Cerebral palsy is one of the most common crippling disorders of childhood, with an incidence of between 2 and 2.5 per 1000 births.<sup>33</sup> Etiologic factors include prenatal infections or diseases of the mother; mechanical trauma to the head before, during, or after birth; or exposure to nerve-damaging poisons or a period of reduced oxygen supply to the brain. Neonatal hypoglycemia, **kernicterus**, prematurity, and low birth weight are also risk factors. Often the cause is multifactorial, and in many cases a single cause cannot be identified.<sup>34</sup>

**Clinical manifestations.** Spastic cerebral palsy manifests with hyper-tonia, prolonged primitive reflexes, exaggerated deep-tendon reflexes, clonus, rigidity of the extremities, scoliosis, and contractures. This type of cerebral palsy is the most common. Spastic paralysis often affects one entire side of the body (hemiplegia), both legs (paraplegia), both legs and one arm (triplegia), or all four extremities (quadriplegia). A “scissors” gait and toe walking are common. Dyskinetic/athetoid cerebral palsy manifests with extreme difficulty in purposeful movement and fine-motor coordination. Movements are slow, jerky, uncontrolled, and abrupt, resulting from injury to the **basal ganglia** or **extrapyramidal tracts**. The uncontrolled movements may increase during times of stress and disappear during sleep.<sup>34,35</sup> Ataxic cerebral palsy is associated with gait disturbances and instability. The infant with this type of cerebral palsy may have hypotonia at birth, but stiffness of the trunk muscles develops by late infancy. Persistence of truncal stiffness affects the child's gait and ability to maintain equilibrium. Pure ataxic cerebral palsy is rare. This palsy denotes maldevelopment of the cerebrum or its pathways, which if severe may be associated with significant cognitive impairment.<sup>34,35</sup> More typically, a child will have a mixed disorder with clinical manifestations of each of the types.

Children with cerebral palsy often have neurologic complications such as seizures, intellectual difficulties ranging from mild to severe, and visual problems.<sup>33,34</sup> Other associated clinical manifestations include hearing impairment, communication disorders, respiratory problems, bowel and bladder problems, and orthopedic disabilities.

**Treatment.** There is no cure for cerebral palsy, and the goal of management is to increase functionality. Treatment varies according to the nature and extent of brain damage. As a result of problems with muscle spasticity and contracture, muscle relaxation is a large part of therapy. Muscle relaxant medications are common. Several studies have also supported the use of botulinum toxin type A (Botox) to reduce pain and increase joint range of motion.<sup>36</sup> Anticonvulsant drugs are necessary when seizures are among the symptoms of the disorder.

Orthopedic surgery, casts, braces, and traction may be useful to correct some types of associated disability. A comprehensive rehabilitation program including early muscle training and special exercises may help the child with cerebral palsy lead a more productive life.

#### KEY POINTS

- Cerebral palsy refers to a diverse group of crippling syndromes that appear during childhood and involve permanent, nonprogressive damage to motor control areas of the brain.
- Cerebral palsy may be classified on the basis of neurologic signs and symptoms, with the major types involving spasticity, ataxia, or dyskinesia, or a mix of two or more of these three symptoms.
- Etiologic factors include prenatal infections or diseases of the mother; mechanical trauma to the head before, during, or after birth; or exposure to nerve-damaging poisons or a period of reduced oxygen supply to the brain.
- Treatment varies according to the nature and extent of brain damage. Muscle relaxants, anticonvulsant drugs, orthopedic surgery, casts, braces, and traction are among the therapies used.

### Hydrocephalus

**Etiology.** Hydrocephalus is a condition caused by abnormal accumulation of cerebrospinal fluid (CSF) in the cerebral ventricular system. Figure 45-6 illustrates the normal flow of CSF. Hydrocephalus is generally associated with a congenital defect, usually a neural tube defect. Viral infections or other neurotoxic agents acquired during pregnancy have been implicated with the congenital forms. It also occurs occasionally in adults and elderly persons as a consequence of

mass lesions, trauma, hemorrhage, or infections such as meningitis. There are three types of hydrocephalus: (1) normal-pressure hydrocephalus; (2) obstructive/noncommunicating hydrocephalus; and (3) nonobstructive/communicating hydrocephalus.

Normal-pressure hydrocephalus is a condition in which CSF volume increases without change in intracranial pressure because brain tissue has been lost. The cause of normal-pressure hydrocephalus remains unknown, but it is thought to be from an abnormality of the normal absorption of CSF. Ventricles become distended, compressing brain tissue and the cerebral vessels. There is no net change in intracranial pressure. Patients with this form of hydrocephalus demonstrate a triad of symptoms: gait instability, urinary incontinence, and dementia.<sup>37</sup> If the problem is identified quickly, symptoms may improve/resolve with appropriate treatment.

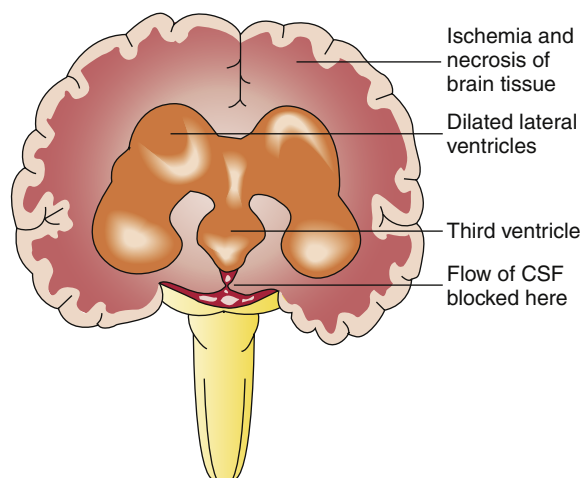

Obstructive/noncommunicating hydrocephalus is most common in children and attributable to an abnormality of the cerebral aqueduct or a lesion in the fourth ventricle. The cause is usually a congenital abnormality, such as stenosis of the foramina of the fourth ventricle or spina bifida cystica.<sup>38</sup>

Nonobstructive/communicating hydrocephalus (sometimes referred to as *acquired communicating hydrocephalus*) is identified by an abnormality in the capacity to absorb fluid from the subarachnoid space. There is no obstruction to the flow of fluid between the ventricles. Infections, trauma, and tumors have been identified as etiologic factors.<sup>38</sup> In premature infants this usually results from an intraventricular hemorrhage.

**Pathogenesis and clinical manifestations.** Usually the obstructive type of hydrocephalus is caused by a block in the aqueduct of Sylvius, resulting from premature closure before birth in affected babies or from a brain tumor at any age (Figure 45-7). As fluid is formed by the

**FIGURE 45-6** Ventricular system of the brain and distribution of cerebrospinal fluid (CSF). CSF is formed in the ventricles, passes to the subarachnoid space outside the brain and spinal cord, and moves through small valvelike structures into the large veins of the head.

**FIGURE 45-7** Hydrocephalus. CSF, Cerebrospinal fluid. (From Gould BE, Dyer R: *Pathophysiology for the health professions*, ed 4, Philadelphia, 2011, Saunders.)

choroid plexus in the two lateral and the third ventricles, the volumes of these three ventricles increase greatly. This flattens the brain into a thin shell against the skull. In neonates, the increased pressure also causes the entire head to swell because the skull bones have not fused.

The communicating type of hydrocephalus is usually caused by blockage of fluid flow in the **subarachnoid space** around the basal regions of the brain or blockage of the **arachnoid villi** themselves. Fluid therefore collects both inside the ventricles and on the outside of the brain. If it occurs in infants when the skull is still pliable and can be stretched, the head swells tremendously.

**Treatment.** Medical treatment has been used with only limited success in controlling the secretion of CSF and relieving hydrocephalus. The most effective treatment is surgical correction employing a shunting technique. The basic components of the shunt are a ventricular catheter, a valve, and a distal catheter. Multiple perforations along the ventricular catheter permit the drainage of fluid from the ventricle. The valve is constructed so that fluid will flow in one direction only, and some valves have a pumping chamber to facilitate drainage. The distal catheter may be positioned at any of a number of sites, the most common being the peritoneal cavity (ventriculoperitoneal shunt) (Figure 45-8). The shunt thus extends all the way from one of the ventricles to the peritoneal cavity where the fluid can then be absorbed and excreted. Another surgical approach is endoscopic third ventriculostomy. This involves making a hole in the third ventricle to allow free flow of CSF into the basal cisterns for reabsorption. This surgery is used for obstructive hydrocephalus.<sup>38</sup> It should be emphasized that the correlation between degree of hydrocephalus and impaired cognitive function often results from additional complications, such as severe congenital malformations, acute or chronic infections, or progressive brain tumors.

#### KEY POINTS

- Hydrocephalus is a condition characterized by abnormal accumulation of CSF in the cerebral ventricular system.
- There are three types of hydrocephalus: normal-pressure hydrocephalus, caused by an increased volume of CSF without a change in CSF pressure; obstructive hydrocephalus, attributable to an obstruction to the flow of CSF; and communicating hydrocephalus, in which absorption of CSF is abnormal.
- The most effective treatment for hydrocephalus is surgical correction employing a shunt.

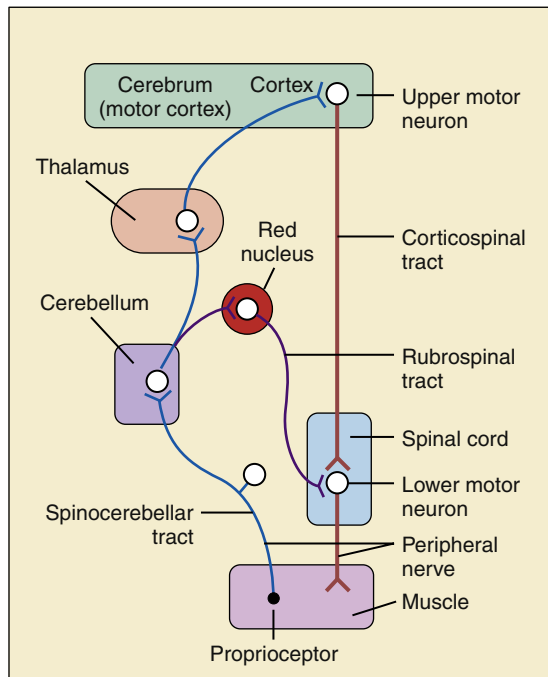

**FIGURE 45-8** Ventriculoperitoneal shunt placed for chronic hydrocephalus. (From Black JM et al: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1933.)

#### Cerebellar Disorders

The cerebellum performs three general functions in the control of skeletal muscles: (1) together with activity of the cerebral cortex, it coordinates the activities of muscle groups to produce skilled movement; (2) it functions below the level of consciousness to maintain posture and make movements smooth, steady, efficient, and coordinated; and (3) it controls skeletal muscles to maintain balance (see Chapter 43). Figure 45-9 illustrates the cerebrum and cerebellum working together to coordinate muscle movement. Impulses from the motor control areas of the cerebrum travel down the corticospinal tract and through peripheral nerves to skeletal muscle tissue. Simultaneously, the impulses go to the cerebellum. The cerebellum compares the motor commands of the cerebrum to information coming from receptors in the muscle. In effect, the cerebellum compares the intended movement to the actual movement. Impulses then travel from the cerebellum to both the cerebrum and the muscle tissue to adjust or coordinate the movements to produce the intended action.<sup>39</sup>

**Etiology and clinical manifestations.** Cerebellar disorders may have myriad causes. Abscess, hemorrhage, tumors, trauma, viral infection, and chronic alcoholism have been implicated. Identification and eradication of the causal agent determine treatment and prognosis. The clinical manifestations of cerebellar disorders primarily include **ataxia** (muscle incoordination), hypotonia, intention tremors, and disturbances of gait and balance.<sup>39</sup> Disturbances of gait and balance vary, depending on the muscle groups involved. The walk, for instance, is often characterized by staggering or lurching and by a clumsy manner of raising the foot too high and bringing it down with a clap. Loss of cerebellar function does not result in paralysis.<sup>39</sup>

**FIGURE 45-9** The cerebrum and cerebellum work together to control muscles. Impulses from the cerebrum travel simultaneously to skeletal muscle and to the cerebellum. The cerebellum compares the intended movement with the actual movement and sends impulses to both the cerebrum and the muscle tissue, coordinating and smoothing muscle activity. (Redrawn from Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 5, St Louis, 2003, Mosby.)

#### KEY POINTS

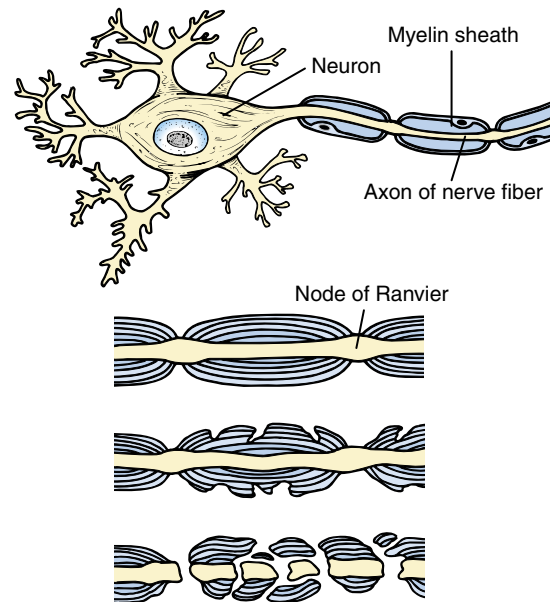

- The cerebellum is responsible for coordinated control of muscle action, excitation and inhibition of postural reflexes, and maintenance of balance.
- Etiologic factors in cerebellar disorders may include the following: abscess, hemorrhage, tumors, trauma, viral infection, or chronic alcoholism.
- Clinical manifestations of cerebellar disorders primarily include ataxia, hypotonia, intention tremors, and disturbances of gait and balance.

## SPINAL CORD AND PERIPHERAL NERVE DISORDERS

### Multiple Sclerosis

**Etiology.** Multiple sclerosis (MS) is a chronic demyelinating disease of the CNS that causes significant disability in young adults. It is thought to be an autoimmune disorder that results in inflammation and scarring (sclerosis) of the myelin sheaths covering nerves. It is estimated that 400,000 Americans have MS. The age of onset ranges from 20 to 50 years, and MS is two to three times more common in women than in men. Epidemiologic studies show that MS occurs at a higher rate among individuals from Caucasian northern European descent and those who live in northern latitudes. Several studies indicate that those who were born and spent the early years of life (first 15 years) in northern areas carry an increased risk of MS even if they migrate south at some time later in their lives.<sup>40</sup>

MS is an unpredictable disease with a wide variety of clinical presentations. Symptoms can vary daily, and the disease may cause only mild disability with occasional exacerbations. In some individuals, however, MS may cause extreme progressive disability. Despite great

**FIGURE 45-10** Changes in the nerve sheath, as seen in multiple sclerosis. Myelin is made by oligodendrocytes and coats nerves, facilitating nervous impulse. In patients with multiple sclerosis, the myelin degenerates in patches, causing nerve transmission to become erratic. (From Black JM et al: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1909.)

advances in research, the exact cause of MS is unknown. Genetics may have a role. Non-twin first-degree relatives have a 1 in 40 risk of developing MS.<sup>40</sup>

**Pathogenesis.** In MS, the demyelination of nerves can occur anywhere in the CNS. There does not seem to be any predictable pattern in the timing or location of the lesions. However, structures most frequently affected are the optic nerves; the oculomotor nerves; and the corticospinal, cerebellar, and posterior column systems. Figure 45-10 illustrates demyelination. Myelin facilitates nerve conduction; the inflammation and scarring that occurs with MS slows or interrupts the conduction of nerve impulses. The triggering event for this process is not understood. It is theorized that an exposure to a viral infection or environmental toxin initiates the autoimmune attack in a genetically predisposed individual. Both humoral and cellular immune factors have been implicated in demyelination. Antibodies to specific myelin proteins have been found in both the serum and the CSF of MS patients. T-cell lymphocyte-mediated injury to the myelin has also been implicated in causing the autoimmune damage and sustaining inflammation.<sup>41,42</sup>

**Clinical manifestations and treatment.** Symptoms of MS vary widely and depend upon the location of damage to the myelin. They include impaired visual acuity or blurred vision, diplopia, weakness, numbness, tingling, extreme fatigue, imbalance, movement disorders, spasticity, coordination difficulties and gait disturbance, bladder and/or bowel difficulties, vertigo, pain, and paresthesia. Neurobehavioral symptoms may include depression, emotional lability, sexual dysfunction, as well as memory and cognitive impairment (Table 45-1). In later stages of the disease, spastic paralysis of the limbs may be present because of upper motor neuron damage. Symptoms may be exacerbated by heat, infection, trauma, and stress. Relapses are also common in the postpartum period following pregnancy.<sup>43</sup> There are four main categories to classify the clinical course of MS (Table 45-2).

There is no conclusive diagnostic test for MS. The diagnosis is based on clinical characteristics, imaging studies, and laboratory evidence. The current diagnostic criteria for MS require documentation of two or more episodes of symptoms and two or more signs that reflect pathology in anatomically different areas of the CNS.<sup>42,43</sup> Advances in neuroimaging techniques have become quite useful in the diagnosis of MS. MRI of the brain and spinal cord may show the presence of demyelination (plaques). CNS lesions that are disseminated in time and space with no better explanation is one diagnostic criterion for MS.<sup>33</sup> Evoked potential recording of nerve stimulation in the visual and other nerve pathways may be helpful. Laboratory tests may show mild lymphocytosis and elevated serum protein levels, especially following an acute relapse. Elevated levels of immunoglobulin G (IgG) in

the CSF with the presence of discrete bands of IgG (oligoclonal bands) may also be present.<sup>44</sup>

There is no cure for MS. Treatment centers not only on managing the symptoms of the disease but also on minimizing the damage inflicted by the autoimmune attack on myelin. Corticosteroids such as prednisone are used to reduce edema and the inflammatory response in acute exacerbations. Recovery may be hastened by the use of these agents; however, the extent of recovery is unchanged.<sup>42</sup> Five drugs are currently approved by the FDA as disease-modifying agents for use in treating MS. Four are administered by injection: interferon beta-1a (Avonex and Rebif), interferon beta-1b (Betaseron), and glatiramer acetate (Copaxone). These medications reduce the number of attacks in relapsing-remitting MS. A fifth medication, mitoxantrone (Novantrone), is an antineoplastic medication that has been shown to be most helpful in decreasing symptoms of progressive-relapsing MS. Natalizumab (Tysabri) is a monoclonal antibody that has been shown to decrease the movement of myelin-damaging autoantibodies across the blood-brain barrier. Its use is limited under a special prescription program when benefits outweigh the risks of side effects.<sup>43,44</sup>

Management of symptoms frequently requires participation from multiple disciplines, including medicine, nursing, speech pathology, neuropsychiatry, social services, and vocational services. Treatment with an array of medications such as antispasmodics, anticholinergics,

**TABLE 45-1 MULTIPLE SCLEROSIS SYMPTOMS**

AREA OF DYSFUNCTION	SYMPTOMS
Cranial nerve dysfunction	Blurred central vision; faded colors; blind spots (optic neuritis) Diplopia Dysphagia
Motor dysfunction	Facial weakness, numbness, pain Weakness Paralysis Spasticity Abnormal gait
Sensory dysfunction	Paresthesias Lhermitte sign (electric shock–like sensation radiating down spine into extremities) Decreased proprioception Decreased temperature perception
Cerebellar dysfunction	Dysarthria Tremor Incoordination Ataxia Vertigo
Bowel and bladder dysfunction	Fecal urgency, constipation, incontinence Urinary frequency, urgency, hesitancy, nocturia, retention, incontinence
Cognitive dysfunction	Decreased short-term memory Difficulty learning new information Word-finding trouble Short attention span Decreased concentration Mood alterations (depression, euphoria)
Sexual dysfunction	Women: decreased libido, decreased orgasmic ability, decreased genital sensation Men: erectile, orgasmic, and ejaculatory dysfunction
Fatigue	Overwhelming weakness not overcome with increased physical effort

**TABLE 45-2 CLINICAL COURSE OF MULTIPLE SCLEROSIS**

COURSE	CHARACTERISTICS
<b>Relapsing-Remitting</b>	
Most common form; approximately 85% of MS patients have this form	Clearly defined exacerbations (relapses) with acute decline in neurologic function; followed by periods of partial/complete recovery and remissions; remissions may last months to years
<b>Primary-Progressive</b>	
Relatively rare; approximately 10% of MS patients have this form	Slow but almost continuous decline in neurologic function; plateaus or temporary minor improvements may occur; relapses/remissions not present; severe disability develops early
<b>Secondary-Progressive</b>	
Before use of disease-modifying drugs; approximately 50% of relapsing-remitting patients develop this form	Begins as relapsing-remitting; followed by steady decline in neurologic function with or without occasional relapses, remissions, or plateaus
<b>Progressive-Relapsing</b>	
Relatively rare; approximately 5% of patients have this form	Progressive from outset, but with clear exacerbations with or without recovery

Adapted from Goodin DS, Hauser LS: Multiple sclerosis and other demyelinating diseases. In Longo DL, Fauci AS, Kasper DL et al, editors: *Harrison's principles of internal medicine*, ed 18, New York, 2012, McGraw-Hill. Available at [www.accessmedicine.com.proxy.heal-wa.org/content.aspx?aID=9147780](http://www.accessmedicine.com.proxy.heal-wa.org/content.aspx?aID=9147780). Accessed 3/24/12. From Kerchner GA: Chapter 24: Nervous system disorders. In McPhee SJ, Papadakis MA, Rabow MV, editors: *Current medical diagnosis and treatment 2012*, New York, 2012, McGraw-Hill. Available at [www.accessmedicine.com.proxy.heal-wa.org/content.aspx?aID=12507](http://www.accessmedicine.com.proxy.heal-wa.org/content.aspx?aID=12507). Accessed 3/24/12.

antidepressants, and antimicrobials helps to manage symptoms. Treatment also includes avoidance of complications such as urinary tract infections, constipation/impactions, respiratory tract infections, and pressure sores.

Research in MS continues to examine the immune system role. Viruses such as the Epstein-Barr virus have been implicated.<sup>45</sup> Low levels of vitamin D have also been implicated as an associated risk factor, because this is a common finding in people living in higher latitudes.<sup>46</sup>

#### KEY POINTS

- MS is a demyelinating disease of the CNS that primarily affects young adults. The risk of contracting MS is greater for persons living in higher latitudes. The cause of MS is unknown, but immunologic abnormalities and environmental factors are suspected.
- Demyelination can occur throughout the CNS but most frequently affects the optic and oculomotor nerves and spinal nerve tracts.
- In most cases symptoms are slowly progressive, and the disease is marked by exacerbations and remissions.
- Symptoms include double vision, weakness, poor coordination, and sensory deficits. Bowel and bladder control may be lost. Memory impairment is common.
- Management is symptomatic. Short-term steroid therapy may be helpful during acute exacerbations, and immune-modifying drugs may slow the progression of symptoms.

### Spina Bifida

**Etiology and pathogenesis.** Spina bifida is a developmental anomaly characterized by defective closure of the bony encasement of the spinal cord (neural tube) through which the spinal cord and meninges may or may not protrude. If the anomaly is not visible, the condition is called *spina bifida occulta*. If there is an external protrusion of the saclike structure, the condition is called *spina bifida cystica* and is further classified according to the extent of neural involvement (e.g., meningocele, meningocele, or myelomeningocele) (Figure 45-11).

Both environmental factors and genetics appear to be a factor in the etiologic development of neural tube defects.<sup>47</sup> These include alcohol, vitamin deficiency (folate), congenital rubella, anti-acne (Accutane) and anticonvulsant drugs, and chromosomal abnormalities. Increased maternal age, obesity, and diabetes are also risk factors.<sup>47,48</sup> Substituting another anticonvulsant drug may be recommended for pregnant women or for those considering pregnancy. Supplementation of folic acid before conception and during pregnancy also appears to decrease the prevalence of neural tube defects.<sup>47,48</sup>

**Clinical manifestations.** In spina bifida occulta, the posterior vertebral laminae have failed to fuse. The defect is extremely common and occurs to some degree in 10% to 20% of the population.<sup>49</sup> The vast majority of these vertebral defects are located in the lumbosacral regions, most commonly in the fifth lumbar vertebra and the first sacral vertebra, and may be detected prenatally through ultrasound and  $\alpha$ -fetoprotein testing.

**FIGURE 45-11** Photographs of infants with spina bifida cystica. **A**, Spina bifida with meningocele in the lumbar region. **B**, Spina bifida with myeloschisis in the lumbar region. Note that the nerve involvement has affected the lower limbs. (In Moore KL, Persaud TVN: *The developing human: clinically oriented embryology*, ed 8, Philadelphia, 2008, Saunders. Courtesy Dr. Dwight Parkinson, Department of Surgery and Department of Human Anatomy and Cell Science, University of Manitoba, Winnipeg, Manitoba, Canada.)

Spina bifida occulta may be manifested by changes in the skin and body hair: either very coarse or silky hair along the spine; a midline dimple with or without a sinus tract; a cutaneous port-wine angioma; and/or a subcutaneous mass typically representing a lipoma or dermoid cyst.<sup>49</sup> Spina bifida occulta usually causes no serious neurologic problems. Common lumbosacral defects can cause gait disturbances, positional deformities of the feet, or bladder/bowel dysfunction. These symptoms become evident in childhood during periods of rapid growth.

In the **meningocele** form of spina bifida cystica, a saclike cyst filled with CSF protrudes through the spinal defect but does not involve the spinal cord. Meningoceles occur with equal frequency in the cervical, thoracic, and lumbar areas. A **myelomeningocele** or **meningomyelocele** deformity contains meninges, CSF, and a portion of the spinal cord that protrude from the vertebral defect in a cystlike sac. These defects most often occur in the lumbar or lumbosacral region of the spine, since these are the last areas of the neural tube to close during fetal development. These defects may be detected in prenatal ultrasound and with  $\alpha$ -fetoprotein testing.<sup>50</sup> The bony prominences of the unfused neural arches are palpable at the lateral borders of the defect. The sac includes a transparent membranous covering that may have neural tissue attached to its inner surface. This membrane may be intact at birth or leak CSF, thereby increasing the risk of infection and neural damage. These infants are delivered via cesarean section to decrease the trauma to the exposed neural tissue, and surgical closure is attempted soon after delivery.<sup>51</sup> Affected infants often suffer from permanent neurologic damage resulting in motor weakness or paralysis and sensory deficit below the level of the spinal defect; bowel and bladder dysfunction; scoliosis; hydrocephalus; and seizures. Often the problems worsen as the child grows and the cord ascends within the vertebral canal, pulling primary scar tissue and thereby tethering the cord.<sup>49</sup> Attempts at closing the defect surgically in utero before delivery are currently being studied, and early results appear promising.<sup>51</sup>

**Treatment.** Treatment for this common disorder is based on the severity of the defect and neurologic dysfunction. Supplementation with folic acid during the period before conception has been shown to significantly decrease the risk of having a child with a neural tube defect. It is recommended that all women of childbearing age take 0.4 mg of folic acid daily for prevention. In fact, in the United States common foods are being supplemented with folic acid to decrease the incidence of this deformity.

#### KEY POINTS

- Spina bifida is a developmental anomaly characterized by defective closure of the bony encasement of the spinal cord (neural tube) through which the spinal cord and meninges may or may not protrude.
- If the anomaly is not visible, the condition is called *spina bifida occulta*. If there is an external protrusion of the saclike structure, the condition is called *spina bifida cystica*, and is further classified according to extent of neural involvement (e.g., meningocele, myelomeningocele).
- The natural history of myelomeningocele supports an early and aggressive operative approach before significant clinical deterioration begins. A cesarean section before rupture of amniotic membranes and onset of labor may decrease the degree of paralysis.
- Folic acid supplementation taken before conception and during pregnancy appears to decrease the prevalence of neural tube defects.

### Amyotrophic Lateral Sclerosis

**Etiology and pathogenesis.** Amyotrophic lateral sclerosis (ALS) is a progressive degenerative disease affecting both the upper and the lower motor neurons characterized by muscle wasting and atrophy of the hands, arms, and legs. There are pathologic changes in the spinal

cord that include degeneration of the lateral columns where the corticospinal tracts are located. ALS is also known as Lou Gehrig disease after the famed “Iron Man” of the New York Yankees who died from the disease. ALS affects an estimated 30,000 Americans at any given time. It most commonly strikes between the ages of 40 and 60 with a higher incidence in men than women. The majority of ALS cases occur at random; however, 5% to 10% of cases are familial.<sup>52</sup> There is also a higher incidence of the disease in military veterans, especially those of the Persian Gulf.<sup>53</sup> Although ALS is classified as a single disease entity, emerging evidence suggests that it is a clinical syndrome with several possible causes. It appears that sporadic cases of ALS are multifactorial and related to several environmental factors and a genetic predisposition. Smoking is the only probable risk factor identified at this point. Several unproven risk factors have been considered. These include lead or agricultural chemical exposure, viral infection, lymphoproliferative disease, and physical prowess.<sup>54</sup>

Genetic research has determined at least four different genetic mutations that are involved in ALS. One in particular involves a gene responsible for coding the free radical-scavenging enzyme superoxide dismutase 1 (*SOD1*). *SOD1* is the basis for much ALS research, and there seem to be multiple intracellular enzymatic pathways affected and causing premature programmed cell death, or **apoptosis** (see Chapter 4), of the neurons. Like Alzheimer and Parkinson diseases, ALS has been linked with oxidative stress and cellular damage. Neurons are highly susceptible to damage from oxygen free radicals and the activation of immune cells that propagate further cellular injury. High levels of the neurotransmitter glutamate have also been found in the CSF of ALS patients and are thought to be associated with the neuronal degeneration.<sup>55,56</sup> Other factors that may be involved in the pathogenesis include protein aggregation, mitochondrial dysfunction in motor neurons, and defective axonal transport.<sup>55</sup>

**Clinical manifestations and treatment.** Most patients with ALS demonstrate muscle weakness and atrophy. The earliest symptoms may be muscle twitching, cramping, and stiffness. Often the hands or upper extremities are affected first. The weakness is progressive and eventually affects the muscles that control speech, swallowing, and breathing. Finding hyperreflexia in a weak atrophied extremity is highly suggestive of ALS. Most individuals die from respiratory failure within 3 to 5 years from the onset of symptoms.<sup>54</sup> Despite the marked physical disability, most patients maintain their sensory and cognitive functions.

ALS is a diagnosis of exclusion, based on the patient’s clinical signs and symptoms. Electromyography (EMG), nerve conduction studies, MRI, and serum laboratory testing may be used to rule out other causes of weakness, such as MS, brain and spinal tumors, human immunodeficiency virus, and Lyme disease.

The only FDA-approved treatment for ALS is riluzole (Rilutek), a glutamate inhibitor. This medication is not a cure, but its use can prolong life for several months and may delay the need for mechanical ventilation.<sup>54</sup> Patients with ALS benefit from a multidisciplinary approach to care to prevent complications from immobility as well as to address both physical and psychological needs.

#### KEY POINTS

- ALS is a progressive disease affecting both the upper and the lower motor neurons. The cause of ALS remains unknown. Weakness and wasting of the upper extremities usually occur, followed by impaired speech, swallowing, and respiration.
- ALS usually strikes between the ages of 40 and 60, and it is more common in men than in women. The mean survival time is about 3 years from the time of diagnosis.

- Clinical manifestations include weakness, atrophy, cramps, stiffness, and irregular twitching of muscle fibers.
- Diagnosis is based on clinical signs and symptoms, EMG results, nerve conduction studies, MRI studies, and serum laboratory testing.
- Riluzole (Rilutek) is a glutamate inhibitor, which may be helpful in management of ALS.

### Spinal Cord Injury

Spinal cord injuries are among the most devastating and costly problems faced by patients and their families. Marked changes in lifestyle are required for survivors. Medical advances in the emergent management of spinal cord injuries and their associated complications have been responsible for increasing survival rates. Continuing research is focused on minimizing the incidence of injury and the mortality/morbidity of spinal cord injury.

**Etiology.** Spinal cord injury is primarily a problem of the young. Males are three to four times more likely to have suffered a spinal cord injury, and these injuries are most common on the weekends and during the summer months. Motor vehicle crashes contribute the highest number of spinal cord injuries, followed by violence (primarily gunshot wounds), falls, and recreational accidents.<sup>57</sup> Alcohol use and risk-taking behavior are often involved. Other causes of spinal cord injuries include birth injuries, herniated intravertebral disk, or bone spurs related to degenerative changes of aging and osteoporosis. Injuries to the spinal cord are classified by level, degree (complete or incomplete), and mechanism of injury (Box 45-2).

**Pathogenesis.** Spinal cord injury results from compression (tumor, hematoma, or bony encroachment) and from blunt trauma causing contusion or penetration/transection of neural tissue. The major mechanisms of injury are hyperflexion, hyperextension, and compression (Figure 45-12). Flexion injury with tearing of the posterior ligaments and dislocation is the most unstable injury and is often associated with severe neurologic deficits. Hyperextension injury is the most common. Aside from the primary injury to the spinal cord, damage also results from secondary injury. Secondary events result in edema, ischemia, excitotoxicity, and inflammation, causing increased cell death, disruption of the blood-brain barrier, cavitation, and demyelination, which are detrimental to functional recovery. Not all of these processes are well-understood, but substantial damage occurs because of these events. Neutrophils are the first immune cells to appear at the primary injury site.<sup>58</sup> Oxidative and proteolytic enzymes produced by the neutrophils sterilize the damaged area and prepare it for “repair.” However, these neutrophils can cause further damage. Macrophages also infiltrate the area and contribute to further damage by releasing proinflammatory cytokines, reactive oxygen species, nitric oxide, and proteases. T lymphocytes, which are responsible for cell-mediated immunity, have also been identified in the site of injury. Whether T lymphocytes cause secondary injury or help with healing is still a matter of debate.<sup>58</sup>

The systemic hemodynamic changes that occur after spinal cord injury are a major factor in the resulting damage to the spinal cord. Because of the injury to the spinal cord, autoregulation is lost, resulting in a profound drop in systemic blood pressure. This adds to the ischemia of the tissue. In addition, spinal cord injuries are often accompanied by trauma to other organ tissue causing hypoxia, hypotension, hyperthermia/hypothermia, and hypoglycemia/hyperglycemia.

**Clinical manifestations.** Immediately following injury to the spinal cord, there is complete loss of function below the level of injury. This may occur even in incomplete injuries to the spinal cord, causing the injury to appear more severe than it actually is. This phenomenon,

### BOX 45-2 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

- A** = Complete: No motor or sensory function is preserved in the sacral segments S4 to S5.
- B** = Incomplete: Sensory function (but not motor function) is preserved below the neurologic level and includes the sacral segments S4 to S5.
- C** = Incomplete: Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
- D** = Incomplete: Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or more.
- E** = Normal: Motor and sensory function are normal.

Standards for Neurological Classification of SCI Worksheet (Dermatome Chart), 2011. From American Spinal Injury Association. Available at <http://www.asia-spinalinjury.org/publications>.

known as **spinal shock**, can last from a few hours to a few weeks. Symptoms below the level of injury include flaccid paralysis of all skeletal muscles; loss of all spinal reflexes; loss of pain, proprioception, and other sensations; bowel and bladder dysfunction with paralytic ileus; and loss of thermoregulation. A return of spinal reflexes indicates the end of spinal shock. As reflex function returns, spastic paraplegia or quadriplegia develops with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord affected. The bladder and bowel may regain some reflex function.

In patients with cervical or upper thoracic cord injury, **neurogenic shock** is a life-threatening complication. Neurogenic shock is a form of distributive shock caused by the loss of brainstem and higher center control of the sympathetic nervous system. The loss of sympathetic outflow results in hypotension caused by peripheral vasodilation. Bradycardia occurs (secondary to the overriding parasympathetic influence), and there is a loss of the cardiac accelerator reflex. The loss of impulses from the temperature regulatory center in the brain prevents the ability to sweat below the level of injury.

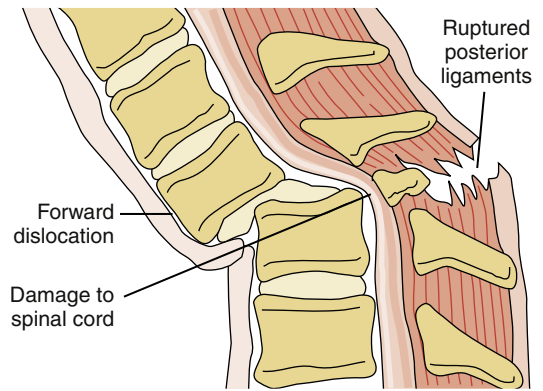

A chronic, ongoing complication of spinal cord injuries occurring at or above the T6 vertebra is **autonomic dysreflexia**. This is a potentially life-threatening complication that may occur any time after spinal shock has resolved. It is characterized by a sudden episode of hypertension, headache, bradycardia, upper-body flushing and lower body vasoconstriction, piloerection (goose bumps), and sweating. The usual stimulus initiating autonomic dysreflexia is activation of visceral or cutaneous pain receptors below the level of injury. A full bladder or constipation is a common cause.

Stimulation of afferent pain receptors causes activation of sympathetic efferents in the cord and reflex vasoconstriction. Sustained activation of sympathetic neurons below the level of cord injury increases blood pressure significantly. The hypertension initiates the baroreceptor response. Baroreceptors mediate inhibition of heart rate and vasodilation of vessels above the level of injury. This is responsible for the upper body flushing. Descending signals from the brain cannot pass the cord injury, so inhibition of sympathetic neurons below the level of injury does not occur. Blood pressure may be dangerously high, and may require aggressive treatment.

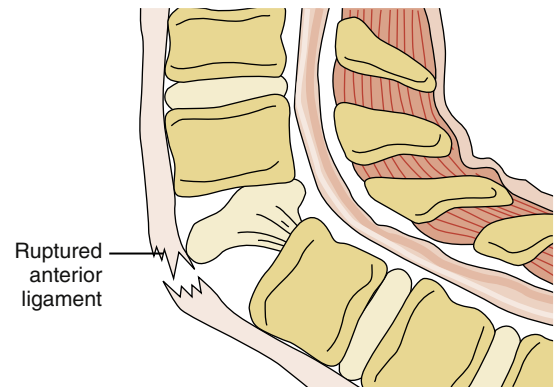

**Treatment.** Management of spinal cord injuries includes appropriate stabilization of spinal vertebra components to prevent further trauma to the spinal cord. This may be accomplished surgically with internal fixation; or with external fixation and bracing.<sup>59</sup> During

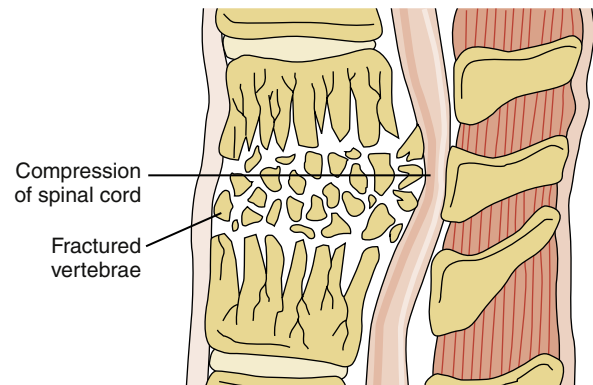

A Flexion

B Hyperextension

C Compression

**FIGURE 45-12** Mechanisms of spinal cord injury. Many situations may produce these consequences. This figure shows examples only. **A**, Flexion injury of the cervical spine ruptures the posterior ligaments. **B**, Hyperextension injury of the cervical spine ruptures the anterior ligaments. **C**, Compression fractures crush the vertebrae and force bony fragments into the spinal canal.

neurogenic shock, patients require intensive care to maintain oxygenation and blood pressure. The use of high-dose methylprednisolone initiated within the first 8 hours after injury and continued for 24 hours may preserve some function by decreasing the secondary injury to the spinal cord.<sup>60</sup> The benefit of this medication is modest at best, but it offers some hope of improving function. Ongoing assessment is critical. Methodical neurologic evaluations are important in determining

improvement or deterioration in function. Treatment for autonomic dysreflexia includes removing or alleviating the painful stimulus, and in certain situations the use of adrenergic receptor–blocking medications to manage the hypertensive crisis.

Individuals suffering from spinal cord injuries have chronic and ongoing problems with spasticity and contracture related to upper motor neuron damage. They are also at high risk for respiratory and

**TABLE 45-3 LEVELS OF INJURY AND EXPECTED FUNCTIONAL ABILITY FOR PATIENTS WITH SPINAL CORD INJURY**

LEVEL	NORMAL ACTIVITY	FUNCTIONAL EXPECTATION
C4	Head control Mouth control Shoulder/scapular movement Diaphragm movement	Can use adaptive devices (i.e., mouth stick) for phone, reading, computer Total dependence for transfers/ADLs Pulmonary hygiene concerns; skin care issues
C5	Shoulder flexion Elbow flexion Increased scapular motion	Can use adaptive devices for self-feeding; can move wheelchair short distances (electric wheelchair preferred); can perform ADLs and bed mobility with assistance; needs pulmonary hygiene assistance
C6	Good elbow flexion Wrist extension Shoulder rotation and abduction	Independent with grooming/feeding with adaptive devices; weak hand grasp; can roll over in bed; can drive with car adaptations; can transfer with assistance; can self-propel wheelchair
C7	Elbow extension Strong wrist extension Good shoulder movement	Can transfer to wheelchair independently; can perform most ADLs independently; excellent bed mobility
T1	Normal hand strength Normal upper body strength	Bed and wheelchair independent; can perform self-catheterization
T10	Normal strength/motion above umbilicus	May stand for exercise with braces; still wheelchair dependent for ambulation
L2-L5	Some leg and thigh movement	Can ambulate indoors with braces/canes
Sacral segments	Mild weakness in lower extremities	Can ambulate with braces/canes; still significant bowel/bladder dysfunction

ADLs, Activities of daily living.

urinary tract infections, skin pressure sores, septicemia, and fecal impaction. Much of the care of patients with spinal cord injuries is aimed at preventing these complications and maximizing function. The rehabilitation phase for these patients is lengthy with emphasis on independence and self-care. Ongoing care of patients with spinal cord injuries is multidisciplinary and should also address the psychosocial impact of this life-changing event. Levels of injury and expected functional ability are summarized in Table 45-3.

#### KEY POINTS

- Spinal cord injury is usually traumatic, a result of motor vehicle accidents, falls, penetrating wounds, or sports injuries. The cord may be compressed, transected, or contused. Further injury may result from hemorrhage, swelling, and ischemia after injury.
- Spinal shock occurs immediately following injury and is characterized by temporary loss of reflexes below the level of injury. Muscles are flaccid, and skeletal and autonomic reflexes are lost. The end of spinal shock is noted when reflexes return and flaccidity is replaced by spasticity.
- Neurogenic shock may occur after spinal cord injury due to peripheral vasodilation. Hypotension and circulatory collapse may occur. High spinal cord injuries may also affect respiratory muscles, leading to ventilatory failure.
- Autonomic dysreflexia is an acute reflexive response to sympathetic activation below the level of injury. Visceral stimulation (full bladder or bowel) and activation of pain receptors below the injury are common initiating stimuli. Manifestations include hypertension, bradycardia, flushing above the level of injury, and clammy skin below the level of injury. Prompt removal of the offending stimulus is indicated.

### Guillain-Barré Syndrome

**Etiology and pathogenesis.** Guillain-Barré syndrome, also known as *acute idiopathic polyneuropathy* or *polyradiculoneuropathy*, is an inflammatory demyelinating disease of the *peripheral* nervous system or a lower motor neuron disorder. Between 1 and 4 cases per 100,000 individuals occur annually, with an increasing incidence in the aging

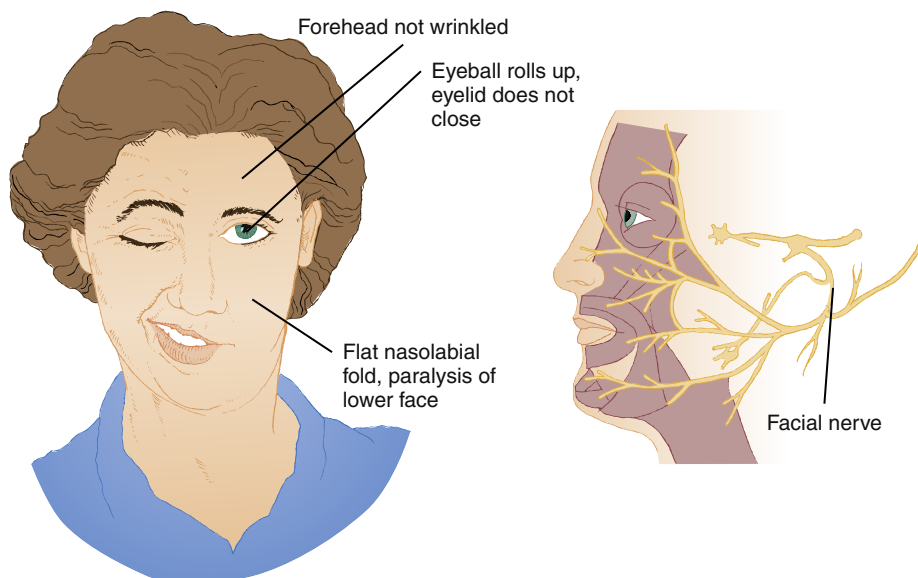

population. It is one of the most common causes of nontraumatic paralysis in the Western world. There is a slight male preponderance.<sup>61</sup>

The cause of Guillain-Barré syndrome is not well understood, but it sometimes follows an infection, inoculation, or surgical procedure 1 to 8 weeks before the onset of signs and symptoms. *Campylobacter jejuni* enteritis has been associated with the syndrome.<sup>61</sup> The basis for Guillain-Barré syndrome is probably immunologic, but the exact mechanism is unknown. There is segmental demyelination, and most evidence suggests that this damage is T-cell and B-cell mediated. Aggregates of lymphocytes are found at the sites of demyelination. This process slows or stops nerve conduction. Primarily motor neurons are affected, but sensory nerves may also be involved.<sup>61</sup>

**Clinical manifestations and treatment.** Patients with Guillain-Barré syndrome have progressive ascending weakness or paralysis. It usually begins in the legs, spreading often to the arms and face. The respiratory muscles may also be affected. The severity and extent of neurologic deficit may vary greatly between patients. Most patients reach the peak of disability in 10 to 14 days. Sensory nerves may also be affected, but to a lesser extent than motor neurons. Patients may experience paresthesia or dysesthesia; neuropathic pain may also be present. During this time, patients may demonstrate loss of autonomic regulation, with consequent changes in blood pressure and heart rhythm, and may require intensive care for ventilatory and circulatory support.

Diagnosis of Guillain-Barré syndrome is made through patient history, physical examination, and nerve conduction studies. The CSF characteristically contains high protein concentrations. Other laboratory studies and imaging are used to rule out other causes for neurologic dysfunction.

The majority of patients experience spontaneous recovery; however, 10% to 15% of patients may be left with a mild disability.<sup>61</sup> Gradually, neurologic function returns, often in a descending pattern with upper extremities recovering earlier than lower extremities. Treatment within 14 days of onset of symptoms with plasmapheresis, especially in those with severe or rapidly progressing symptoms, has been shown to have some value. Intravenous immunoglobulin is also helpful.

**FIGURE 45-13** Bell palsy. Locations of the branches of the facial nerve (cranial nerve VII) correspond to the areas of peripheral facial paralysis. (From Black JM et al: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2008, Saunders, p 1886.)

However, nearly 5% to 10% of patients may experience one or more exacerbations of symptoms.<sup>62</sup> Nursing care of these patients is aimed at preventing complications of immobility.

#### KEY POINTS

- Guillain-Barré syndrome is characterized by muscle weakness that begins in the lower extremities and spreads to the proximal spinal neurons.
- The cause is unknown; however, a postinfectious immunologic mechanism is suspected.
- Treatment is supportive, and spontaneous recovery usually occurs.

### Bell Palsy

**Etiology and pathogenesis.** Bell palsy is an acute idiopathic paresis or paralysis of the facial nerve involving an inflammatory reaction at or near the stylomastoid foramen or in the bony facial canal with probable occurrence of compression, ischemia, and demyelination. The incidence peaks in the 40- to 49- year-old age group.<sup>63</sup> There is mounting evidence that Bell palsy is caused by a viral infection. Antibodies to the herpes simplex and herpes zoster viruses have been found in patients with Bell palsy.

**Clinical manifestations and treatment.** Symptoms of Bell palsy develop rapidly over 24 to 48 hours. Physical examination shows unilateral facial weakness with facial droop and diminished eye blink, **hyperacusis**, and decreased lacrimation (Figure 45-13). Patients may complain of a heavy sensation in their face as well as a decreased sense of taste, but sensation of the face is generally intact. Posterior auricular

pain may be present. In the diagnosis of Bell palsy, other causes of facial paralysis, such as bacterial infection (otitis media), tumor, trauma, and cerebrovascular accident (stroke), must be ruled out. MRI, CT, and EMG can be helpful in certain situations. Laboratory testing is of limited value.

Management of Bell palsy is controversial. Most patients recover facial nerve function spontaneously within approximately 3 weeks. However, approximately 15% of patients are left with some level of residual disability.<sup>63</sup> Patients with the poorest prognosis for complete recovery are individuals older than 60 years, those with diabetes, and those who have had symptoms lasting longer than 3 months.<sup>3</sup> Prevention of corneal damage resulting from the inability of the eye to close is vital. Lubricating drops, ointments, and nighttime eye patching may be necessary. The use of corticosteroids has been shown to improve the likelihood of complete recovery. Because of the association of viruses with Bell palsy, the use of antiviral medications such as acyclovir or valacyclovir is recommended. Studies regarding the use of these medications have shown inconsistent results, but two recent studies show benefit when these drugs are combined with corticosteroids.<sup>3</sup> Surgical decompression of the nerve has not been shown to confer great benefit.<sup>3</sup>

#### KEY POINTS

- Bell palsy, or neuropathy of the facial nerve, results in paralysis of the muscles on one side of the face. Often a self-limiting condition with unknown cause, Bell palsy may last only a few days or weeks.
- Treatment is supportive, and spontaneous recovery usually occurs.

## SUMMARY

A traumatic event, such as a spinal cord injury, or a chronic neurologic disease, such as dementia, can transform an individual from a relatively healthy state to one of almost complete dependence. At best, some of the neurologic states described in this chapter may resolve spontaneously or require only minor lifestyle adjustment, but more commonly, chronic neurologic conditions require lifetime rehabilitation.

The process of life care planning includes taking stock of current health status, future health care concerns, appropriate resources, and associated costs to address lifelong disability and illness management.

In general, the goal of rehabilitation is to increase self-care and promote a meaningful lifestyle that incorporates the neurologic disability. The primary goal of such tertiary prevention is to help the affected individual maintain the highest possible level of wellness.

The human body has countless sense organs that fall into two main categories: general sense organs and special sense organs. By far the most numerous are the general sense organs or receptors. The receptors function to produce the general or somatic senses. Examples of these senses are touch, temperature, and pain, and the receptors that initiate various reflexes necessary for maintaining homeostasis (see Chapter 43). The largest general sense organ in the body is the skin.

Special sense organs, by comparison, function to produce the unique sensations of hearing, balance, vision, smell, and taste. These senses allow humans to interact with their environment in a meaningful way.

Alterations in sensory function may be acute/short-term, chronic/long-term, or progressive in nature. They may result from such factors as genetics, disease, infection, trauma, and normal aging. Alterations in special sensory function require prompt assessment, evaluation, and treatment from appropriate health professionals. Equally important is an assessment of how the sensory impairment affects the individual's activities of daily living. This chapter discusses special sensory function with regard to physiologic processes, sensory impairment, and the diagnosis and management of these impairments.

## HEARING AND BALANCE

### STRUCTURE AND FUNCTION OF THE EAR

#### External Ear

Hearing results from normal functioning of several complex structures both external and internal to the body. Sound consists of waves of vibrations in the air, produced in the environment. These vibrations travel much like ripples in a pool of water. Externally, these vibrations are caught and funneled into the ear canal by the auricles (Figure 46-1). Even though the auricles are in a fixed position and lie close to the head, their shape serves to concentrate sound waves, especially high-frequency waves. The auricles also have an important role in sound localization.

The ear canal has a somewhat S shape from its opening to its termination at the tympanic membrane. This configuration affords both protection from airborne foreign objects and access to sound. The outer portion of the ear canal contains hair to filter out unwanted substances. Along the ear canal are also glands that secrete cerumen. This brown, waxlike substance coats the hairs in the canal to help prevent the entrance of foreign bodies into the ear canal. After entering the

ear canal, sound waves strike the tympanic membrane (eardrum) and cause it to vibrate. The tympanic membrane is a thin, elastic membrane that is very sensitive to changes in pressure.

#### Middle Ear

The middle ear is a bony, air-containing space that functions primarily as a structure by which sound energy is transmitted from the air to the fluids of the inner ear. The tympanic membrane is connected to the first of the **ossicles**, the malleus (hammer), followed by the incus (anvil) and stapes (stirrup). The ossicles further amplify the sound waves and then transfer airborne sound waves to the fluid-filled inner ear at the oval window.

The eustachian tube is also part of the middle ear, and although it does not contribute directly to the transmission of sound through the ear, absence of proper function can greatly affect hearing. This tube has a mucosal lining and extends from the middle ear cavity to the nasopharynx. It makes equalization of pressure against the inner and outer surfaces of the tympanic membrane possible, thus improving mobility of the membrane for sound transduction. A patent eustachian tube prevents membrane rupture and discomfort that marked pressure differences can produce.

#### Inner Ear

The inner ear is composed of the oval window, the cochlea, and the semicircular canals. Within the cochlea are three parallel tubes: the scala vestibuli, the scala media, and the scala tympani. Movement of the perilymph, a fluid much like cerebrospinal fluid, in the scala vestibuli and the scala tympani is eventually dissipated by movement of the round window (Figure 46-2). The scala tympani and the scala vestibuli are continuous with one another at the apex of the cochlea through an opening called the *helicotrema*.

Transmission of the sound stimulus from the scala vestibuli to the vestibular membrane results in displacement of the endolymph, the fluid contained in the membranous labyrinth of the scala media and the basilar membrane. The organ of Corti, which contains the receptors for hearing, lies on the basilar membrane. Perilymph and endolymph transmit the mechanical vibrations from the footplate of the stapes to the organ of Corti. Endolymph also transports nutrients to the organ of Corti. No direct communication between endolymph and perilymph is normally present.

The organ of Corti consists of a series of sensory hair cells and supporting cells. These cells are innervated by the sensory fibers from the

FIGURE 46-1 Anatomic structures of the ear.

vestibulocochlear nerve (cranial nerve VIII). Overhanging the organ of Corti is a flexible flap of tissue called the *tectorial membrane* (Figure 46-3). Hairs of the sensory cells of the organs of Corti are in contact with the tectorial membrane. The wave of perilymph induces movement of the basilar membrane, which causes a pull or shearing force on the hair cells in contact with the tectorial membrane. This action transforms the mechanical energy of sound into electrical impulses stimulating the vestibulocochlear nerve. Impulses are relayed through nuclei in the medulla, pons, midbrain, and thalamus before reaching the auditory area of the temporal lobe.

## Balance

The ear has dual sensory functions. In addition to its role in hearing, it also functions as the sense organ of **equilibrium**. The stimulation or “trigger” responsible for balance involves activation of receptor hair cells contained in the semicircular canals. Movement of the head causes movement of the endolymph contained in the semicircular canals. The receptor hair cells in turn create a nerve impulse in the vestibular portion of the vestibulocochlear nerve (cranial nerve VIII), where the stimulus is transmitted to the brain. Signals from the inner ear are involved not only in keeping individuals upright but also in controlling the eye muscles so that the eyes can remain fixed on the same point despite changes in the position of the head.

**Vertigo.** Vertigo is a common symptom of vestibular disorders rather than a well-defined disease. It is either a sensation of motion without any actual motion or an exaggerated sense of motion; it is not simply a sensation of “spinning.” Accompanying symptoms may include nausea, vomiting, pallor, and sweating. **Nystagmus** often is also noted. It is not associated with a loss of consciousness or a feeling of impending loss of consciousness more common to syncope. Vertigo can have a peripheral vestibular cause or central causes. In the case of

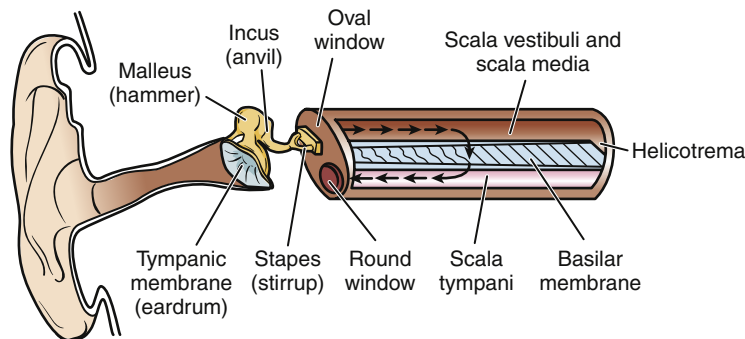

Meniere disease (discussed later in this chapter), a disorder in which vertigo is common, the cause is unknown.

Disorders of the brainstem or cerebellum that may also cause vertigo include tissue ischemia secondary to atherosclerosis, tumors, or conditions such as psychiatric disorders, migraine headaches, or multiple sclerosis. However, in these cases, additional neurologic signs and symptoms are typically present. Drugs may also cause vertigo (alcohol, anticonvulsants, sedatives). Management of vertigo is usually aimed at the cause if known. Medications such as antihistamines and anticholinergics can be helpful.<sup>1</sup>

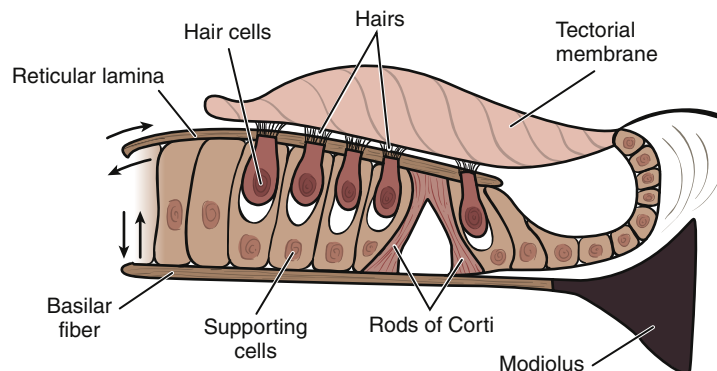

## GENERAL MANIFESTATIONS OF HEARING IMPAIRMENT

Hearing impairment is a very common disorder and a leading chronic health problem in the United States. Approximately 17% (36 million) of American adults report some degree of hearing loss. Out of 1000 U.S. children, 2 to 3 are born deaf or hard of hearing.<sup>2</sup>

Hearing may be impaired in many ways, and impairments can occur across the age spectrum. Disorders may affect the outer ear, such as impacted cerumen and foreign bodies in the ear canal. The middle ear may be affected by fluid **effusion**, infection (otitis media), tumors, or diseases such as otosclerosis. Hearing loss may also be caused by repeated exposure to loud sounds or **ototoxic** medications such as aminoglycoside antibiotics, chemotherapeutic agents, and high-dose loop diuretics. Some of these medications can cause hearing loss even when administered at therapeutic doses.<sup>3</sup> Other causes of hearing loss, especially in children, include infection (measles, meningitis), environmental teratogens (radiation), intrauterine infections (cytomegalovirus, herpes simplex virus, human immunodeficiency virus, and *Toxoplasma*), maternal metabolic disorders (diabetes,

**FIGURE 46-2** Movement of fluid in the cochlea after forward thrust of the stapes.

**FIGURE 46-3** Stimulation of hair cells by the back-and-forth movement of the hair cells in the tectorial membrane.

hypothyroidism), and exposure to industrial chemicals (solvents or pesticides). In adults poor nutrition and smoking also contribute to hearing loss.<sup>4,5</sup> By whatever mechanism hearing impairment occurs, the signs and symptoms are similar.

Symptoms of hearing impairment may be manifested in behavior such as inattentiveness, speaking out of turn in conversations, withdrawal from social situations, increased volume of voice when speaking, increased volume of radio or television, confusion, loss of reaction to loud sounds, and emotional outbursts. Children with hearing impairment may demonstrate inattentiveness and difficulty with articulation and the development of speech. Alterations in hearing function can generally be classified into two categories, conductive and sensorineural, depending on the cause of the impairment. Some hearing impairments have a component of both. The following alterations in hearing function are categorized according to the primary cause of dysfunction.

## HEARING IMPAIRMENT DISORDERS

### Conductive Hearing Impairment

Conductive hearing loss occurs when sound cannot reach the cochlea. Individuals with conductive hearing impairment have a decreased sensitivity to sound. This type of hearing impairment is caused by dysfunction in the external or middle ear. Four mechanisms, each resulting in impairment of the passage of sound vibrations to the inner ear, lead to conductive hearing impairment: (1) obstruction (cerumen impaction), (2) mass loading (middle ear effusion), (3) stiffness effect (otosclerosis), and (4) discontinuity (ossicular disruption). Conductive hearing loss is generally correctable with medical or surgical therapy—or in some cases both.<sup>3</sup>

#### Loss Caused by Cerumen Impaction and Foreign Body Occlusion

**Etiology.** Cerumen impaction is a common and frequently overlooked cause of conductive hearing loss, especially in the elderly. In most cases, cerumen impaction is self-induced through attempts at cleaning the ear with objects such as cotton swabs. Foreign bodies in the ear canal occur most frequently in children. Objects such as small stones, pieces of wood, peas, beans, and paper are fairly common.

**Clinical manifestations and treatment.** Sometimes no symptoms are present and the foreign body is discovered on routine examination. If the foreign body is an insect, beating of its wings and movement may cause distress. When symptomatic, however, foreign bodies can cause pain or drainage of pus from the ear. The external ear canal is very sensitive to touch and bleeds easily, which increases the risk for subepithelial hematomas from minor trauma. Therefore, removal of solid foreign bodies carries a risk of additional trauma to the ear canal, as well as tympanic membrane rupture, if the individual is not completely cooperative or removal is difficult. Light anesthesia may be necessary. Firm materials may be removed from the canal with loop or hook instruments, taking care not to push the object further into the canal. Irrigation should not be performed on organic foreign bodies (beans, peas) because water may cause them to swell. Living insects may be immobilized with lidocaine before removal.<sup>3</sup> Excess cerumen may be removed with gentle irrigation.

#### Otosclerosis

**Etiology.** Otosclerosis is a progressive conductive, sensorineural, or mixed hearing impairment caused most often by stapedial fixation. Resorption of bone is followed by the formation of new sponge-like bony lesions usually occurring on and around the ossicles of the middle ear. Lesions involving the footplate of the stapes cause decreased

transmission of sound waves to the oval window. However, when otosclerotic lesions impinge on the cochlea, permanent sensorineural hearing loss can occur. The basic initiating factors are unknown, but up to 50% of individuals with clinical otosclerosis have a history of the disease in the family.<sup>6</sup> Several types of inheritance patterns have been suggested. The disease is most common in Caucasian middle-aged women. Pregnancy may accelerate the otosclerotic process.<sup>6</sup> Viral infections and autoimmune processes are also thought to be possible causes. The age of onset is variable due to the insidious progression of the disorder, but the most common ages are between 15 and 45. There may be periods of symptom worsening, followed by times of little apparent change.

**Diagnosis and treatment.** The diagnosis of otosclerosis is made through careful history taking and radiologic studies, along with audiometric studies. Generally, hearing loss begins in one ear, but 80% to 90% of affected individuals will develop bilateral impairment.<sup>6</sup> Although hearing loss may be severe, speech discrimination is preserved except in the instance of cochlear involvement. The individual may report being able to hear better in a noisy environment than in a quiet one. **Tinnitus** is often present. Hearing tests reveal a conductive loss of varying severity.

Management of otosclerosis at this point is generally surgical, in an effort to prevent the conductive hearing loss. The limitation on treatment options for otosclerosis is related largely to the lack of exact knowledge regarding the cause and pathogenesis of the disease. The universally accepted operation for otosclerosis is stapedectomy, or removal of the focus of the disease by removing the stapes and inserting a prosthesis. In the case of otosclerosis involving the cochlea, treatment with oral sodium fluoride and bisphosphonates is associated with some decrease in development of the sensorineural hearing loss.<sup>7</sup> Amplification with hearing aids is another approach.

### Sensorineural Hearing Impairment

In sensorineural hearing impairment, the hearing mechanism is disturbed in the inner ear in the cochlea or the vestibulocochlear nerve to the brain. Long-term exposure to loud sounds, ototoxic medication, trauma, metabolic causes, aging, and certain disease states cause sensorineural hearing impairment. Sensorineural hearing loss is usually irreversible. Progress, however, is being made in using novel approaches to protect the hair and supporting cells of the inner ear.<sup>8</sup>

#### Loss Caused by Ototoxic Medications

Drug toxicity is an increasingly important cause of sensorineural hearing loss. The drugs most well-known for this effect are the aminoglycoside antibiotics, salicylates, quinine and related antimalarials, and cytotoxic antineoplastic drugs. Most ototoxic drugs affect the hair cells of the cochlea. Unfortunately, these ototoxic effects may not become apparent during drug administration but may occur days to weeks after the therapy has been terminated. Ototoxicity may also be unilateral. Aspirin can produce a temporary hearing loss and tinnitus in individuals receiving high doses. In most cases, however, both of these symptoms disappear after aspirin use is terminated.

#### Loss Caused by Trauma

**Etiology.** Acquired sensorineural hearing loss caused by chronic, repeated exposure to loud sounds is common in the U.S. population. Four million people work each day in an environment with damaging levels of noise, and in 2008 approximately 2 million employees were exposed to workplace noise levels that put them at risk for hearing loss.<sup>9</sup> Noise-induced hearing loss can be associated with the use of firearms, personal stereo systems, and power tools and with occupations such as firefighting, construction, agriculture, mining, manufacturing, transportation, and the military.

The loudness of sound/noise is measured in the logarithmic units of decibels (dB). A normal whisper is measured at approximately 30 dB, a conversation at 3 feet at 50 to 60 dB. In contrast, ambulance sirens have been measured at 120 dB, lawnmowers and motorcycles at 90 dB.<sup>10</sup> Sounds exceeding 85 dB are considered potentially injurious, and chronic noise exposure is the most damaging. If exposure is severe enough, most structures of the inner ear can be damaged, including the organ of Corti. Sensory hair cells and supporting cells are lost because of overexposure. Noise-induced hearing loss typically is bilateral and affects higher (speech) frequencies first.<sup>3</sup>

Noise exposure has two phases: the first is a temporary *threshold* shift. When the ear is exposed to a loud sound, it will show a loss of sensitivity (a rise in the threshold for sound). If the hearing returns to normal after the sound has been removed, the shift was temporary and no permanent damage has occurred. If hearing does not return to normal, damage has occurred and the hearing impairment is permanent. Such a permanent threshold shift is the second phase of the damage. The ears of some individuals are more easily affected by noise, and considerable damage may occur before individuals are aware of the hearing loss.

**Clinical manifestations.** Individuals with hearing loss caused by noise trauma report that they are unable to discriminate words, particularly in noisy environments. Complaints about tinnitus are expressed more often than complaints about hearing loss. A diagnosis of noise-induced hearing loss is made through careful history and audiometric testing. Because noise-induced hearing loss is irreversible, no medical therapy can help once the problem has been established. Prevention is presently the only treatment for this type of hearing impairment.

Sensorineural hearing impairment can also occur with head trauma and subsequent damage to the structures of the inner ear. If blood is coming from the ear or the temporal bone is fractured, damage should be suspected. As a rule, hearing loss from trauma or head injury is permanent if the cochlea is damaged. A rare condition of sudden sensorineural hearing loss usually occurs in adults with middle ear problems. A viral or ischemic pathology is postulated. Prompt evaluation and treatment are necessary for these individuals. The prognosis is mixed but hearing may be recovered with intratympanic infusion of steroids.<sup>3</sup>

## Presbycusis

Presbycusis is a sensorineural hearing loss and the most common form of hearing loss in older adults. Approximately 25% of people ages 65 to 75 and 50% of those older than 75 suffer from age-related hearing loss.<sup>3</sup> Typically, the hearing impairment is of gradual onset, is bilateral, and results in difficulty hearing high-pitched tones and conversational speech. Presbycusis can progress to involve the middle and lower tones. Frequently, individuals complain that people are mumbling to them but deny any other type of hearing loss.

**Etiology.** Four categories of presbycusis have been theorized: (1) sensory, characterized by atrophy and degeneration of the sensory and supporting cells; (2) neural, typified by loss of neurons in the cochlea and central nervous system; (3) metabolic, characterized by atrophy of the wall of the cochlea affecting central auditory processing; and (4) mechanical, in which the middle ear undergoes changes in properties with a resulting conductive hearing loss.<sup>3,8,11,12</sup> Some of these age-related changes are shown in the Geriatric Considerations: Changes in Hearing box. An endless list of genetic, environmental, and disease states can also cause hearing loss in an older adult, many of which may occur concurrently. Thus uncertainty remains regarding the exact cause of presbycusis.

**Diagnosis.** Assessment of an individual with suspected presbycusis should begin with exclusion of all other causes of hearing impairment. Diseases such as diabetes, stroke, and heart disease may produce effects similar to those seen with hearing loss and must be ruled out. The diagnosis is made by obtaining a thorough history and performing audiometric studies. Individuals with presbycusis respond well to hearing aids that amplify sound. Many simple lifestyle adjustments that will be mentioned at the end of this section can dramatically improve the quality of life for an individual experiencing presbycusis. It is important in these patients to avoid excessive noise exposure and ototoxic drugs, which may cause further deterioration of hearing loss.<sup>8</sup>

## Meniere Disease

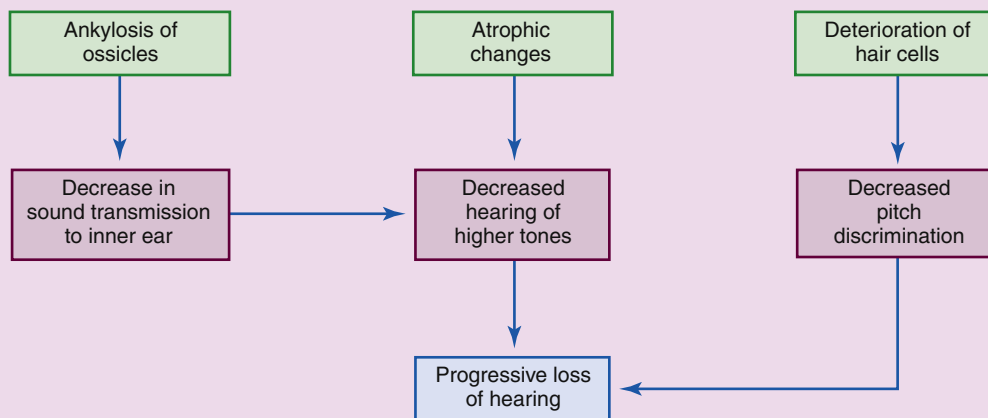

**Etiology and pathogenesis.** Meniere disease is an excessive accumulation of endolymph in the membranous labyrinth. The volume of endolymph increases with distention of the scala media until the

## GERIATRIC CONSIDERATIONS

### Changes in Hearing

Presbycusis, or age-related hearing problems, occurs after age 50 and is thought to be caused by structural changes in the organs of hearing. **Ankylosis** of the ossicles can lead to a functional decrease in transmission of sound to the inner ear.

In the inner ear or cochlea, degeneration of hair cells, changes in the basilar membrane, or atrophic changes can lead to decreased hearing of higher tones. With these changes is also noted a decline in pitch discrimination. As hearing is progressively lost, even lower pitch tones will be more difficult to hear.

membrane ruptures. Consequently, the neural end organs of the cochlea degenerate. Many conditions including allergies, viral and bacterial infections (such as syphilis), head trauma, metabolic derangements, and chronic stress have been suggested as causative agents, but the precise cause cannot be established in most cases.<sup>3,13</sup> Men and women are equally affected by this disorder, and the onset of symptoms is typically in the fourth decade of life.<sup>13</sup>

**Clinical manifestations.** Clinical manifestations of Meniere disease include tinnitus, fluctuating sensorineural hearing loss, vertigo, and sensations of ear fullness. In the early stages, hearing loss fluctuates, with return to normal after the rupture heals. Remissions and exacerbations are typical. The hearing loss is usually in the low tones. As the disease progresses, hearing loss becomes permanent. Symptoms initially usually are unilateral; the mean time for the manifestation of bilateral symptoms is approximately 7 years.<sup>13</sup>

Episodes of vertigo may be immediately preceded by the sensation of pressure in the ear, increased hearing loss, increased tinnitus, or an alteration in the quality of these symptoms. The onset of vertigo is usually sudden, reaches maximal intensity within a few minutes, usually lasts for an hour or more, and either subsides completely or continues as a sensation of unsteadiness for several hours or days. The tinnitus is typically a low buzzing or blowing sound and is frequently louder before the attack of vertigo. The attacks are not precipitated by positional changes and may be several weeks or months apart. In the initial stages of the disease they may be years apart. If not treated, the episodes may become more frequent and severe. Nystagmus, which occurs only during acute attacks, may be directed to the side opposite the involved ear.

**Diagnosis and treatment.** Physical examination, including neurologic and otolaryngologic examination, is generally normal in those with Meniere disease. Radiologic studies are often used to rule out other causes of the symptoms of Meniere disease such as acoustic neuroma. Electrophysiologic studies, such as auditory brainstem response testing and electrocochleography, and audiometric tests as well as glycerol dehydration testing can lead to a diagnosis of Meniere disease.<sup>13</sup> Caloric testing (irrigating the ears with warm and cool water) commonly reveals loss or impairment of thermally induced nystagmus on the involved side.<sup>13</sup>

Treatment for Meniere disease consists of providing symptomatic relief during acute episodes with antiemetics and anticholinergics such as meclizine. Between acute attacks, eating a low-sodium diet and using diuretics may help reduce the volume of endolymph. Cessation of smoking, management of stress, and elimination of caffeine from the diet are also suggested.

Several surgical interventions are used to manage Meniere disease. Shunts can be placed to drain excess endolymph, and ablation of portions of the eighth cranial nerve and destruction of the labyrinth

are options. In refractory cases, patients may undergo intratympanic corticosteroid or gentamycin injections. These interventions have different indications, risks, and benefits associated with them. Almost all patients who choose surgical intervention have failed to respond to medical treatment.<sup>3</sup>

## OTITIS MEDIA

Otitis media is an inflammation of the middle ear. It is almost always due to poor functioning of the eustachian tube and is often diagnosed by the presence of **effusion**. It is the most common reason for a child to require medical attention. In 2006 approximately 9 million children from newborns to 17 years of age were reported to have ear infections or otitis media.<sup>14</sup>

Otitis media is more common in the winter months when viral and bacterial infections are most prevalent. Upper respiratory tract infections can cause eustachian tubes to become blocked and predispose individuals to middle ear inflammation. Children are especially susceptible because of shorter, more flexible and horizontally positioned eustachian tubes. The dysfunction of the eustachian tube prevents middle ear secretions from draining and creates negative pressure in the middle ear space. Negative pressure leads to the introduction of infected nasopharyngeal secretions into the middle ear. Risk factors for otitis media include use of pacifiers, second-hand cigarette smoke exposure, gastroesophageal reflux, poor socioeconomic conditions, daycare attendance, and propped bottles. Males, Native Americans, Eskimo children, children with craniofacial abnormalities such as cleft palate, and individuals with Down syndrome have a higher incidence of otitis media.<sup>15</sup>

Much confusion surrounds the use of terminology in categorizing otitis media. This confusion relates to the presence of effusion and the length of illness (Table 46-1).

### Acute Otitis Media

Acute otitis media is characterized by the sudden onset of ear pain in association with symptoms of upper respiratory tract infection. Most children have spontaneous resolution within 7 to 14 days.<sup>15</sup> Although older children and adults complain of pain, younger children may demonstrate irritability, difficulty eating and sleeping, or tugging at the affected ear, as well as fever. Physical examination reveals a reddened tympanic membrane that has poor mobility. Bulging or rupture of the tympanic membrane may also be present.

In 2004 the American Academy of Pediatrics and the American Academy of Family Physicians published guidelines for the management of acute otitis media. Antibiotic therapy was recommended for all children younger than 6 months of age, for children ages 6 to 24 months with a confirmed diagnosis, and for all children older

TABLE 46-1 COMPARISON OF OTITIS MEDIA TYPES

TYPE	ONSET/DURATION	SYMPTOMS	TREATMENT OPTIONS
Acute otitis media	Sudden onset, associated with upper respiratory tract infections	Reddened tympanic membrane with poor mobility, may be bulging or ruptured, ear pain	Antibiotics, analgesics, antipyretics, or “watch and wait”
Recurrent acute otitis media	3 or more episodes in 6 months	Same as above	Daily doses of prophylactic antibiotics in some cases, ventilation tube placement
Chronic otitis media	Duration of more than 12 wk, may develop as consequence of acute otitis media	Thick immobile tympanic membrane, purulent drainage from ear, may have conductive hearing loss, pain is rare	Removal of debris from middle ear, ventilation tube placement
Otitis media with effusion	May precede or follow any type of otitis media	Ear popping, feeling of pressure in middle ear, hearing loss, retraction of tympanic membrane, fluid line or bubbles	Treat acute otitis media or “watch and wait”

than 2 years with severe infection. In children older than 2 years with milder symptoms, a “wait and see” approach may be used. Adequate pain relief and fever control are important as well as repeated evaluation. Providing the parent with a “rescue or safety net” prescription for antibiotics is one approach.<sup>16</sup> In children 6 to 23 months of age, amoxicillin-clavulanate is an appropriate choice.<sup>17</sup> Surgical placement of ventilation tubes in the tympanic membrane is also done in cases of recurrent otitis media. Complications of unresolved otitis media include hearing loss, mastoiditis, meningitis, osteomyelitis of the skull bones, and facial paralysis.

### Chronic Otitis Media

Chronic otitis media is inflammation in the middle ear lasting longer than 12 weeks. Irreversible damage has occurred to structures in the middle ear. This damage manifests in many forms, including atrophy or perforation of the tympanic membrane or adhesions in the middle ear causing tympanic membrane retraction. Calcification of the ossicles may occur, as well as the formation of cholesteatomas (benign, slowly growing collections of skin tissue) within the middle ear space. The hallmark clinical sign of chronic otitis media is purulent drainage from the ear. Pain is an uncommon finding, and conductive hearing loss may occur. Chronic otitis media generally develops as a consequence of acute otitis media, but it may follow other diseases or trauma. Management of chronic otitis media generally includes surgical removal of debris in the middle ear, placement of ventilation tubes in the tympanic membrane, and adenoidectomy to assist with eustachian tube function.

## INTERVENTIONS FOR INDIVIDUALS WITH HEARING IMPAIRMENT

In general, interventions for individuals with hearing loss are aimed at maximizing their residual hearing ability and allowing for compensation with other senses. To improve communication, adequate visual contact should be made. Lighting and positioning should be such that the individual can see the speaker’s lips. Reductions should be made in background noise. Speech should be at a normal rate and rhythm and at normal volume. Shouting can distort sounds and actually make them more difficult to hear. The speaker should use shorter sentences and gestures such as pointing when appropriate.

Devices that amplify sound or transform sounds into tactile or visual signals may be helpful. Amplifiers for the telephone, television, or radio; closed-captioned television; and teletypewriters are examples of these devices. Others include doorbells and telephones that glow as well as ring, and flashing smoke detectors and alarm clocks.

Implanted hearing devices such as cochlear implants may be helpful for patients over the age of 2 years with profound hearing loss. Surgically implanted cochlear electrodes work together with an external processor that converts sound waves to electrical signals that can be recognized by the brain. These devices can improve communication and provide psychosocial benefits.

### KEY POINTS

- Perception of sound requires that sound waves be transmitted through the outer ear canal, across the tympanic membrane, and through the ossicles to the oval window. Movement of the oval window initiates movement of perilymph, which causes movement of endolymph through the vestibular membrane. This fluid’s motion stimulates the neurosensory organs of hearing—the hair cells. Bending of the hair cells induces action potentials in the cochlear nerve, which projects to the brainstem. Neural projections to the auditory area in the temporal lobe result in sound perception.

- Balance is controlled by hair cells contained in the semicircular canals. Stimulation of these cells by head movement causes nerve impulses to be transmitted to the brain to keep individuals upright and control eye movement.
- Vertigo, the sensation of motion or aggravation of motion, is a cardinal symptom of disorders of the vestibular system. Vertigo is often associated with nystagmus and nausea.
- Hearing loss may result from interruptions in any part of the sound transmission pathway. Disorders of the outer and middle ear are generally termed *conductive* because sound waves are not reliably conducted to sensory organs of hearing. Accumulation of wax in the outer ear, ossification of bones, and middle ear infections and edema may result in conductive hearing loss. Conductive hearing loss is amenable to treatment.
- Sensorineural hearing loss is due to dysfunction of the hair cells or neural pathways to the brain. Chronic exposure to loud noise, ototoxic drugs, head trauma, and aging changes may lead to sensorineural hearing loss. Sensorineural hearing loss is not as amenable to treatment as conductive loss.
- Otosclerosis is a disorder characterized by resorption of healthy bone and deposition of weak, spongelike bone in the ossicles of the middle ear, most frequently the stapes. These bony lesions lead to progressive conductive hearing loss.
- Presbycusis is a gradual sensorineural hearing loss common in older adults. Its cause is unclear and difficult to distinguish from other types of hearing loss, especially noise trauma.
- Meniere disease is a chronic inner ear disease of unknown cause characterized by vertigo and progressive unilateral sensorineural hearing loss.
- Otitis media, or inflammation of the middle ear, is most frequently seen in children and commonly results from eustachian tube dysfunction after upper respiratory tract infections. Otitis media can be both acute and chronic.

## VISION

Healthy vision requires three basic processes to function appropriately: formation of an image on the retina, stimulation of rods and cones, and conduction of nerve impulses to the brain. Malfunction of any of these processes can disrupt normal vision.

## STRUCTURE OF THE EYE

The eye is a spherical structure contained in the bony cavity of the eye socket, composed of three basic layers: the sclera, the choroid, and the retina (Figure 46-4). The sclera is white and opaque, and is made up of dense connective tissue. It aids in protecting the inner structures of the eye, and helps maintain the shape of the eye. The sclera merges with the coverings of the optic nerve on the posterior of the eye. The clear front portion of the sclera is the cornea. The cornea is also composed of dense connective tissue and has a greater curvature than the sclera that causes it to protrude from the sclera. No blood vessels are located in the cornea. Deep within the anterior portion of the sclera, at its conjunction with the cornea, lies a ring-shaped venous sinus: the canal of Schlemm. Affixed to the sclera are the **extraocular** muscles that control eye movement.

The choroid layer of the eye is highly vascularized and darkly pigmented. Attached to this layer is the iris. The iris is a muscular diaphragm whose pigments are responsible for eye color. The iris controls the size of the pupil, the opening through which light stimuli enter the posterior portion of the eye. Behind the pupil is a clear lens. The lens is a transparent, avascular elastic membrane. This elasticity assists in focusing light stimuli on the retina.

The eye is composed of anterior and posterior chambers separated by the lens and iris. The anterior chamber is filled with aqueous humor, the transparent protein-free liquid that is formed in the ciliary body and

FIGURE 46-4 Anatomic structures of the eye.

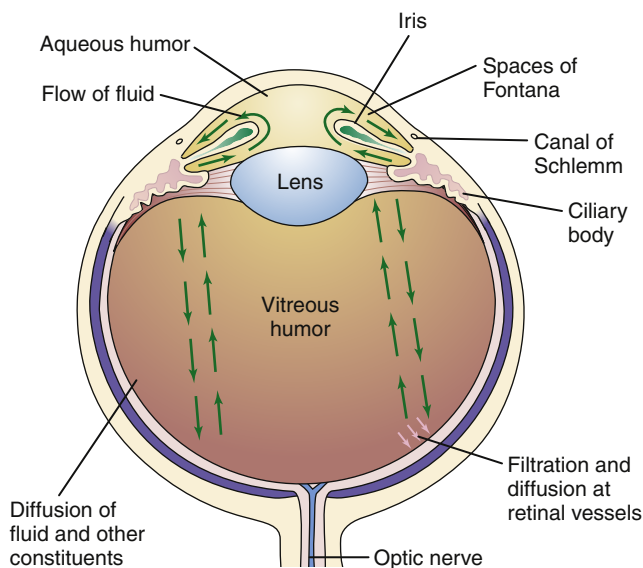

FIGURE 46-5 Circulation of the aqueous and vitreous humor of the eye.

drained through the canal of Schlemm (Figure 46-5). Aqueous humor provides oxygen and nutrients to the lens and cornea and is continually being formed and reabsorbed. The balance between formation and reabsorption of aqueous humor regulates the total volume and pressure of the **intraocular fluid**. The posterior chamber is the portion of the eye behind the lens that contains a thicker fluid, vitreous humor.

## VISUAL PATHWAYS

The innermost layer of the eye is the retinal layer. It is here that light waves are transformed into nerve impulses. Three layers of neurons comprise the major portion of the retina (Figure 46-6). The outermost layer is composed of **photoreceptor** neurons, the rods and cones.

FIGURE 46-6 Three-neuron organization of the retina. (Redrawn from Hall JE: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, 2011, Saunders, p 617.)

Cones are responsible for daylight vision, color vision, and visual acuity. The greatest concentration of cones occurs in the macula. This area is devoid of retinal vessels and is responsible for the most detailed vision. Rods are important for nighttime and peripheral vision and outnumber cones by nearly 20 to 1. The pigmented layer of the retina or the retinal pigment epithelium is one cell thick. It functions to protect and nourish the retina. The retinal pigment epithelium also removes metabolic cellular debris from the photoreceptor cells, prevents new blood vessel growth into the retina, and absorbs light to diminish scattering and thereby enhance vision.

Action potentials from the rods and cones are communicated throughout the other layers of the retina. All axons of the ganglion

**FIGURE 46-7** Visual pathways. (From Jarvis C: *Physical examination and health assessment*, ed 6, Philadelphia, 2012, Saunders.)

neuron extend back to a small circular area in the posterior of the eye, the optic disk, where the optic nerve passes through the sclera. When an image is focused on the retina, it is projected upside down and reversed left to right. An object in the upper temporal visual field of the right eye reflects its image on the lower nasal area of the retina. The optic disk is a blind spot because it does not contain any rods or cones. The optic nerve maintains the spatial arrangement of upside-down and reversed images, and at the optic chiasm just anterior to the pituitary gland half of the nerve fibers cross over to the other side of the brain (Figure 46-7). The left optic tract contains fibers from the left half of each retina, and the right optic tract contains fibers from the right half of each retina. The nerve impulse travels through the optic nerves to connections in the thalamus and finally connects with the neurons of the occipital cortex.

## GENERAL MANIFESTATIONS OF VISUAL IMPAIRMENT

Visual impairment may occur or become evident at any time during the life span. If these impairments occur during infancy or early childhood and are not immediately detected and managed, vision may not develop normally (see Pediatric Considerations: Development of Newborn Vision). In older children, academic performance may suffer. In adults and elderly individuals, poor eyesight affects activities of daily

living and can limit an individual's ability to function normally and meaningfully in the environment. The various effects of aging on the eye can be seen in Geriatric Considerations: Changes in the Eyes.

Clues that may indicate a visual impairment include squinting, closing one eye, tilting the head, having redness of the eye or excessive tearing, and eye rubbing. These signs are especially helpful in identifying children who may be unable to verbalize visual difficulties. In older children and adults, complaints of blurred vision, halos, "floaters" in the visual fields, headaches, and eye pain may indicate a visual impairment. A thorough health history and physical examination along with *visual acuity testing* and *ophthalmoscopic examination* will provide health care providers with the necessary information to appropriately treat or refer individuals with visual impairment.

## DISORDERS OF THE EYE

### Errors of Refraction

Focusing a clear image on the retina is essential for good vision. In a normal eye, light rays enter the eye and are focused into a clear, upside-down image on the retina. The brain can easily "right" the upside-down image in conscious perception but cannot correct an image that is not sharply focused (Figure 46-8).

### Myopia, Hyperopia, Presbyopia, and Astigmatism

If the eye is elongated, the image focuses in front of the retina rather than on it. The retina receives only a fuzzy image. This condition, called *myopia* or nearsightedness, can be corrected with concave contact lenses or glasses. Frequently seen in late childhood or early adolescence, individuals with myopia are unable to see distant objects clearly.

If the eye is shorter than normal, the image focuses behind the retina, also producing a fuzzy image. This condition, called *hyperopia* or farsightedness, can be corrected with convex lenses. *Presbyopia* is the loss of **accommodative capacity**. This inability to see near objects clearly occurs most commonly in middle age and is frequently corrected with reading glasses. An irregularity in curvature of the cornea or lens, termed *astigmatism*, produces a distorted image, and is corrected with glasses or contact lenses that are formed with the opposite curvature.

### Age-Related Disorders

#### Strabismus

To make visual perceptions meaningful, the visual images in the two eyes normally fuse with each other on corresponding points of the two retinas. Strabismus, also called *squint* or *cross-eyedness*, is a condition of ocular misalignment. The eyes appear misaligned on examination. Symptoms include squinting and frowning when reading, closing one eye to see, having trouble picking up objects, being dizzy, and having headaches. Strabismus is often caused by an abnormal "set" of the fusion mechanism of the visual system and is most commonly found in children. Strabismus affects 2% to 4% of the population.<sup>18</sup> Studies have shown that advanced maternal age, cigarette smoking during pregnancy, and low birth weight contribute to the incidence of strabismus. There also may be a genetic link predisposing children to certain types of strabismus.<sup>18</sup>

In the early efforts of the child to fixate the two eyes on the same object, one of the eyes fixates satisfactorily but the other fails to fixate, or both eyes fixate satisfactorily but never simultaneously. Soon the patterns of conjugate movements of the eyes become abnormally set so that the eyes never fuse.

Treatment of strabismus includes occlusion therapy, or patching of the good eye to force use of the weak eye, use of corrective lenses, surgery on the eye muscles, use of prisms, and exercises for the eye. If

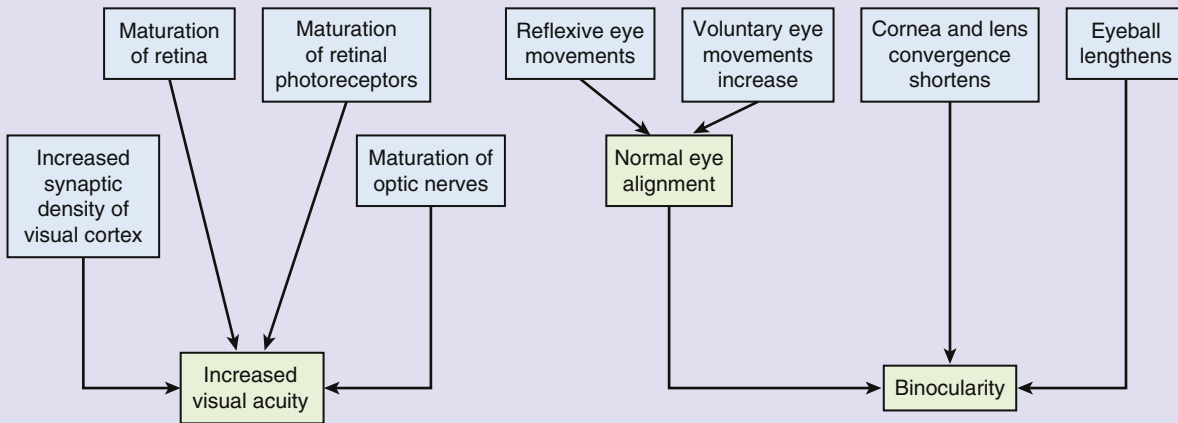

**PEDIATRIC CONSIDERATIONS**

**Development of Newborn Vision**

At birth, the newborn's visual acuity is 20/400. By 6 months of age, the infant's visual acuity is 20/30 because of increased synaptic density of the visual cortex and maturation of the retina, retinal photoreceptors, and optic nerves. The newborn has several reflexive eye movements such as the blink reflex, corneal reflex, and pupillary reactions to light. The newborn is unable to coordinate the head and eyes at birth, so the doll's eyes reflex is present. As the infant begins to explore the environment visually, the voluntary eye movements increase. The reflexive and voluntary movements begin to coordinate to create normal eye

alignment. Eyes must be close to alignment for vision. If a strabismus (eyes not properly aligned) occurs, it can lead to blindness. The shapes of the eyeball, cornea, and lens change as the infant grows. The eyeball is less spherical than the adult eye and is too short for the lens. As the eyeball lengthens, convergence created by the cornea and the lens decreases, which helps create binocularity. Binocularity is perceived vision from both eyes simultaneously; it begins to develop at age 6 weeks and is established at 4 months. Stereopsis or depth perception develops by 7 months of age.

**GERIATRIC CONSIDERATIONS**

**Changes in the Eyes**

Aging affects all parts of the eye. Minor changes include decreased skin elasticity, alterations in lacrimal gland function, and shrinking of the vitreous body. The changes in the lens and retina of the eye are more significant. These changes cause decreased color vision and discrimination, reduced contrast sensitivity, and diminished accommodation. As a result, the elderly need brighter light to see and do not differentiate color well. The elderly also have less dynamic visual acuity.

The retina is affected by a loss of the luteal pigment in the macular areas, as well as reduced light-sensing thresholds of the rods and cones. These changes lead directly to a slowing of dark adaptation and a decrease in the ability to discern brightness and colors, particularly shorter light wavelengths such as blues and greens.

A primary change in the aging eye is the development of presbyopia. Presbyopia is caused by a decrease in the elasticity of the lens and a decrease in the effectiveness of the ciliary muscle, which lead to an inability to focus on near objects.

**FIGURE 46-8** **A**, Light rays are focused to produce a clear visual image (emmetropia). **B**, In myopia, light rays are focused in front of the retina. A concave lens moves the focus back onto the retina and results in a clear image. **C**, In hyperopia, light rays are focused behind the retina. A convex lens moves the focus forward so that the light rays fall directly on the retina.

management of strabismus is begun before 24 months of age, amblyopia may be prevented.

### Amblyopia

Amblyopia is poor vision, even with the proper optical correction, in one or both eyes. It is the most common cause of decreased vision in the pediatric population, affecting 1% to 4% of children.<sup>19</sup> It results from altered visual development despite normal-appearing retinal and optic nerve pathways. Amblyopia occurs when the normal course of visual development is interrupted, such as when visual images do not fuse as in the case of untreated strabismus, or when severe refractive errors are present. Conditions such as congenital cataracts, uncorrected astigmatism, and other errors of refraction may also interfere with visual development.

The diagnosis of amblyopia is confirmed when a complete ophthalmologic examination reveals a decrease in visual acuity that cannot be explained by organic causes. Although screening for it is much easier in older children, treatment is more difficult at this point. Therefore, screening must take place at an early age. Successful management of amblyopia depends on several factors. The most important is the age of onset and the length of time between onset and the commencement of treatment. Management of amblyopia includes the use of atropine to blur vision or patching of the “stronger” eye. This forces the brain and weaker eye to work together to stimulate vision.<sup>20</sup>

### Cataracts

Cataracts are a clouding or opacity of the lens that leads to gradual, painless blurring of vision and eventual loss of sight. Most people older than 60 years of age have some degree of cataracts.<sup>20</sup> Cataracts result from the process of aging (senile), trauma (causing lens rupture and swelling), congenital factors (Down syndrome, intrauterine rubella infection), metabolic disease (diabetes mellitus, hypoparathyroidism), and certain medications (systemic or inhaled corticosteroids). Cigarette smoking and heavy alcohol consumption may also increase the risk of cataract formation.<sup>21</sup>

Oxidative stress and exposure to ultraviolet light are factors contributing to the development of cataracts.<sup>21</sup> Both eyes may be affected, but at different rates. Patients with cataracts may experience increased glare at night, blurred vision, and altered color perception. Persons with opacity in the central portion of the lens can generally see better in dim light when the pupil is dilated. The degree of visual loss corresponds to the density of the cataract.

A diagnosis of cataracts can be made through examination of the eye with an ophthalmoscope or slit lamp. As the cataract worsens or “matures,” visualization of the retina becomes increasingly difficult until finally the pupil appears white and the retina cannot be visualized at all. Treatment for cataracts involves surgical removal and replacement of the lens. This procedure is completed on an outpatient basis, with individuals returning home immediately after surgery.

FIGURE 46-9 Retinal detachment.

## Retinopathy

Retinopathy is any disorder of the retina. Damage to the retina impairs vision because even a well-focused image cannot be perceived if some or all of the light receptors do not function properly. Retinopathies can result from a variety of causes, the most common being trauma and vascular disease, especially in individuals with diabetes mellitus and hypertension.

### Retinal Detachment

Detachment of the retina is usually spontaneous but may be secondary to trauma such as sudden blows to the head. Spontaneous detachment occurs most frequently in individuals older than 50 years.<sup>22</sup> Eye tumors, myopia, and cataract extraction are other common predisposing factors. Retinal detachments are classified into three categories. Exudative (or serous) detachments result from accumulation of serous or hemorrhagic fluid in the subretinal space, generally due to hydrostatic factors (e.g., severe, sudden hypertension), inflammation (sarcoidosis), or neoplastic effusions. The second type, tractional retinal detachment, occurs when mechanical forces on the retina caused by fibrosis and scarring pull it away from the underlying epithelium (injury or surgery to the eye). The third type of retinal detachment is spontaneous or rhegmatogenous. As individuals age, the vitreous humor shrinks and traction develops, causing separation.<sup>22</sup>

Tearing of the retina allows vitreous fluid to flow behind the retina and cause traction and progressive detachment (Figure 46-9). The area of detachment increases rapidly, and visual loss is progressive. Common manifestations of retinal detachment include the sudden appearance of floating spots that may decrease over a period of weeks and odd flashes of light that appear when the eye moves. Other symptoms include blurring of vision in a single eye that appears as though “a curtain is being pulled down over the eye.” If untreated, the retina may detach entirely and result in total blindness in the affected eye. However, if diagnosed and treated early, permanent vision loss can be prevented. Retinal detachments may also cause vitreous hemorrhage.<sup>23</sup>

Retinal detachments are diagnosed through ophthalmoscopic examination. The retina appears to hang in the vitreous humor like a gray cloud. One or more retinal tears, generally crescent-shaped, are usually present. Management of retinal detachment is aimed at closing tears in the retina and positioning the fragments of the retina so that reattachment can occur.

## Diabetic Retinopathy

**Etiology and pathogenesis.** Diabetic retinopathy is one of the most common complications of diabetes, afflicting about 20% of adults with the disease.<sup>24</sup> Symptoms increase in prevalence and severity with increasing duration of illness and poorer control of blood glucose levels.<sup>22</sup> Diabetic retinopathy is a disease of the vasculature of the retina. In diabetes, the retinal capillary becomes diseased; it loses the ability to transport red blood cells and thus oxygen and nourishment to the retina, with consequent tissue hypoxia and ischemia. Diabetic retinopathy can be divided into two categories: nonproliferative and proliferative.

In nonproliferative diabetic retinopathy, retinal veins become dilated and microaneurysms develop. This effect is a result of damaged vascular epithelium. Small retinal hemorrhages and cotton-wool spots (infarctions in the nerve fibers) occur. Early in the process, visual changes may be minimal or resolve after a few days. As the disease progresses, retinal edema occurs. If the edema involves the macular area, visual acuity is noticeably affected. This form is more common in persons with type 2 diabetes.<sup>25</sup>

Proliferative diabetic retinopathy is characterized by the development of new but abnormal blood vessels (neovascularization) caused by the loss of retinal blood flow and ischemia. These new vessels affect vision in two ways: first, because they are abnormal, they are prone to leakage of blood into the vitreous cavity and may thus result in vitreous hemorrhage. Second, the vessels firmly attach themselves to the retina and grow out into the vitreous humor. The subsequent traction on the retina increases the risk for retinal detachment. This form is more common in persons with type 1 diabetes.<sup>25</sup>

**Clinical manifestations.** Diabetic retinopathy is associated with complaints of blurred, darkened, and distorted vision. Visual changes may fluctuate in severity. Some individuals complain of being unable to read or have vague changes in vision.

**Diagnosis and treatment.** The diagnosis of diabetic retinopathy is made through careful history taking, visual acuity testing, and performing ophthalmologic examination and retinal angiography. The most important factor in the management of diabetic retinopathy is prevention. Intensive blood glucose level control and blood pressure management have been shown to slow the progression or reduce the risk of developing diabetic retinopathy.<sup>25</sup> Laser treatments are also used to prevent further vision loss. Because the retina is nervous system tissue, it does not regenerate efficiently. Therefore, treatment may prevent any further injury to eye tissue, but it cannot restore vision.

Management of proliferative diabetic retinopathy must be instituted as soon as possible to prevent blindness. Surgical intervention and laser procedures are used in conjunction with the measures used for nonproliferative retinopathy. Because of the risk of diabetic retinopathy, it is recommended that individuals with diabetes mellitus have annual ophthalmologic examinations.

## Age-Related Macular Degeneration

**Etiology and pathogenesis.** Age-related macular degeneration (AMD) is the leading cause of blindness among people ages 55 years and older.<sup>26</sup> The exact causes of macular degeneration are unknown, but the outcome is bilateral progressive macular deterioration with central vision loss. Risk factors for developing AMD include age, female gender, history of cigarette smoking, family history of AMD, increased serum cholesterol level, cardiovascular disease, hypertension, obesity, and previous cataract surgery. Oxidative stress and inflammatory chemicals appear to be key factors in development of the disorder.<sup>22,26,27</sup> There is also a strong relationship between AMD and nutrition.<sup>28</sup> Dietary supplements have been shown to delay progression from intermediate to advanced forms of the disease; however, some studies suggest they do not prevent the disease. AMD includes

a wide spectrum of findings that can be divided into two subgroups. Manifestations, diagnosis, and management of each subgroup differ.

“Dry” or non-neovascular geographic atrophic AMD is the most common form, causing visual loss attributable to degeneration of the outer retina, the pigmented layer, and the choroidal layer. There are subretinal accumulations of cellular debris known as *drusen*, along with metabolic dysfunction of the retina. Hard drusen may be seen during ophthalmologic examination and appear as discrete yellow deposits on the retina. Atrophic AMD often affects just one eye initially but later develops in the unaffected eye. It causes a gradual decline in vision.

In “wet” neovascular or exudative AMD, visual loss is usually more rapid in onset and causes more severe visual disruption. Impairment of barrier function allows for subretinal fluid collections, which may cause retinal detachments and/or neovascularizations. These fluid buildups may be visualized on retinal examination.

**Clinical manifestations.** AMD is generally painless. In the atrophic form, the initial symptom is slightly blurred vision and decreased ability to see fine detail. Often patients need more light for completing fine tasks such as reading and needlework. As the disorder progresses, the area of central vision loss becomes larger and darker.

Exudative AMD may also be manifested by a progressive blurring of vision. A hallmark of this form of AMD is the wavy appearance of straight lines. This occurs because of distortion of the retina from fluid accumulations behind it. Vision may be lost rapidly or occur suddenly in previously undiagnosed patients attributable to retinal detachment or hemorrhage.

**Diagnosis and treatment.** AMD is diagnosed with thorough history and physical examination to rule out other causes of visual loss, visual acuity testing, dilated retinal examination, and use of the Amsler grid (Figure 46-10). If AMD is suspected, fluorescein angiography may be completed by the ophthalmologist. In this examination, fluorescein dye is injected into the patient. Photos of the retina show characteristic changes of the choroidal vascular layer.

Management of AMD depends on the type and severity of the disease. Antioxidant/zinc vitamin supplementation has been shown to slow/delay the progression of AMD.<sup>22</sup> Other treatment modalities are aimed at correcting the vascular changes and include laser photocoagulation and photodynamic therapy. Research is currently focusing on a variety of antiinflammatory therapies including corticosteroids and immune-modulating drugs.<sup>27</sup> As with all progressive diseases, patients with AMD should have regular comprehensive eye examinations and daily self-evaluation using the Amsler grid.

## Glaucoma

Glaucoma is characterized by increased intraocular pressure and progressive loss of vision. As fluid pressure inside the eye and against the retina increases, blood flow through the retina slows. Reduced blood flow causes degeneration of the retina and thus loss of vision. Glaucoma can be categorized into two main types: chronic open-angle and acute closed-angle (narrow-angle) (Figure 46-11).

Glaucoma is more common in the elderly, African Americans, those with a family history, those with myopia, and individuals with

**FIGURE 46-10** Left, What an Amsler grid looks like to an individual with normal vision. Right, What an Amsler grid might look like to an individual with macular degeneration. (From Macular Degeneration Network. Available at [www.macular-degeneration.org/](http://www.macular-degeneration.org/).)

**FIGURE 46-11** Closed-angle (narrow-angle) glaucoma compared with open-angle glaucoma. **A**, In closed-angle glaucoma, the outflow of aqueous humor is obstructed by the iris root of the dilated pupil. **B**, In open-angle glaucoma, the obstruction to outflow of aqueous humor is in the drainage canals.

diabetes. It may also occur as a result of trauma, inflammation, or exposure to corticosteroids.<sup>22</sup>

### Chronic Open-Angle Glaucoma

**Etiology and pathogenesis.** The cause of open-angle glaucoma is not clear. The drainage channels for aqueous humor appear normal. The disease is often bilateral and has a genetic component. Open-angle glaucoma accounts for the majority of all cases of glaucoma.

Open-angle glaucoma has an insidious onset with no symptoms in the early stages. However, the intraocular pressure is consistently elevated, and, over a period of months or years, symptoms including gradual loss of vision in the periphery resulting in tunnel vision appear. Affected individuals may have complaints of vague but persistent dull eye pain or an inability to distinguish colors. Halos may appear around lights if the intraocular pressure is markedly elevated.

**Diagnosis and treatment.** The diagnosis of open-angle glaucoma is made through intraocular pressure measurement, ophthalmoscopic examination of the optic disk, and central visual field testing. Because of the insidious nature of the disorder, it is recommended that all individuals older than 40 years have an intraocular pressure measurement and ophthalmoscopic examination every 3 to 5 years. If a family history of glaucoma is present, more frequent examination is recommended.

Management of open-angle glaucoma is aimed at increasing drainage of aqueous humor and decreasing intraocular pressure. Prostaglandin analogue eye drops (latanoprost 0.005%, bimatoprost 0.03%) are first-line agents.  $\beta$ -Adrenergic-blocking eye drops, such as timolol, are used to help decrease intraocular pressure by decreasing aqueous humor production. Miotics such as pilocarpine are also useful in that they constrict the pupil and thereby stimulate the ciliary muscles to pull on the trabecular meshwork surrounding the canal of Schlemm to increase the flow of aqueous humor. If the intraocular pressure elevation persists or the optic nerve damage progresses despite treatment, laser surgery aimed at the trabecular meshwork may be done to lower intraocular pressure.<sup>22</sup>

### Acute Angle-Closure Glaucoma

**Etiology and pathogenesis.** Primary acute angle-closure glaucoma is caused by abnormality of the angle between the pupil and lateral cornea. This angle is narrow and blocks outflow of aqueous humor when the pupil is dilated. Angle-closure glaucoma is much less common than open-angle glaucoma but is more prevalent in the elderly, hyperopes, and Asian populations.<sup>22</sup> This form of glaucoma has a rapid onset and is treated as an emergency. Angle-closure glaucoma is associated with pupillary dilation and thus might occur when an individual is sitting in a darkened room or during times of stress. Forward displacement of the iris toward the cornea with dilation narrows or closes the chamber angle, obstructing the outflow of aqueous humor (see Figure 46-11).

Manifestations of angle-closure glaucoma include severe eye pain, nausea and vomiting, blurred vision with halos around lights, redness of the eye, a steamy cornea, and a dilated pupil that is nonreactive to light. This form of glaucoma is an emergency situation because permanent blindness can occur within 2 to 5 days after onset of symptoms.<sup>22</sup>

**Diagnosis and treatment.** Diagnosis of angle-closure glaucoma involves the same tests as used for diagnosis of open-angle glaucoma. Treatment again in this case is aimed at decreasing intraocular pressure. Acutely, carbonic anhydrase inhibitors such as acetazolamide and miotics may be used to decrease aqueous humor production and blockage. Laser iridectomy usually results in a permanent cure. Novel therapies are currently being explored aimed at reducing cell death/apoptosis and improving retinal cell survival.<sup>29</sup>

## Visual Field Deficits

### Visual Field Loss

**Etiology and pathogenesis.** Visual field loss can be caused by changes in the eye itself, as is the case in cataracts, or result from tumors, vascular lesions, and demyelinating lesions near or in the neural pathways of the retina, optic nerve, or the visual cortex of the brain.

Damage to the visual pathway does not always result in a total loss of vision. Depending on where the damage occurs, only part of the visual field may be affected (Figure 46-12). Monocular field loss indicates disease of the retina or optic nerve. For example, a certain form of neuritis often associated with multiple sclerosis can cause loss of only the center of the visual field, called a *scotoma*.

Damage or lesions may also cause bilateral visual field losses or loss of half of the visual field, called **hemianopsia**. Lesions of the optic chiasm, usually caused by pituitary tumors, characteristically produce a bitemporal hemianopsia. Lesions occurring behind the optic chiasm cause a homonymous hemianopsia, which is a visual field loss involving the same side in both eyes. The more posterior the lesion in the visual pathway, the more congruous (similar size, shape, location) are the defects in the two eyes. Cerebrovascular accidents (strokes) and tumors are responsible for most of these lesions.

**Diagnosis and treatment.** Visual field deficits are easily and rapidly assessed through confrontation (i.e., comparison of the patient's vision to the examiner's vision). Visual field deficits should be suspected if patients demonstrate one-sided neglect of their environment or eye deviation toward the side of the lesion. Treatment for visual field loss includes managing the underlying cause (tumor removal), adapting the patient's environment, and teaching compensatory techniques.

## INTERVENTIONS FOR INDIVIDUALS WITH VISION IMPAIRMENT

Once the visual impairment of an individual has been thoroughly investigated, specific interventions may be prescribed. Interventions may be classified into three general categories: assistive devices, environmental adaptations, and behavioral techniques. Proper care and cleaning of contact lenses and eyeglasses directly influences the effectiveness of the prosthesis. Tinted lenses are generally available and may be effective in reducing glare for some individuals. Pocket magnifiers are frequently useful for persons with an acuity impairment. Large print is now available on many household items (e.g., watches, playing cards, telephones, books), and various textures are used in further modifications for the visually impaired.

An unchanging, structured environment where items are kept in fixed locations familiar to the visually impaired person promotes safety and independence. Attempts to structure temporary environments, such as by introducing personal items into a hospital room, might yield positive results if consistently considered by the staff. Attention to adequate lighting, glare reduction, and appropriate use of contrasting colors enhances safety and independent function of those with visual impairment.

Behavioral techniques for the health care professional and visually impaired individuals can promote client comfort, safety, and independence. Such techniques for the professional include announcing oneself at all interactions and explaining sensory occurrences. Encouraging independence and social interaction often benefits individuals inasmuch as they may experience anger, frustration, or changes in self-concept as a result of their visual deficit.

Visually impaired individuals may be taught to wait several minutes for changes in dark-light adaptation and avoid abrupt changes in lighting. Individuals should be discouraged from looking directly into bright lights to reduce glare. Assessment of the visually impaired patient's ability to summon help in the health care and home settings is advised.

1. Retinal damage

- Macula—central blind area (e.g., diabetes):

- Localized damage—blind spot (scotoma) corresponding to particular area:

- Increasing intraocular pressure—decrease in peripheral vision (e.g., glaucoma). Starts with paracentral scotoma in early stage:

- Retinal detachment. Person has shadow or diminished vision in one quadrant or one half of visual field:

2. Lesion in globe or optic nerve. Injury here yields one blind eye, or unilateral blindness:

3. Lesion at optic chiasm (e.g., pituitary tumor)—injury to crossing fibers only yields a loss of the nasal part of each retina and a loss of both temporal visual fields. Bitemporal (heteronymous) hemianopsia:

4. Lesion of outer uncrossed fibers at optic chiasm (e.g., aneurysm of left internal carotid artery exerts pressure on uncrossed fibers). Injury yields left nasal hemianopsia:

5. Lesion of right optic tract or right optic radiation. Visual field loss in right nasal and left temporal fields. Loss of same half of visual field in both eyes is homonymous hemianopsia:

**FIGURE 46-12** Visual field losses. (From Jarvis C: *Physical examination and health assessment*, ed 6, Philadelphia, 2012, Saunders.)

**KEY POINTS**

- Visual acuity depends on the formation of discrete patterns of light on the retina. Errors of refraction such as myopia and hyperopia cause light to focus in front of or behind the retina, respectively. Irregular curvature of the cornea results in astigmatism. These disorders are correctable with lenses to refract the light to the appropriate retinal location.
- Strabismus occurs when both eyes do not focus together to form a single image. If this is not corrected, the brain may ignore the image from one eye in an attempt to avoid double imaging; eventually, amblyopia can result.
- Cataracts are due to opacification of the lens that blocks and scatters light. Cataracts may be congenital, traumatic, or associated with aging.
- Retinopathy is any disorder affecting the retina. Trauma and systemic disorders such as diabetes mellitus, hypertension, and vascular disease are the most common causes of retinopathy.
- Retinal detachment is characterized by tearing of the retina away from the choroid layer of the eye, with seepage of vitreous humor behind the retina causing further detachment.
- Diabetic retinopathy is a disorder of the retinal vessels characterized by the formation of microaneurysms and hemorrhage (nonproliferative) or neovascularization and subsequent leakage and retinal detachment (proliferative).
- Macular degeneration is an age-related, progressive loss of central vision attributable to atrophic or exudative changes to the macula of the retina.
- Glaucoma occurs when intraocular pressure is increased by a decrease in the outflow of aqueous humor from the anterior chamber of the eye. Open-angle glaucoma has an unclear cause because no clear obstruction impedes the outflow of aqueous humor. Angle-closure glaucoma occurs when the angle between the pupil and lateral aspect of the cornea is narrow and blocks outflow when the pupil is dilated.
- Visual field losses are caused by lesions anywhere along the visual pathways. The location of the lesion determines monocular or binocular involvement and the portion of vision lost.

**SMELL AND TASTE**

The senses of smell and taste allow separation of noxious or even lethal agents from those that are desirable. The sense of smell has a protective function in signaling danger: animals use smell to recognize the proximity of other animals, and humans use smell to sense harmful substances, such as smoke or spoiled food items, in the environment. The sense of taste allows a person to select food in accordance with desire and perhaps also in accordance with tissue needs. Both senses are strongly tied to primitive emotional and behavioral functions of the nervous system. These chemical senses are interrelated and will be discussed together.

Nerve fibers of the **olfactory** system have their cell bodies in the mucous membrane of the upper and posterior parts of the nasal cavity. The sense of smell begins with chemical stimulation of these cells. Axons of these receptor cells pass through the cribriform plate and travel to the olfactory area of the cortex through the first cranial nerve. These nerves lie under the frontal lobes of the brain. It has been long thought that olfactory impulses reach the cerebral cortex without relay through the thalamus, making olfaction unique among the sensory systems. However, newer pathways have been identified that pass through the thalamus and are thought to aid in the conscious analysis of odor.<sup>30</sup>

Like stimuli for smell, stimuli for taste are chemical. Food particles dissolved in fluid stimulate sensory receptors (taste buds) located on the surface of the tongue and in lesser density on the palate, pharynx, and larynx.<sup>30</sup> Stimulation from the sensory receptors is conducted through the cranial nerves of taste (VII, IX, X) to connections in the brainstem and thalamus with eventual termination in the **gustatory** cortex in the parietal lobe. The gustatory sensory receptors have a heightened sensitivity for one of the primary taste sensations (sweet,

salty, sour, or bitter); however, they can respond to a variety of stimuli. The number of sensory receptors for taste diminishes with age, often affecting nutritional status.

**Disorders of Smell and Taste**

**Etiology and pathogenesis.** Olfactory disorders range from loss or reduction in the sense of smell to distortions and olfactory hallucinations. Commonly the sense of smell is diminished in those who smoke and in individuals with conditions involving congestion and swelling of the nasal mucosa, such as allergies and sinusitis. Head trauma often results in the loss of smell because of actual shearing of the neuronal fibers as they traverse the cribriform plate. Tumors and large cerebral aneurysms of the anterior cerebral and anterior communicating arteries are lesions capable of diminishing olfactory sense. Epilepsy and psychiatric disorders may be associated with olfactory hallucinations.

A decreased gustatory sense can also result from heavy smoking, as well as extreme dryness of the tongue and mucous membranes. A variety of medications are known to alter the sense of taste, including certain antidepressants, antithyroid, antirheumatic, and anticancer medications. In addition, influenza-like illnesses and lesions on the thalamus and parietal lobe may impair taste sensation.

**Clinical manifestations.** Individuals with smell dysfunction frequently complain of a diminished ability to taste. They may experience a decreased appetite and use excessive amounts of salt, sugar, or other seasonings on their foods. These individuals may stop reacting to strong smells and not notice their own body odor. Smell dysfunction increases the risk of accidents in that these individuals may not detect signs of imminent danger such as gas or smoke. In addition, spoiled food may be ingested, and excessive use of salt is associated with health risks.

**Diagnosis and treatment.** Assessment of the sense of smell is done by asking the individual to smell different known odors while keeping the eyes closed. Irritating substances such as ammonia should be avoided because they stimulate the trigeminal nerve. Assessment of gustatory sense should include the primary taste sensations in appropriate areas of the tongue, with the surface of the tongue wiped clean between substances. Questions regarding weight loss and appetite add valuable information to the assessment data.

Interventions for those with smell and taste dysfunction focus on augmenting the stimulus, teaching the individual to rely on other senses, and changing the environment. Because their senses of smell and taste are unreliable in identifying spoiled foods, people with these dysfunctions are encouraged to adhere to a strict schedule for discarding leftovers and be aware of expiration dates on food products. Because significant nutritional problems may occur, it is important to educate and monitor the individual's diet. The creative use of seasonings and spices along with variations in the texture and presentation of food may enhance appetite. Individuals with taste impairments are encouraged to avoid blended foods and to practice frequent oral hygiene. Smoke detectors should be installed in all rooms where smell-impaired individuals sleep, and fire safety should be emphasized.

**KEY POINTS**

- The senses of smell and taste result from chemical stimulation of specialized nerve fibers located in the nose and the tongue and are closely related to each other. Nerve impulses travel through the cranial nerves to separate areas of the brain.
- Changes in smell and taste most commonly result from smoking and inflammation caused by colds, sinusitis, or allergies. A change in smell or taste sensation in the absence of an obvious cause may indicate a brain tumor and should prompt a thorough neurologic evaluation.

## SUMMARY

Humans interact with their environment by means of the special senses of hearing, vision, smell, and taste. Through a variety of stimuli, including chemicals, light, and sound, individuals are able to enjoy everything from a symphony performance to a hot fudge sundae. The special senses also protect individuals from harm by allowing the perception of smoke or alarms. Only when these special senses are impaired does their importance become apparent.

Loss of these senses may result from congenital conditions, trauma, tumors, illness, or unknown causes. Loss may also be a consequence of aging. The mechanism of impairment may be a disruption of the mechanical aspect of the special sense, as in the obstruction of sound

waves from cerumen impaction in the ears, or may be a neurologic event, as in the occurrence of homonymous hemianopsia after a stroke.

Regardless of the cause of loss of the sense of hearing, vision, smell, or taste, prompt intervention and treatment can make tremendous differences in outcome. The loss may be totally corrected, or its progression may be slowed. Treatment may be aimed at the underlying cause of the sensory impairment or at altering the individual's behavior or environment to maximize the remaining function. In working with individuals who have alterations in special sensory function, health care professionals have the opportunity to make a great difference in that person's quality of life.

### KEY QUESTIONS

- How do the processes of transduction, transmission, perception, and modulation relate to the phenomenon of nociception?
- How is neurotransmission of pain signals modulated at the receptor, spinal cord, and brain?
- How do acute pain and chronic pain differ with regard to cause and clinical manifestations?
- Why are some painful sensations perceived at a distance from the site of injury (referred)?
- Why is it important to adequately manage pain?

Pain is a complex physiologic and perceptual phenomenon. Because pain is very much a subjective experience, defining and assessing it are difficult. Merskey defined pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.”<sup>1</sup> McCaffery offered a clinically useful definition: “Pain is whatever the experiencing person says it is,

existing whenever the experiencing person says it does.”<sup>2</sup> Accurate assessment and optimal management of pain are extremely important not only because relief of pain and suffering is ethically desirable but also because unrelieved pain is physiologically harmful. Studies have documented the benefits of adequate pain control on the rate of recovery, health care costs, and postoperative morbidity. In fact, The

Joint Commission (TJC) has developed standards of care regarding the assessment and management of pain that must be followed by all accredited agencies. Pain has been referred to as the fifth vital sign.

## PHYSIOLOGY OF PAIN

The physiologic mechanisms involved in the pain phenomenon are termed **nociception**. Nociception can be divided into four stages: transduction, transmission, perception, and modulation. Transduction is the process of converting painful stimuli to neuronal action potentials at the sensory receptor. Transmission refers to the movement of action potentials along neurons that make their way from the peripheral receptor to the spinal cord and then centrally to the brain. Perception occurs when the brain receives pain signals and interprets them as painful. The complex mechanism whereby synaptic transmission of pain signals is altered is called modulation. It is clinically useful to conceptualize pain physiology according to these four processes because each stage provides an opportunity for intervention in the pain experience (Figure 47-1).

### Transduction

Most pain begins in the periphery when free nerve endings called **nociceptors** are stimulated. Nociceptors transduce noxious stimuli into neuronal action potentials that progress centrally to the spinal cord and then the brain. Nociceptors are found in skin; muscle; connective tissue; the circulatory system; and the abdominal, pelvic, and thoracic viscera. Stimulation can be the result of direct damage to nerve endings, or it can result from release of chemicals at the site of injury.

Numerous substances participate in the initiation of nociceptive impulses. Some of these substances are released as a direct result of

**FIGURE 47-1** Four processes of pain signaling: transduction, transmission, perception, and modulation.

tissue injury, whereas others may be produced as part of the inflammatory response to the injury. Important chemical mediators of pain include  $K^+$ ,  $H^+$ , lactate, histamine, serotonin, bradykinins, and prostaglandins.<sup>3</sup> These chemicals alter the membrane potential of the pain receptor, and if depolarization is sufficient, action potentials are generated. When these impulses are conducted centrally, the second step (transmission) is initiated.

Prostaglandin involvement in the process of nociceptor stimulation is of particular interest because prostaglandin inhibitors such as aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) are commonly used to manage pain. Prostaglandins are formed when cells are damaged and an enzyme, phospholipase A, breaks down phospholipids in the cell membrane and converts them to arachidonic acid<sup>4</sup> (Figure 47-2). Arachidonic acid undergoes further breakdown by the enzyme cyclooxygenase to form prostaglandins. Sensitization by prostaglandins lowers the threshold of nociceptive fibers so that stimuli that would not cause pain under normal circumstances are now pain producing. NSAIDs prevent prostaglandin production by inhibiting the action of cyclooxygenase.

### Transmission

Stimulated nociceptors transmit impulses to the central nervous system (CNS) by means of specialized sensory fibers. The primary sensory fibers involved in the transmission of nociceptive impulses are the  $A\delta$  and C fibers.<sup>3</sup> The characteristics and functions of these fibers are summarized in Table 47-1. In general, the larger, myelinated  $A\delta$  fibers transmit the nociceptive impulses very quickly as an initial response to tissue injury. The nature of the pain carried by the fast-traveling  $A\delta$  fibers is characterized as sharp, stinging, and highly

**FIGURE 47-2** Tissue injury results in the release of prostaglandins from the breakdown of phospholipids in cell membranes. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit the cyclooxygenase enzyme and block the production of prostaglandins.

**TABLE 47-1 AFFERENT SENSORY PAIN FIBERS**

FEATURE	$A\delta$ FIBERS	C FIBERS
Structure	Myelinated	Unmyelinated
Amount	10%	90%
Source	Thermal, mechanical stimuli	Polymodal stimuli (mechanical, thermal, chemical)
Speed	Fast traveling, 5-10 m/sec	Slower traveling, 0.6-2 m/sec
Sensory quality of pain mediated	Sharp, stinging, cutting, pinching	Dull, burning, aching

localized. In contrast, unmyelinated C fibers transmit pain more slowly. Pain transmitted by C fibers is poorly localized and has a dull or aching quality that lingers long after the initial sharp pain abates. The majority of pain sensations travel via C fibers and project to areas of the brain that evoke emotional responses such as displeasure and anxiety.

Most sensory afferent pain fibers enter the spinal cord by way of the posterior nerve roots (Figure 47-3). The cell bodies of pain neurons are located in the dorsal root ganglion. As the afferent neurons enter the dorsal horn, collateral branches spread up and down the spinal cord for two to three segments by way of the tract of Lissauer. These spinal connections are important for reflex postural adjustments when a painful body part is suddenly withdrawn from the painful stimulus.

Sensory afferent neurons synapse with interneurons, anterior motor neurons, and sympathetic preganglionic neurons in specific regions of the spinal cord (see Figure 47-3). A $\delta$  fibers and C fibers carry excitatory impulses from cutaneous pain receptors in small, localized areas of the skin to interneurons in lamina I. Many of the neurons originating in lamina I cross the spinal cord to activate neurons in the anterolateral tract.

Laminae II and III represent a key anatomic region of the cord involved in pain transmission known as the **substantia gelatinosa**. The substantia gelatinosa is characterized by multiple synaptic connections among primary sensory afferent neurons, interneurons, and anterolateral ascending fibers. There is much opportunity at this point for pain signal transmission to be modulated by other sensory input or from CNS activity. Pain signals can be either enhanced or blocked at these synapses.

Another key synaptic area involved in nociception is lamina V. Numerous A $\delta$  and C fibers deliver somatic input from mechanical, thermal, and chemical receptors in the periphery to lamina V. Sensory afferent neurons from visceral receptors also terminate in lamina V. The convergence of both somatic and visceral fibers in lamina V may help explain the phenomenon of referred pain, in which pain from a visceral organ is perceived at the body surface.<sup>3,5</sup> The remaining, deeper laminae VI to VIII receive sensory input from muscles, joints, and visceral afferent fibers.

A number of neurotransmitters and neuropeptides are involved in synaptic transmission in the spinal cord. Substance P is a

well-known example. Others include excitatory amino acids (glutamate),  $\gamma$ -aminobutyric acid (GABA), cholecystokinin, and calcitonin gene-related peptide. These neurotransmitters bind to the next neurons in the pathway and thereby initiate action potentials. The pain signal is propelled along its pathway toward the brain. Interruption of these synaptic processes can inhibit pain transmission. The synapses in the spinal cord are extremely important points of pain modulation by both endogenous and exogenous means.

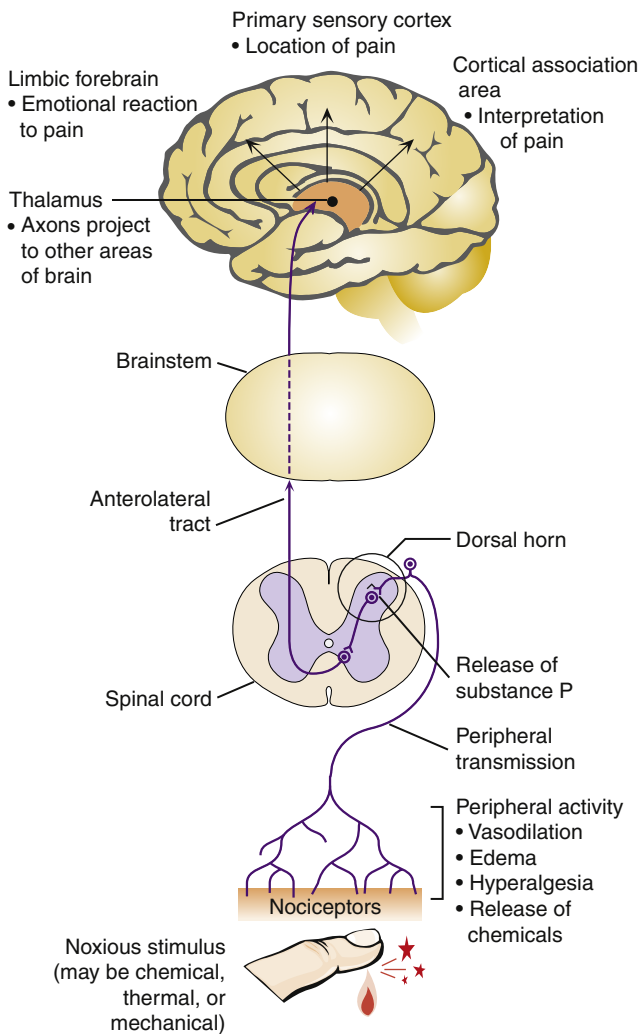

The excitatory neurotransmitter glutamate is involved in carrying the nociceptive message from primary afferent fibers to secondary neurons. Glutamate binding to its *N*-methyl-D-aspartate (NMDA) receptors on the postsynaptic neuron is thought to induce a kind of synaptic memory in the pain pathway. Excessive or repeated stimulation of C fibers sensitizes the spinal cord neurons so that even mild stimulation may be perceived as painful.<sup>5,6</sup> This phenomenon has been termed “wind-up” and may be an important mechanism in the development of chronic pain syndromes. Drugs that inhibit glutamate production may impede the wind-up response, thereby controlling pain before synaptic memory of the pain develops in the pain pathways.

Pain signals transmitted by the spinal interneurons are then conducted to the brain by ascending spinal pathways (Figure 47-4). The major pathway for pain signal transmission up the spinal cord is the anterolateral tract, so named because it travels in the anterolateral portion of the white matter of the spinal column. This tract is also called the *spinothalamic tract* in some texts and has two divisions: the neospinothalamic tract and the paleospinothalamic tract. Both divisions cross at the spinal segment and carry pain signals up the contralateral (opposite) side of the cord. Thus nociceptor input from the right side of the body travels in the anterolateral tracts on the left side of the cord, whereas pain signals from the left side of the body travel on the right side of the cord.

The neospinothalamic division has fewer synapses in the cord and projects first to the thalamus and then to the primary somatosensory cortex. A $\delta$  fiber signals are transmitted in this tract and reach the brain quickly to provide specific information about pain location with little emotional connotation. C fiber impulses travel mainly in the paleospinothalamic division, which makes a greater number of synapses and reaches the brain more slowly. The paleospinothalamic tract projects to widespread brain areas and stirs aversive emotional responses. The

**FIGURE 47-3** Spinal cord segment showing primary afferent pain fibers, A $\delta$  and C fibers, entering the dorsal horn, synapsing on interneurons, crossing to the opposite side, and traveling to the brain in the anterolateral tract.

**FIGURE 47-4** Anterolateral nociceptive pathways travel up the spinal cord and project to the thalamus, somatosensory cortex, cortical association areas, and limbic structures.

paleospinothalamic tract travels with the neospinothalamic tract in the anterolateral portion of the spinal cord to the level of the medulla and then sends diffuse projections to the reticular formation, the mesencephalon, and, finally, the thalamus. From the thalamus, further projections to the cerebral cortex, limbic system, and basal ganglia occur. The pain sensation from C fibers is poorly localized, longer lasting, and more distressing than A $\delta$  fiber pain. Pain impulses entering the brainstem reticular activating formation, thalamus, and other lower brain centers cause conscious perception of pain, but the cortex is important in interpreting pain quality.<sup>3</sup>

The brain can localize a pain sensation to a particular part of the body because nociceptor pathways are kept in specific anatomic order in the cord and somatosensory cortex. Each spinal nerve contains the nociceptor fibers for a particular area of the body surface, called a *sensory dermatome* (Figure 47-5). Dermatomal maps are useful for locating a source of neurologic pain. Pain that follows a dermatomal distribution is due to spinal nerve compression or trauma and is called a *radiculopathy*. Vertebral disk disease is a common cause of radiculopathy. Peripheral neuropathies, in contrast, do not follow a dermatomal pattern. Examples of peripheral neuropathies are carpal tunnel syndrome (median nerve) and diabetic neuropathy, which often affects both legs in a stocking-like pattern.

## Perception

Perception is the result of neural processing of pain sensations in the brain. Perception includes an awareness and interpretation of the meaning of the sensation. Pain perception is influenced by attention, distraction, anxiety, fear, fatigue, and previous experience and expectations. Pain perception is not localized to a specific brain area.<sup>3</sup> Complete removal of the somatic sensory areas of the cerebral cortex does not destroy an animal's ability to perceive pain.<sup>3</sup> Numerous neuronal networks are necessary to localize, process, and interpret painful sensations. The primary somatosensory cortex, association cortex, frontal lobe, and limbic structures all participate in this processing.

Pain perception can be described in terms of pain threshold and pain tolerance. Pain threshold is the level of painful stimulation required to be perceived and is remarkably similar from one individual to another. Pain tolerance is the degree of pain that one is willing to bear before seeking relief. Pain tolerance varies widely among individuals and within the same individual under differing conditions. Age, culture, family upbringing, gender, and previous pain experience influence tolerance to pain. Environmental factors, including noise, bright light, and interrupted sleep, may affect pain tolerance.

Pain expression is the way in which the pain experience is communicated to others. Pacing, writhing, jaw clenching, facial grimacing, muscle guarding, crying, moaning, groaning, and verbal descriptions may be used to express pain. Thus the highly variable nature of pain expression among individuals makes accurate pain assessment difficult.

## Modulation

Modulation of pain signals occurs at multiple sites along the pain pathway. A fair amount is known about pain modulation at the spinal cord, where neurons from nociceptors, somatosensory receptors, and descending neurons from the CNS all converge and interact. Modulation also occurs at the peripheral nociceptor ending and within the brain; however, these mechanisms are less well understood.

Attempts to decrease the perception of painful stimuli may be initiated spontaneously by the person experiencing pain. Rubbing, pressing, or shaking the painful area may reduce the intensity of pain. In 1965, Melzack and Wall proposed the gate control theory to explain how stimulation of large "touch" neurons could inhibit the transmission of nociceptor impulses.<sup>7</sup> This theory was very useful in focusing efforts to understand pain signal processing at the spinal cord level.

Central to the gate control theory is the capacity for interneurons in the spinal cord to modify the transmission of nociceptor impulses. The original gate control theory suggested that impulses carried by large myelinated cutaneous fibers (A $\beta$ ) could "close the gate" on nociceptor impulses so that pain signals would be blocked in the spinal cord and not allowed to progress centrally to the brain. The physiologic process underlying the closing-the-gate mechanisms has been the subject of much study. Numerous interneurons, neurotransmitters, and neuropeptides have been implicated in this complex gating mechanism.

Descending pathways from the brain to the dorsal horn region of the spinal cord are important modulators of the pain response (Figure 47-6). These descending pathways originate in a brainstem nucleus called the *raphe magnus* and project to the dorsal horn regions of laminae I, II, and IV.<sup>3</sup> Neurotransmitters released by these neurons can inhibit synaptic transmission of pain signals. One way to inhibit synaptic transmission is through presynaptic inhibition of substance

**FIGURE 47-5** Sensory dermatomes. Pain located in the pattern of a dermatome occurs with spinal nerve injury and is referred to as *radiculopathy*.

P release from nociceptor neurons (Figure 47-7). **Opioids** such as **endorphins** are thought to be the mediators of presynaptic inhibition. A similar inhibitory effect can be achieved by administering opioid drugs, such as morphine, that bind to opioid receptors and mimic the effect of endorphins.

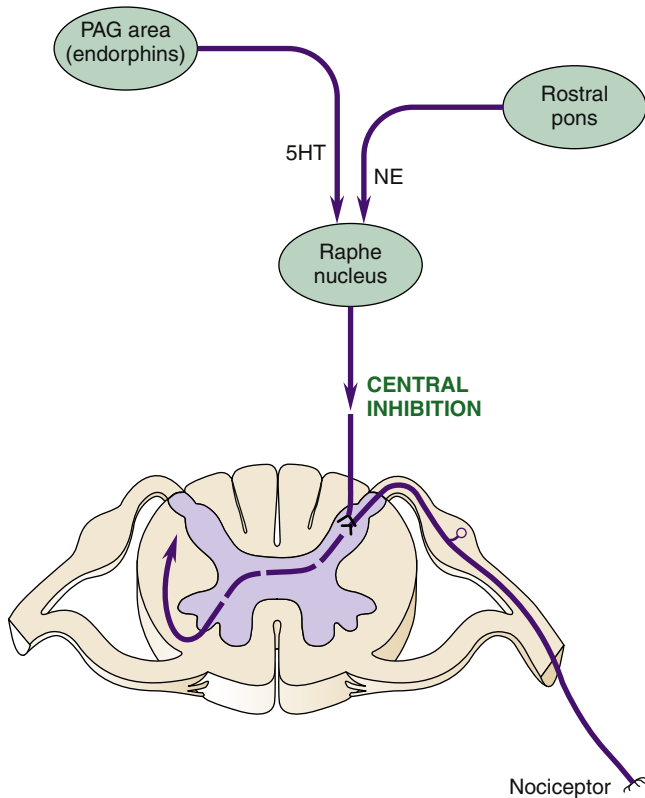

The raphe magnus receives input from two other brain areas important in the pain response: the periaqueductal gray (PAG) area in the midbrain and the rostral pons in the brainstem. The PAG area has a high concentration of endogenous opioids (endorphins and enkephalins) that are known to produce analgesic effects similar to narcotic drugs. Stimulation of the PAG area causes release of these endogenous opioids and also sends nerve impulses to the raphe magnus. Serotonin (5-hydroxytryptamine, 5HT) is the neurotransmitter that conveys analgesic signals from the PAG area to the raphe magnus. This finding helps explain the pain-relieving action of

drugs that enhance serotonin activity in the brain, such as tricyclic antidepressants.

The neurons projecting to the raphe magnus from the rostral pons secrete norepinephrine as the neurotransmitter. Stimulation of these neurons also produces an analgesic effect. Clonidine, a drug that mimics the effect of norepinephrine in the brain, has been shown to have pain-relieving properties.

The descending pathways from the brain provide an important means for gating the flow of pain impulses from the periphery to the brain. The PAG area is apprised of the flow of pain signals because it receives input by way of the thalamus and limbic structures.

Pain modulation occurs not only at the cord level but also in the brain itself. Opioids produced in the brain are thought to be important modulators of pain perception. Specific opioid receptors

**FIGURE 47-6** Descending pathways from the brain are thought to regulate pain impulse transmission in the dorsal horn. These regulatory neurons originate in the brainstem raphe magnus, which receives input from the periaqueductal gray (PAG) area and the rostral pons. Stimulation of these brain areas induces analgesia. *5HT*, Serotonin; *NE*, norepinephrine.

were identified within the brain in the early 1970s.<sup>8</sup> Also discovered around this time were the naturally occurring morphine-like substances termed *endorphins*. The word *endorphin* is a combination of two words: *endogenous* (coming from within the body) and *morphine* (from the Latin word *morpheus*, meaning “sleep inducing”). The term *endorphin* actually refers to two groups of naturally occurring peptides: enkephalins (which are pentapeptides) and three types of endorphin polypeptides ( $\alpha$ -,  $\beta$ -, and  $\gamma$ -endorphin). Of these, most is known about  $\beta$ -endorphin.

During times of stress, pain, or emotion, the brain apparently creates its own analgesia through the secretion of endogenous opioids—a process known as *stress-induced analgesia*. Stress-induced analgesia is reversed by naloxone, a drug that blocks opioid receptors, thus supporting the role of endogenous opioids in the process.<sup>9</sup> As previously described, the PAG area produces large quantities of endogenous opioids that are thought to inhibit pain signal perception within the brain. High concentrations of  $\beta$ -endorphin are also found in the pituitary gland, and it is likely that the release of pituitary stress hormones (adrenocorticotrophic hormone) is accompanied by the release of endorphins. The adrenal glands also produce endogenous opioids as a sympathetic response to stress. Endorphins released into the bloodstream by the pituitary gland and adrenal gland have their effects in the periphery because they cannot effectively cross the blood-brain barrier.

Opioids have different effects depending on the types of receptors they activate. Four types of opioid receptors have been identified: mu ( $\mu$ ), kappa ( $\kappa$ ), sigma ( $\sigma$ ), and delta ( $\delta$ ) (Table 47-2). The distribution of the specific opioid receptors varies throughout the body. The  $\mu$  and  $\kappa$  receptors have analgesic activities. The  $\mu$  receptors are found in high concentration in the brain, where they are thought to modulate pain perception. The  $\kappa$  receptors are concentrated primarily in the spinal cord, where they contribute to pain modulation by CNS descending

**FIGURE 47-7** Pain transmission and inhibition at the molecular level. **A**, Nociceptive transmission to higher levels of the central nervous system. **B**, Nociception inhibited through binding of endogenous opioids (e.g., enkephalin). The release of substance P is prevented. **C**, Nociception inhibited through binding of exogenous opioid (e.g., morphine). Release of substance P is prevented.

pathways. Each opioid receptor subtype is associated with a number of undesirable side effects. Depending on the affinity for certain receptors, different drugs may have differing analgesic potency and side effect profiles (Table 47-3).

	Pruritus	

**KEY POINTS**

- Nociception can be conceptualized as four interdependent processes: stimulus transduction, signal transmission, pain perception, and pain modulation.
- Nociceptor activity is transmitted to the spinal cord by two types of neurons: larger, myelinated A $\delta$  fibers, which transmit sharp, localized sensations; and small, unmyelinated C fibers, which transmit dull, aching, poorly localized sensations.
- Pain signals are transmitted by afferent fibers that enter the spinal cord through the dorsal horn, synapse on interneurons, and then cross the cord and project centrally in the anterolateral tract.
- The anterolateral tract has two divisions: the neospinothalamic tract, which carries A $\delta$  fiber input and projects to the thalamus and then the sensory cortex; and the paleospinothalamic tract, which carries C fiber input and projects diffusely to the reticular formation, mesencephalon, and thalamus.
- Perception of painful stimuli involves several brain structures, including the primary somatosensory cortex, association areas, and limbic structures. Pain perception is influenced by culture, environment, and physical status and varies widely among individuals.
- Afferent pain signals can be modulated at several levels. Descending pathways project from the PAG area and rostral pons by way of the raphe magnus to inhibit pain neurons in the dorsal aspect of the spinal cord. Pain is also modulated within the brain/spinal cord by endogenous opioids (enkephalins, endorphins).

**TYPES OF PAIN**

Pain can be categorized into two major subtypes: physiologic pain and pathologic pain. Physiologic pain occurs when tissue injury has occurred, and aides in prevention of further injury or in some cases survival. This is the pain felt when a person, for example, has touched a hot stove. This injury will likely heal, and the memory of the experience will hopefully prevent future similar injuries. Pain of acute appendicitis

	Kappa ( $\kappa$ )			X	

also may be considered physiologic pain because it alerts a person to a serious problem. In contrast, pathologic pain occurs after tissue injury, but long-term changes occur both within the peripheral and within the central nervous systems. These changes occur along somatosensory pathways from the periphery to the cortex. The pain sensation can be significantly enhanced (**hyperalgesia**), or non-noxious stimuli may cause pain (**allodynia**). These changes in pain perception and modulation serve no beneficial purpose to learning or survival. These underlying changes are theorized to be the cause of neuropathic pain, fibromyalgia, and other chronic pain syndromes.<sup>6,10</sup>

Pain most commonly is classified according to duration (acute, chronic), source (cancer, neuropathic, ischemic), or location and referral pattern. Pain is a symptom of an underlying problem rather than a primary disorder; attempts to alleviate pain should be accompanied by efforts to locate and manage the underlying etiology. The character, location, and duration of pain can provide helpful clues to aid the diagnostic process.

## ACUTE PAIN

Pain is categorized as being acute or chronic, depending on the duration of symptoms. Acute pain results from tissue injury and resolves when the injury heals, usually in less than 3 months. Acute pain is typically accompanied by clinical signs and symptoms of pain that result from stimulation of the sympathetic nervous system. These signs and symptoms include an elevated heart rate, respiratory rate, and blood pressure, as well as pallor, sweating, and nausea (Table 47-4). Persons experiencing acute pain may express pain behavior such as pacing, grimacing, crying, or moaning. Short-term therapy with nonopioid and opioid agents is often helpful. The risk of becoming dependent on pain medications is minimal in persons experiencing acute pain. Adequate management of pain during an acute episode may help prevent the development of some types of chronic pain syndromes.

### Headache

**Etiology and pathogenesis.** Headache is one of the most common causes of acute pain, accounting for approximately 13 million visits each year in the United States to physician's offices, urgent care clinics, and emergency departments.<sup>11</sup> Headaches are classified according to etiologic categories (e.g., tension, migraine, sinus). However, it is very common for headache type to be misdiagnosed, migraines frequently being labeled as tension or sinus headache. In the United States greater than 10% of the population, including children, suffer from migraines.<sup>12</sup> Previous theories of migraine included simply a vascular causation. It was believed that the spasm of cerebral vessels and the ensuing vasodilation caused the throbbing pain typical of migraine. Current theories involve stimulation of the trigeminal nerve in combination with changes in neurotransmitter levels in the CNS and alterations in blood vessel tone.

Migraines probably result from dysfunction of the brainstem areas involved with modulation of craniovascular afferent fibers. There is a release of inflammatory chemicals including local release of calcitonin gene-related peptide, which causes vasodilation. The inflammatory cascade that results in migraine can be initiated by many "migraine triggers." There is a genetic predisposition for sensitivity to these headache triggers. The brainstem becomes activated, causing stimulation of the trigeminal nucleus caudalis. This activation causes pain signals to be sent to the thalamus and cerebral cortex where pain is perceived and is responsible for many signs/symptoms of migraine. Any of the branches of the trigeminal nerve can refer pain signals along this pathway. If left untreated, continuous activation of the trigeminal nucleus caudalis may result in central sensitization and more refractory pain.

Available at [www.merckmanuals.com/professional/neurologic\\_disorders/pain/overview\\_of\\_pain.html](http://www.merckmanuals.com/professional/neurologic_disorders/pain/overview_of_pain.html); Mohn-Brown E, Burke KM, Eby L, editors: *Medical-surgical nursing care*, ed 3, Upper Saddle River, NJ, 2011, Pearson Education.

**Clinical manifestations.** Typical signs of a migraine headache include severe unilateral pounding or throbbing pain that may be accompanied by nausea, vomiting, photophobia, phonophobia, and lacrimation. The pain is increased by routine physical activity. Some migraines may be preceded by an aura such as flashing lights or other visual disturbances, and unilateral paresthesias. Other symptoms may include sinus/nasal congestion, neck muscle stiffness and pain, vertigo, and changes in bowel pattern.

**Diagnosis and treatment.** Headaches are diagnosed through careful history and physical examination. Brain tumors, infection, hydrocephalus, and increased intracranial pressure must be ruled out. Physical assessment should include the ears, nose and throat, sinuses, temporomandibular joint, neck musculature, cranial nerves, and retinal examination. General cognitive, neurologic, and motor function should also be examined. Headaches caused by trauma, following a worsening pattern, accompanied by other neurologic symptoms, or developing suddenly and described as the "worst headache ever" require neuroimaging. The International Headache Society has established criteria for a migraine diagnosis, and this has been adopted by many health care providers (Box 47-1).

Headaches are managed with a wide variety of therapies and medications, each aimed at a different piece of the pathophysiologic puzzle. Depending on the type and frequency of the headache, prophylactic medications may also be used. One mainstay of nonpharmacologic migraine therapy is the avoidance of headache triggers. Patients are encouraged to eliminate vasoactive substances from their diets including caffeine, cheese, chocolate, foods containing nitrates and nitrites, and monosodium glutamate. Adherence to regular sleep-wake schedules is helpful as is the use of stress management techniques in preventing the occurrence of migraines. Other nonpharmacologic therapies for headache include resting in a quiet, darkened room or applying cold packs to the head and back of the neck. There are numerous medications used to control migraines and other types of headaches. A key to successful treatment is the prompt use of these agents at the onset of pain. Prophylactic therapy employing administration of antiepileptics (topiramate), antidepressants (selective serotonin reuptake inhibitors, tricyclic antidepressants),  $\beta$ -blockers (propranolol),  $\alpha$ -blockers

(clonidine), or calcium channel blockers (verapamil); injections of botulinum toxin type A (Botox) into the scalp; or manipulation of hormone levels in younger female patients may be necessary. Refer to Table 47-5 for a comparison of pharmacologic therapies for the acute management of migraine headache.

**CHRONIC PAIN**

Pain is considered chronic when it lasts more than several months beyond the expected healing time (usually more than 6 months). When chronic pain is not due to a malignancy, its cause is often difficult to ascertain. In chronic pain, pain is no longer protective and appears to be self-perpetuating. Two concepts have emerged as probable mechanisms for this phenomenon. Peripheral sensitization represents a reduction in threshold and an amplification in the responsiveness of nociceptors that occur when the peripheral terminals of the primary sensory neurons are exposed to inflammatory mediators and damaged tissue. Increased peripheral transduction sensitivity develops.<sup>10</sup> Central sensitization results in changes in the properties of neurons in the CNS. It is an abnormal state of responsiveness or increased gain of the nociceptive inputs. When neurons in the dorsal horn of the spinal cord are affected by central sensitization, they develop increased spontaneous activity and a reduction in the threshold for activation by peripheral stimuli, show increased responsiveness to stimulation, and have an enlargement of receptor field.<sup>6,10</sup>

**TABLE 47-5 ACUTE MIGRAINE THERAPIES**

DRUG	ROUTE OF ADMINISTRATION	COMMENTS
<b>Serotonin Receptor Agonists (Triptans)</b>		
Sumatriptan (Imitrex) Zolmitriptan (Zomig) Rizatriptan (Maxalt) Naratriptan (Amerge) Eletriptan (Relpax)	PO, nasal spray, SubQ injection, dissolvable tablet	Increases serotonin; cannot be given with monoamine oxidase inhibitors; contraindicated in renal/hepatic failure; risk of serotonin syndrome if given with selective serotonin reuptake inhibitors
<b>Ergot Alkaloids</b>		
Ergotamine with caffeine (Wigraine, Ercaf, Cafergot)	IV, IM, SubQ, PO, rectal suppository, inhaler	Rarely used because of development of newer agents with less side effects; increases serotonin; causes intracerebral vasoconstriction; best if given early after onset; contraindicated in patients with cardiovascular disease and pregnancy; may cause nausea/vomiting
Dihydroergotamine mesylate (DHE, Migranal)		Rarely used now
<b>Nonsteroidal Antiinflammatories and Nonopiates</b>		
Acetaminophen (Tylenol) Ketorolac (Toradol) Naproxen sodium (Naprosyn, Aleve) Ibuprofen (Motrin, Advil) Aspirin	PO, IV, IM	May cause gastrointestinal upset/bleeding; frequent use may cause "rebound" headache
<b>Barbiturate-Hypnotic Combinations</b>		
Butalbital with aspirin and caffeine (Fioricet, Fioricet with codeine)	PO	High abuse/addictive potential; may cause sedation; rebound headache with frequent use; withdrawal potential
<b>Opiates/Combinations</b>		
Acetaminophen with codeine, oxycodone, or hydrocodone (Tylenol no. 3/4, Percocet, Lorcet)	PO	High abuse/addictive potential; may cause sedation; considered "rescue medications"
Butorphanol (Stadol)	Nasal spray

Available at [www.accessmedicine.com.proxy.heal-wa.org/content.aspx?alD=9094791](http://www.accessmedicine.com.proxy.heal-wa.org/content.aspx?alD=9094791).  
 IM, Intramuscular; IV, intravenous; PO, oral; SubQ, subcutaneous.

Chronic pain is generally not associated with signs and symptoms of sympathetic activity. As the body becomes accustomed to pain, the sympathetic nervous system desensitizes itself to the noxious input; therefore, symptoms are more often psychological. Lack of sleep because of pain causes fatigue and irritability. Loss of a job or loss of body image because of pain causes personal and family difficulties. Treatment failures may create a sense of hopelessness or distrust of caregivers.

Depression is a common finding in individuals experiencing chronic pain. In many cases the cause of the chronic pain cannot be determined, and therefore treatment is difficult. The use of narcotic pain relievers is discouraged because of the necessity of long-term therapy and therefore a risk of dependency. Satisfactory treatment may require numerous coordinated approaches, and the patient may benefit from the services of a pain clinic that specializes in multimodal therapies.

### Fibromyalgia Syndrome

**Etiology and pathogenesis.** Fibromyalgia syndrome (FMS) is a chronic pain syndrome affecting an estimated 2% of the population. Women are affected more frequently than men.<sup>13</sup> FMS is a collection of symptoms without a clear physiologic cause. It is neither degenerative nor progressive. Patients have a history of chronic widespread pain affecting all four extremities. FMS was once a controversial diagnosis classified as a psychosomatic illness. It can now be objectively identified using criteria established by the American College of Rheumatology.

The cause of FMS is unknown. However, etiologic studies have identified several risk factors for the development of the syndrome. Individuals with a medical history of excessive stress, trauma (both physical and emotional), sexual abuse, viral infections (parvovirus, hepatitis C, Epstein-Barr), and endocrine disorders (hypothyroidism) are more commonly affected. Disordered pain mechanisms in the CNS

are a suspected factor in FMS. Patients with FMS have a lower threshold for pain than those without the disorder. Pain maintenance and modulation mechanisms in the brain and spinal cord are also suspect. Central sensitization is thought to be a key factor.

**Clinical manifestations.** Patients complain of pain that waxes and wanes, and does not follow a dermatomal pattern. The pain tends to be exacerbated by physical exertion. Hyperalgesia and allodynia are common. Musculoskeletal examinations are generally normal. Other symptoms commonly seen associated with FMS include sleep disturbance/insomnia with nonrestorative sleep and irritable bowel syndrome. Fatigue is a hallmark of the syndrome. Depression and anxiety are also common along with cognitive difficulties such as problems with attention and short-term memory.

**Diagnosis and treatment.** FMS is a diagnosis of exclusion. Thyroid disorders, myopathies, rheumatoid arthritis, and chronic viral infections (e.g., human immunodeficiency virus) must be excluded. In FMS there is a lack of objective or laboratory findings. However, the American College of Rheumatology has established criteria to assist in the diagnosis of FMS. An individual must complain of widespread pain in all four extremities and the axial skeleton that has been present for at least 3 months without other reasonable explanation. The presence of pain in 11 of 18 “trigger” or “tender” points when pressure is applied to these areas (Figure 47-8) is also diagnostic.

Management of FMS begins with patient education. Although sometimes disabling, FMS is not a fatal illness and does not affect life span. Treatment includes a variety of medications including antidepressants, such as the selective serotonin reuptake inhibitors and the tricyclic antidepressants. Restoration of sleep patterns seems to be a key factor of successful treatment. NSAIDs and muscle-relaxing agents are also helpful. Opioid medications and corticosteroids are generally avoided because these are not effective long-term therapies.<sup>14</sup> There are three FDA-approved therapies for the pain of FMS. Pregabalin (Lyrica)

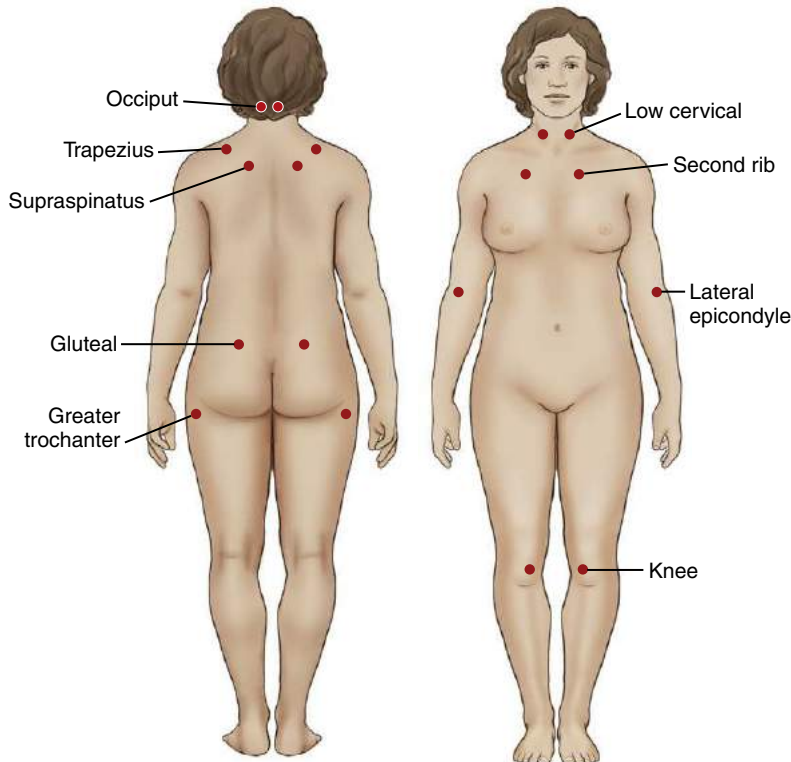

FIGURE 47-8 Posterior and anterior trigger points in fibromyalgia.

is an analogue of the neurotransmitter GABA ( $\gamma$ -aminobutyric acid). Milnacipran (Savella) and duloxetine (Cymbalta) are in the class of medications of serotonin-norepinephrine reuptake inhibitors.<sup>15</sup> Non-pharmacologic therapies include regular physical exercise, good nutrition, and psychological counseling.

## CANCER-RELATED PAIN

Cancer pain is a subcategory of chronic pain, although it may be associated with acute pain episodes. Malignant pain differs from nonmalignant chronic pain in that it often has an identifiable cause. Pain associated with cancer may result from infiltration of organs or compression of structures by an expanding tumor, or it may occur as a result of treatments that damage tissue such as radiation therapy or chemotherapy. In patients with cancer pain, clinical signs and symptoms are often a mixture of sympathetic nervous system activation and behavioral changes. Unremitting cancer pain requires a multifaceted approach and use of potent medications. Often the quality of life is a larger consideration than the length of life, and adequate pain control is a major factor affecting the quality of life.

## NEUROPATHIC PAIN

Neuropathic pain is a complex, often disabling chronic pain that results from tissue injury in which the nerves themselves become damaged or dysfunctional. This may occur in the peripheral or central nerves. The pain results from the actual damage or dysfunction of the nerves rather than stimulation of the pain receptors.<sup>10</sup> Nerve injury from surgery, tumor growth, metastasis, radiation therapy, chemotherapy, elevated blood glucose level, viral infection, or trauma often causes neuropathic pain. It is characterized by constant aching sensations that may be interrupted by bursts of burning or shocklike pain in the affected area. Allodynia is common. Neuropathic pain may not occur immediately after an injury. Days, weeks, or even months after the tissue-damaging source of pain has resolved, the onset of neuropathic pain can initiate a new and complex pain state. Pain often seems to be out of proportion to the area of tissue damage.

Neuropathic pain is thought to result from altered central processing of nociceptive input. Nerve injury may initiate excitotoxic and apoptotic cell death of neurons within the spinal cord dorsal horn. GABAergic interneurons are significantly depleted. GABA is an inhibitory neurotransmitter in the spinal cord, and a reduction in GABA-secreting neurons may be the cause of the hyperalgesia and allodynia. In some cases, excessive responsiveness to ongoing stimulation of afferent pain fibers appears to be important; however, central perception of pain may occur in the absence of any nociceptor input.<sup>10</sup> Examples of neuropathic pain include postherpetic neuralgia, diabetic neuropathy, trigeminal neuralgia, epidural spinal cord compression, cauda equina compression, plexus injuries, and phantom limb pain. Sympathetically maintained pain is a unique type of neuropathic pain that may occur in the absence of nerve injury. Sympathetically maintained pain is attributed to hyperactivity of the sympathetic nervous system. Release of norepinephrine from sympathetic nerve endings sensitizes nociceptors such that they respond to a lower level of nociceptor stimuli.<sup>10</sup> Not all patients affected by this type of pain exhibit the same symptoms; however, the most prevalent clinical manifestations are allodynia, hyperalgesia, atrophy of the affected extremity, coldness in the affected area, and dystrophic changes, most often manifested as hair loss and a shiny appearance of the skin. Neuropathic pain is difficult to manage. It is frequently unresponsive to opioid or other pharmacologic therapy.

## Trigeminal Neuralgia

**Etiology and pathogenesis.** Trigeminal neuralgia is a form of neuropathic pain that can be quite disabling for patients. It appears as sudden, momentary, and excruciating pain along the second and third divisions of the trigeminal nerve. Trigeminal neuralgia is more common in women than in men, and occurs more frequently in middle-aged or older individuals.<sup>16</sup> If trigeminal neuralgia occurs at an earlier age, multiple sclerosis should be ruled out.<sup>16</sup> Other causes of trigeminal neuralgia include lesions or tumors of the brainstem. Chronic compression of the trigeminal nerve by a vessel is suspected in most cases. This causes demyelination of the trigeminal nerve and interruption and alteration in nerve signaling.

**Clinical manifestations.** The pain of trigeminal neuralgia is often described as sharp or shooting; some have compared it to the pain of an electrical shock. Patients may be pain free between episodes or complain of a dull ache in the affected area. Sometimes patients may only have a few episodes of pain followed by a long remission period. However, others may unfortunately experience an increase in frequency and duration of the pain. Anxiety is common, since patients worry about when their next attack may occur.

**Diagnosis and treatment.** Diagnosis of neuralgia is most frequently based on the clinical history. The results of neurologic evaluation are normal if there is no underlying lesion. Management of trigeminal neuralgia includes use of antiseizure medications such as carbamazepine (Tegretol), phenytoin (Dilantin), or gabapentin (Neurontin). Surgical nerve decompression has been used successfully for trigeminal neuralgia in patients who do not respond to or cannot tolerate the medications. Gamma-knife radiosurgery is the newest treatment for this condition.<sup>16</sup>

## Diabetic Neuropathy

**Etiology and pathogenesis.** One of the most common complications of diabetes, diabetic neuropathy affects approximately 60% to 70% of all persons with diabetes.<sup>17</sup> Diabetic neuropathy is caused by damage to the peripheral nerves. The exact pathogenetic mechanism is unknown, but this damage is thought to be mediated by occult inflammation and demyelination of the larger peripheral nerves, leaving an excess of smaller myelinated fibers. This causes a loss of inhibitory input from the spinal cord with unopposed nociceptive afferent bombardment. Ischemic damage to nerves is also a contributing factor. Some also hypothesize that hyperglycemia and related biochemical changes in the nerve microenvironment cause nerve malfunction and injury. It is unclear why patients develop such varying levels of nerve dysfunction and pain. Strict blood glucose level control does not always prevent or improve the condition. More attention is now being focused on the role of peripheral and central sensitization.<sup>18</sup>

**Clinical manifestations.** Although pain is the most common feature, patients also complain of numbness and tingling, mild weakness, and loss of vibratory sense and proprioception. Fine touch and vibratory sensation are decreased. Patients complain of burning pain in the distal bilateral lower extremities, often with a symmetric distribution. Pain is frequently worse at night.

**Diagnosis and treatment.** Diabetic neuropathy is confirmed through careful physical examination. Diabetic patients are encouraged to maintain strict control of their blood glucose levels to prevent neuropathy. Management of this disorder includes the use of a wide variety of topical and systemic pain medications. Systemic therapeutic agents include tricyclic antidepressants, serotonin-norepinephrine reuptake inhibitors, and anticonvulsants.<sup>18</sup> Although opioids can help with pain relief of diabetic neuropathy, their use has been limited because of tolerance and dependence issues. Side effects of all of these medications can limit their usefulness, especially in elderly patients or those with other

comorbid conditions. Many patients use a combination of topical and systemic therapies. An important nonpharmacologic treatment for diabetic neuropathy is the prevention of further complications. Diabetic patients are strongly encouraged to perform daily foot examinations, taking precautions against the development of foot sores and ingrown toenails. The combination of numbness and impaired circulation make diabetic patients at high risk for undetected injuries that do not heal and become easily infected. Amputation is a common outcome.<sup>17</sup>

### Postherpetic Neuralgia

**Etiology and pathogenesis.** A common but disabling complication of the varicella virus is herpes zoster. Years after an individual has recovered from the chickenpox virus, herpes zoster (shingles) may occur. This is a reactivation of the latent virus that has lain dormant along the nerve roots.

Postherpetic neuropathy is persistent pain that lasts for more than 8 weeks after the onset of skin lesions. Approximately 10% to 15% of patients with herpes zoster develop postherpetic neuralgia.<sup>19</sup> Risk factors for the development of this neuralgia are advanced age and history of immune compromise.

**Clinical manifestations.** Herpes zoster is characterized by a burning pain that follows along a dermatomal pathway and is accompanied by a blistering rash. It occurs in individuals who have a history of varicella infection (chickenpox). Frequently the pain is present before the eruption of the blisters.

**Diagnosis and treatment.** The diagnosis is most often made clinically; however, cultures can be used to determine the presence of the virus. The early use (within 72 hours of eruption of rash) of antiviral medications such as acyclovir (Zovirax) can decrease the risk of developing postherpetic neuralgia.<sup>19</sup>

Management of the neuralgia includes both topical and systemic therapies. Transdermal lidocaine and capsaicin cream may be helpful in mild cases. Anticonvulsants and tricyclic antidepressants are also useful. NSAIDs and opioids may be mildly helpful as well.<sup>19</sup> There is also a vaccine that adults may receive that will prevent or lessen the severity of a varicella-zoster outbreak, and decrease the risk of postherpetic neuralgia.

### ISCHEMIC PAIN

Pain resulting from a sudden or profound loss of blood flow to the tissues in a particular part of the body may result in ischemic pain. Decreased perfusion leads to tissue hypoxia and injury, with release of inflammatory and pain-producing chemicals. Ischemic pain is described as aching, burning, or prickling (paresthesia). The symptoms of ischemic pain depend on the origin of the ischemia. For example, pain of cardiac origin is visceral and radiates to the arm or jaw. This pain is perceived as being deep, aching, diffuse, and pressing. Ischemia resulting from acute deep venous occlusion is also aching and has a deep quality and gradual onset. Acute arterial occlusion may be felt as either burning or aching but has a sudden onset.

Chronic ischemic pain can occur in atherosclerotic syndromes. Arteriosclerosis obliterans occurs gradually as plaque develops in the intima of the arteries, most often arteries of the lower extremities. In the early stages, the pain, called *intermittent claudication*, is associated with physical activity, is alleviated with rest, and has a cramping quality. In severe cases, ischemic neuropathy may ensue and cause a more consistent burning, shooting pain in the leg or foot.

Management of ischemic pain is directed at improving blood flow and reducing tissue hypoxia. Acute ischemia is usually associated with a thrombus or embolus and can be managed with drugs to dissolve the clot or surgery to remove it. Chronic ischemia is most often associated with atherosclerosis and may be improved through lifestyle changes, including smoking cessation, weight loss, reduction of lipid levels, and

regular exercise. Surgical bypass procedures or placement of intravascular stents are other therapeutic modalities.

### REFERRED PAIN

Referred pain is perceived in an area other than the site of the injury. It is often felt at some distance from the point of nociceptor activation. A familiar example is the pain of myocardial infarction that is felt in the jaw or left arm. Other examples of referred pain include shoulder pain after pelvic procedures, diaphragmatic irritation from peritonitis, and cutaneous abdominal pain experienced with visceral irritation or tension. Common patterns of referral are shown in [Figure 47-9](#). Pain is generally referred to other structures in the same sensory dermatome. Convergence of nociceptors from internal organs with somatic afferents from the body surface occurs in the dorsal horn of the spinal cord.<sup>3</sup> The brain cannot differentiate the two sources of pain signals and tends to attribute the visceral pain to a body surface location. Patterns of referred pain are fairly uniform and can be used to help locate a source of visceral pathologic process.<sup>3</sup>

#### KEY POINTS

- Acute pain results from tissue injury and generally resolves when the injury resolves. The clinical manifestations result from activation of the sympathetic nervous system (elevated heart rate, blood pressure, and respiratory rate; dilated pupils; perspiration; and pallor).
- Headaches are a common but disabling cause of acute pain. Migraine headaches are caused by an interaction between neurotransmitters and cerebrovascular mechanisms and may be triggered by factors such as stress, foods, and sleep deprivation. There are a variety of treatments for headaches, but all must be initiated early in the course of the headache.
- Chronic pain lasts several months beyond the expected healing time and is often not associated with sympathetic manifestations of pain owing to physiologic adaptation. Instead, changes in personality or lifestyle may occur. Individuals may experience acute and chronic pain simultaneously, as commonly occurs in advanced cancer.
- Fibromyalgia syndrome (FMS) is a poorly understood cause of chronic pain. It is more common in women and has many associated signs and symptoms. FMS is best treated with multiple approaches, both pharmacologic and nonpharmacologic.
- Neuropathic pain results from injury to peripheral or central nerves as a consequence of surgery, tumor, trauma, or drugs and has a constant, aching, or shocklike quality. The sympathetic nervous system may maintain neuropathic pain by releasing norepinephrine onto nociceptors.
- Ischemic pain occurs when inadequate blood flow to tissues results in cellular injury and release of chemicals that stimulate and/or damage nociceptors.
- Referred pain is a painful sensation perceived at some distance from an injury but generally within the same dermatome. Referred pain is thought to occur because of the convergence of visceral nociceptor activity with primary somatic afferents in the posterior horn of the cord.

### PHYSIOLOGIC RESPONSES TO PAIN

The autonomic nervous system, which is responsible for much of the physiologic response to pain, includes both the sympathetic and parasympathetic divisions. Activation of the sympathetic nervous system results in a predictable cluster of physical signs and symptoms, including an elevated heart rate, blood pressure, and respiratory rate, as well as dilated pupils, perspiration, and pallor<sup>20</sup> (see [Table 47-4](#)). Sympathetic stimulation results in constriction of superficial vessels to divert blood to striated muscle, heart, and lungs; bronchodilation; increased

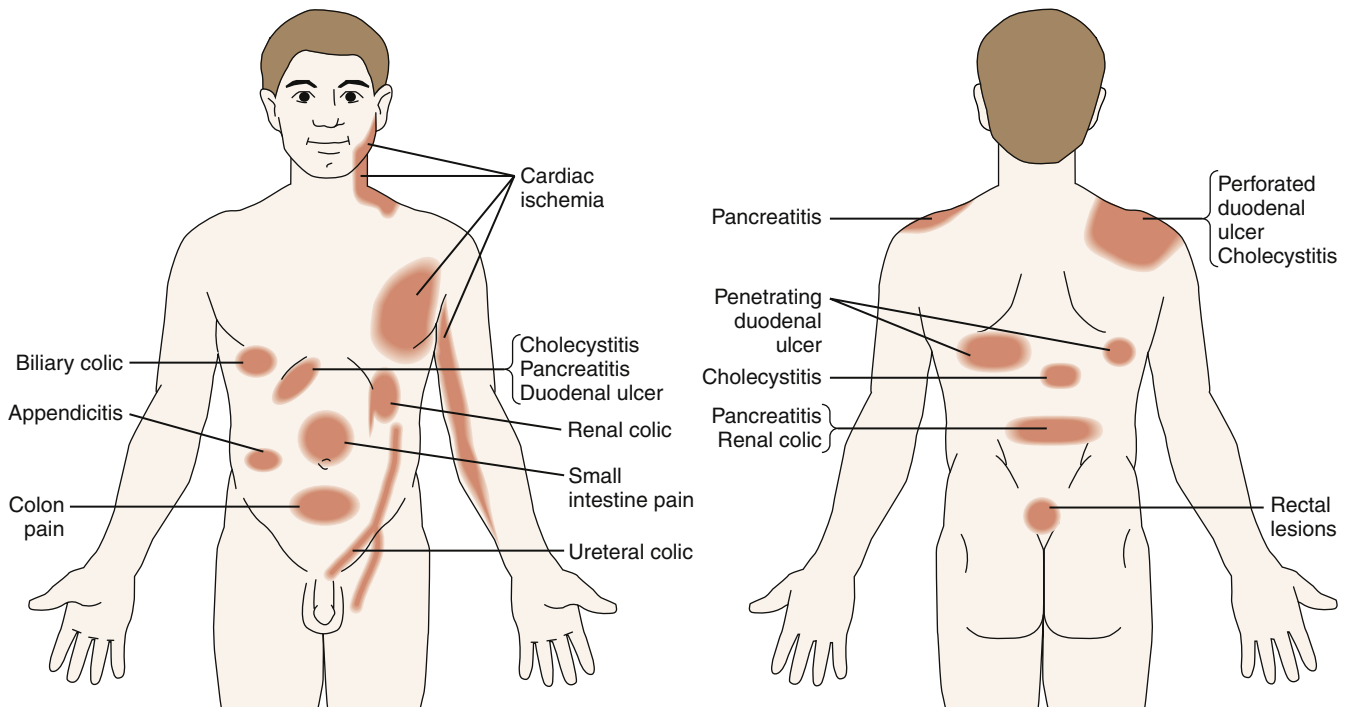

FIGURE 47-9 Areas of referred pain.

cardiac contractility; and increased levels of circulating blood glucose. In addition, although gastrointestinal motility and secretion decrease, sphincter tone increases. Nausea, vomiting, and even paralytic ileus may develop. Hypomotility of the bladder and ureters can also result from sympathetic activation and lead to urine retention. Pain stimulates the release of numerous stress hormones, including antidiuretic hormone, aldosterone, and cortisol. These hormones help the kidneys conserve fluid and stimulate the release of glucose from the liver.

The sympathetic responses to pain may be physiologically helpful in the short term but become deleterious if excessive or prolonged. The body cannot sustain this level of activation for long periods. Eventually, physiologic adaptation occurs and the observed sympathetic response to pain abates. Thus the heart rate, blood pressure, and respiratory rate return toward normal or baseline. Signs and symptoms of sympathetic nervous system activation may be an important clue in pain assessment when present, but their absence does not guarantee the absence of pain sensations.

## PAIN IN THE YOUNG AND THE ELDERLY

Many myths and misconceptions surround the issue of pain, especially in the very young and the elderly. As a result, often the young and the old receive inadequate treatment of their pain. It was previously thought that neonates were unable to perceive pain. Because their central nervous systems had not yet fully developed and they were unable to recall painful events, neonates often did not receive pain medication or anesthesia for surgery. It has since been found that infants do indeed have pain perception and that inadequate pain control may lead to persistent behavioral changes and physical changes in the CNS.<sup>21</sup>

In the elderly, it has also been theorized that pain perception is decreased. Research in this area has been inconclusive.<sup>22</sup> Social expectations interfere with the adequacy of pain control in the elderly, because pain is often an expected part of aging. Cognitive factors also hinder pain treatment, especially in patients with dementia who are unable to communicate their need for pain medication. However, it has been found that pain has a significant effect on an elderly individual's quality

of life. No matter what the age of the patient, adequate pain control is important to his or her care.

## TREATMENT MODALITIES

### PHARMACOLOGIC AND NONPHARMACOLOGIC PAIN MANAGEMENT

Many pain management strategies are available. By understanding the basic mechanisms of pain transmission, one can readily identify potential sites where various types of treatment modalities could interrupt pain transmission and perception. Pain management interventions can be directed at three points: (1) interrupting peripheral transmission of nociception; (2) modulating pain transmission at the spinal cord level; and (3) altering the perception and integration of nociceptive impulses in the brain.

#### Interrupting Peripheral Transmission of Pain

Modalities that interrupt the peripheral transmission of nociceptive impulses are often the first step in controlling pain. The basic action of splinting an injured limb or area of the body alters the peripheral transmission of pain by minimizing or reducing tissue injury. Applying heat or cold to an injured area also helps reduce peripheral nociception by altering blood flow to the area or by reducing swelling.

Pharmacologic treatments such as NSAIDs or local anesthetic agents also exert their analgesic effects by interrupting peripheral transmission at an early stage. NSAIDs and local anesthetic agents are used as a primary intervention for pain management. Inhibition of prostaglandin production by NSAIDs reduces the number of pain chemicals available to stimulate nociceptors in the peripheral tissues. NSAIDs include indomethacin, ibuprofen, naproxen, sulindac, piroxicam, ketorolac, and many others. Blocking the production and action of prostaglandins is not without side effects. For example, prostaglandins are responsible for maintenance of the gastric mucosa, and blocking their actions can result in gastrointestinal bleeding. Prostaglandin inhibition can also lead to decreased platelet aggregation and

renal insufficiency. Knowledge of the risks and prescribing guidelines is essential for safe patient care, especially for prolonged periods. Many of these agents are available over-the-counter, and patient teaching regarding benefits and precautions may be needed.

Local anesthetic agents can be applied either to nerve endings at the site of injury or to the nerve plexus supplying the area. By providing localized or regional blockade, peripheral pain transmission is interrupted. Local anesthetic agents diminish or block conduction of the nociceptive impulses by blocking sodium influx during phase 0 of the action potential. The degree of blockade achieved with local agents depends on the amount of drug applied and hence the extent of sodium channel blockade. Local infiltration of a wound or surgical site with local anesthetic agents such as bupivacaine or lidocaine is common practice, even when the patient is also receiving a general anesthetic.

### Modulating Pain Transmission at the Spinal Cord

Numerous procedures and agents are used to modulate pain transmission at the level of the spinal cord. Nonpharmacologic techniques that inhibit pain transmission include several types of cutaneous stimulation. Cutaneous stimulation activates and recruits large sensory fibers that can block the central progression of nociceptive transmission at the interneurons. Examples of cutaneous stimulation include transcutaneous electrical nerve stimulation (TENS), massage, acupuncture, application of heat or cold, and therapeutic touch.

Pharmacologic measures that act at the level of the spinal cord include epidural and intrathecal analgesia. Spinal analgesia can be achieved with opioids, local anesthetics, and  $\alpha$ -adrenergic blocking agents. Intraspinous opioids work by binding with opioid receptors in the posterior horn of the spinal cord, thereby decreasing the release of neurotransmitters such as substance P. Intraspinous local anesthetic agents block nerve conduction at the posterior nerve root. Epidural administration of an  $\alpha$ -adrenergic blocking agent such as clonidine is thought to achieve analgesic effects by blocking sympathetically mediated pain transmission.

Dorsal column stimulators, sometimes used in chronic pain management, also work at the level of the spinal cord to “close the pain gate” by modulating descending input from the brain to the spinal cord.

### Altering the Perception and Integration of Pain

The traditional modality for managing moderate to severe pain is the administration of systemic opioids. This pharmacologic intervention has stood the test of time. Opioids work at specific receptor sites that are located throughout the body but are highly concentrated in the brain. Opioid analgesic agents such as morphine and other derivatives alter the perception of pain by the brain. Opioid analgesics have similar mechanisms of action but vary widely in potency. This difference in potency has led to the development of equianalgesic tables to help clinicians prescribe these drugs appropriately (Table 47-6).

Opioid administration is associated with numerous side effects that may limit effectiveness (nausea, vomiting, respiratory depression, constipation). Long-term use of opioids leads to physical dependence and tolerance. Although the incidence of opioid addiction in persons experiencing acute pain is very low, fears about addiction contribute to inadequate pain therapy. Physical dependence is characterized by withdrawal symptoms if treatment is stopped abruptly. Tolerance to opioids is characterized by the need for increasing dosages to achieve the same analgesic effect. Dependence and tolerance are expected responses to long-term opioid therapy. Drug addiction is a behavioral pattern characterized by craving and preoccupation with obtaining the drug.

Nonpharmacologic techniques of pain management include such activities and procedures as distraction, guided imagery, relaxation, biofeedback, and hypnosis. With distraction, the number of

**TABLE 47-6 EQUIANALGESIC TABLE FOR COMMON OPIOID ANALGESICS**

DRUG	APPROXIMATE EQUIANALGESIC DOSE	
	ORAL	PARENTERAL
Morphine	30 mg q3-4h	10 mg q3-4h
Codeine	30-60 mg	—
Controlled-release morphine (MS Contin)	90-120 mg q12h	—
Hydrocodone	5 mg q4-6h	—
Hydromorphone (Dilaudid)	7.5 mg q3-4h	1.5 mg q3-4h
Meperidine (Demerol)	300 mg q2-3h	100 mg q3h
Methodone	20 mg q6-8h	10 mg q6-8h

Data from *Opioid equianalgesic chart*. Available at <http://champ.bsd.uchicago.edu/PalliativeCare/documents/pallpaincard2009update.pdf>.

generalized stimuli reaching the brain increases. Because the brain has a limited capacity to sort and attend to multiple and varied stimuli, it is less able to integrate the pain experience when other competition is present. Imagery may alter the perception of painful stimuli in the higher centers of the brain and produce relaxation as well as analgesia. Biofeedback is a conditioned response that can be learned as a pain-control strategy. Biofeedback is thought to control pain by increasing blood flow (usually as a consequence of relaxation) to targeted body areas. The increased blood flow decreases the concentration of pain-inducing chemicals in the area. Biofeedback may also increase the amount of endorphins produced and released.

A combination of nonpharmacologic and pharmacologic strategies may help reduce the need for high doses of medications. The choice of drug therapy should correspond to the severity of the pain. It has been recommended that mild pain be managed with nonopioid analgesics such as NSAIDs or acetaminophen, whereas moderate pain may require low-potency opioids such as codeine. Severe pain requires larger and more potent doses of opioids like morphine and fentanyl. The value of combination therapy in blocking pain transmission at multiple sites has been recognized. In the arena of chronic pain management, further research is delving into the central and peripheral sensitization theories. Questions remain as to why these develop and which patient populations are at highest risk for developing these complications. Great opportunity lies in the development of novel therapies for the control of chronic pain.

#### KEY POINTS

- Treatment is aimed at moderating pain transmission at specific points along the pain pathways. Potential sites of pain moderation are at the peripheral nociceptor, spinal cord, and brain.
- Nociceptor activation can be altered by prostaglandin inhibitors (NSAIDs), heat and cold, and local anesthetics that block sodium influx through fast channels.
- Spinal cord transmission can be altered by cutaneous stimulation (gate control theory), intraspinal analgesics (opioids, local anesthetics,  $\alpha$ -adrenergic blockers), and dorsal column stimulators.
- The perception of pain can be altered within the brain by systemic opioids and by nonpharmacologic means such as hypnosis, distraction, and biofeedback.

## SUMMARY

The human experience of pain, although unpleasant, is a normal and expected phenomenon in response to injury. Pain sensations alert the individual to a physiologic problem and help ensure that timely treatment is sought. However, prolonged severe pain serves no good purpose and can be physiologically and psychologically harmful.

Appropriate efforts to alleviate pain may enhance recovery from illness and prevent the development of some types of chronic pain syndromes. As understanding of pain physiologic mechanisms grows, treatment strategies can more effectively combine the best of pharmacologic and nonpharmacologic therapies.

*Major Depressive Disorder, 980*

*Bipolar Disorder, 984*

#### Women and Mental Illness, 986

**Cultural Considerations, 987**

**Geriatric Considerations, 987**

Abnormal behavior is typically considered the opposite of mental well-being. Current internationally recognized clinical diagnostic schemes rely on categorical systems to define mental disorders and provide standardized criteria for each diagnosis. The two most widely established systems are: (1) *ICD-10*, Chapter V: Mental and Behavioural Disorders, which is part of the *International Classification of Diseases* published by the World Health Organization,<sup>1</sup> and (2) the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*,<sup>2</sup> published by the American Psychiatric Association. Although historically there have been significant differences between these systems, in recent years there has been convergence so that both sets of codes are broadly comparable. There are more than 300 different psychiatric disorders listed in the fourth text revision of *DSM (DSM-IV-TR)*, with more added each revision. The fifth edition of *DSM (DSM-5)* will be published in May 2013.<sup>3</sup> Although there will be changes in nomenclature and disorder criteria in the newest version, *DSM-5* will continue its clinical utility, be guided more heavily by research evidence, and attempt to maintain continuity with previous editions.

The *National Survey on Drug Use and Health (NSDUH)* defines serious mental illness (SMI) as a mental, behavioral, or emotional disorder (excluding developmental and substance use disorders) that is diagnosable currently or within the past year, is of sufficient duration to meet diagnostic criteria specified within *DSM-IV-TR*, and results in serious functional impairment that substantially interferes with or limits one or more major life activities.<sup>4</sup> Using the SMI nomenclature, we now know that currently in the United States approximately 5% of all adults meet criteria for SMI. It is also known that 26.2% of the U.S. adult population will have experienced an SMI in the previous year, and 22.3% of these cases will be classified as “severe.” In addition, 46.3% of adolescents between 13 and 18 years of age will be diagnosed with an SMI. Research also shows that SMIs occur more frequently in women than in men, are more prevalent in individuals between the ages of 18 to 49, and are least likely to be seen in American individuals of Asian descent. **Table 48-1** provides a review of the most common SMIs by lifetime prevalence; 12-month health care service utilization is also provided for each disorder. Some SMIs have very high lifetime

TABLE 48-1 LIFETIME PREVALENCE OF SERIOUS MENTAL ILLNESS (IN U.S.)

NAME OF DISORDER	OVERALL CLASSIFICATION	LIFETIME PREVALENCE (%)	AVERAGE AGE OF ONSET (yr)	TREATMENT AND SERVICES USE (ANY TYPE) (%)
Social phobia	Anxiety disorders	29.9%	13	45.6%
Major depression	Mood disorder	16.5%	32	56.8%
Attention deficit disorder with hyperactivity (ADHD)	Attention deficit disorder (13-18 yr old)	9.8%	Not reported	Not reported
Posttraumatic stress disorder (PTSD)	Anxiety disorders	6.8%	23	57.4%
Generalized anxiety disorder	Anxiety disorders	5.7%	31	52.3%
Avoidant personality disorder	Personality disorders	5.2%	Not reported	Not reported
Panic disorder	Anxiety disorders	4.7%	24	65.4%
Bipolar disorder	Mood disorders	3.9%	25	55.5%
Obsessive-compulsive disorder	Anxiety disorders	1.6%	19	Not reported
Borderline personality disorder	Personality disorders	1.6%	Not reported	42.4%
Schizophrenia	Schizophrenia	1.1%	Not reported	64.3%
Antisocial personality disorder	Personality disorders	1.0%	Not reported	46.1%
Autism spectrum disorders	Autism spectrum disorders	0.9%	8	Not reported

prevalence but only moderate treatment service use (e.g., social phobia). Alternately, other SMIs have low lifetime prevalence but very high treatment service utilization (e.g., schizophrenia). Based on a combination of the lifetime prevalence rates and health care service utilization, the *most frequently occurring SMI disorders* and those with the *highest health care utilization* will be reviewed in Chapters 48 and 49.

## THOUGHT DISORDER, DELIRIUM, AND DEMENTIA

Psychosis is a term used to describe a serious and debilitating mental state. The most restricted definition refers to delusions and prominent hallucinations, which occur in the absence of insight into their pathologic basis.<sup>2</sup> The broadest definition of psychosis includes other positive symptoms that are characteristics of schizophrenia, such as disorganized speech and grossly disorganized or catatonic behavior. Hallmark symptoms of psychosis are delusions, hallucinations, cognitive disorganization, and altered reality. These symptoms characterize a small number of specific mental disorders; however, a wide range of different physical and mental conditions can produce psychotic symptoms. The neurobiological basis of psychosis can be summarized as acute or chronic alterations in neuron anatomy and physiology and cellular biochemical processes. Although psychosis occurs most often with schizophrenia and mood disorders, it may also manifest with substance disorders, delirium, dementia, amnesic disorders, and acute stress disorder. Groundbreaking research in brain imaging techniques and psychopharmacology now allows highly precise definitions of the various biochemical pathways associated with psychosis. This chapter addresses three disorders that are associated with psychosis: schizophrenia, major depressive disorder (MDD), and bipolar disorder (BD).

### Schizophrenia

Schizophrenia refers to a chronic, remitting, and relapsing psychotic disorder that is associated with significant impairment in social and vocational functioning.<sup>5,6</sup> Literally, the term is defined as “split mind,” and once was believed to be a disorder that caused the personality to split into multiple subtypes. Schizophrenia is now correctly understood as a split or separation among normally well-synchronized brain functions. This loss of synchronized brain functioning leads to thoughts, behaviors, and feelings that are disordered, disorganized,

and disconnected from reality—a condition generally referred to as psychosis.<sup>7</sup>

The global incidence rate of schizophrenia has consistently been estimated to be about 1% of the world population,<sup>7</sup> and is fairly equally distributed across genders. Unfortunately, schizophrenia appears to be associated with an average lifespan reduction of 15 to 25 years.<sup>5,6,8</sup> Women show symptom onset and are diagnosed typically between the ages of 25 and 35 years, men between the ages of 15 and 25 years. Women with schizophrenia appear to have better outcomes than men.<sup>9</sup> Possibly, the later age of onset, the protective nature of female hormones such as estrogens, or a better drug response accounts for this difference.<sup>9</sup> People with schizophrenia may be at increased risk for type 2 diabetes and cardiovascular disorders,<sup>10-13</sup> perhaps attributable to the side effects of antipsychotic medications, poorer overall physical health, less healthy lifestyles, and substandard health care. However, newer antipsychotic medications alone do not appear to account for the increased incidence of diabetes and cardiovascular disease.<sup>10-12</sup>

### Etiology and neurobiology

**Dopamine effects.** Several decades ago it was hypothesized that abnormalities in dopaminergic pathways in specific regions of the brain were the cause of schizophrenia. This conclusion was reached after noting that dopamine antagonists (competitive) reduce symptoms of schizophrenia whereas dopamine agonists (complementary) produce schizophrenic symptoms. Dopamine-specific neurons in the brain primarily are located in the ventral tegmentum of the mesencephalon, medial and superior to the substantia nigra. These regions, as a whole, are referred to as the mesolimbic dopaminergic system. The long nerve fibers leaving this system mainly project into the medial and anterior portions of the limbic system. The limbic system contains three powerful centers of behavior control: the nucleus accumbens, the amygdala, and the anterior caudate nucleus.

Generally speaking, we now know that decreased neurotransmission and connectivity is the neurobiological basis of schizophrenia. Frankle and colleagues<sup>14</sup> reported that the core biochemical process of schizophrenia involved an excess of subcortical dopaminergic transmission at dopamine D<sub>2</sub> receptors and a deficit of glutamate transmission at N-methyl-D-aspartate (NMDA) receptors. The dopamine pathogenesis of schizophrenia can be thought of as disordered synaptic organization. In the brain, normal synaptic organization implies

Controls

Schizophrenics

**FIGURE 48-1** Individual variation in positron emission tomography (PET) scans. Four normal individuals (*top row*) and four schizophrenics (*bottom row*) show range of hypofrontality and diminished basal ganglia metabolism. (From Buchsbaum MS, Haier RJ: Functional and anatomical brain imaging: impact on schizophrenia research, *Schizophr Bull* 13[1]:115-132, 1987. Reproduced by permission of Monte S. Buchsbaum, MD.)

the provision for normal communication among brain cells. Specific schizophrenia symptoms have been associated with neurotransmission dysregulation that diminishes or elevates dopamine activity. Hyperdopaminergic states have primarily been associated with positive symptoms of schizophrenia, such as hallucinations, delusions, and psychosis. Hypodopaminergic states have primarily been associated with negative symptoms of schizophrenia, such as cognitive difficulties, lack of energy and motivation, and depression.<sup>15</sup> Dopamine D<sub>2</sub> receptors have been associated with positive symptoms and psychosis, whereas dopamine D<sub>1</sub> receptors have been associated with negative symptoms.

That said, dopamine receptor activity and synaptic transmission are subject to a variety of mediators such as brain-derived neurotrophic factor (BDNF), a neurotrophin that increases synaptic activity and neurotransmitter output.<sup>16</sup> Dopamine synaptic activity also has been closely linked with stress-related cortisol activity and drugs of abuse (cocaine, amphetamines, morphine, nicotine, and ethanol).<sup>17</sup> Although dopamine dysregulation clearly is the driving force behind the neurochemical processes of psychosis, other experts suggest considering the role of biopsychosocial contextual factors in shaping and aggravating the expression of biochemical dysregulation.<sup>18</sup>

Positron emission tomography (PET) brain images have enabled researchers to further examine the overall role of dopamine activity in psychosis and schizophrenia. PET studies have demonstrated low glucose metabolism rates in the frontal cortex and dopamine regions<sup>19</sup> of the brains of persons with schizophrenia (Figure 48-1). Of the many different types of dopamine brain cell receptors identified, dopamine D<sub>2</sub> receptors once again were found to be strongly associated with symptoms of schizophrenia. Similar research has shown that dopamine D<sub>2</sub> receptors are particularly responsive to antipsychotic drugs.

Thus, the dopamine hypothesis, which postulates that schizophrenia symptoms result from presynaptic dysregulation of dopamine transmission, continues to be the focus of neurobiological studies. The specific neuropathologic mechanism of schizophrenia appears

to be caused by a functional excess of postsynaptic dopamine receptor activity and dopamine receptor hypersensitivity, either alone or in combination.

**Genetic effects.** In the absence of any other condition, a family history of schizophrenia by itself does not lead to schizophrenia: Schizophrenia can and does develop in persons with no family history of the disease. Initial interest in identifying possible genetic contributions to schizophrenia was based on early research on monozygotic (identical) and dizygotic twins, by studying twins born to parents with schizophrenia but reared apart from their parents. Results suggested that nearly 50% of these offspring developed schizophrenia.<sup>20</sup> Children of two parents with schizophrenia have a 40% to 68% risk of developing the illness, whereas children with one parent with schizophrenia have a 9% to 16% risk.<sup>9</sup> The risk of a non-twin sibling of a brother or sister with schizophrenia developing the disease is slightly less at 8% to 14%. The obvious limitation of these findings is that they do not explain why an at-risk offspring does not develop schizophrenia.

Several additional conditions are thought to be involved in the transformation from genetic risk to actual illness. Factors such as prenatal infections, malnutrition, birth complications, and brain injury have been associated with the development of schizophrenia in persons who have increased genetic risk.<sup>21</sup> Moreover, different gene locations are also relevant to the illness onset. Experts question whether inherited genetic risk for schizophrenia could explain observed differences in incidence and prevalence rates based on gender and race. Lastly, genetic models of schizophrenia typically do not address risk in terms of the subtype of schizophrenia, such as paranoid schizophrenia as opposed to schizophrenia without paranoia. Given the high standards of proof required for gene typing, a purely genetic explanation of an illness as complex as schizophrenia seems unlikely. Increased genetic risk of schizophrenia appears to be a critical part of a puzzle composed of many pieces. Thus, for individuals who are genetically predisposed, some aspects of schizophrenia will probably be determined

**FIGURE 48-2** Photographic comparison of hippocampal tissue at CA 2/3 interface in a control (*top*) and in a person with chronic schizophrenia (*bottom*). (Original magnification of the Nissl-stained tissue,  $\times 100$ . From Kovelman JA, Scheibel AB: A neurohistological correlate of schizophrenia, *Biol Psychiatry* 19:1601-1621, 1984.)

by biopsychosocial characteristics.<sup>22</sup> Researchers continue to study the actual versus potential genetic risks of schizophrenia.

**Gestational effects.** Early findings noted that in persons with schizophrenia, pyramidal cells in the hippocampus were not lined up like a “picket fence,” as they were in control subjects (Figure 48-2). Instead, the cells appeared to be rotated at 70-degree to 90-degree angles.<sup>23</sup> Pyramidal cells migrate during the second trimester of gestation and later become fastened by neuronal cell adhesion molecules (N-CAMs). Researchers focused on the possibility of pyramidal cell misalignment and lost N-CAM adhesive effects as links between gestation and schizophrenia. Researchers noted that in pregnant women living in Scandinavia and England who were exposed to the 1957 flu epidemic during their second trimester, 300% more of their children were diagnosed with schizophrenia than those of women who experienced flu during the first or third trimester.

These findings were considered significant for two reasons: (1) neuronal migration peaks during the second trimester, and (2) the influenza virus is one of very few viruses that produce capsular neuraminidase, an enzyme that can change the adhesive properties of N-CAMs.<sup>24</sup> Hippocampal, parahippocampal gyrus, and amygdala neurons process information and emotional expression. Other researchers have suggested that delivery complications could be an additional factor, playing a mediating role between prenatal influenza exposure and later development of schizophrenia.<sup>25</sup>

More recent studies of gestational abnormalities focus on specific brain regions and stages of prenatal neurodevelopment.<sup>26</sup> This research is exemplified in a well-controlled Canadian study that examined the association of hippocampal formation abnormalities and first adult episode of schizophrenia. The main functions of the hippocampus are learning and new-memory formation. Both abilities may be lost when hippocampal functioning is impaired. Macroscopic cell abnormalities, such as fewer synapse connections and diminished synapse activity, result in reduced hippocampal volume. Reduced hippocampal volume has been associated with severe stress, mood disorders, and schizophrenia.<sup>27</sup> The Canadian researchers hypothesized that schizophrenia was associated with incomplete formation of the hippocampus during the second trimester of development. They used magnetic resonance images to compare the brains of newly diagnosed patients with healthy matched controls. Although the number of participants in the study was too small to allow for generalizations to be drawn, the magnetic resonance images of the newly diagnosed patients clearly showed enlarged hippocampal fissures or disrupted hippocampal formation. Interestingly, obstetric complications during pregnancy were not significant factors.

**Neurologic effects.** Observed neuroanatomic differences in persons with schizophrenia led researchers to study anatomic and functional abnormalities in the limbic region and frontal lobe parts of the brain. Structural abnormalities in these brain regions would suggest that abnormal functioning might contribute to the disrupted cognitive processes or symptoms of schizophrenia. Beginning in 1976, computed tomography (CT) studies revealed enlarged brain ventricles in persons with schizophrenia. A groundbreaking 1980 study showed that the neurochemical basis of schizophrenia might involve two processes: dopamine neurotransmission dysregulation and abnormal cerebral structure.<sup>28</sup>

Magnetic resonance imaging (MRI) studies of persons with chronic schizophrenia indicated larger-than-normal lateral and third ventricles and reduced temporal lobe gray matter<sup>29</sup> (Figure 48-3). MRI findings also showed reduced frontal lobe blood flow and relative decreases in frontal lobe metabolic activity. Prefrontal cortex structure and functioning deficits were consistently observed when the subject was simultaneously placed under stress. The stress used in the study was primarily psychological, such as contingency planning exercises or divergent thinking during performance of a cognitive task that utilized specific regions of the prefrontal cortex.<sup>30</sup>

Subsequent studies of brain structure in persons with severe schizophrenia replicated the earlier findings of abnormal limbic-cortical structures and smaller, misarranged hippocampal pyramidal cells. This includes replication of MRI findings of reduced bilateral temporal lobe volume, decreased hippocampal volume, and reduced volume in the parahippocampal gyrus region of the brain. Studies of brain regions other than the limbic system revealed frontal lobe structural alterations in the dorsolateral area of the prefrontal cortex and in the cingulate and motor cortices. The finding of decreased frontal lobe glucose metabolism associated with schizophrenia also has been replicated (Figure 48-4).<sup>31</sup>

Postmortem brain tissue studies indicated fewer nicotinic receptors present in the hippocampus of schizophrenics. Tobacco dependence is a common secondary disorder with schizophrenia. The finding of fewer nicotinic receptors was of particular interest to researchers in that previous studies had shown that smoking could temporarily normalize auditory sensory gating that typically becomes impaired with schizophrenia.<sup>32</sup> Since then, researchers found that a neurophysiologic deficit at chromosome 15, at the *OC7* nicotinic receptor gene, may partially explain the inheritance of this neurophysiologic symptom.<sup>33</sup> Although the development of schizophrenia is associated with any number of specific abnormalities, early neurodevelopmental alterations that result in dysfunction of the limbic and prefrontal regions of the brain appear to be critical.

**FIGURE 48-3** Loss of brain volume associated with schizophrenia is clearly shown by magnetic resonance images comparing the size of ventricles (butterfly-shaped, fluid-filled spaces in the midbrain) of 44-year-old male identical twins, one of whom has schizophrenia (*right*). The ventricles of the person with schizophrenia are larger, suggesting structural brain changes associated with the illness. Note that such magnetic resonance images cannot be used to diagnose schizophrenia in the general population because of normal genetic variation in ventricle size; many unaffected people have large ventricles. (From Fortinash KM, Worret PA, editors: *Psychiatric mental health nursing*, ed 5, St Louis, 2011, Mosby, p 264. Courtesy Daniel R. Weinberger, MD, Chief Researcher, Clinical Brain Disorders Branch, National Institute of Mental Health, Bethesda, MD.)

**FIGURE 48-4** Positron emission tomography (PET) scan with  $^{18}\text{F}$ -deoxyglucose shows metabolic activity in a horizontal section of the brain in a control subject (*left*) and in an unmedicated client with schizophrenia (*right*). Red and yellow indicate lower activity in the white matter areas of the brain. The frontal lobe is magnified to show reduced frontal activity in the prefrontal cortex of the client with schizophrenia. (From Fortinash KM, Worret PA, editors: *Psychiatric mental health nursing*, ed 5, St Louis, 2012, Elsevier, p 279. Courtesy Monte S. Buchsbaum, MD, Mt. Sinai School of Medicine, New York.)

**Clinical manifestations.** Schizophrenia is characterized by positive (reality distortion and disorganization), negative, cognitive, and mood symptoms.<sup>7</sup> The types and severity of symptoms differ among patients and change over the course of the illness. Positive symptoms typically reflect an excess or distortion of normal functions. In contrast, negative symptoms reflect a decrease or loss of normal functions. *Positive symptoms* include the psychotic dimension, or distortions in thought content (delusions) and perception (hallucinations), as well as the disorganization dimension, or disorganization in speech and behavior. The resulting positive symptoms also include the inability to self-monitor behavior, which results in grossly disorganized or catatonic behavior. *Delusions*, or systematic, fixed, false beliefs, usually involve themes of persecution, reference, somatization, religiosity, or grandiosity. *Hallucinations* are sensory perceptions with no apparent stimulus. They occur in any sensory system (such as auditory, visual, olfactory, gustatory, or tactile) but usually auditory hallucinations are the norm. Auditory hallucinations are commonly experienced as voices, distinct from the person's own thoughts, and out of the range of normal experience. *Disorganized thinking* is usually evaluated by an individual's speech, and is frequently characterized by frequent derailment or loose associations, invented words, tangential ideas, and, when most severe, incomprehensible speech. *Grossly disorganized behavior* can range from childlike silliness to unpredictable agitation, and impairs the individual's ability to complete tasks of daily living. When individuals display catatonic motor behaviors, they show a decrease in reactivity to environmental events, to such an extreme that they can maintain a rigid posture and resist efforts to be moved. The positive symptoms<sup>13</sup> of schizophrenia are thought to result from excessive dopamine  $\text{D}_2$  receptor activity in the brain. *Negative symptoms* are considered to be restricted affect, or avolition and asociality. Negative symptoms represent deficits in functioning and can be more difficult to recognize than positive symptoms. Negative symptoms<sup>13</sup> of schizophrenia are considered to be associated with dopamine  $\text{D}_1$  receptor activity in the brain. Poor *cognitive functioning* in schizophrenia includes difficulties with memory, attention (e.g., poor concentration, distractibility, selective attention), and decision making.

**FIGURE 48-5** Neuroleptic (antipsychotic) action. Neurotransmitter (NT) action at the synapse is modified by neuroleptics, which block postsynaptic receptor sites to reduce nervous stimulation (reducing symptoms of schizophrenia). (From Fortinash KM, Worret PA, editors: *Psychiatric mental health nursing*, ed 5, St Louis, 2012, Elsevier, p 265.)

According to the workgroup responsible for developing *DSM-5*,<sup>3</sup> the active phase of schizophrenia is characterized by two or more of the following symptoms that must be present for a significant portion of time during a 1-month period (or less if successfully treated): (1) delusions; (2) hallucinations; (3) disorganized speech; (4) grossly abnormal psychomotor behavior; and (5) negative symptoms. At least one of these symptoms should include delusions, hallucinations, or disorganized speech. In addition, for a significant portion of the time since the onset of the disturbance, schizophrenia is also characterized by social/occupational dysfunction in one or more major areas: work, interpersonal relations, or self-care. All of these are markedly below the level achieved before the onset of the illness (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement). Regarding duration, typically continuous signs of the disturbance exist for at least 6 months, with at least 1 month of symptoms (or less if successfully treated) that meet criteria for the active phase (delusions, hallucinations, disorganized speech), and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more of the active-phase symptoms in an attenuated form (e.g., odd beliefs, unusual perceptual experiences). Finally, for an individual to receive the diagnosis of schizophrenia, the diagnoses of schizoaffective disorder and mood disorder with psychotic features must be ruled out. In addition, symptoms cannot be due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition.<sup>7</sup>

Schizophrenia has been divided into five subtypes in *DSM-IV-TR*:<sup>2</sup> paranoid; disorganized; catatonic; undifferentiated; and residual. In each subtype there is predominant symptomatology at the time of evaluation; these can change over time, such as at a subsequent diagnosis. In addition, an individual may have symptoms characteristic of more than one subtype. *DSM-V* may introduce a different classification of subtypes. The paranoid and disorganized types are the least severe (in that order). The undifferentiated type is essentially a catch-all category for individuals who do not meet criteria for any of the other subtypes. The residual type indicates that the disturbance has continued, but the active-phase symptoms are no longer met.

**Pharmacologic treatment.** When untreated, schizophrenia is associated with increased mortality, impaired vocational and social functioning, and reduced quality of life.<sup>5</sup> Unfortunately, the extent

to which treatment does actually improve life span and psychosocial functioning is not specifically clear. Because antipsychotic medications do decrease the likelihood of relapse, they are encouraged.

When effective, antipsychotic medication can be expected to diminish or remit hallucinations or reduce their impact on functioning.<sup>34</sup> The ability to reason should improve; ambivalence, delusions, and suspiciousness should be greatly reduced; agitation and confusion should be relieved; and social behavior should improve. Antipsychotic medications are designed to have specific effects on targeted neurotransmitters. Newer antipsychotic medications, typically called second-generation agents (SGAs) (atypical), are intended to generally manage psychosis as well as both positive and negative schizophrenia symptoms.<sup>5</sup> Older antipsychotic medications, traditionally called first-generation agents (FGAs) (conventional), were less effective in managing negative schizophrenia symptoms. They mainly acted as dopamine antagonists, blocking the dopamine receptors ( $D_2$ ). This action diminishes the amount of dopamine received by the receptor sites (Figure 48-5).

All FGAs and SGAs appear to be equally effective in reducing the positive symptoms and disorganization associated with schizophrenia, hence blocking the dopamine  $D_2$  receptor.<sup>5,34</sup> Neither antipsychotic agent appears to improve the cognitive symptoms in patients with schizophrenia; in fact, findings suggest that they worsen cognitive impairment.<sup>5</sup> Although the maximum drug response may not be reached for many months, patient response over the first 2 to 4 weeks of antipsychotic medication use will typically predict long-term response. Antipsychotic response will vary as a result of the stage of illness, with first-episode patients responding faster and at a higher rate than those at later stages.<sup>5</sup> In addition, both FGAs and SGAs play a substantial role in decreasing the likelihood of relapse.

FGAs and SGAs differ most notably in their side effect profiles and their potential for interacting with other medications. FGAs (e.g., chlorpromazine) had relatively nonspecific neurotransmitter effects and numerous side effects, the most difficult being extrapyramidal symptoms (EPS). Haloperidol was the first FGA that had significantly less anticholinergic and hypotensive side effects. By 1990, SGAs became widely available; the SGAs have generally shown a lower risk of EPS but a higher risk of other metabolic adverse effects. The first SGA, clozapine, was quickly followed by a generation of new atypical antipsychotics (risperidone, olanzapine, quetiapine, ziprasidone), each promising still fewer side effects, better relief of both positive and negative schizophrenic symptoms, and minimal risk of EPS, specifically

TABLE 48-2 NEUROTRANSMITTERS IN SCHIZOPHRENIA: TYPE AND FUNCTION

NEUROTRANSMITTER	TYPE	FUNCTION
Dopamine	Catecholamine	Regulates motor behavior in extrapyramidal nerve tracts and also transmits in cortex. Increases vigilance and may increase aggression. Excess may produce psychosis; deficiency may cause movement disorders (EPS).
Serotonin	Indolamine	Brainstem transmitter; modulates mood; lowers aggressive tendencies. Deficiency may be responsible for some forms of schizophrenia.
Acetylcholine	Cholinergic	Transmits at nerve-muscle connections (central nervous system and autonomic nervous system). Deficiency may increase confusion and acting-out behavior. Controls EPS.
Norepinephrine	Catecholamine	Transmits in sympathetic nervous system. Induces "fight or flight" syndrome (hypervigilance). May be insufficient in clients with schizophrenia who display anhedonia (loss of pleasure).
Cholecystokinin	Peptide	Excites limbic neurons. Deficiency is related to avolition (lack of motivation) and flat affect.
Glutamate	Amino acid	Excitatory neurotransmitter. Impairment in <i>N</i> -methyl- <i>D</i> -aspartate affects glutamate metabolism, which can lead to problems with cognition, delusions, and possibly some negative symptoms of schizophrenia.
$\gamma$ -Aminobutyric acid (GABA)	Amino acid	Inhibitory neurotransmitter; predominantly a brain transmitter. Promotes balance between dopamine and glutamate and thus inhibits impulsive behaviors.

From Fortinash KM, Worret PA: *Psychiatric mental health nursing*, ed 5, St Louis, 2012, Elsevier, p 265.  
EPS, Extrapyramidal symptoms.

those associated with tardive dyskinesia. Some worrisome side effects are clinically significant weight gain, glucose dysregulation, and dyslipidemia.<sup>35,36</sup> Experts have speculated that hyperglycemia may have to do with dopamine receptor involvement in the regulation of insulin secretion. Numerous explanations for weight gain as a major side effect of antipsychotic medication continue to be developed and tested. The glutamate neurobiological model<sup>37</sup> of psychosis and schizophrenia, an alternative to the dopamine model, may be the basis for the next new generation of antipsychotic medications.

The glutamate deficit<sup>37</sup> model attempts to focus attention on the cause of excessive dopamine receptor activity rather than the excessive activity itself.  $\gamma$ -Aminobutyric acid (GABA) is the most important inhibitory brain neurotransmitter. GABA synthesis depends on and is controlled by the enzyme glutamic acid decarboxylase (GAD). GAD activity is modulated by the glutamate receptor NMDA. GAD dysregulation is thought to lead to insufficient GABA activity and, consequently, excessive dopamine activity. Reduced GAD activity has been observed in the dorsolateral prefrontal cortex and hippocampus of patients with schizophrenia. The interesting observation for pharmacologic researchers is that a broad range of different drugs has been shown to be capable of affecting GAD activity. Although the glutamate deficit model is not new, the model still may lead to a class of antipsychotic medications unlike any previous generation.

Dopamine  $D_2$  continues to remain the lead neurotransmitter target of the atypical antipsychotics.<sup>34</sup> Researchers found that the most common side effects of antipsychotic medication could be reduced if the drug's impact on dopamine  $D_2$  receptors was not excessive. Lower receptor occupancy, less receptor affinity, and faster release<sup>38</sup> of the receptor were methods shown to be associated with fewer side effects. More recently, the aim for effective antipsychotic medication is to stabilize rather than reduce dopamine activity. The newest SGAs, such as aripiprazole, paliperidone, iloperidone, asenapine, and lurasidone, show greater affinity for serotonin receptors (negative symptoms) and moderate affinity for dopamine and norepinephrine receptors (positive symptoms).<sup>5,38</sup> Effective antipsychotic medications have significant dopamine effects; however, schizophrenia symptoms are highly complex and likely to involve other neurotransmitters, particularly serotonin and norepinephrine (Table 48-2).

**Nonpharmacologic treatment.** Psychosocial treatments that offer integrated care are essential for all patients with schizophrenia. At a minimum this should include case management in order to maintain the system of care, permit the most efficacious treatment in the least

restrictive setting, and optimize quality of life and social function. However, cognitive-behavioral therapy (CBT), cognitive remediation and rehabilitation, social skills-based therapies, vocational rehabilitation, and family therapy have all proven to be effective supplemental care for schizophrenia.<sup>7</sup>

#### KEY POINTS

- *DSM* and *ICD* are the two main systems for the classification of mental illness; *DSM-IV-TR* will be revised as *DSM-5*, which will be published in 2013. There are more than 300 different types of mental illness classifications today.
- Schizophrenia is characterized by altered perceptions of reality and disordered thinking. Genetic predisposition and environmental factors are thought to interact to produce biological changes in the brain, particularly in the hippocampus, temporal lobes, and dopaminergic pathways that project to the limbic system. Exposure to influenza virus during the fifth to sixth months of gestation appears to predispose to schizophrenia.
- The average age at onset for schizophrenia is 15 to 25 years for men and 25 to 35 years for women. There is a higher incidence in industrialized societies.
- The positive symptoms of schizophrenia are thought to be due to excessive dopamine  $D_2$  receptor activation in the brain. Disorganized thinking (inability to connect thoughts logically), disorganized speech (rambling, tangentiality), delusions (fixed system of false beliefs), and hallucinations (sensory perceptions when no apparent stimulus exists) are typical positive symptoms. Delusions are often persecutory, grandiose, or controlling. Hallucinations are most often auditory but may also be visual, olfactory, gustatory, or tactile. Positive symptoms respond to drugs that decrease dopamine activity in the brain (e.g., olanzapine, quetiapine).
- Negative symptoms are thought to be mediated by dopamine  $D_1$  receptors in the brain. Drugs that block  $D_1$  receptors (e.g., clozapine) may alleviate some of the negative symptoms, which include social withdrawal, flat affect, poverty of speech, ritualistic posturing, and autism.

#### Major Depressive Disorder

Major depressive disorder (MDD), once referred to as endogenous depression (or depression that arises from innate characteristics of the person), is now understood to be a complex illness involving inherited genetic susceptibility and symptoms associated with specific alterations in brain structures and functioning. According to *DSM-IV-TR*<sup>2</sup> the diagnosis of MDD requires the presence of multiple symptoms that

TABLE 48-3 RISK FACTORS FOR MAJOR DEPRESSION AND BIPOLAR DISORDERS

RISK FACTOR	MAJOR DEPRESSION	BIPOLAR DISORDER
Lifetime prevalence (%)	Overall: 5.2-17.1 Females: 7.4-21.3 Males: 2.8-12.7	Bipolar I: 0.9-1.6 Bipolar II: 0.3-3 Spectrum: 3-6
Female/male ratio (U.S.)	1.7-2.6	No significant differences
Age at onset (yr) (U.S.)	23.8-25.6	18-27
Social class	No clear relationship	Slight increase in upper classes
Marital status	Divorced and separated have 2× increase compared to married or never married	More frequent in people with multiple divorces and unmarried
Race and ethnicity	No relationship	No relationship
Family history	Ranges from 14.7 to 24.2 per 100 in probands; depends on severity and age of onset of depression For monozygotic twins, ranges from 31% to 71%; for dizygotic twins, ranges from 20% to 25%; higher for females	Bipolar I 7× more frequent in relatives of proband Twin studies suggest 50% to 60% increase

From Hirschfeld RMA, Weissman MM: Risk factors for major depression and bipolar disorder. In Davis KL, Charney D, Coyle JT, Nemeroff C, editors: *Neuropsychopharmacology: the fifth generation of progress*, Brentwood, TN, 2002, American College of Neuropsychopharmacology, pp 1017-1025.

are intense enough to cause distress and to persistently impair psychosocial functioning. Depression with one or two symptoms that last 2 years or more is commonly referred to as *dysthymia*. More than 40% of adults with MDD remain untreated, probably because of underdetection.<sup>39</sup> Some people experience a seasonal pattern to depression (i.e., seasonal affective disorder [*SAD*]), where depression is more likely to occur in the fall or winter months. This occurs in one third of the cases, enough that *SAD* is a new entry for *DSM-IV-TR*.<sup>2</sup> MDD frequently occurs as a comorbid disorder to serious physical illness as well as other mental disorders. MDD can develop as a serious secondary illness or illness complication. For example, as early as 1937, researchers were able to show that cardiac patients with severe depression had higher cardiac death rates than their counterparts. Recent studies confirm that depression continues to be a significant risk factor for 1-year mortality rates in myocardial infarction patients.<sup>40</sup> Similarly, systematic reviews and longitudinal studies validate that patients with comorbid renal disease, cardiovascular disease, and cancer demonstrate significant improvement in overall morbidity and mortality when depressive symptoms are effectively treated.<sup>41</sup>

Significant rates of MDD are observed across all ages, races, education, and income groups.<sup>42</sup> Globally, females are diagnosed with MDD two times more often than males.<sup>43</sup> Depressed individuals with a family history of MDD have a onefold to twofold increased risk for developing dysthymia and anxiety disorders.<sup>44</sup> The complexity of managing severe depression in adolescents<sup>45</sup> and older adults<sup>46,47</sup> has made these population groups particularly concerning. As a result of the potentially serious disability, morbidity, and mortality risks directly associated with MDD, the World Health Organization (WHO) has ranked major depression among the top five global health problems.<sup>48</sup>

**Etiology and neurobiology.** Improved neurobiological research techniques have allowed for advances in the understanding of the neurobiological mechanisms of MDD. Nevertheless, the specific *cause* of MDD remains unknown. Table 48-3 summarizes mood disorder risk factors.

Cognitive processing models of depression describe dysfunctional thoughts and beliefs that occur during depression. These dysfunctional thoughts are believed to result from underlying schemas, or ways in which attention, memory, and information are organized with a negative bias. The depressed person focuses on negative information, emotions, and memories and selectively attends to negative material with automatic negative thoughts. This reinforces the continuation of the dysfunctional depressive schemas, creating a self-referent bias towards negative thoughts and expectations. When the

depressed person ruminates, everything is interpreted through a negative filter.<sup>49-51</sup> Research suggests that depressive states are indeed associated with slower cognitive processing, impaired attention, and bias towards negative stimuli; these appear to abate as depression goes into remission.<sup>52,53</sup>

Neurobiological changes associated with MDD are thought to involve neurotransmission dysregulation,<sup>46</sup> altered hippocampal and prefrontal cortex cell structure and functioning,<sup>54</sup> and impaired hypothalamic-pituitary-adrenal (HPA) system activation<sup>55</sup> (Table 48-4). Based on observations of low central nervous system levels of serotonin (Figure 48-6) in persons with severe symptoms of depression, the basic neurobiology of depression has been hypothesized to be reduced brain serotonin neurotransmission activity either through excessive presynaptic uptake or through stress-related down-regulation of postsynaptic receptors. Chronic or persistent vulnerability to depression is thought to be related to decreased hippocampal volume or capacity<sup>56</sup> and suppressed hippocampal neurogenesis.<sup>57</sup>

Some of the biological factors associated with depression are illustrated in Figure 48-7. HPA axis dysfunction has been associated with depression. Although no single gene has been identified as a cause of MDD,<sup>49</sup> both family studies<sup>58</sup> and twin studies<sup>59</sup> suggest an increased risk of heritability. Genetic susceptibility to depression may also mediate the link between stress and depression.<sup>60,61</sup>

Other theorists propose that increased stress hormone levels can lead to significant decreases in the expression of brain-derived neurotrophic factor (BDNF). Reduced BDNF activity has been shown to lead to hippocampal cell atrophy and, consequently, reduced neurotransmission activity in this area of the brain.<sup>62</sup> According to the researchers, effective antidepressant medications seemed to improve BDNF activity and thereby promote the growth and survival of serotonin neurons in this vital brain region. Significant reduction in BDNF activity, as a result of severe stress, has also been demonstrated in research animals. The HPA model of depression supports the development of novel treatments that can target cortisol activity (e.g., mifepristone) rather than serotonin activity (e.g., selective serotonin reuptake inhibitors [SSRIs]).<sup>63</sup>

Circadian rhythms (synchronizing cycles) are closely associated with symptoms of major depression.<sup>49</sup> The pineal gland in the brain produces the hormone melatonin. Brain melatonin levels can fluctuate significantly, with annual and daily increases and decreases in light and dark periods. Melatonin helps regulate circadian rhythms; in turn, these cycles govern body temperature changes and the urge to sleep. Depressed persons have been shown to suffer from low melatonin

**TABLE 48-4 PREFRONTAL CORTEX AND SEROTONIN INTERCONNECTIONS: IMPLICATIONS IN DEPRESSION**

INTERCONNECTED BRAIN STRUCTURES	HYPOTHESIZED ROLE OF THESE INTERCONNECTIONS IN DEPRESSION
Prefrontal cortex	Covering the frontal lobes, it is unique within the central nervous system for its strong interconnections with all other areas of the brain; it receives information that has already been processed by other sensory areas and then merges this information with other emotional, historical, or relevant information, thus attending to both feelings and intellect.
Limbic system structures <ul style="list-style-type: none"> <li>• Hippocampus</li> <li>• Amygdala</li> <li>• Cingulate gyrus</li> </ul>	Prefrontal cortex modulates limbic system activities (emotional and instinctive) by way of these three structures: <ul style="list-style-type: none"> <li>• Major importance in cognitive function, including memory</li> <li>• Major importance in modulating feelings such as aggression, anger, love, and shyness</li> <li>• Involved in motivation and interest</li> </ul>
Brainstem	Responsible for regulating the general state of arousal and tone of brain function; also the location of structures that manufacture various neurotransmitters, such as serotonin (5-HT), norepinephrine (NE), and dopamine (DA).
Raphe nuclei	Located in the brainstem, they manufacture 5-HT; they also modulate excessive stimuli, and the organization and coordination of appropriate responses to these stimuli.
Hypothalamus	This interconnection allows for direct prefrontal input into neuroendocrine function via the hypothalamic-pituitary axes.
Suprachiasmatic nucleus	Located in the hypothalamus, it regulates circadian (24-hr) rhythms and circannual rhythms; thus it is also implicated in seasonal affective disorder.

From Stuart GW, editor: *Principles and practice of psychiatric nursing*, ed 9, St Louis, 2009, Elsevier, p 292.

**FIGURE 48-6** The serotonin neurotransmitter system implicated in depression. (From Stuart GW, editor: *Principles and practice of psychiatric nursing*, ed 9, St Louis, 2009, Elsevier, p 290.)

levels when their symptoms include disturbed sleep. In theory, natural light acts as a zeitgeber, or a biological clock synchronizer that is based on the 24-hour day-night cycle. It has been hypothesized that persons with seasonal affective disorder who are exposed to additional natural light will experience improvement in their sleep-wake cycle and, consequently, improved mental health.<sup>49</sup>

**Clinical manifestations.** To be diagnosed with MDD, an individual must experience five (or more) of the following criteria during the same 2-week period; this must also represent a change from previous functioning.<sup>2</sup> In addition, at least one of the symptoms must be either depressed mood or loss of interest or pleasure. *Depressed mood,*

occurring most of the day, nearly every day, is indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). In children and adolescents, depressed mood can be irritable mood. Depressed mood associated with MDD is qualitatively different from normal sadness or grief associated with loss; it is typically experienced as painful, numbing, and bottomless. Markedly *diminished interest or pleasure* in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others), is another hallmark symptom of MDD. Even if the depressed person does engage in activities that were previously enjoyable, interest and pleasure are not experienced. There is

also significant *appetite disturbance* that results in weight loss (when not trying to diet) or weight gain (e.g., a change of more than 5% of body weight in a month). Depression is also associated with *insomnia or hypersomnia* nearly every day. Sleep symptoms include difficulty falling asleep and/or staying asleep, early-morning awakening, frequent awakenings, and waking feeling extremely tired. *Psychomotor agitation or retardation* can occur nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down). This can make normal daily activities difficult to perform. There is frequently *fatigue or loss of energy* nearly every day. Depressed people may associate their severe or sudden fatigue with serious physical illness such as cancer or cardiovascular disease. The fatigue can also make ordinary daily activities, once performed automatically, nearly impossible. Individuals experience *feelings of worthlessness or excessive or inappropriate guilt* (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick). Negative self-appraisals range from pointless guilt to self-hate. In some cases, the guilt reaches delusional proportions or is markedly disproportionate to actual misdeeds or perceived failings. Negative thinking, expressed as negative views of self, life, and the future, is a common symptom of depression. There is often a *diminished ability to think or concentrate, or indecisiveness*, nearly every day (either by subjective account or as observed by others).

**FIGURE 48-7** Biological factors related to depression. *EEGs*, Electroencephalograms; *DST*, dexamethasone suppression test; *TRH*, thyroid-releasing hormone. (From Stuart GW, editor: *Principles and practice of psychiatric nursing*, ed 9, St Louis, 2009, Elsevier, p 293.)

Finally, individuals with MDD have *recurrent thoughts of death* (not just fear of dying), display recurrent suicidal ideation without a specific plan, adopt a specific plan for committing suicide, or actually complete a suicide attempt.<sup>49</sup> Individuals may think about suicide passively, attempt suicide, or develop a specific plan for suicide. The clinician should ask directly about suicidal ideation to determine the presence of these thoughts, the intention to act on these ideas, and the extent of plans or preparation for suicide. If a method to complete suicide is identified, the lethality, the patient's expectation about the lethality, and the accessibility to the means of committing the plan (e.g., availability of firearms or medications) should be assessed. The client should also be interviewed to determine psychiatric risk factors, including agitation, pervasive insomnia, and impulsiveness; comorbidities, including substance abuse, psychosis (especially with command hallucinations), or personality disorder; family history of suicide; previous history of suicide attempts; and history of recent exposure to suicide.

*Psychosis* associated with MDD is thought to result from extreme symptoms, prolonged symptom duration, or comorbid illness complications. Hallucinations (especially auditory), delusions (especially nihilistic or somatic), and disorganization may become prominent in psychotic depression and require treatment with antipsychotic medications. Usually the psychosis is ego-syntonic, meaning that the hallucinations or delusions are consistent with their negative view of themselves, the world, and the future. Severely depressed older adults are at increased risk of depression-associated psychosis.

**Pharmacologic treatment.** Most antidepressants currently available act by improving brain norepinephrine and serotonin activity (Figure 48-8). Earlier generations of antidepressants had less specific effects on these neurotransmitters and significantly more side effects. Monoamine oxidase inhibitors (MAOIs) blocked the destruction of norepinephrine and serotonin once they were released into the synaptic cleft. Tricyclic antidepressants (TCAs) blocked the reuptake of norepinephrine and serotonin, thereby allowing more neurotransmitter activity. Selective serotonin reuptake inhibitors (SSRIs) include medications such as fluoxetine, paroxetine, and sertraline. Response rates vary across studies but range from 60% to 75%. No single SSRI is more effective than another. Although the side effect profile of SSRIs represents real improvement over earlier antidepressants, SSRIs are not side effect free.<sup>64</sup> Serotonin syndrome,<sup>65</sup> a serious side effect that results from excessive serotonin activity, includes altered mental status, restless agitation, myoclonus, hyperreflexia, sweating (diaphoresis), shivering, tremor, gastrointestinal upset, ataxia,

**FIGURE 48-8** Positron emission tomography (PET) scan of glucose use in depressed subject (figure on left) showing frontal hypometabolism (left side of figure). This improves after treatment with antidepressant medication (figure on right); note increased glucose metabolism in frontal lobe (left side of figure). (From Stuart GW, editor: *Principles and practice of psychiatric nursing*, ed 9, St Louis, 2009, Elsevier, p 291.)

and headache. Sexual dysfunction, evidenced by loss of interest, impaired arousal, and anorgasmia, is also thought to result from SSRI-induced excessive serotonin activity. Less severe but equally troublesome side effects include gastrointestinal upset, headache, allergy, dry mouth, constipation, urination difficulties, diaphoresis, and significant weight gain. In general, it takes 3 to 6 weeks for depressed patients to notice improvements in symptoms after beginning any type of pharmacotherapy.

SSRI cellular and neurochemical mechanisms continue to be the subject of a great deal of basic and clinical research. It would appear that the SSRIs share the basic action of boosting neurotransmission activity of mood-related monoamines. More recent research findings suggest that SSRIs may also alter the genetics-based expression of BDNF and cell neurogenesis in the hippocampus.<sup>47</sup>

**Nonpharmacologic treatment.** *Electroconvulsive therapy (ECT)* has been shown to be useful for patients who have inadequate response to two to three other antidepressant treatment modalities or require intensive therapy because of psychotic features or active suicidality; ECT is also efficacious in pregnant women who cannot receive pharmacotherapy.<sup>49</sup> *Phototherapy*, which consists of 30 minutes per day of direct facial exposure to a 10,000-lux intensity full-spectrum white-light box, can augment antidepressant therapy or be used alone, especially when a seasonal pattern has been identified.<sup>49</sup> There are several *psychotherapeutic interventions* that have been shown to be effective with depression, namely, cognitive-behavioral therapy and interpersonal therapy. With mild to moderate uncomplicated MDD, these psychotherapies can be used as the first-line treatment option. When used in conjunction with pharmacologic agents, a more rapid therapeutic response can be found, especially when a client has severe, recurrent MDD.<sup>66,67</sup> In addition, behavioral therapies combined with maintenance pharmacotherapy appear more successful at preventing relapse than use of pharmacotherapy alone.<sup>49</sup>

## Bipolar Disorder

Bipolar disorder (BD) is a highly complex mood disorder characterized by recurring symptoms of depression and elation that can become severe enough to produce psychosis. The most recognizable course of illness with BD is the sudden onset of severe mania lasting from weeks to months. Although mania is the hallmark of BD, the depressive phase actually represents the greatest burden on patients,<sup>68</sup> and it is more common for BD patients to present with depressive symptoms. BD patients experience three times more days with depression than do persons with any other mood disorders, and frequently have a continuous presence of subthreshold depressive symptomatology.<sup>69</sup> Because they are less likely to volunteer information about manic or hypomanic symptoms, accurate diagnosis of BD when the initial symptom profile is depression can be quite difficult or delayed. When the initial symptoms of mania are severe enough to produce psychosis, BD can be mistaken for schizophrenia.

Within the last decade, there has been a marked increase in the rate at which children are being assigned the diagnosis of BD.<sup>70,71</sup> BD in children is characterized by irritability, cyclical mood changes, and associated attentional deficit disorder with hyperactivity. The clinical course is often more chronic and undulating, with fewer discrete mood episodes. Some researchers have suggested that severe, nonepisodic temporal dysregulation is characteristic of pediatric BD.<sup>72</sup>

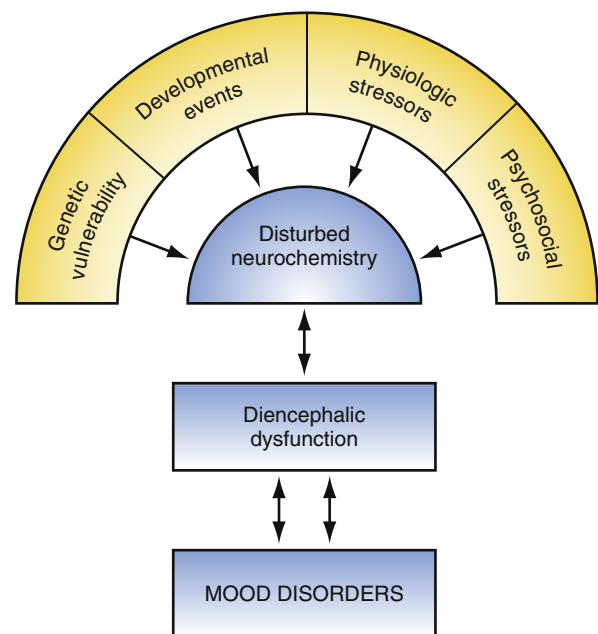

The two basic forms of bipolar disorder are bipolar I and bipolar II. A diagnosis of bipolar I disorder requires any past or present history of a full manic episode. There is usually a history of depressive episode(s) meeting criteria for MDD, but depression is not a requirement for the diagnosis of bipolar I disorder. Bipolar II disorder requires any past or present history of hypomania (never full mania), and a history of depression consistent with MDD. Thus what differentiates bipolar I from bipolar II disorder is the intensity of manic symptoms: bipolar I has a history of at least one full manic episode; bipolar II has a history of hypomanic

episodes (never a full manic episode). Three additional types of BD have been proposed (types II½, III, and IV), which further differentiate types I and II and better represent the clinical complexity of bipolar symptoms.<sup>73</sup> This suggests the concept of a bipolar spectrum and allows for earlier and more accurate diagnosis and treatment of persons who clearly suffer from mood dysregulation but who do not meet the narrow symptom criteria for bipolar I or bipolar II disorder. There are no known gender differences in the incidence of BD. The risk in the general population is 1%.

**Etiology and neurobiology.** Decades of clinical and genetic research findings indicate that the increased risk of developing BD is both inherited and acquired, with genetic risk reported to range from 60% to 85%.<sup>2,74</sup> Figure 48-9 illustrates a unified model of mood disorders. Efforts to identify the neurobiological factors that characterize BD have yielded mixed results. First, the similarities between psychosis associated with mania, psychosis associated with depression, and psychosis associated with schizophrenia are a major hurdle. Second, the depressive symptoms associated with BD differ very little from the depressive symptoms that characterize MDD (although response to treatment differs). Third, when bipolar symptom onset is gradual, changes in behavior can be mistaken for personality disorder or substance use disorder.

The neurotransmission model of BD follows the basic catecholamine hypothesis for major depression and schizophrenia. Neurotransmission activity deficits are thought to promote depression symptoms associated with BD, whereas excessive activity is believed to promote symptoms of mania and psychosis. There is a general assumption that the depression and mania of BD are the result of two different neurobiological processes. Alternately, BD is seen as the result of a neurotransmission dysregulation that leads to mood stabilization. Given the fact that it is not uncommon in persons with BD to have a mixed mood state that includes symptoms of both mania and depression, the mood destabilization hypothesis is of great interest. Both models focus on serotonin, norepinephrine, and dopamine as the neurotransmitters involved.<sup>75</sup>

Neuroimaging studies of brain structural changes associated with BD indicate findings potentially similar to those of major depression. For example, ventricular enlargement, increased numbers of

**FIGURE 48-9** Unified model of mood disorders. (Redrawn from Stuart GW, Sundeen SJ: Disturbances of mood. In Stuart GW, Sundeen SJ, editors: *Principles and practice of psychiatric nursing*, ed 4, St Louis, 1991, Elsevier, p 429.)

T2 signal hyperintensities, and tissue loss in the basal ganglia, lateral and mesial temporal structures, and cortical regions have been observed. At the same time, other researchers have reported no significant tissue changes associated with BD. Experts suggest that tissue changes probably are linked with greater mania symptom severity and duration. For example, symptom onset in older age has been related to greater tissue changes.<sup>49</sup> Neurobiological studies of the evidence of tissue changes associated with BD thus far have not linked specific changes with depression, elation, or mania. Nevertheless, impaired functioning has consistently been associated with tissue changes. Findings such as these lend important support to the hypothesis of impaired emotion processing and impaired regulation of emotional behavior as the probable neurobiological mechanisms of BD.<sup>75</sup>

**Clinical manifestations.** *Mania* is characterized by an abnormally and persistently elevated, expansive, or irritable mood that lasts for 1 week or more (or any duration if hospitalization is required). During the period of mood disturbance, the person also typically experiences three to four of the following symptoms: *inflated self-esteem or grandiosity* (e.g., self-appraised importance, claims of limitless expertise, and insulting derogatory statements). This perceived self-importance can reach delusional proportions resulting in the person's attempting to act on his or her perceived importance, genius, and infallibility. Serious negative consequences of grandiose actions as well as financial and criminal schemes are not uncommon. Other manifestations that may become evident during the manic phase of BP include *decreased need for sleep; increased talkativeness or pressure to keep talking; flight of ideas or subjective experience that thoughts are racing; distractibility; increased goal-directed activity* (such as social, work or school, sexual) or *psychomotor agitation*; and *excessive involvement in pleasurable activities that have a high potential for painful, long-term consequences* (e.g., unrestrained buying spree, sexual indiscretions). The mood disturbance must be severe enough to cause marked impairment in functioning and/or maintaining relationships with others, or necessitate hospitalization to prevent harm to self or others; in addition, psychotic features in the mood disturbance may also be evident.

The *difference between mania and hypomania* can be characterized by a difference in severity and duration. For example, although the symptoms are the same, hypomanic symptoms persist for 4 days or more (instead of 7). Typically, hypomania does not include psychosis or impaired functioning. Instead, the individual experiencing hypomania has a sudden onset of increased energy, expanded self-esteem, and decreased anxiety; these symptoms typically are reported to have improved the affected individual's productivity and are experienced as an acceptable natural high. Unlike mania, it is possible for an episode of hypomania to run its course without being recognized as hypomania.

*Hallucinations and delusions* can occur with the psychosis that typically develops with severe, prolonged mania. Unlike the hallucinations and delusions associated with schizophrenia, the alterations in perceptions and thinking that occur with mania generally are mood congruent. In other words, grandiose mood is likely to be mirrored by grandiose delusions and hallucinations.

**Pharmacologic treatment.** BD is a complex condition. Although the "depression" in BD appears similar to unipolar depression, it is different with regards to pathology, outcome, and management. Caution needs to be taken to avoid manic switches or rapid-cycling induction with antidepressants.<sup>76</sup> Appropriate pharmacologic treatment for BD requires accurate diagnosis. Before BD diagnosis and treatment are considered, the possibility of a primary medical condition or drug reaction as the cause of depression, elation, mania, or psychosis must be considered. Because of the many overlapping symptoms, it is not uncommon for persons with BD to be misdiagnosed as depressed or schizophrenic for many years before a diagnosis of BD is made.<sup>77</sup>

Even though most BD patients present with symptoms of depression and do not volunteer information about mania, treatment guidelines typically focus on the management of hypomania and mania, rather than depression.<sup>68</sup> Most treatment guidelines since 2005 emphasize using antidepressant medications only in combination with antimanic agents. In general, medications presently indicated for use as mood stabilizers include lithium, anticonvulsants, and atypical antipsychotics. For patients not yet in treatment for BD, with severe mania or mixed episodes, lithium (most typically) or valproates are commonly used in combination with an antipsychotic to stabilize mood. Many individuals with severe BD symptoms require additional antidepressant and antipsychotic medications to achieve optimal symptom management. Antipsychotic medications have been found to be effective in remitting symptoms of psychosis as well as in preventing their recurrence. Managing the depression symptoms of BD can prove more complicated. In some cases antidepressant medications can trigger mood switching or destabilize mood; as such, antidepressant monotherapy is not recommended.

Growing numbers of anticonvulsants now are being considered for use as mood stabilizers. These include various reformulations of carbamazepine, divalproex, and lamotrigine. Several treatment guidelines suggest that lamotrigine can also be used as the first-line choice.<sup>68</sup> Many of the pharmacodynamic and pharmacokinetic properties of the commonly used mood-stabilizing medications have been well-defined.<sup>78</sup> A variety of potential mechanisms of action have been proposed for lithium. The neurotransmission effects of lithium have been attributed to calcium-dependent cell wall depolarization. Through this process, dopamine and norepinephrine are released, and major secondary messenger neurotransmitter signals are released. Lithium is absorbed in the gastrointestinal tract but is not metabolized; more than 90% is excreted by the renal system. Any interference with the excretion of lithium (e.g., fluid volume depletion, angiotensin-converting enzyme inhibitors, diuretics, ibuprofen) can lead to rapidly increasing plasma lithium levels and toxicity. Continuous patient education and routine plasma lithium level measurements help to reduce the risk of toxicity. Early symptoms of lithium toxicity include confusion, nausea, and fatigue. Prelithium assessment of liver, renal, and thyroid functioning is required. In some cases, lithium leads to hypothyroidism that requires treatment. Lastly, lithium treatment for BD requires multiple daily doses, generally twice a day or more often. Multiple daily doses can exacerbate patient ambivalence about taking lithium. Euphoria, mania, and long symptom-free periods typically are misperceived as signs that lithium no longer is needed. There is some evidence that the degree of response to lithium treatment is familial.<sup>79</sup>

Divalproex often is the next best choice when lithium cannot be taken. This anticonvulsant has been found to have neuroprotective effects similar to those of lithium.<sup>78</sup> Unlike lithium, divalproex is highly bioavailable, is metabolized by the liver, produces an active metabolite, has a long half-life, and can be used to manage acute mania. Persons with impaired liver functioning or liver disease cannot take divalproex, and the routine evaluation of plasma levels is required to reduce the risk of toxicity.

Several atypical antipsychotic medications show promise as potentially effective mood-stabilizing medications. Of these, olanzapine, risperidone, quetiapine, and ziprasidone have received considerable attention. These medications exhibit a range of dopaminergic, serotonergic, and norepinephrinergic effects that improve many bipolar symptoms, particularly when the symptoms include full mania rather than hypomania. Once-daily dosing is an important advantage. The two atypical antipsychotics that have emerged as the best treatment options for bipolar depression are either quetiapine monotherapy or quetiapine with olanzapine-fluoxetine combination (OFC),<sup>68</sup> if psychotic features are present, then an antipsychotic such as olanzapine, quetiapine, or risperidone is suggested. It is critical to discontinue

medications that no longer seem effective, although most treatment guidelines provide little information about a specific time frame before interrupting or switching medications.

**Nonpharmacologic treatment.** Although pharmacotherapy is the first-line treatment choice, supplemental psychotherapy can be extremely helpful in the treatment of BP.<sup>52</sup> Psychoeducational approaches have been shown to reduce relapse rate by educating the patient about the illness and medication, gaining insight into early signs of relapse, and promoting regular sleep-wake cycles. Cognitive-behavioral therapy that focuses on treatment adherence and addressing barriers to treatment has been associated with fewer bipolar episodes, reduced hospitalizations, and reduced episode duration.<sup>80</sup> Family-focused treatment has also proven to be effective.<sup>81</sup> It is usually easier to engage patients during their depressive cycles than manic, because the mania itself is associated with lack of insight and motivation.

## WOMEN AND MENTAL ILLNESS

Globally, women are more than twice as likely as men to suffer from depression (including unipolar depression, dysthymia, and bipolar disorder) and anxiety disorders (including panic disorder, posttraumatic

stress disorder, generalized anxiety disorder, social anxiety, and phobias) (Table 48-5). These gender differences begin in adolescence and continue throughout midlife, occurring throughout childbearing years. There is very likely both a biological basis for this gender difference and an inherent vulnerability associated with the conditions of women's lives, including marital status, work and roles in society, and exposure to sexual abuse, assault, and physical violence.<sup>43</sup> Biologically, women and men have different physiologic responses to stress, and the hypothalamic-pituitary-adrenal axis (HPA) and sympathoadrenomedullary systems are known to play important roles in both depression and anxiety disorders. In addition, serotonin 1A (or 5-hydroxytryptamine, 5-HT<sub>1A</sub>) receptors have been implicated in both depression and anxiety, and there are known gender differences in 5-HT<sub>1A</sub> receptor and 5-HT binding potentials.<sup>43</sup> Reproductive hormones also play an important role, because they impact HPA responsiveness, glucocorticoid feedback sensitivity, and brain GABA activity, and possibly destabilize homeostatic systems in vulnerable women, exacerbating anxiety and depression.<sup>43</sup> Thus, as hormonal levels change throughout the menstrual cycle (e.g., after parturition and during menopause), the balance and homeostasis of serotonin-specific neurotransmitter function are disrupted, and hence affect mood.

**TABLE 48-5 GLOBAL HEALTH CONSIDERATIONS: PREVALENCE OF DEPRESSION AND ANXIETY IN WOMEN**

COUNTRY/REGION	PREVALENCE OF DEPRESSION AND ANXIETY	POSSIBLE CULTURAL FACTORS THAT CONTRIBUTE TO DEPRESSION AND ANXIETY
Sub-Saharan Africa	18.2% Uganda 30.8% Zimbabwe	Female genital mutilation; abuse of women; PMDD (premenstrual dysphoric disorder) Multiple roles women fulfill in society: wives, mothers, caretakers, employees Continuing impact of HIV/AIDS
East Asia/China	24.2% older Chinese female	Female infanticide High suicide rate in Chinese Stressors of multiple roles (wives, mothers, caretakers, employees) Major social and economic changes
North America	8-11% perinatal depression 6-13% postpartum depression 36% all anxiety disorders (U.S.) 20% major depression	High incidence of rape Stressors of multiple roles (wives, mothers, caretakers, employees) Strong inverse relationship between social position and mental health outcomes Large socioeconomic inequalities linked to health inequalities
Western and Central Europe	18.2% Europe 44% Russia 40% Poland 34% Czech	High incidence of rape Stressors of multiple roles (wives, mothers, caretakers, employees) Strong inverse relationship between social position and mental health outcomes Large socioeconomic inequalities linked to health inequalities
South and South-East Asia	16.2% antenatal depression India 26.3% depression in Asia	Dowry death; domestic violence; other violence against women Burnings: in 1990, 87,000 women in India died in fires Stressors of multiple roles (wives, mothers, caretakers, employees) Major social and economic changes
Central and South America	Unclear; probably similar	Domestic violence, other violence against women Stressors of multiple roles (wives, mothers, caretakers, employees) Major social and economic changes
Middle East and North Africa	13-18% in Middle East and North Africa	Traditional arranged marriage; preference for males Stressors of multiple roles (wives, mothers, caretakers, employees)
Oceania	36% primary care have symptoms of psychological disorders; 20.5% of those have depression and anxiety symptoms	Australia: strong inverse relationship exists between social position and mental health outcomes Social disadvantage and discord, exposure to adverse life events

## CULTURAL CONSIDERATIONS

There are known differences in how cultures and regions around the world view mental health, and as such, how they express concerns about the body, self, and emotions. There are also aberrant behavioral patterns, indigenous to specific cultures that do not easily fit into *DSM-IV-TR* or *ICD-10* diagnostic categories. These aberrant behaviors, considered to be an “illness” by the indigenous population, are referred to as culture-bound syndromes in *DSM-IV-TR*. To be labeled as having a culture-bound syndrome in *DSM-IV-TR*, the disorder must be a discrete, well-defined syndrome; recognized as a specific illness in the given culture; expected, recognized, and sanctioned as a response to certain precipitants in the culture; and have a higher incidence or prevalence in societies where the disorder is culturally recognized, compared to other societies.

In addition to culture-bound syndromes, it is important for the clinician to consider the cultural identity of the individual and how that identity will influence cultural explanations of mental illness and their personal psychosocial environment. Cultural elements will also come into play in the relationship between the patient and the clinician, and in the patient’s participation in diagnosis and care (e.g., adherence to psychotropic medication regimen). The clinician must consider all of these factors when formulating a treatment plan to be a culturally competent mental health provider.

## GERIATRIC CONSIDERATIONS

Schizophrenia and delusional disorder may continue into old age or may appear later in life. Late-onset schizophrenia, which emerges after age 45 years, occurs more often in women than in men. Psychiatric admissions of older individuals are characterized by significantly more major depression and less dysthymia than that seen in younger adults. The incidence of BD in the geriatric age group should approach that of lifetime risk. It is extremely rare for BD to emerge after age 60 years, and all BD patients who survive to old age continue to be vulnerable to that illness.

Mood disorders in the elderly are likely to be associated with concomitant illnesses or their treatments.

Management of late-appearing psychoses is complicated by a number of factors. Older patients are more sensitive to medication than younger patients, and their response varies more than that of younger patients; they may suffer cognitive impairment; they may have visual or auditory impairment; they may be taking drugs for other chronic disorders; and they may forget to take their medications or take incorrect doses. In addition, older patients may suffer side effects such as tardive dyskinesia, a disorder related to antipsychotic drug dosage and duration and characterized by involuntary chewing motions and darting of the tongue. It is a generally accepted practice that antidepressants should be prescribed at lower dosages and titrated upward more

slowly in the elderly (often referred to as “start low and go slow”). Some investigators have argued that this strategy delays response, and they suggest that as an alternative different TCAs should be used (such as nortriptyline). There has been little research on the effectiveness of SSRIs in the elderly; electroconvulsive therapy (ECT) has been shown to be effective and safe.<sup>49</sup>

### KEY POINTS

- Mood disorders are due to disordered affect. Included in this category of psychoses are BD (periods of mania and depression) and MDD. The average age at onset is 30 years for BD and 40 years for MDD. Depression affects women twice as often as men.
- A biochemical basis for BD is supported by observations that levels of brain monoamines (norepinephrine, serotonin) are below normal or the ratio of norepinephrine to serotonin is altered. Depression is thought to occur when serotonin and norepinephrine activity in the brain is low. Mania may be due to a relative excess of norepinephrine in the context of low serotonin or acetylcholine activity. Plasma membrane transport of small molecules such as lithium also is different. BD has a familial pattern of expression, suggesting a genetic cause.
- Psychosocial factors that may affect the development and expression of mood disorders include loss (real, anticipated, or perceived) and low self-esteem. Sleep disorders accompany both extremes of mood. Depression is associated with altered rapid eye movement (REM) sleep and decreased slow-wave sleep. Mania is associated with short periods of sleep and reduced fatigue.
- Depression is manifested by low energy, inability to experience joy, difficulty initiating tasks, reduced decision-making ability, difficulty sleeping, poor appetite, weight loss, and decreased libido. Thoughts may focus on guilt, futility, emptiness, hopelessness, helplessness, and suicide.
- The management of MDD is aimed at increasing norepinephrine and serotonin activity in the brain. MAOIs reduce the rate of neurotransmitter destruction; TCAs inhibit reuptake; newer agents (fluoxetine) selectively prevent serotonin reuptake.
- Mania is manifested by high energy; inflated self-esteem; hyperactivity; inability to focus or concentrate; low sensitivity to fatigue, injury, or pain; rapid or incoherent speech; hallucinations; delusions; increased appetite and libido; decreased sleep; poor judgment; and poor impulse control. Mania is managed with lithium, a compound that inhibits the action of norepinephrine and serotonin in the brain.
- In general, BD is managed with mood stabilizers, including lithium, anticonvulsants, and atypical antipsychotics. Anticonvulsants as mood stabilizers are aimed at increasing norepinephrine and serotonin activity in the brain. MAOIs reduce the rate of neurotransmitter destruction; TCAs inhibit reuptake; newer agents (fluoxetine) selectively prevent serotonin reuptake. Depression, a common symptom in BD, is managed by using antidepressant medications only in combination with antimanic agents.

## SUMMARY

The clinical symptoms, causes, and neurobiological mechanisms of schizophrenia, MDD, and BD have been presented. Significant risk of psychosis is a common characteristic shared among these seemingly unrelated disorders. Brief overviews of the neurobiological basis of medications used to manage the symptoms of these disorders reflect

the tremendous neurobiological advances that have been accomplished. Nevertheless, these three illnesses are potentially disabling conditions that all too often rob the affected person of academic goals, meaningful work, close relationships, self-actualization, and, in some circumstances, survival.

### KEY QUESTIONS

- What neurobiological alterations have been associated with panic disorder, generalized anxiety disorder, obsessive-compulsive disorder, and post-traumatic stress disorder?
- What neurobiological alterations have been associated with attention-deficit/hyperactivity disorder and autism spectrum disorder?

### CHAPTER OUTLINE

#### Anxiety Disorders, 990

*Panic Disorder (PD), 990*

*Generalized Anxiety Disorder (GAD), 992*

*Obsessive-Compulsive Disorder (OCD), 993*

*Posttraumatic Stress Disorder (PTSD), 994*

#### Neurodevelopmental Disorders, 996

*Attention-Deficit/Hyperactivity Disorder (ADHD), 996*

*Autism Spectrum Disorder (ASD), 997*

Neurobiological mechanisms of mental disorders that do not cause psychosis may prove to be more similar than different from those of mental disorders associated with psychosis. These conditions already show similarity in that they are categorized by altered neuronal structures and functioning, genetic risk factors, and neurotransmission dysregulation. A major difference between psychotic and nonpsychotic illnesses is that individual variations in nonpsychotic conditions can be extensive. Greater individual variations increase the difficulty of defining the hallmark symptomatology and neurobiological basis of the condition. In addition, much has been learned about the neurobiological impact of stress response systems in psychotic illnesses, whereas the impact of stress response systems in nonpsychotic illnesses is less well understood. In the past, simple contrasts, such as comparing schizophrenia with eating disorders, invited the false assumption that one disorder may be more or less serious than another. For the affected person, such comparisons are unhelpful. Mental disorders, by definition, cause profound suffering and impairment.

### ANXIETY DISORDERS

This section presents four anxiety disorders: panic disorder (PD), generalized anxiety disorder (GAD), posttraumatic stress disorder (PTSD), and obsessive-compulsive disorder (OCD).<sup>1</sup> Although anxiety disorders have many similar physical symptoms, they differ greatly in terms of symptom onset triggers, symptom duration, and symptom management. Because anxiety disorders are primarily characterized by physical symptoms, physical illnesses (e.g., hyperthyroidism) and medication reactions (e.g., antidepressants, steroids, anticholinergic medications) must be ruled out before a diagnosis of anxiety disorder can be made. Together with depression, anxiety disorders are the most common of all psychiatric illnesses, and aside from social phobia and OCD, occur two times more often in women than in men.

#### Panic Disorder (PD)

Panic disorder (PD) is characterized by acute episodes of anxiety symptoms that are unexpected, sudden, and recurrent and generate

intense feelings of fear. Sudden symptom onset can cause affected persons to seek emergency health care for what they believe is a cardiac arrest, respiratory arrest, or “nervous breakdown.” Panic attacks can be situation-bound, and hence occur in other anxiety disorders such as a specific phobias, social phobia, and PTSD.<sup>2</sup>

Depending on the subtype, panic disorder is diagnosed two to three times more often in women than in men.<sup>1</sup> Rates of 1% to 2% are most commonly reported. Initial onset usually occurs in late adolescence or young adulthood, with a mean age of onset of 26.6 years. Initial symptom onset in older age adults is less typical.

**Etiology and neurobiology.** The risk of anxiety disorder symptom onset has been associated with moderate genetic, psychological, and biological system alterations.<sup>3</sup> Family, twin, and adoptive family studies have consistently shown a strong genetic liability for these disorders. However, experts now speculate that the etiology question is no longer nature versus nurture. Current models seek to explain the *interactions* of nature and nurture that can create susceptibility to anxiety. Brain regions that underpin the experiences of fear, anxiety, and stress are thought of as circuits that can be shaped and altered by a wide range of forces. Neurobiological conditioning is one force shown to impact such circuits and thus is of particular importance to understanding the development of anxiety disorders.

Brain serotonin activity has been revealed to interact with both genes and environment, and these interactions contribute to what has come to be referred to as *synaptic plasticity*.<sup>3</sup> In this way, genes are linked with brain cell neurochemistry and psychological characteristics such as temperament. More specifically, evidence of genetic variability in negative emotions, such as anxiety, has been found in studies of serotonin transporter cells. In this research, gene variability is in gene allele length. For example, family studies have shown that siblings with serotonin transporter cells with the short-form gene allele had higher neuroticism scores than their siblings with the long-form gene allele. Research aimed at gene typing mental disorders clearly is in its infancy and findings such as these are inconclusive, but they demonstrate the possibility of genetics-based neurobiological models of anxiety.

Susceptible persons who breathe air with high levels of carbon dioxide will experience an acute onset of panic anxiety symptoms.<sup>4</sup> A small study of persons with panic anxiety disorder, using an infusion of doxapram (respiratory stimulant) to cause profound hyperventilation, examined the effectiveness of cognitive interventions to reduce respiratory anxiety symptoms.<sup>5</sup> Cognitive interventions were designed to minimize misinterpretation of drug-induced hyperventilation as a sign of danger and thereby reduce the odds of the respiratory stimulant triggering panic anxiety. Breath-by-breath analyses of the patients and healthy controls were performed. The researchers<sup>5</sup> hypothesized that if the respiration anxiety symptoms were the result of dysregulation within the brain respiratory control center, cognitive interventions would not be particularly effective. They found that less fearful thinking did reduce panic, but some respiratory anxiety symptoms persisted despite less fearful thinking. In other words, respiratory anxiety symptoms appeared to result both from anticipatory anxiety and from dysregulation within the brain respiratory center.

Surges of physiologic activation and physiologic instability are thought to be the hallmark neurobiological processes underlying panic anxiety disorder.<sup>6</sup> Multiple organ systems, including the cardiovascular and respiratory systems, are thought to be involved. Observations such as these help to explain why, for example, caffeine triggers panic anxiety symptoms in susceptible individuals. Physiologic instability may prove to be the key to identifying a genetics-based marker for susceptibility to panic. However, the biopsychological marker for the disorder is likely to be the overinterpretation of physical anxiety

symptoms (e.g., sudden increase in heart rate) as life threatening. This thinking, referred to as *learned panic*, is thought to result from inordinately high levels of life stress in early childhood.

Overwhelming life stress can increase the level of circulating glucocorticoids (stress hormones) and stimulate the release of glutamate (which inhibits neurogenesis).<sup>7</sup> Early-childhood life stress, specifically abuse and neglect, has been studied as a possible predictor of various adult-onset anxiety disorders. These models are based on altered serotonin, norepinephrine, and dopamine neurotransmission; glutamate release; and physiologic instability. Repeated and prolonged childhood exposure to overwhelming stress is thought to create adult susceptibility to anxiety disorders. The leading theory is that early life stress leads to an *overspecialized* or excessive stress response.

Early life stress is thought to produce adult susceptibility to anxiety by altering critical neuron structures and functioning during this critical stage of human growth and development. Brain regions most vulnerable to alteration as a result of early life stress include the hippocampus (glucocorticoid receptors), amygdala ( $\gamma$ -aminobutyric acid [GABA] and benzodiazepine receptors), corpus callosum (glial cells critical to myelination), cerebellar vermis (glucocorticoid receptors), and the prefrontal cortex (glucocorticoid receptors, dopamine projections, and inhibition of hypothalamic-pituitary-adrenal [HPA] axis activation).<sup>7,8</sup> When the developing brain of a young child is exposed to overwhelming life stress, the stress response system appears to adapt by overbuilding or building additional brain stress response pathways. Later, under less stressful adult circumstances, this overbuilt stress response system becomes maladaptive. Like a very large overpowered car on a small, winding road, the overbuilt stress response system could become the source of physiologic instability that has come to be associated with panic anxiety.<sup>9</sup>

**Clinical manifestations.** With panic disorder, no single experience consistently triggers symptom onset, although the first attack(s) frequently occur(s) during a life-threatening illness or accident, loss of a close interpersonal relationship, or separation from family. After that, they can occur during any routine activity, from reading to driving. When patients experience their first few panic attacks they frequently think they are either having a heart attack or losing their mind and it is common to seek emergency medical treatment.<sup>2</sup> *Physical* symptoms are most prominent and emphasized, and include respiratory distress, heart palpitations, tachycardia, pounding heart, chest pain, smothering or choking sensation, dizziness, lightheadedness, faintness, sweating, trembling, shaking, hot flushes, chills, numbness, tingling, nausea, abdominal distress, and urinary frequency.<sup>2</sup> *Psychological* and *cognitive* symptoms include expressed fears of dying, fear of cardiac arrest, fear of losing control, fear of nervous breakdown, derealization, depersonalization, and perceptual distortions. *Behavioral* symptoms include hyperkinesis, pressured speech, and exaggerated startle response. The attacks usually last between 5 and 20 minutes, although they can last as long as an hour. They can happen in a wavelike manner, so that they occur successively, or as described earlier, as part of another clinical disorder. Some people experience such severe anticipatory anxiety that it is hard to separate when the attack starts and ends, so that the panic attack is experienced as continuous.

Panic disorder is characterized by two important psychological symptoms: anticipatory anxiety and avoidance anxiety. *Anticipatory anxiety* refers to fearful expectation of panic anxiety onset. People with the disorder tend to develop a morbid dread of events or experiences that they come to believe *might* trigger panic anxiety. *Avoidance anxiety* refers to personal strategies used to increase feelings of control and thereby decrease the risk of panic anxiety. Persons with panic disorder strive to avoid situations and circumstances they associate with their symptoms. This helps to explain why panic disorder and agoraphobia

(the phobic avoidance of public spaces beyond personal control, e.g., airports and shopping malls) often coexist.

**Treatment.** Panic anxiety disorder can be effectively managed with cognitive-behavioral therapy aimed at reducing fearful thinking and desensitization of cognitive and physical stress responses. When panic symptoms are disabling, medication for symptom management is recommended.<sup>2</sup> Long-acting benzodiazepines, such as clonazepam, are the sedatives of choice when short-term calming and symptom relief are mandatory. Tolerance to benzodiazepines develops with continuous use regardless of dosage. Misuse of benzodiazepines represents a serious health hazard. Although these drugs are useful in blocking the panic attack, they do not always decrease the anticipatory anxiety and avoidance, especially when drug regimens are initially undertaken. Many atypical psychiatric medications that can target serotonin, dopamine, or norepinephrine receptors have been clinically tested and shown to be effective treatment for anxiety symptoms. Examples of such medications found to be helpful include paroxetine, sertraline, citalopram, and fluoxetine. Unless contraindicated,  $\beta$ -blocker medications that dampen physical anxiety symptoms may also be helpful.

### Generalized Anxiety Disorder (GAD)

GAD is characterized by chronic and persistent worry, as well as physical anxiety symptoms. The anxiety is excessive, pervasive, difficult to control, and associated with marked distress or impairment.<sup>1</sup> Typically, the patient experiences multiple anxiety symptoms including restlessness, fatigue, impaired concentration, irritability, muscle tension, muscle pain, and disturbed sleep.<sup>10</sup> Lacking clear symptom onset patterns, GAD is easily overlooked or misdiagnosed. GAD is a chronic condition, and earlier onset is associated with more overall impairment. There is high comorbidity with substance use and other anxiety disorders, depression, and personality disorders. Higher rates of GAD occur in women than men. The prevalence of GAD does not decline with age, and appears to account for most of the anxiety disorders in the elderly.<sup>11</sup>

**Etiology and neurobiology.** GAD<sup>10</sup> differs from other anxiety disorders in that the cognitive, psychological, and behavioral symptoms are relatively constant. Psychoanalysts developed most of the original etiologic theories concerning persistent worry. What now is referred to as persistent worry was then described as anxious expectation. Even at that early stage of discovery, it was apparent that generalized anxiety rarely occurred without comorbid conditions such as depression. This *psychodynamic* view of generalized anxiety prevailed until the late 1980s and early 1990s. More recently, *cognitive theorists* view GAD as having its origins in early attachment to the primary caretaker. Conceptually, worry is seen as an avoidance strategy for negative affect; as a distraction from realistic and proximal threats that need immediate solutions; and as a coping method to “prevent” the feared outcome, such as occurs with magical thinking. Unlike panic disorder, where the worry is more typically about physical catastrophes, in GAD, worries are more about interpersonal confrontation, competence, and acceptance. Technologically advanced research methods have now made it possible to precisely define GAD symptoms in terms of their actual qualities, intensity, and duration, but physical GAD symptoms continue to be viewed as *somatic* expressions of psychological problems.<sup>10</sup>

Unlike other anxiety disorders, GAD onset typically is gradual with symptom duration measured in years. As has been observed with other anxiety disorders, vulnerability to GAD likely is inherited. Twin and family study findings indicate a 30% increase in risk of GAD among the relatives of persons with the disorder.<sup>2</sup> Efforts to describe the neurobiological basis of GAD will no doubt be greatly advanced by theoretical models of inherited vulnerability as well as improved understanding of GAD symptoms. The most important unanswered question likely

will have to do with the fact that the alterations in brain structure and functioning shown to be associated with GAD also are consistent with alterations observed with other disorders.

Preliminary positron emission tomography (PET) studies measuring brain glucose metabolism rates in GAD have shown higher than normal rates in patients at rest.<sup>12</sup> With GAD, apparently some brain regions undergo both increases and decreases in glucose metabolism rates. This mixed response is most apparent in the frontal and cingulate areas of the cortex, the brain region associated with worry and hypervigilance. Findings such as these lend support to the basic GAD explanatory hypothesis of anxiety symptoms as manifestations of hyperactive brain circuits. Just the opposite condition (hypoactive brain circuits) is thought to be the fundamental basis of depressive disorders.<sup>12</sup>

Neurotransmitter findings with GAD, as with other disorders that produce mood, thinking, and behavior symptoms, point to alterations in GABA receptors, benzodiazepine receptors, norepinephrine systems, serotonin systems, HPA axis activation, and plasma cortisol levels. Thus far, no specific alterations that can consistently explain GAD symptoms have been identified.<sup>12</sup> Nevertheless, one interesting observation shows considerable promise. At rest, no obvious alterations in neurotransmission are noted in GAD patients. Only when subjected to laboratory activities designed to induce stress responses is significant neurotransmitter overactivity observed. Evidence of norepinephrine receptor down-regulation lends additional support to this stress response model. Attempting to modulate overactive responses, receptor down-regulation is thought to occur automatically when subjected to prolonged, recurrent, excessive, or hyperactive neurotransmitter activity.

Whereas norepinephrine activity is thought to be associated with physical symptoms of GAD, anticipatory and avoidance symptoms are thought to be associated with activity along a key serotonin pathway linking the amygdala and frontal cortex. As might be expected, insufficient serotonin activity in specific brain regions is thought to be associated with GAD. Given the obvious symptom overlap between stress and anxiety, hyperactivity within the HPA axis and high plasma cortisol levels continue to be leading models in GAD research. Much of the difficulty in defining the neurobiological basis of GAD has to do with significant individual variations in GAD symptomatology. Uncontrollable worry (frontal cortex) is the only symptom likely to show meaningful consistency over time and from individual to individual. A second major research difficulty has to do with the frequency with which GAD symptoms co-occur with depression symptoms—so much so that some experts now view mixed depression-anxiety as a specific disorder.<sup>2</sup>

**Clinical manifestations.** The symptoms of GAD typically fall into two categories: apprehensive expectation and worry, and physical symptoms. The *worry* is often about minor issues, where the person anticipates the worst possible outcome, and finds it difficult to control. No areas of life are excluded, and worry is not limited to any single area of concern (e.g., children). *Physical* symptoms vary greatly, but people often feel “keyed up,” which results in muscle tension, light-headedness, sweating, palpitations, dizziness, and stomach distress. Concentration is typically severely impaired, and irritability is common. Diffuse anticipatory anxiety, avoidance anxiety, and dysphoria are common. Behavioral symptoms include severe sleep disturbance and fatigue. Although much of the behavior associated with GAD is likely to be the result of maladaptive methods of coping with physical and psychological GAD symptoms, impaired social and academic/employment functioning are common.

**Pharmacologic treatment.** Effective psychological and drug treatments for GAD can be relatively complex. When alcohol is comorbid,

it may limit the effectiveness of treatment and/or delay the onset of benefits. Delayed onset of benefits from treatment is likely to be seen when GAD symptoms are long-standing and highly disabling. Lastly, neurobiological research findings indicate that effective drug treatment is likely to require one or more medications that are reliable modulators of multiple neurotransmission systems across multiple brain regions. Medications shown to relieve and in some cases remit GAD symptoms include long-acting benzodiazepines (e.g., clonazepam), partial serotonin (i.e., 5-hydroxytryptamine, 5-HT<sub>1A</sub>) agonists (e.g., buspirone), tricyclic antidepressants (e.g., imipramine), selective serotonin reuptake inhibitors (e.g., sertraline), serotonin-norepinephrine reuptake inhibitors (e.g., venlafaxine), and long-acting  $\beta$ -blockers (e.g., propranolol).<sup>13</sup>

**Nonpharmacologic treatment.** Cognitive-behavioral therapy combined with relaxation training appears to be more effective than nondirective and supportive therapy for the treatment of GAD. In addition, cognitive-behavioral therapy is also superior to behavioral therapy alone.<sup>2</sup>

### Obsessive-Compulsive Disorder (OCD)

Although listed here as an anxiety disorder, OCD will very likely be classified under a new category of disorders called *Obsessive Compulsive and Related Disorders* in the upcoming *DSM-5*.<sup>14</sup> The inclusion under *Anxiety Disorders* has occurred because anxiety is frequently associated with the symptoms and because yielding to compulsions temporarily decreases anxiety. However, recent research suggests that OCD more aptly belongs with a separate grouping of compulsive spectrum disorders.<sup>2</sup> Typically the disorder is characterized by persistent, involuntary thoughts that then provoke anxiety and involuntary anxiety management rituals. Unlike the acute onset and short duration of panic anxiety symptoms or the chronic symptoms of GAD, the obsessions and compulsions that characterize OCD are localized but nevertheless impact all areas of functioning.

More than 50% of patients diagnosed with OCD have a chronic and progressive course, 25% to 33% have a fluctuating course, and less than 15% have a phasic course with periods of complete remission.

Occasionally, there can be sudden onset of symptoms, especially when there is a neurologic basis for the illness. Predictors for poor prognosis include an early age of onset, longer duration of the illness, presence of obsessions and compulsions, poorer baseline social functioning, and presence of magical thinking.<sup>2</sup>

People with OCD typically strive to avoid disclosing their symptoms to relatives, friends, and health professionals. As such, accurate incidence and prevalence statistics are nearly impossible to determine. The lifetime OCD prevalence rate for the general population is 2.2%, whereas the risk in first-degree relatives is 9.2%.<sup>2</sup> Some experts consider this general-population estimate to be an underestimate. OCD is a severe disorder that typically begins in adolescence or early adulthood; the median age of symptom onset is about 23 years. However, 31% of the initial episodes have reportedly occurred between 10 and 15 years of age.<sup>2</sup> Although there is no gender difference in the prevalence rates of OCD, there is some indication that OCD might have its onset or worsen during pregnancy.<sup>15</sup> In addition, of children diagnosed with OCD, 70% are males.

**Etiology and neurobiology.** Neurobiological research findings indicate that there is a strong genetic or inherited risk of OCD.<sup>2</sup> Twin and family studies show a greater degree of concordance for OCD among monozygotic twins compared to dizygotic twins. Once an adult family member has been diagnosed with the disorder, child relatives are more likely to be diagnosed. Depression, anorexia, and Tourette syndrome are common OCD comorbid disorders. Close links between OCD and the hereditary neurologic disorder Tourette syndrome have been reported, but it is not clear whether this link represents an increased risk of OCD or whether Tourette syndrome and OCD are related in some other way.

OCD studies using PET brain scans have shown significant increases in glucose metabolism rates in the frontal lobes, caudate nucleus, and cingulate gyrus regions of the brain (Figure 49-1). These brain regions are directly associated with response to strong emotions. However, several OCD models of altered brain functioning have been hypothesized. One model proposes that a causal pathway for OCD exists between the frontal cortex region and basal ganglia region of the

**FIGURE 49-1** Hyperactivity of the orbitofrontal cortex has been a consistent finding in more than a decade of brain imaging research on patients with obsessive-compulsive disorder (OCD). These positron emission tomographic images are from the initial report of this finding by a UCLA group. This excessive metabolic activity could generate spurious “error detection” signals that result in patients with obsessive-compulsive disorder experiencing repetitive adventitious feelings that “something is wrong.” (Originally adapted from Baxter LR Jr, et al: Local cerebral glucose metabolic rates in obsessive-compulsive disorder: a comparison with rates in unipolar depression and in normal controls, *Arch Gen Psychiatry* 4[3]:211-218, 1987. As published in Schwartz JM: Obsessive-compulsive disorder, *Sci Med* 4:16, 1997.)

brain. This model draws on the observation that similar illnesses with well-defined etiologic factors have been shown to involve both cognitive and motor brain regions. Predictably, serotonin activity dysregulation and dysfunction also represent possible OCD models.

As shown in Figure 49-1, PET scans of the brain of a person with OCD reveal significant increases in glucose metabolism activity in the prefrontal cortex brain region. Magnetic resonance imaging (MRI) findings have suggested widely distributed cellular abnormalities such as significantly lower amounts of total white matter (connection fibers) and greater cortex cell volume. More recent models of OCD focus on the possibility of deficient serotonin inhibitory action in the basal ganglia region of the brain, which then permits excessive release of dopamine, a stimulating neurotransmitter.

PET, functional MRI (fMRI), and single-photon emission computed tomography (SPECT) studies of persons with OCD have confirmed the correlation between OCD symptoms and abnormal brain circuit activity in the orbitofrontal cortex, caudate nucleus, anterior cingulate cortex, and thalamus.<sup>15-19</sup> An fMRI study of medicated OCD patients and comparison subjects explored the possibility of meaningful links between anterior cingulate cortex activity and the severity of OCD symptoms by observing this activity under laboratory stress designed to trigger symptom onset. Hyperactivity was observed in one brain region (anterior cingulate cortex) and was significantly related to error making and expressed doubt, suggesting a neurobiological model for the disabling self-corrective urges associated with OCD.<sup>19</sup>

There are few prevailing psychological theories about the origin of OCD. Research on the cognitive thought processes suggests that cognitions do contribute to the maintenance of the disorder, even if they are not the genesis.<sup>20</sup> The following are some examples of faulty cognitions observed in patients with OCD: responsibility and overestimation of threat; perfectionism and intolerance of uncertainty; and importance and control of thoughts.<sup>21</sup> There is some evidence that people with OCD have deficits in selective attention,<sup>22</sup> memory bias towards disturbing themes,<sup>23</sup> and decreased confidence in memory.<sup>24</sup>

**Clinical manifestations.** The hallmarks of OCD are obsessions and compulsions. Symptom clusters are as follows: concern about dirt and contamination, counting, and a third group that is purely obsessional (with no compulsions). In the obsessional-only group, “slowness” is the main symptom, where patients often conduct daily activities at an extremely slow pace. Overall 90% of the patients have features of both obsessions and compulsions. However, 28% are most bothered by obsessions, 20% by compulsions and 50% by both.<sup>2</sup> *Obsessions* are strong, persistent, intrusive, uncontrollable thoughts. Obsessive thoughts manifest as ideas, images, and urges that dominate normal thinking and functioning. Affected persons recognize that their obsessions are products of their own mind and may judge them as senseless. Nevertheless, they are unable to stop, govern, or resist their obsessions. *Compulsions* are repetitive, ritualistic behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person performs with urgency and rigidity. They are typically content-related to the obsession. A recent meta-analysis with more than 2000 patients found four consistent “syndromes”: symmetry/ordering; contamination/cleaning; hoarding; and obsessions/checking.<sup>16</sup> Other types of subtypes include sexual, religious, aggressive, or somatic obsessions. “Washers” comprise from 25% to 50% of the OCD samples and are concerned with dirt, contaminants, and germs. These people frequently spend hours each day washing hands or showering. “Checkers” compulsively check to see if they have done something, such as run over someone with a car or left the door unlocked. “Hoarding,” the inability to dispossess of meaningless, worthless objects, is one example of the more complex compulsions.<sup>17</sup> Some investigators suggest that hoarding behaviors occur in

about 25% to 30% of individuals with OCD.<sup>18</sup> Mental compulsions should not be overlooked, because they are quite common and are often undetected since most clinicians only ask about behavioral rituals. Approximately 80% of OCD patients have both behavioral and mental compulsions; these are the third most common type of compulsions. Uncertainty is also hallmark of the compulsions: uncertainty results from a discrepancy between sensory information and internal beliefs.

**Treatment.** Either exposure therapy and response prevention (ETRP)<sup>25</sup> or CBT, when combined with effective medication treatment, can effectively diminish OCD obsessions and compulsions.<sup>2</sup> Nevertheless, the disorder itself makes entering treatment extremely difficult if not impossible. To be successful, CBT must target the person’s obsessions and compulsions. This would require full disclosure, and as stated earlier, disclosure is very difficult. Higher doses of anti-anxiety and antidepressant medications (fluvoxamine, paroxetine, sertraline, venlafaxine, fluoxetine) have generally proven to be effective in reducing OCD symptoms.<sup>2</sup> Atypical antipsychotics, such as risperidone, in combination with antidepressants and  $\beta$ -blockers may be considered when OCD symptoms are disabling. Effective OCD symptom relief has been reported with the tricyclic antidepressant clomipramine, and some experts recommend the seizure medication gabapentin.<sup>26</sup>

### Posttraumatic Stress Disorder (PTSD)

First introduced in *DSM-III*, PTSD validated that the constellation of symptoms experienced by war veterans did, in fact, cause real impairment. Although anxiety is the most prominent symptom of PTSD, depression and dissociation are common as well. PTSD is currently classified under *Anxiety Disorders* in *DSM-IV-TR*; however, many investigators believe that it should be included in a new section in *DSM-5*, titled *Trauma and Stressor-Related Disorders*.<sup>14</sup> Acute stress disorder is very similar to PTSD, because both are precipitated by a traumatic event. The main difference is in the time frame since the event: acute stress disorder occurs up to 1 month after the event; PTSD occurs beyond 1 month.

PTSD is typically a chronic condition. One longitudinal study with young adults reported that more than half of the sample showed no signs of remission after a 3- to 4-year period.<sup>27</sup> Other studies have indicated that as long as 5 years after trauma, 82% of the sample was not in remission.<sup>28</sup> Women appear to take four times longer to recover from PTSD than men, and are two times more likely to meet the criteria for PTSD than men.<sup>29</sup> Although this may be attributed to the higher rates of trauma and sexual violence that women have experienced as children, it is probably also because women respond to trauma differently than men. For example, women may be more likely to blame themselves for the event than men. There appears to be a strong relationship between PTSD and suicidal thoughts and behaviors<sup>30</sup> and PTSD is associated with poorer treatment outcome posttreatment.<sup>31</sup>

**Etiology and neurobiology.** Acute stress disorder is highly predictive of PTSD. Additional psychological risk factors include the following: past history of trauma (and PTSD), especially childhood trauma; depression; anxiety disorders; comorbid personality disorders; familial history of anxiety disorders, PTSD, and disrupted parental attachments; and severity of exposure to trauma.<sup>2</sup> High intelligence appears to be protective of PTSD. *DSM-5* is considering a special section for preschool children because their manifestation of the disorder is very different than that observed in adults.

One theory that has found support both in animal models and with patients is that during or after trauma, the stress response becomes dysregulated and chronic autonomic hyperactivity occurs. The result is hyperarousal and intrusive recollections, or the so-called “positive” symptoms of PTSD.<sup>32-35</sup> Evidence suggests that there is limbic

hyperactivity in the amygdala and cingulate, cortical hypo-responsivity in both prefrontal and Broca areas, HPA axis dysregulation, noradrenergic activation, and heightened physiologic response to traumatic stimuli. Endogenous opioid systems also appear to be overreactive in PTSD; that is, individuals who have sustained prolonged or repeated trauma have endogenous opiates readily released with any reminder of the trauma, which leads to analgesia and psychic numbing.<sup>36,37</sup> Less is known about the role of the serotonergic system in PTSD, but the theory is that irritability and outbursts are related to serotonergic deficit. Some investigators have suggested that there are separate subgroups of PTSD subjects, where some show serotonin deficits and others exhibit noradrenergic sensitization.<sup>38</sup>

Multiple studies on brain neuroanatomy and neurocircuitry suggest that PTSD patients show decreased right and left hippocampus volumes compared to traumatized and nontraumatized control subjects.<sup>39</sup> It remains unclear whether hippocampi size plays a role in contributing to preexisting vulnerability to PTSD, acts as a developmental determinant, or is the outcome of traumatic stress. Limited research is available to compare brain neuroanatomy before and after PTSD treatment; some results do show that treatment using selective serotonin reuptake inhibitors (SSRIs) promotes hippocampal neurogenesis and increased volume.<sup>40,41</sup>

Cognitive and behavioral models of PTSD suggest that classical conditioning may play a role. Behaviorally, patients with PTSD could have higher sympathetic system arousal at the time of conditioning, which then allows them to be “more” conditionable than trauma-exposed individuals without PTSD.<sup>42</sup> Some studies suggest a higher incidence of PTSD after severe traumatic brain injury with loss of consciousness and few traumatic memories; this suggests that trauma itself could mediate PTSD at an implicit level.<sup>43</sup> There are also impairments in explicit memory associated with PTSD that could be attributable to hippocampal toxicity.<sup>44</sup>

Research on gender differences in the expression of PTSD suggests that women’s response to stress is probably different than men’s stress response, which sets the stage for women’s higher incidence of PTSD. For example, women have lower cortisol levels, reduced HPA responses, and decreased serotonin transporter gene promoter polymorphism than men.<sup>45</sup> They also appear to have higher levels of non-sulfated dehydroepiandrosterone (DHEA) than men, who have higher levels of sulfated DHEA. The increased exposure of women to adverse events is also associated with depression and anxiety, and probably mediated by corticotropin-releasing factor (CRF).<sup>46</sup>

**Clinical manifestations.** There are five main characteristics of PTSD.<sup>14</sup> First, the person must have been *exposed to a traumatic event* (actual or threatened) by personally experiencing the event(s), witnessing the event(s), learning about the event(s), or experiencing repeated or extreme exposure to the event’s details. Second, the person *experiences intrusive symptoms* associated with the traumatic event(s) including spontaneous or cued recurrent, involuntary, and intrusive distressing memories of the traumatic event(s); recurrent distressing dreams related to the event(s); dissociative reactions such as flashbacks that feel as if the traumatic event(s) was (were) recurring; intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s); and marked physiologic reactions to reminders of the traumatic event(s).

Third, the person persistently *avoids all stimuli* associated with the traumatic event(s) including internal reminders (thoughts, feelings, or physical sensations) and external reminders (people, places, conversations, activities, objects, situations) that arouse recollections of the traumatic event(s). Fourth, there are *negative cognitive and mood changes* associated with the traumatic event(s), including the inability to recall the event(s) (typically dissociative amnesia; not due to head

injury, alcohol, or drugs); persistent and exaggerated negative expectations about one’s self, others, or the world; persistent distorted blame of self or others about the cause or consequences of the traumatic event(s); pervasive negative emotional state (e.g., fear, horror, anger, guilt, or shame); markedly diminished interest or participation in significant activities; feelings of detachment or estrangement from others; and persistent inability to experience positive emotions (e.g., unable to have loving feelings, psychic numbing). Finally, there is a *change in arousal and reactivity* associated with the traumatic event(s), including irritability, aggression, recklessness, self-destructiveness, hypervigilance, exaggerated startle response, problems with concentration, and sleep disturbance. None of these symptoms can be the direct physiologic effects of a substance (e.g., medication or alcohol) or a general medical condition (e.g., traumatic brain injury, coma).

Although both men and women report hyperarousal, reexperiencing, avoidance, and numbing, it is more common for women to feel anxious, to have more trouble feeling emotions, and to avoid things that remind them of the trauma. Women are also more likely than men to experience depression and general anxiety, whereas men with PTSD are more likely than women to have problems with alcohol or drugs. In contrast, men with PTSD are more likely to express anger and have anger management issues than women.<sup>29</sup>

**Pharmacologic treatment.** SSRIs are the first-line treatment for PTSD and are associated with marked improvement.<sup>47</sup> To date, most studies on SSRIs have been with fluoxetine,<sup>48,49</sup> sertraline,<sup>50</sup> and fluvoxamine.<sup>51,52</sup> Newer studies have reported success with venlafaxine extended release<sup>53</sup> and mirtazapine.<sup>54</sup> Tricyclic antidepressants (TCAs) have not been reported to be very effective, but adrenergic blockers show some improvement with both PTSD and acute stress disorder symptoms.<sup>55</sup>

**Nonpharmacologic treatments.** CBT approaches have been found to be helpful in the treatment of PTSD. Most treatment protocols include gradual or graded exposure to the trauma with imagination, real-life, and/or virtual reality therapy. Treatment also typically includes cognitive restructuring or reformulations<sup>56</sup> and relaxation techniques. One relatively new treatment is called eye movement desensitization and reprocessing (EMDR); results may be comparable to those achieved from use of exposure and stress inoculation.

#### KEY POINTS

- Anxiety disorders are characterized by irrational and debilitating fears. The four major categories of anxiety disorders are panic disorder, GAD, OCD, and PTSD. These disorders show some evidence of heritability, and biochemical correlates are suspected. Defects in serotonin pathways have been proposed as etiologic factors. Panic disorder, GAD, and PTSD are more likely to occur in females than males.
- Panic disorder is characterized by acute episodes of severe anxiety accompanied by dyspnea, chest pain, and a sense of impending doom. Palpitations, hyperventilation, dizziness, paresthesias, and diaphoresis may occur during an attack, which may last 5 to 30 minutes. Anticipatory anxiety and phobic avoidance may develop in individuals with panic disorder.
- GAD is characterized by a continuous but moderate degree of anxiety without discrete periods of acute attacks. Agoraphobia rarely develops, but chronic headaches, muscle tension, abdominal discomfort, and sleep disturbances are common.
- OCD is characterized by obsessive thoughts and compulsive behavior. Obsessive thoughts manifest as ideas, images, and urges that dominate normal thinking and functioning. Compulsions are repetitive, ritualistic behaviors (e.g., hand washing, ordering, checking) or mental acts (e.g., praying, counting, repeating words silently) that the person performs with

urgency and rigidity. They are typically content-related to the obsession. There are four consistent syndromes: symmetry/ordering; contamination/cleaning; hoarding; and obsessions/checking, but they can also include sexual, religious, aggressive, or somatic content. Uncertainty is also a hallmark of the compulsions: uncertainty results from a discrepancy between sensory information and internal beliefs. OCD will not be categorized as an anxiety disorder in *DSM-5*.

- PTSD has previously been characterized as an anxiety disorder but in *DSM-5* it will likely be included in a section titled *Trauma and Stressor-Related Disorders*. It is usually precipitated by a traumatic event, after which the person typically experiences intrusive symptoms, avoids all stimuli associated with the event(s), has negative cognitive and mood changes, and experiences a change in arousal and reactivity. PTSD is frequently chronic, and women take longer to recover than men.
- Benzodiazepines and antidepressants may be used to manage all anxiety disorders; cognitive-behavioral therapy has proven to be quite successful.

## NEURODEVELOPMENTAL DISORDERS

Under the proposed *DSM-5*, *Neurodevelopmental Disorders* will contain diagnoses that were previously listed in *DSM-IV* under the chapters of *Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence*.<sup>14</sup> Neurodevelopmental disorders are disabilities experienced by children that are primarily associated with the functioning of the neurologic system and brain. Examples include intellectual disability (previously known as mental retardation), attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder, and learning disabilities.<sup>57</sup> Children with these disorders typically experience problems in language and speech, motor skills, behavior, memory, learning, or other neurologic functions. Although the symptoms and behaviors can change as a person ages, many children with neurodevelopmental disorders will have permanent disabilities. As many as 12% of children in the United States ages 3 to 17 years are affected by at least one neurodevelopmental disorder, such as ADHD, learning disorders, or intellectual disability.<sup>57</sup> Some investigators believe that the prevalence of certain neurodevelopmental disorders, specifically autism and ADHD, has increased during the past 40 years. For example, the percentage of children reported to have ever been diagnosed with autism rose from 0.1% in 1997 to 0.7% in 2008. Because of a lack of long-term data and changes in awareness and diagnostic criteria, it is difficult to determine whether this is true.<sup>57</sup> Most neurodevelopmental disorders result from a combination of genetic, biological, psychosocial, and environmental risk factors, as well as behavioral risk factors such as alcohol, tobacco, or illicit drug use. There are also known environmental contaminants that can damage a child's developing brain and nervous system, such as lead, methyl mercury, and polychlorinated biphenyls.

### Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD is the most common childhood psychiatric disorder. It typically begins in childhood and continues throughout adolescence and adulthood. ADHD is characterized by difficulty staying focused and paying attention, difficulty controlling behavior, and hyperactivity (overactivity). There are three subtypes: predominantly hyperactive-impulsive; predominantly inattentive; and combined hyperactive-impulsive and inattentive. Children with ADHD typically have poorer academic performance and higher rates of learning disabilities.<sup>57</sup> It is also common for these children to need special classroom placement, tutoring, or even to repeat a grade. When diagnosing ADHD, it is important to use several sources such as parent, child, and teacher ratings.

*DSM-IV-TR* estimates that ADHD occurs between 3% and 7% of school-age children, although the range varies widely across studies (e.g., 1.9% to 14.4%).<sup>58</sup> It accounts for as many as 3% to 50% of all mental health service referrals for children,<sup>59</sup> and occurs four times more often in males. In females, the inattentive type occurs more frequently than the hyperactive type. Interestingly, the gender ratio disappears in adults, but this could be due to methodological differences in studies.<sup>57</sup> Risk factors include family history of ADHD, psychosocial adversity, and comorbidity with oppositional defiant disorder (ODD) (50%) and conduct disorder (CD) (30%), mood disorder (15% to 20%), and anxiety disorders (20% to 25%) as well as tic disorders.<sup>59</sup> In fact, as many as two thirds of all individuals diagnosed with ADHD are diagnosed with other psychiatric disorders. When diagnosed with both ADHD and either ODD or CD, the child will typically have greater disability and longer persistence of symptoms. As the child grows into adolescence, ADHD is highly associated with substance use disorders. It can be difficult to differentiate ADHD symptoms from BD symptoms in children, because many of the symptoms overlap (e.g., distractibility, impulsivity, hyperactivity, mood swings, and irritability). Usually children with BD have elevated mood, decreased need for sleep, and grandiosity. As many as 75% of the children diagnosed with ADHD continue to have problems into adulthood, with the hyperactivity and impulsivity remitting and the inattention remaining.<sup>60,61</sup>

**Etiology and neurobiology.** There are a number of biological and environmental factors that have been implicated in ADHD, and a biopsychosocial model is best incorporated. Genetic models indicate that 25% to 50% of cases occur in families. First-degree relatives have a 15% to 25% chance of the disorder, and 50% if both parents have the disorder.<sup>61</sup> Research suggests that there are abnormalities in genes coding for proteins in central nervous system dopamine function,<sup>62</sup> and specific genes include the dopamine receptor gene, the dopamine transporter gene, and the dopamine- $\beta$ -hydroxylase gene.<sup>63</sup> The specific pathophysiology of ADHD remains unclear, but research has shown that the neural circuits of the prefrontal cortex and striatum as well as the brainstem catecholamine systems that innervate these circuits show abnormalities. Exposure to toxins during pregnancy does appear to contribute to the development of ADHD, including maternal smoking<sup>64</sup> and lead and alcohol exposure. In addition, low birth weight, antepartum hemorrhage, prolonged labor, and low Apgar scores are associated with ADHD.<sup>57</sup> The role of diet (e.g., preservatives, artificial dyes, food allergies) on hyperactivity remains controversial.<sup>57</sup> Many scientists believe that this disorder is caused by a combination of factors, such as genetic susceptibility with exposure to environmental contaminants, rather than by any one factor.

**Clinical manifestations.** To be diagnosed with ADHD, a child must have symptoms for 6 or more months (symptoms within the cluster) and to a degree that is greater than that found in other children of the same age.<sup>1</sup> For either type of ADHD, symptoms are present by age 12 and are apparent in two or more settings (e.g., at home, school, or work; with friends or relatives; or in other activities). The symptoms must also interfere with or reduce the quality of social, academic, or occupational functioning.

Children who have symptoms of *inattention* are described in the following ways: (a) fails to give close attention to details; (b) has difficulty sustaining attention in tasks or play activities; (c) often does not seem to listen when spoken to directly; (d) frequently does not follow through on instructions; (e) often has difficulty organizing tasks and activities; (f) characteristically avoids, seems to dislike, and is reluctant to engage in tasks that require sustained mental effort; (g) frequently loses objects necessary for tasks or activities; (h) is often easily

distracted by extraneous stimuli; (i) is often forgetful in daily activities, chores, and errands.<sup>1</sup>

Children who have symptoms of *hyperactivity and inattention* are described in the following ways: (a) often fidgets or taps hands or feet or squirms; (b) often restless during activities when others are seated; (c) often runs about or climbs on furniture and moves excessively in inappropriate situations; (d) is often excessively loud or noisy during play, leisure, or social activities; (e) often “on the go,” acting as if “driven by a motor”; (f) often talks excessively; (g) often blurts out an answer before a question has been completed; (h) has difficulty waiting his or her turn or waiting in line; (i) often interrupts or intrudes on others; (j) tends to act without thinking; (k) often impatient; (l) uncomfortable doing things slowly and systematically; (m) finds it difficult to resist temptations or opportunities.<sup>1</sup>

**Treatment.** Most ADHD treatments focus on reducing the symptoms in order to improve functioning. Medication treatments especially do not cure the disorder but treat the symptoms, only while the medication is taken. Treatment typically includes medication, psychotherapy, education or training, or a combination of these treatment modalities.<sup>57,59</sup> Medication treatments most commonly comprise psychostimulants, which paradoxically have a calming effect, and are known to reduce inattention, impulsivity, and hyperactivity, and occasionally CD and anxiety disorders.<sup>57</sup> Stimulant medications are available in multiple forms (e.g., pill, capsule, liquid, skin patch) and in short-acting, long-acting, or extended-release varieties. The most commonly used psychostimulant is methylphenidate, which is available in both short-acting and long-acting agents (e.g., Concerta, Metadate CD, and Ritalin LA). Side effects are minor and typically disappear over time; these include delayed sleep, decreased appetite, and sometimes anxiety and irritability. Some children also report mild stomachaches or headaches. For children who do not respond well to psychostimulants, atomoxetine (Strattera) can be used, as well as TCAs,  $\alpha$ -agonists, and some anxiolytic medications.<sup>57</sup>

**Nonpharmacologic treatment.** Psychosocial interventions are effective in teaching the child behavioral and social skills.<sup>57,59</sup> These can range from practical assistance (such as helping the child organize tasks or complete schoolwork) to assistance in crisis situations (such as helping the child cope with emotionally difficult events). Behavioral therapies can also teach children to monitor their own behavior, by controlling anger or by thinking before acting. Psychotherapy also can teach basic social skills, such as how to wait their turn, share toys, ask for help, or respond to teasing.

### Autism Spectrum Disorder (ASD)

Autism was first introduced in the *DSM-III* in the early 1980s, and reclarified in the *DSM-IV* in the mid-1990s. In past versions of *DSM*, autism, Asperger disorder, and child disintegrative disorder were each separate disorders. Because of a wide research-base that is both reliable and valid, *DSM-5* will group these and similar disorders together under the category of *Autism Spectrum Disorder (ASD)*.<sup>14</sup> ASD will be defined by a common set of behaviors: social/communication deficits and fixated interests and repetitive behaviors. For example, ASD patients may be interested in social interactions, but they lack the skills for reciprocal interaction. Normal attachment appears to be impaired and often there is a lack of social referencing, where others are seen and treated as objects. Individuals with autism frequently show difficulty with change and often perform ritualized, compulsive behaviors or thoughts that are reflected in repetitive questions and physical mannerisms. Clients with ASD also typically have unusual responses to sensory stimuli as well as poor

motor imitation, gait, and tone. In the past, language delays were a defining feature of the disorder. The *DSM-5* will consider language delays only as factors that influence the clinical symptoms; instead, they will be placed into the categories of social/communication or restricted, repetitive patterns of behavior. In addition, autistic symptoms must be present in early childhood (although they may not fully manifest until social demands exceed limited capacities), and symptoms must limit and impair everyday functioning. Autism has been associated with intellectual disability because between 66% and 75% of all individuals with autism have intellectual impairment. However, mental retardation and autistic disorder are considered distinct entities.

Based on past diagnostic criteria, investigators believe that the prevalence for autism is between 0.15 and 34.00 per 10,000<sup>65</sup> whereas that for Asperger syndrome is between 0.6 and 10.0 per 10,000 persons.<sup>57</sup> There appears to be a male predominance of 4:1, although females appear to be affected more severely and have greater cognitive impairment.<sup>57</sup> Prevalence rates for both disorders have increased since the mid-1990s. It is unclear whether this is due to an actual increase in incidence or because of an increase in both public awareness and more specific diagnostic criteria.

**Etiology and neurobiology.** To date, there is no known identifiable cause for autism. Popular media sources frequently suggest that measles-mumps-rubella vaccine or thimerosal exposure plays a role in the etiology; however, this has not been supported by research.<sup>66,67</sup> There are some medical illnesses that are associated with autism and these include tuberous sclerosis, fragile X syndrome, maternal rubella, congenital hypothyroidism, phenylketonuria, Down syndrome, neurofibromatosis, and Angelman syndrome.<sup>57</sup> There is also limited evidence for a genetic basis of autism, including higher concordance in monozygotic twins and low concordance in dizygotic twins, as well as greater than expected incidences of anxiety disorders, major depressive disorder (MDD), and motor tics in first-degree family members. In addition, parents of autistic children show higher rates of associated behaviors, such as rigidity, aloofness, anxiety, and restricted friendships.<sup>68</sup> It is fair to say that this is a very new area for research and future editions may shed more light on its neurobiology.

**Clinical manifestations.** First, in *DSM-5*, ASD will be defined by *persistent deficits in social communication and social interactions across contexts*.<sup>14</sup> This will include social-emotional reciprocity; deficits in nonverbal communicative behaviors used for social interaction; and deficits in developing and maintaining relationships, appropriate to developmental level (beyond those with caregivers). Second, ASD will be defined by *restricted, repetitive patterns of behavior, interests, or activities* including stereotyped or repetitive speech, motor movements, or use of objects; excessive adherence to routines, ritualized patterns of verbal or nonverbal behavior, or excessive resistance to change; highly restricted, fixated interests that are abnormal in intensity or focus; and hyperreactivity or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment. Both the social communication and the restricted, repetitive patterns of behavior will be assigned a severity level, ranging from “1” (requiring support), to “2” (requiring substantial support), to “3” (requiring very substantial support). Thus, in the past, “milder” autism was often identified as Asperger disorder; under the new rubric, it would be assigned as level 1 ASD.

**Treatment.** To date, there are no established pharmacologic treatments for ASD. Research in the developmentally disordered population suggests that SSRIs may be effective in treating associated symptoms of ASD such as compulsive and repetitive behavior, behavioral rigidity, and aggression<sup>69,70</sup>; or that  $\alpha$ -agonists may

be effective in targeting impulsivity, hyperactivity, and poor concentration. Because there is anecdotal clinical evidence to suggest that individuals with ASD respond to very low doses (i.e., trivial) of psychoactive medications, clinicians recommend “starting low and going slow.”<sup>57</sup>

There is a strong body of literature that supports the use of evidence-based behavioral interventions for children with ASD. These types of treatment are known to focus on social skills acquisition and environmental modifications, such as the use of schedules, visual cueing, and structured settings. One long-established method is the applied behavioral analysis approach, developed by Dr. Ivar Lovas, that starts with ASD children as young as 2 to 3 years of age and provides intensive, daily sessions. The goal of treatment is to focus on expansion of communication, emergence of new play skills, development of interactive relationships and more appropriate reaction to sensory input, and development of other pivotal skills such as imitation and requesting. Long-term results have proven successful in both raising IQ and adaptive behavior<sup>71-73</sup> with a sizable minority of children achieving normal educational and intellectual functioning by 7 years of age, especially with early intervention.

## SUMMARY

Hypotheses regarding the cause and pathogenesis, clinical manifestations, and implications for management of representative subsets have been presented. It is important to recognize that these disorders

## KEY POINTS

- There are a number of biological and environmental factors that have been implicated in both ASD and ADHD, and a biopsychosocial model is best incorporated. Early research on genetic models has suggested a limited basis of contribution to these disorders.
- ADHD subtypes include symptoms of inattention or hyperactivity and impulsivity. The disorder typically continues into adulthood, with symptoms of inattention most common. Psychostimulant medications can effectively reduce the symptoms and improve daily functioning in most children and adults, but there is no “cure” for the disorder. Psychosocial interventions offer both practical assistance (such as help organizing tasks or completing schoolwork) and assistance in crisis situations (such as dealing with emotionally difficult events); in addition, these interventions teach behavioral self-control.
- ASD captures the features of autism and Asperger syndrome. Children are given a severity rating from 1 (requiring support) to 3 (requiring substantial support) for symptoms that fall into the categories of (a) deficits in social communication and social interaction and (b) restricted, repetitive patterns of behavior, interests, or activities. There are no established pharmacologic treatments for ASD; however, behavior intervention, especially if provided early, assists children in developing behavioral, communication, and social skills.

represent a mixture of biological, psychological, social, and environmental factors. Researchers have yet to unravel all of the mysteries surrounding the neurobiological mechanisms of nonpsychotic illnesses.

Movement is one of the most characteristic and visible aspects of human life. Ease of movement adds to self-worth and well-being because the ability to move is closely connected to independence. A working knowledge of the system responsible for body movement is imperative to the health care provider. This chapter examines the basic characteristics of the firm support of bone and joint structures that make motion possible and the properties of skeletal muscles that are responsible for actually moving the body's framework.

## STRUCTURE AND FUNCTION OF BONE

The primary purposes of the skeletal system are to protect internal organs, provide bony attachments for muscles and ligaments, present rigid levers to allow functional movement of the body and its separate parts, and store mineral and marrow elements for forming new blood cells. Bone is highly vascular and is metabolically active from birth to death.

### Composition

Bone is comprised of three main components: an organic matrix, an inorganic mineral content, and water. Accounting for approximately 25% of bone weight is an organic matrix (called **osteoid**) that is composed mostly of collagen fibers (about 94% of matrix). These collagen fibers, extending along lines of tension, give bone its tensile strength and some flexibility. Also part of the organic matrix is a homogeneous ground substance composed of protein polysaccharides, particularly **proteoglycan**, which binds between collagen fibers. These proteins may serve to transfer mechanical information within the matrix to bone cells.<sup>1</sup>

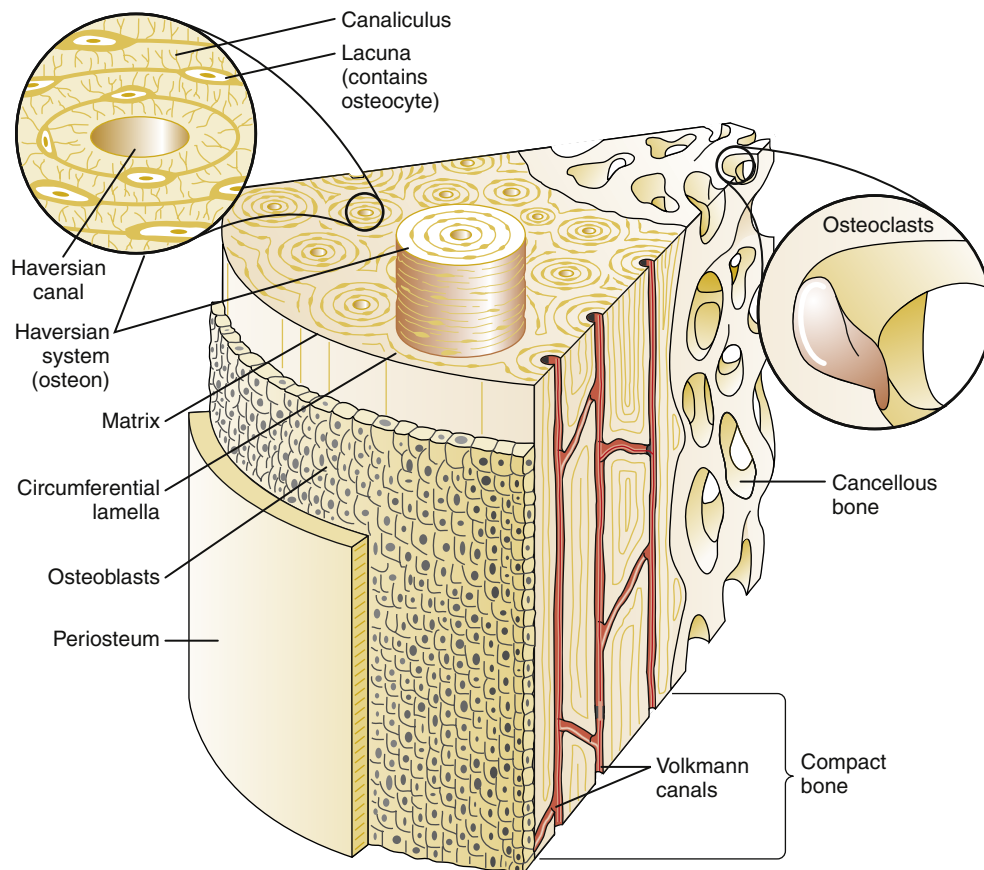

The cellular component of the organic matrix includes predominantly osteoblasts, osteocytes, and osteoclasts. **Osteoblasts**, formed

from osteoprogenitor cells that line bone surfaces, produce the organic matrix (osteoid), which is subsequently mineralized to form new bone. Osteoblasts communicate with each other in a network of cell extensions to exchange minerals, nutrients, and stimulatory signals. When an osteoblast becomes engulfed in its own calcified matrix, it becomes a mature **osteocyte** within the bone but is still connected with other cells via its extended cell processes. **Osteoclasts** migrate to the bone surfaces in response to certain stimuli and are responsible for bone resorption and mobilization of minerals.

The second and largest component of bone is the inorganic material (mineral salts such as calcium and phosphate), which accounts for approximately 70% of bone weight. This mineral content, bound and embedded within the matrix mostly in crystals of calcium hydroxyapatite, gives bone its hard, rigid structural strength while also serving as the body's main reservoir for calcium and phosphorus.<sup>1</sup>

Approximately 5% of bone weight is from water located within the organic matrix surrounding collagen fibers and ground substance and within the canals that carry nutrition to bone tissues.

Microscopically, the basic unit of bone is the **osteon** or the **haversian system** (Figure 50-1). The haversian canal lies at the center of each osteon and contains blood vessels and nerve fibers. A concentric series of lamellae of mineralized matrix surrounds the central canal. Bordering the lamellae are small cavities (lacunae) that contain a bone cell, the **osteocyte**. Many small channels, the canaliculi, connect adjacent lamellae with each other and eventually with the main haversian canal. This canal system allows nutrients from blood vessels in the haversian canal to reach osteocytes. Collagen fibers connect one lamella to another within the osteon and increase the mechanical strength of bone.<sup>2</sup>

**FIGURE 50-1** Microscopic anatomy of bone. The section has been enlarged to show the periosteum, osteoblasts, the haversian system, lacunae, and osteoclasts.

At the tissue level, bones are classified as two types: **cancellous** or **trabecular** bone and **compact** or **cortical** bone (Figure 50-2). **Cancellous bone** is formed in thin plates called trabeculae found within the center of long bones, vertebral bodies, and flat bones such as the pelvis. Trabeculae are laid down in response to stress and are shaped

**FIGURE 50-2** Structure and composition of a typical long bone. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

to accommodate loads placed on the bone. Cancellous bone is covered by compact bone. **Compact bone** is quite resistant to compression and is dense in structure. Compact bone is laid down in concentric layers. A tough fibrous membrane called the *periosteum* covers all bones. The periosteum is highly vascularized and provides nutrition for bone via Volkmann canals (see Figure 50-1). An inner layer of the periosteum contains **osteoblasts**, which are responsible for bone growth and repair. The periosteum covers the entire bone except for the ends, which are covered by hyaline cartilage.

In longer bones, a central cavity (**medullary cavity**) is present (see Figure 50-2). A thin membrane called the **endosteum** covers this cavity. The central cavity is filled with fatty marrow. Osteogenic cells are located in the endosteum.

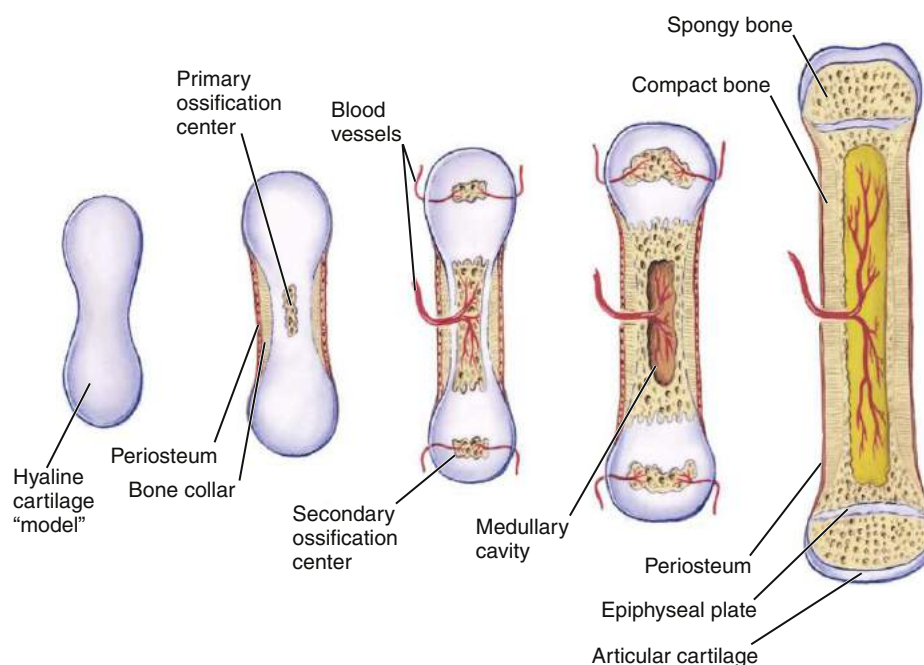

Blood vessels are distributed through the haversian canals. Living cells in bone communicate with each other and the haversian system via threadlike processes.

### Functional Properties

#### Growth and Ossification

The process of longitudinal bone growth involves endochondral ossification. In this type of growth, cartilage is replaced by bone; this process of growth is evident in embryonic development, fracture healing, and some bone tumor growth. In children, fracture through the shaft of a long bone stimulates bone growth, possibly because of increased nutrition to growth cartilage from the hyperemia associated with fracture healing. Particular attention to bone alignment or overlapping of fracture ends must be paid when managing a fracture in a child younger than 10 years of age because bone overgrowth or skeletal arrest can lead to limb length discrepancies.<sup>3</sup>

Circumferential bone growth occurs via intramembranous ossification. In this case, connective tissue is transformed into bone. Interstitial growth is not possible in bone. Bone can grow in length only by a process of growth within cartilage, followed by endochondral ossification (Figure 50-3). Two sites of cartilage growth are available in a long bone: articular cartilage and epiphyseal plate cartilage. In longer bones, the epiphysis provides the only growth plate for the entire bone.

**FIGURE 50-3** Events in endochondral ossification. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

### Continuous Growth

The **epiphyseal plate** (see Figure 50-3) allows for lengthening of the metaphysis and diaphysis of a long bone and is the site of continuous growth. Growth and thickening of cartilage cells of the plate move the epiphysis away from the metaphysis. Calcification and replacement of cartilage occur on the metaphyseal surface (endochondral ossification). Injuries to this growth plate in children may lead to limb length discrepancies. In addition, inflammatory arthritis in children (particularly of the knee) can lead to increased blood flow to the epiphyseal plate, which also may accelerate growth or lead to premature plate closure. This also can lead to leg length abnormalities.

The function of the epiphyseal plate in the growth process may be illustrated by examining the specific zones of the plate (Figure 50-4) and determining how they contribute to the growth process. The **zone of resting cartilage** maintains adherence of the plate to the epiphysis. Immature chondrocytes and vessels penetrate this first zone from the epiphysis and nourish the plate. The **zone of young proliferating cartilage** demonstrates the most active cartilage cell growth. The **zone of maturing cartilage** contains the enlarged and mature cartilage cells as they migrate toward the metaphysis. The final zone is the **zone of calcifying cartilage**, which is a very thin line of chondrocytes and the weakest segment of the epiphyseal plate. These chondrocytes are no longer living because of calcification of the matrix.

Bone is also deposited quite actively on the metaphyseal side of the plate. With the addition of new bone, the metaphysis becomes longer.

Osteoblasts in the inner layer of the periosteum are responsible for growth in the width of bones. This process is called **intermembranous ossification**. Resorption of bone, through a process of osteoclastic resorption, causes the medullary cavity to enlarge, causing additional widening of bone.

Hormones influence bone growth. Inadequate secretion of thyroxine by the thyroid gland or insufficient growth hormone secretion from the pituitary gland results in dwarfism. Oversecretion of growth hormone results in gigantism. Sex hormones, such as estradiol, are produced in higher amounts during and after puberty and can cause more rapid maturation and fusion of the epiphyseal plates. These hormones may limit the growth spurts of puberty, and early sexual maturity, especially in girls, can lead to shorter stature.

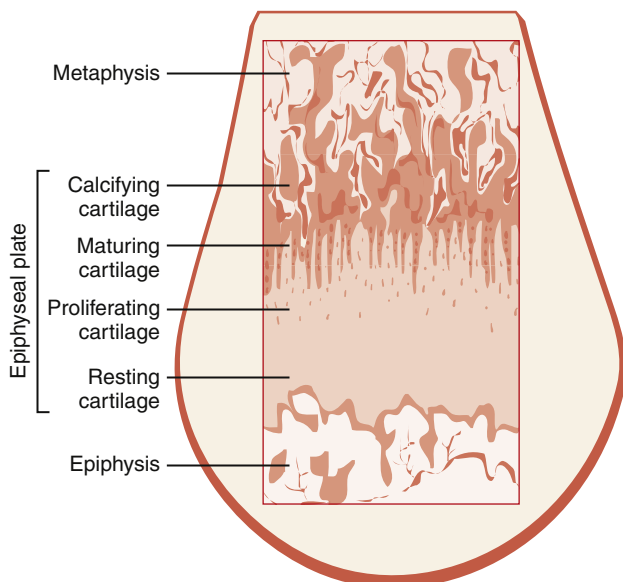

FIGURE 50-4 Zones of the epiphyseal plate.

### Bone Remodeling

Even in adulthood, bone is in a continuous state of turnover, a process that begins very early in skeletal development. This occurs in cycles of bone resorption and new bone formation called remodeling, with each complete cycle termed a **bone remodeling unit**. In a normal state, bone formation and resorption are closely coupled and balanced, serving to maintain the skeleton's peak strength by removal and repair of damaged areas, which contributes to osteocyte viability and impacts the body's calcium homeostasis.<sup>2</sup>

A bone remodeling unit occurs in a sequence of phases: stimulation and recruitment of osteoclasts to the area, resorption of bone, reversal and stimulation of osteoblasts, secretion of new matrix, mineralization of new bone, and completion of a resting phase.<sup>4</sup> The stimulation of a remodeling cycle is thought to occur with osteoblastic production of factors that stimulate the recruitment and activity of osteoclasts (such as osteoclast differentiating factor, also called receptor activator of nuclear factor  $\kappa$ B ligand, or RANKL). One such signal of the need for bone remodeling could come from mature osteocytes within the bone sensing bone deformation or damage.<sup>2</sup> Osteoclasts gather at the site on the bone surface and form large multinucleated cells that begin the process of removal of bone matrix and minerals. This resorptive phase creates a pit in the bone, which is next filled with osteoblasts that begin to fill the space with bone matrix (osteoid). When the bone pit is filled, the new bone matrix is mineralized to complete the cycle (Figure 50-5).

### Calcium Homeostasis

Almost all of the body's calcium supply is held within bone, but the small amount of calcium circulating in blood is essential for a wide variety of cellular functions and therefore its concentration is tightly controlled. Much of this regulation of calcium balance in bone and blood depends on hormonal effects. Parathyroid hormone maintains serum calcium levels by increasing bone resorption as well as calcium reabsorption from renal tubules. Vitamin D metabolites can increase bone mineralization by increasing calcium absorption from the intestinal tract; however, in the setting of calcium deficiency, vitamin D can stimulate bone resorption to help maintain mineral supply in the blood. Calcitonin can act as an inhibitor of bone resorption but likely only plays a minor role in adults. (See Chapter 51 for further discussion.<sup>4</sup>)

### Response to Injury, Stress, and Aging

The ability of bone to remodel after injury is important. Although remodeling of bone continues throughout life, death of the osteon or removal of calcium from bone requires that new bone be deposited to retain strength and function. Physical stresses lead to the realignment of bone trabecular systems and the deposition of additional bone at the site of increased stress. The response of bone to stress is summarized by **Wolff's law**, which states that bone is laid down where it is needed and resorbed where it is not needed.<sup>5</sup> If bone is immobilized or not subjected to mechanical stress, as occurs with prolonged bed rest, the activity of bone-resorbing cells increases.<sup>6</sup> Without external forces (or loads), osteoclast activity is greater than osteoblast activity and bone mass decreases. It is probable that during bed rest, age-related bone loss might be temporarily accelerated and may result in a greater decline in bone mass over time. Patients becoming mobile after prolonged bed rest are at risk for fractures because of a combined loss of muscle and bone strength. With loss of muscle, gait becomes unsteady and patients are more prone to falls.

Internal fixation of a fracture may also cause decreased bone strength. With metal implants, mechanical stress is dispersed from bone and carried by the implant. Bone under the plate is resorbed, and "stress relief" osteoporosis may occur. Care must be taken once implants are removed, and the bone must be protected until strength returns. Some implants are designed to compress fracture fragments to aid healing.

**FIGURE 50-5** Bone remodeling cycle. First, osteoclasts begin bone resorption, creating the pit. Then osteoblasts enter the pit and produce bone matrix, which then calcifies. *PTH*, Parathyroid hormone. (From Garg AK: *Implant dentistry: a practical approach*, St Louis, 2010, Mosby.)

## GERIATRIC CONSIDERATIONS

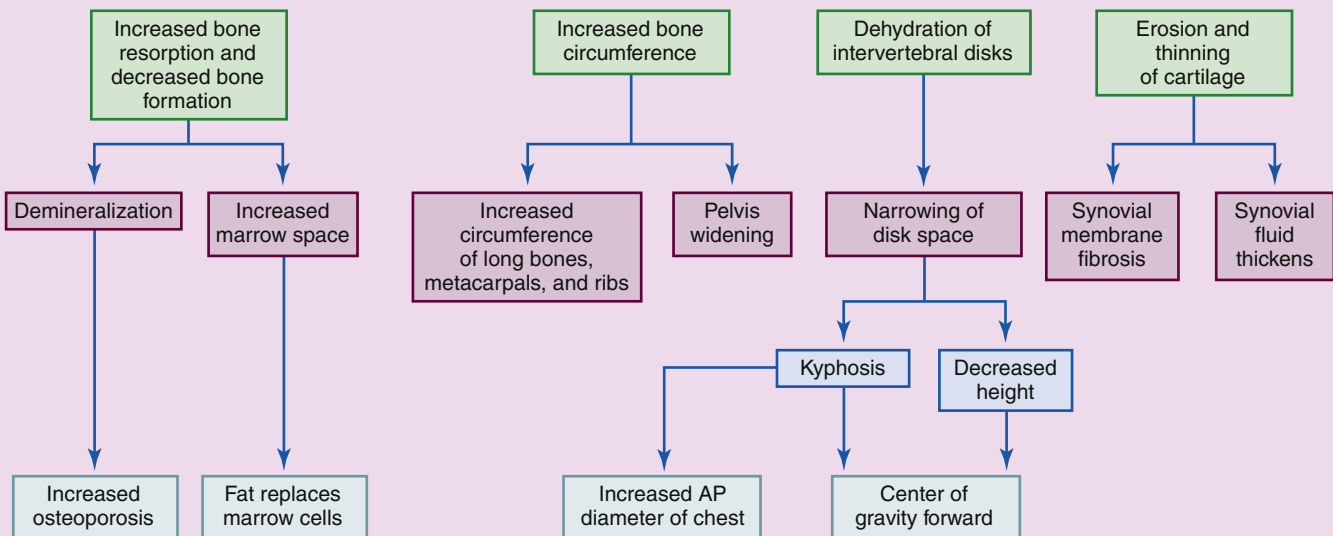

### Changes in the Skeletal System

With aging, bone absorption exceeds bone formation. There is a net loss of bone mass and bone protein matrix. The interior of the long and the flat bones is absorbed faster than that of other bones. Trabecular bone destruction is greater than cortical bone loss. Compared to aging men, aging women have a greater amount of bone loss. The bone marrow space is decreased, with fat replacing marrow cells.

Although interior bone is lost, the circumference of the bones increases because osteoblasts on the exterior bone beneath the periosteum continue bone formation. The long bones, metacarpals, and ribs become bigger in circumference, whereas the pelvis becomes wider and the skull thicker.

The intervertebral disks become dehydrated, with narrowing of the disk space leading to a decrease in height of 3 to 5 cm. An increase in the thoracic curve occurs, resulting in kyphosis and anterior scapular displacement. This change leads to an increase in the anteroposterior diameter of the chest. A decrease in the lordotic curve results in lumbar flattening and a decrease in lumbar flexibility. Greater flexion of the knees and hips is noted. The relationship between the pelvis and the femoral head and neck also changes.

Fissuring, erosion, and thinning of cartilage occur. With the loss of cartilage, the greater pressure that subchondral bone must withstand results in increased density and the formation of joint margin osteophytes. The synovial membrane undergoes fibrosis and the synovial fluid thickens.

Bone mass decreases with age. Studies have shown that elderly individuals express higher levels of certain markers associated with bone resorption, whereas bone formation markers are much more variable. One common cause of increased bone resorption is calcium and vitamin D deficiency, which causes more rapid mobilization of calcium from bone. A secondary hyperparathyroidism can also result. Decreased levels of estrogen in elderly women and men can contribute

to age-related bone loss because osteoblasts have estrogen receptors and their ability to increase bone formation may be affected by the estrogen deficiency. An increase in the local production of cytokines that influence bone resorption may also occur with decreased estrogen levels. The end result is an imbalance between osteoblast and osteoclast function and progressive decline in bone mass<sup>4</sup> (see Geriatric Considerations: Changes in the Skeletal System).

**FIGURE 50-6** Healing of a fracture. (From Gould BE, Dyer R: *Pathophysiology for the health professions*, ed 4, St Louis, 2011, Saunders.)

Bone mass can also decrease with certain disease processes. For example, osteoporosis is a metabolic bone disease characterized by a severe general reduction in skeletal bone mass and thus a susceptibility to fractures. In short, bone resorption is more rapid than bone formation.

### Fracture Healing

Bone may heal in one of two ways after a fracture. A periosteal or external callus forms in fractures managed by closed methods. The blood supply to surrounding soft tissue and motion at the fracture site contribute to healing. Medullary callous formation takes place with rigid immobilization at the fracture site. The process of bone turnover contributes to healing.

The five stages of fracture healing are: (1) hematoma formation, 1 to 3 days; (2) fibrocartilage formation, 3 days to 2 weeks; (3) callous formation, 2 to 6 weeks; (4) ossification, 3 weeks to 6 months; and

(5) consolidation/remodeling, 6 weeks to 1 year (Figure 50-6). These five stages can be grouped into three phases: (1) inflammatory phase, (2) reparative phase (stages 2 to 4), and (3) remodeling phase.

*Stage 1* begins when a hematoma forms at the fracture site. The size of the hematoma depends on the amount of damage at the fracture site. The hematoma offers some stability to fractured ends. Aseptic inflammation occurs at the fracture site.

Healing continues during *stage 2* with the formation of granular tissue containing blood vessels, fibroblasts, and osteoblasts. The hematoma provides the foundation for reparative tissue and bone healing. Vascular and mechanical factors such as motion and distraction of fragments influence *stage 2*.

Callous formation occurs during *stage 3* after the granulation tissue matures. If this stage is delayed or interrupted, the final stages cannot occur.

*Stage 4*, or ossification, occurs as the space in the bone is bridged and the fractured ends are united. The callus is slowly replaced by trabecular bone along the lines of stress, and unnecessary callus is reabsorbed.

During *stage 5*, consolidation and remodeling occur as the medullary canal is reestablished. Bone is resorbed and deposited along stress lines as bone reshapes to meet its mechanical requirements.

Fractures are usually considered healed when clinical healing is achieved. Clinical healing occurs when the fracture is stable and strong enough to resume its function, the fracture site is free of pain, no gross movement is seen across the fracture site, and radiographs show bone crossing the fracture site.

### KEY POINTS

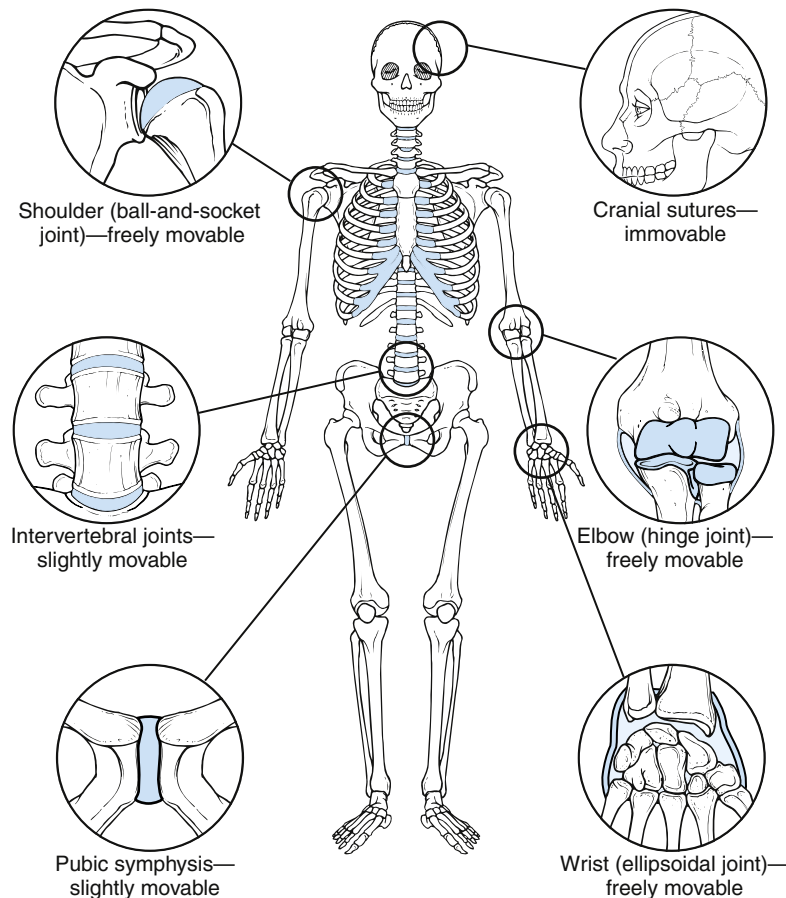

- Bone is capable of altering its shape and density in response to mechanical demands.
- The osteon is the basic unit of bone.
- Bone tissue may be dense and compact (cortical) or lighter and trabecular (cancellous).
- In long bones, the epiphyseal plate is the site of linear growth. Fracture through this plate may lead to limb length discrepancy after fracture healing in children. Increases in bone width are mediated by osteocytes in the periosteum.
- Bone cells responsible for deposition are called *osteoblasts*; osteoclasts mediate bone resorption. The balanced coupling of bone resorption and new bone formation is called remodeling.
- Absence of bone stress because of immobility or altered weight bearing leads to demineralization.

## STRUCTURE AND FUNCTION OF JOINTS

Coordinated movement is only possible because of joint, bone, and muscle structure. Joints permit complex, highly coordinated, and purposeful movements. A **joint**, also called an **articulation**, is a point of contact between bones. Functional articulations between bones in extremities such as the shoulder, elbow, hip, and knee contribute to controlled and graceful movement.

The type and configuration of a joint depend on the functional demands placed on that joint. As is the case with all aspects of the musculoskeletal system, structure determines function (Figure 50-7). When considering the human joint, or articulation, it is also important to remember that once the articulation has developed, the configuration of the joint surface will determine the movement of the joint. Any aberrant joint movement has the potential to disrupt function and cause a breakdown in joint integrity.

Articulations can provide more than a single function, such as flexion and extension. Flexion, extension, adduction, abduction, rotation, opposition, and circumduction may all be functional movements of a joint. The more complex the movements, the more complex is the joint structure.

**FIGURE 50-7** Examples of types of joints. (From Frazier MS, Drzymkowski JW: *Essentials of human diseases and conditions*, ed 5, Philadelphia, 2013, Saunders, p 302.)

Broadly speaking, articulations, or arthroses, in the human body may be divided into two categories based on the composition of the joint and the method in which the joints unite the body components. The two categories are **synarthroses**, or fibrous and cartilaginous (nonsynovial) joints, and **diarthroses**, or synovial joints.

### Synarthroses

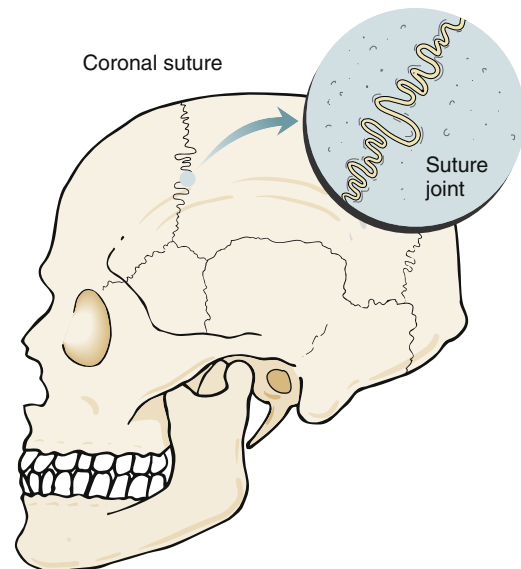

Synarthroses have two subdivisions based on the type of connective tissue used to form the joint. Fibrous and cartilaginous tissues give these joints their names.

#### Fibrous Structure

In a fibrous joint, bones are united by fibrous tissue. Three types of fibrous joints are found in the human body: suture joints, gomphosis joints, and syndesmosis joints. A suture joint unites bones with a thin but dense layer of fibrous tissue. Interlocking bony ends overlap and increase stability. Suture joints are found only in the skull (Figure 50-8). Fusion of the joint occurs later in life. This bony union is called a *synostosis*.<sup>1</sup>

The joint that is found between a tooth and the mandible or maxilla is the only gomphosis joint in the human body. The best description of a gomphosis joint is that of a peg implanted into a hole. Fibrous tissue stabilizes the two bony structures and permits little movement.

A syndesmosis joint is a joint in which the two bony components are joined by a ligament or interosseous membrane. These joints normally allow slight movement and are quite functional. The interosseous membrane joining the fibula and the tibia is an example of a syndesmosis joint (Figure 50-9).

**FIGURE 50-8** A suture joint is found only in the skull.

#### Cartilaginous Structure

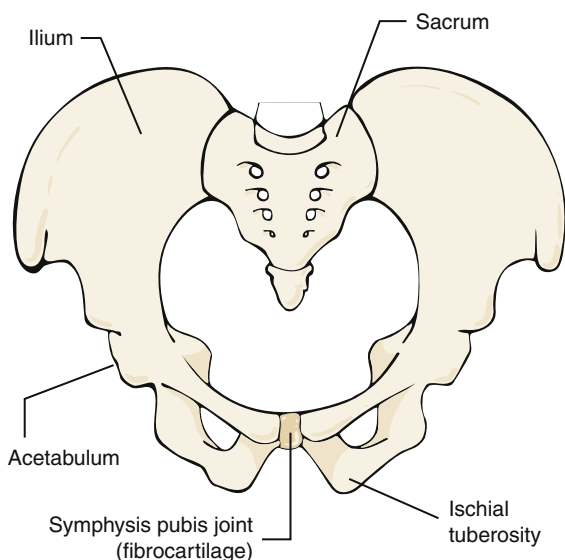

Bony segments connected by fibrocartilage or hyaline growth cartilage are classified as **cartilaginous joints**. Symphysis joints and synchondrosis joints are the two types of cartilaginous joints in the body.

A **symphysis joint** connects bony segments by a fibrocartilaginous plate or disk. The symphysis pubis joint (Figure 50-10) joins the two

**FIGURE 50-9** The interosseous membrane joining the fibula and the tibia is an example of a syndesmosis joint.

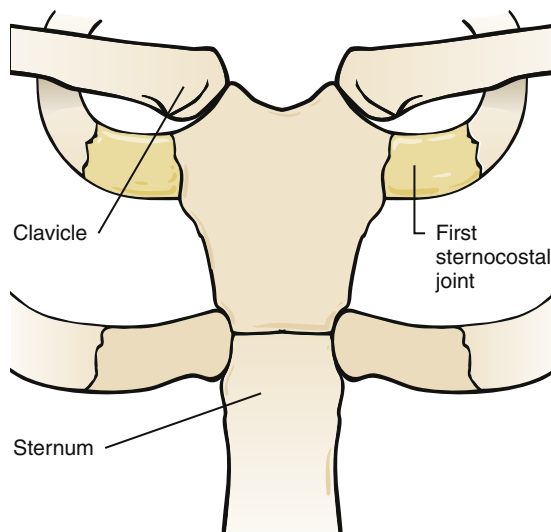

**FIGURE 50-10** Symphysis pubis joint.

pubic bones of the pelvis. This joint is a weight-bearing structure and is important in transmitting stress and providing stability. Little or no motion is permitted or desired.

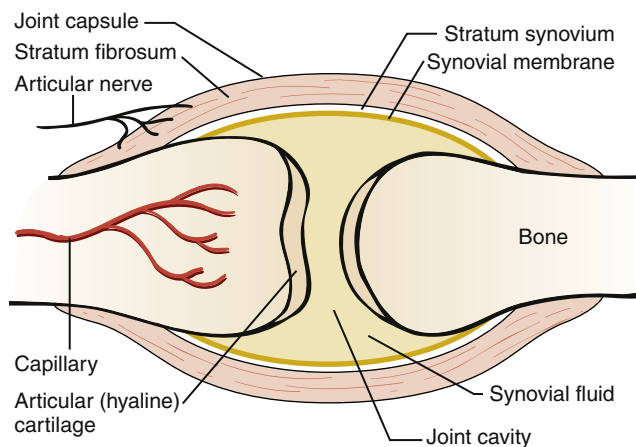

In a **synchondrosis joint**, cartilage connects bony components. This joint allows bone growth while providing stability. This type of joint can be found at growth sites of the body. The first sternocostal joint is an example of a synchondrosis joint (Figure 50-11). When bone growth is complete, these joints ossify and become unions (synostoses).

### Diarthroses

Joints designed to allow mobility are classified as **diarthroses**, or **synovial joints**. These joints are covered with a **joint capsule**, or **synovial sheath**. Movement in these joints is provided by contraction of the muscle-tendon unit, and control depends on the joint

**FIGURE 50-11** First sternocostal joint.

**FIGURE 50-12** Typical synovial joint.

capsule and ligaments. Stability of the synovial joint is enhanced by additional soft-tissue structures—the menisci, disks, and labra. Synovial fluid is produced by fibroblast-like cells lining the joint capsule and is secreted into mobile joints to provide the lubrication necessary to reduce friction between articulating surfaces. In diarthrodial, or synovial, joints, the bony ends are free to move because no cartilaginous tissue connects the adjacent bony surfaces. The synovial joint connects adjacent bony surfaces through a joint capsule that surrounds the joint.

### Synovial Structure

Features common to all synovial joints include: (1) a fibrous joint capsule, (2) a joint cavity enclosed by a joint capsule, (3) a synovial membrane that lines the inner surface of the capsule, (4) lubricating synovial fluid that coats joint surfaces, and (5) hyaline cartilage, which covers the joint surface (Figure 50-12).

Many synovial joints also have accessory structures within the joint capsule. Ligaments, fat pads, disks, and menisci are a few of the structures situated in the capsule that are important to proper function of the joint. Ligaments and tendons keep joint surfaces together and aid in joint motion. Menisci, disks, and synovial fluid limit excessive compression of articulating surfaces.

**FIGURE 50-13** Schematic drawing of a typical diarthrodial (synovial) joint. (From Applegate E: *The anatomy and physiology learning system*, ed 4, St Louis, 2011, Saunders.)

The lateral and medial menisci of the knee are located on top of the tibia between the tibia and femur (Figure 50-13). These semilunar fibrocartilaginous structures function as shock absorbers in the knee. In cross-section, these wedge-shaped cartilages are thinnest on the inner edge. Around the inner edge, the area of the synovial cavity between a femoral condyle and a meniscus is continuous with that between the meniscus and corresponding tibial condyle. On the outer edge, the cartilages are attached to both the synovial and the reticular capsule. The medial meniscus is attached to the collateral ligament. The lateral meniscus has weak attachments to the lateral area of the capsule, from which it is in part separated by the tendon of the popliteal muscle. It is possible that because the medial cartilage is more firmly attached, it is torn more often than the lateral meniscus, which has no attachment to the fibular collateral ligament and is thus more mobile. Both menisci are anchored to the tibia via strong fibrous bands.

**Menisci** facilitate rotation at the knee by allowing better contact of the tibial surfaces with the femoral condyles. They function to evenly distribute load-bearing on the tibial plateau. Menisci are often torn by rotation of the femur when the knee is flexed.<sup>1</sup> The torn portion of the meniscus locks the joint, with accompanying pain and edema in the knee. If torn, the menisci can be removed; however, weight-bearing areas on the femur and tibia may then decrease by almost 50%.

Intervertebral disks are padlike structures between vertebrae that help bind vertebrae together and act as shock absorbers between adjacent vertebrae. These disks allow slight movement between any two adjacent vertebral bodies. Disks contribute to the natural curves of the spine in the cervical and lower lumbar areas.

Each intervertebral disk consists of an outer annulus fibrosus, or outer fibrous layer, and a nucleus pulposus, or soft center.<sup>7</sup> The annulus fibrosus consists of many layers of fibrous tissue and fibrocartilage that are strongly attached to the ends of the bodies adjoining the disks.

The nucleus pulposus is semigelatinous, containing a high percentage of water, and is located closer to the posterior edge of the disk. Because of its high water content, the intervertebral disk is prone to dehydration. Even when the vertebral column is not supporting the weight of the body, as in the supine position, intervertebral disks are maintained under pressure by ligaments connecting the arches.<sup>7</sup>

Although the nucleus pulposus is incompressible, its softness allows it to change shape easily. As the vertebral column bends, the nucleus pulposus becomes wedge-shaped, with the thin edge in the direction of bending. The annulus fibrosus on this side bulges out and on the opposite side is stretched by its attachment to the adjoining vertebrae.<sup>7</sup>

Pain caused by the pressure of a protruded disk on a nerve root or spinal nerve leads to pain in the area innervated by compressed nerve fibers and is called radicular pain.<sup>7</sup>

Standing and moving causes water to be squeezed out of disks into the bloodstream. Bed rest reduces the pressure on disks, and water is reabsorbed from the bloodstream by the disks.

**Joint capsule.** The joint capsule is composed of two layers of connective tissue. The outer layer is the fibrous membrane composed of collagenous tissue. It is dense and encapsulates the entire joint. This dense tissue is solidly attached to the periosteum of the adjacent bony components. The fibrous membrane is poorly vascularized and innervated by joint receptors. Joint receptors are able to detect motion, compression, tension, vibration, proprioception, and pain.<sup>1</sup>

The inner layer, or synovial membrane, is highly vascularized and often only one or two cell layers thick. It is minimally innervated and less pain-sensitive than other joint components. Because the outer joint capsule and the ligaments have more abundant nerve endings, pain can be caused by swelling and stretching of the capsule (as in arthritis or infection) or by injury to the ligaments (as in a strain).<sup>1</sup> Articular cartilage has no nerve fibers. A general rule notes that a joint is innervated by the major nerves that cross it. Specialized cells in the synovial membrane, called *synoviocytes*, synthesize the hyaluronic acid component of synovial fluid. The inner layer of the joint capsule is the entry point for nutrients and the exit point for waste material.

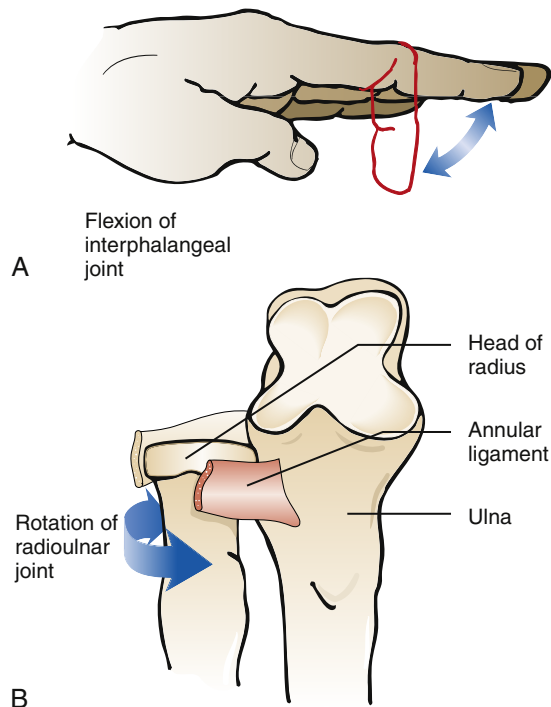

**Synovial fluid.** Synovial fluid contains hyaluronic acid, a high-molecular-weight polysaccharide, and lubricin, a glycoprotein. Hyaluronic acid provides for viscosity and reduces friction between the capsule and joint surfaces. It also helps to maintain synovial fluid volume by slowing diffusion of water out of the joint space. Lubricin is an important lubricant of cartilage and articular surfaces. Synovial fluid resists shear loads, keeps surfaces lubricated to reduce friction, and provides nourishment for cartilage. Although synovial fluid is generally maintained at a constant volume, disease states, such as inflammatory arthritis or infection, can stimulate increased synovial fluid production by synoviocytes. The accumulation of fluid outweighs its clearance, and joint swelling results.<sup>1</sup>

## Range of Movement

Synovial joints can be divided into three main categories according to visible movement allowed at the joint: uniaxial, biaxial, and triaxial.

A **uniaxial joint** allows motion around a single axis of movement. Two types of uniaxial diarthrodial joint are **hinge joints** and **pivot joints**. A hinge, or **ginglymus**, joint permits flexion and extension; an example is the interphalangeal joint of the finger, the elbow, or the knee (Figure 50-14, A). A pivot, or trochoid, joint allows rotation as its single axis movement. The superior radioulnar joint of the elbow and the union between the first and second vertebrae are examples of a pivot joint (Figure 50-14, B).

A **biaxial joint** has two axes of movement and permits movement in two planes. Two kinds of biaxial joints are **condyloid joints** and **saddle joints**. The metacarpophalangeal joint of the hand is an example of a condyloid joint; it permits flexion and extension at one axis and adduction and abduction around another axis (Figure 50-15, parts A and B, respectively). A saddle, or sellar, joint is a joint in which the surfaces are convex in one plane and concave in the other. The surfaces of a saddle joint fit together as a saddle fits a horse. The carpometacarpal

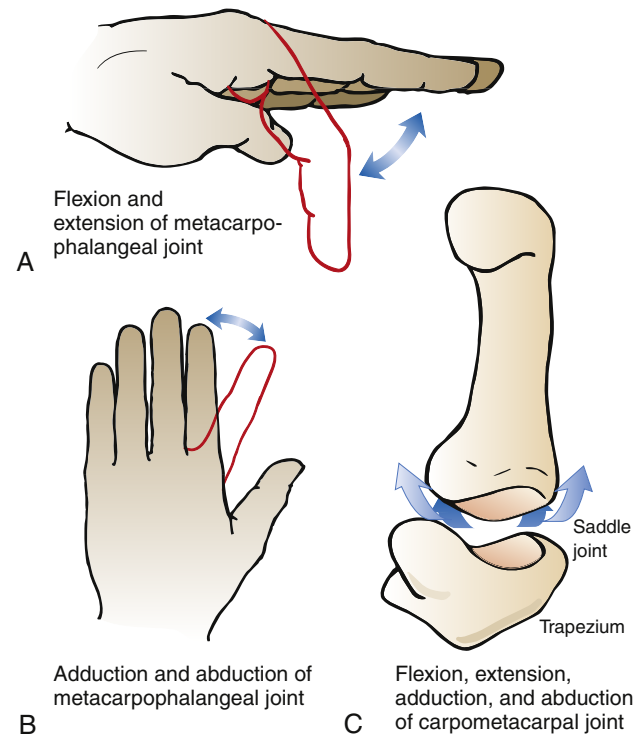

**FIGURE 50-14** A hinge joint permits flexion and extension and is represented by the interphalangeal joint of the finger (**A**). A pivot joint allows rotation and is represented by the superior radioulnar joint of the elbow (**B**). Both the hinge joint and the pivot joint are considered uniaxial joints because they allow motion around a single axis.

joint of the thumb is a saddle joint; it permits both flexion-extension and adduction-abduction movements (**Figure 50-15, C**).

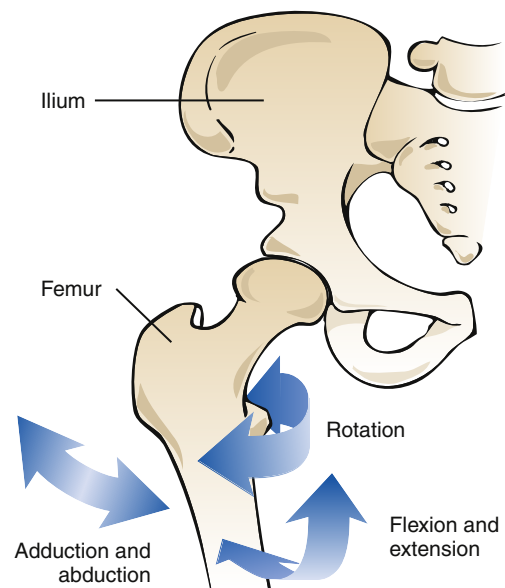

**Triaxial joints** permit movement around three axes so that motion can occur in three planes. A triaxial joint permits gliding movement between two bones and is exemplified by the carpal joints of the hand. The **carpal** joints may glide or rotate relative to the adjacent surfaces. A **ball-and-socket joint** is formed by a ball-like surface fitting into a concave socket. Ball-and-socket joints permit flexion-extension, adduction-abduction, and rotational movements. The hip and shoulder are examples of a ball-and-socket joint (**Figure 50-16**).

#### KEY POINTS

- Joint configuration dictates possible motions of a joint. Types of joint movement include flexion, extension, adduction, abduction, and rotation. Joints that allow these types of movement are called *diarthroses* (synovial joints). The ends of bone in a synovial joint are held together by a joint capsule composed of two layers of connective tissue.
- The lateral and medial menisci in the knee serve as shock absorbers between the femur and tibia. The medial meniscus has strong attachments to the collateral ligaments, whereas the lateral meniscus has weak attachments to the lateral area of the joint capsule. Thus because of its strong attachment, the medial meniscus is more likely to be torn than the lateral meniscus.
- Intervertebral disks are padlike structures that act as cushions between vertebrae. A strong annulus fibrosus surrounds a gelatinous, high-water-content nucleus pulposus that can herniate and press on spinal nerves.
- The joint capsule is composed of two layers of connective tissue: an outer fibrous membrane and an inner synovial membrane.

**FIGURE 50-15** A condyloid joint permits flexion and extension at one axis and adduction and abduction around another axis; it is represented by the metacarpophalangeal joint of the hand (**A** and **B**). Because of its convex and concave surfaces, a saddle joint allows for flexion and extension, as well as adduction and abduction; it is represented by the carpometacarpal joint of the thumb (**C**). Both the condyloid joint and the saddle joint are considered biaxial joints because they have two axes of movement and permit movement in two planes.

**FIGURE 50-16** A ball-and-socket joint permits flexion and extension, adduction and abduction, and rotation; it is represented by the hip joint. A ball-and-socket joint is considered a triaxial joint because it permits movement around three axes; motion can occur in three planes.

- Synovial fluid provides nourishment and lubrication for cartilage. It becomes more viscous with slow movement and low temperatures and less viscous with fast joint movement and high temperatures.
- Synovial joints are classified according to the visible movements that they allow:
  - Uniaxial: Movement in one plane only (e.g., distal hinge joints of the fingers)
  - Biaxial: Movement in two planes (e.g., thumb saddle joint)
  - Triaxial: Movement in three planes (e.g., ball-and-socket hip joint)
- Some bones are held together by joints that allow little or no movement. These joints are called *synarthroses* (nonsynovial joints). Examples include sutures between skull bones, tooth-jawbone joints, and the symphysis pubis joint.

## STRUCTURE AND FUNCTION OF ARTICULAR CARTILAGE

**Articular cartilage** appears smooth, shiny, and white on gross inspection. It is a specialized tissue designed to withstand stress imposed by the movement of bony structures. Articular (hyaline) cartilage covers the ends of bone. It functions to distribute joint loads over a wide area, to decrease the stress of prolonged compression from contracting joint surfaces, and to allow movement of joint surfaces with minimal friction and deterioration. Articular cartilage is devoid of blood vessels, lymph channels, and nerves. If a mechanical defect is present, however, this avascular structure can cause major disruption of joint movement.

### Composition

Cartilage is hydrophilic in nature, with 65% to 80% of it being primarily water with some inorganic salts, proteins, glycoproteins, and lipids. Its extracellular matrix, which consists mostly of collagen fibers, accounts for almost all of the remaining weight. The cellular component of cartilage (chondrocytes) represents less than 2% of its weight.<sup>2</sup> Although sparsely distributed, chondrocytes manufacture the organic component of the matrix. This organic matrix, or ground substance, is composed of a network of collagen fibrils encased in a solution of **proteoglycans**. The extracellular matrix of cartilage consists of a fibrous component that includes elastin and different types of collagen. Articular cartilage is primarily avascular and is very limited in its ability to regenerate and repair itself.

### Functional Properties

Articular cartilage has a biomechanical function. It spreads loads applied to articulating bone ends over a large area to decrease contact stress and limit wear and friction in the joint during movement.

Collagen fibers in articular cartilage are highly structured to provide stability (Figure 50-17). The most important mechanical properties of collagen fibers are strength and tensile stiffness. By themselves, collagen fibrils tolerate tension but not compression.

To improve tolerance to compression, cartilage proteoglycan works with hyaluronate to form proteoglycan aggregates. This proteoglycan aggregation fosters immobilization of the proteoglycans within the collagen meshwork, which adds structural rigidity and better compression tolerance to the extracellular matrix.

The importance of proteoglycans and interaction with collagen does not end with an increase in tolerance to compression. Proteoglycans also associate with collagen as a bonding agent to stabilize cross-links between collagen fibers. By maintaining ordered structure and the mechanical properties of collagen fibers, proteoglycans assist in increasing strength.

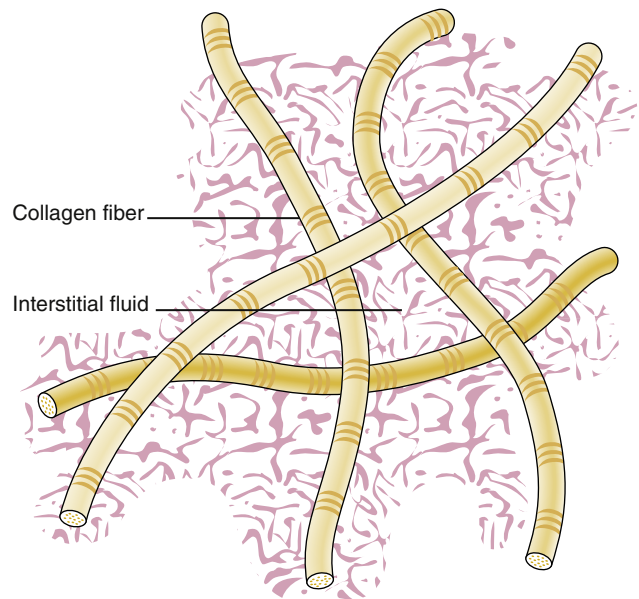

FIGURE 50-17 Collagen fiber in articular cartilage.

Articular cartilage requires a sophisticated lubrication process to ensure a decrease in friction between joint surfaces. Without correct lubrication by synovial fluid, articular cartilage will begin to break down as a result of mechanical action of the joint.

Joints are lubricated by two methods. One method is by the mechanics of joint physiology. A lubricating coating is formed between the joint surfaces when a weight-bearing force or load is applied to the cartilage and fluid is abstracted from the matrix. The movement of fluid under pressure acts as a self-lubricating mechanism. When the load is removed, liquid from the matrix is reabsorbed by the cartilage.<sup>2</sup> The second method is assisted by glycoproteins covering cartilage and providing a lubricated surface. Lubrication of cartilage from a combination of these two methods decreases friction in the joint. Weight bearing and joint motion are essential for healthy cartilage. Cartilage will atrophy if joints are not used because cells cannot be nourished by the synovial fluid.<sup>2</sup>

### Response to Injury, Stress, and Aging

Articular cartilage can experience wear. Wear is the removal of material from solid surfaces by biomechanical action. Articular cartilage may begin to wear through two primary mechanisms: interfacial wear and fatigue wear. Interfacial wear results from the interaction of weight-bearing surfaces by either adhesive or abrasive action. Interfacial wear occurs when joint surfaces come into direct contact as a result of a lack of lubricating film. The nonlubricated surfaces are quite abrasive to each other, and joint surfaces may deteriorate. Fatigue wear results from repeated deformation secondary to weight bearing. Fatigue wear occurs as a result of the accumulation of microscopic injuries from repeated stress.

Because of the changes in the nature of glycoproteins with aging, cartilage becomes less able to retain water. This “drying out” effect can change the biomechanics of cartilage and lead to increased stress fractures or cracks in the collagen network. Over time and with joint wear, microcracks can accumulate and fragments of cartilage can detach into the joint space, creating “loose bodies.” The resulting cartilage surface is rough and irregular and subject to further mechanical wear and degeneration. This process can form the basis of osteoarthritis or degenerative joint disease.<sup>4</sup> The effects of aging on the skeletal system are described in Geriatric Considerations: Changes in the Skeletal System.

FIGURE 50-18 Parallel bundles of collagen fiber in tendons.

#### KEY POINTS

- The ends of bones are covered with articular cartilage, which helps distribute mechanical loads placed on the joint and minimize friction and wear.
- An important component of articular cartilage is collagen, which provides strength and tensile stiffness. A second component, proteoglycan, increases compression tolerance.
- Articular cartilage is avascular and relies on synovial fluid for nutrition and waste removal.
- Synovial fluid lubricates articular surfaces to reduce friction and minimize wear.
- Articular cartilage has limited capacity for repair and regeneration.
- Interfacial joint wear occurs because of insufficient lubrication.
- Fatigue joint wear occurs because of repetitive stress injuries.
- Sudden imposition of excessive stress may also cause trauma to the joint matrix.

## STRUCTURE AND FUNCTION OF TENDONS AND LIGAMENTS

Approximately 200 bones in the human skeleton are connected by joints that provide movement and dynamic stability. Ligaments, tendons, and joint capsules provide joint stability but not movement because they are not contractile structures. Without joint stability, no movement of the limbs would be possible.

Ligaments and joint capsules connect bone to bone, provide mechanical stability to joints, and guide joint motion. Tendons, through attachment to a contractile structure (muscle) and a rigid object (bone), assist in the generation of movement. Injuries to ligaments and tendons are common, so an understanding of their function and properties is important.

### Composition

Tendons and ligaments are dense connective tissue in which collagen fibers are positioned in generally parallel alignment (Figure 50-18). The arrangement of fibers provides greater tensile strength to these tissues. It has been noted that although most collagenous fibers of a tendon are aligned in the same direction, they are not solely parallel. They intertwine to form small bundles, which again intertwine to form the larger parallel bundles that give tendons their unique appearance.

FIGURE 50-19 Schematic representation of a tendon.

FIGURE 50-20 Triple-helix formation of collagen molecules.

As tendons near the bony attachments, larger tendon bundles also intertwine with each other. As a result, pull of any part of the muscle, instead of being limited to a tendon bundle, is spread widely through the tendon. Collagen fibers of the tendon nearest the bone blend into fibrocartilage and then become mineralized, merging into bone and forming a firm attachment.

Ligaments are similar in appearance to tendons, but they unite bone to bone rather than muscle to bone. Most ligaments are composed of dense collagenous tissue, whereas a few consist of almost pure elastic tissue.

Figure 50-19 shows a schematic representation of a tendon. Tendon and ligament tissue is composed of few cells (fibroblasts) and large amounts of extracellular matrix. Approximately 20% of the total tissue is fibroblastic and 80% of the structure consists of extracellular matrix. Of the matrix, 70% is water and 30% is solid material. The solids consist of collagen (75%), ground substance, and small amounts of elastin. Compared to ligaments, tendons contain more collagen.

Collagen molecules are in a triple-helix formation (Figure 50-20), with hydrogen-bonded water bridges or cross-links providing molecular stability. Cross-links give strength to tissue and increase tolerance to mechanical stress.

The protein **elastin** is found in tendons and ligaments. Elastin provides for some elasticity or extensibility. With the exception of the ligamentum flavum, the majority of tendons and ligaments contain very little elastin, and minimal stretch is allowed. Unlike these stiffer tendons and ligaments, the ligamentum flavum connects laminae of adjacent vertebrae and provides stretch and stability to the spine. The ratio of elastin to collagen fibers in the ligamentum flavum is 2:1.

Ground substance in ligaments and tendons consists of a large amount of proteoglycans, as well as glycoproteins and plasma proteins. The proteoglycan aggregate binds extracellular water in the matrix and acts to stabilize collagen fibers and strengthen ligaments and tendons.

### Functional Properties

Tendons and ligaments are quite interesting relative to function. Tendons are extremely strong but can angulate around bony prominences.

This capability enables the pull of muscle to change direction and thus improve mechanical leverage. The smooth movement of tendons across bony prominences is facilitated by the presence of bursae. A bursa is a closed sac lined with mesenchymal cells, and is located where one tissue must glide over another.<sup>2</sup> Ligaments are supple and flexible but at the same time rigid. Ligaments stabilize the joint because of their rigidity but allow mechanically correct movement of the joint because of their suppleness.

The strength of a tendon or ligament is determined by the number and quality of cross-links within collagen molecules. As a child matures into a young adult, the increase in the number and quality of cross-links contributes to an increase in tendon and ligament strength.

### Response to Injury, Stress, and Aging

With disuse of muscle, ligaments and tendons lose elasticity and resiliency. With aging, the tensile strength and stiffness of ligaments and tendons decrease as the proliferative and synthetic activity of fibroblasts declines.<sup>8-9</sup>

Tolerance to stress is also compromised during pregnancy and the postpartum period. During pregnancy, a laxity of tendons and ligaments is noted with a subsequent increased potential for injury. Estrogens relax various pelvic ligaments during pregnancy, and the sacroiliac joint and symphysis pubis become elastic. These alterations allow easier passage of the baby through the birth canal.

Similar to bone, ligaments and tendons respond to mechanical demands placed on them. Increased stress causes these structures to become stronger and tolerate higher mechanical loads. With a decrease in stress, ligaments and tendons become less taut, weaker, and potentially more susceptible to injury. Immobilization may also decrease the tensile strength of ligaments.

#### KEY POINTS

- Ligaments and joint capsules connect bones to bones and provide stability to joints.
- Tendons attach bones to muscles to allow movement.
- Tendons and ligaments are composed of dense connective tissue formed by fibroblasts.
- Collagen and elastin are the primary protein components in tendons and ligaments. Most tendons and ligaments have little elastin, which makes them strong but not very compliant. An exception is ligaments that connect adjacent vertebrae, which have more elastin than collagen.
- Tendons are composed of many very fine fibers, each of which originates on endomysium.
- Ligament and tendon strength is determined by the quantity and quality of collagen cross-links.
- Maximal strength is achieved in young adulthood; pregnancy and aging reduce collagen strength.
- Ligaments and tendons respond to increased functional demand by increasing strength. Disuse results in weakened structures.

## STRUCTURE AND FUNCTION OF SKELETAL MUSCLE

Approximately 40% of the total body weight is composed of skeletal muscle.<sup>1</sup> Nearly another 10% is smooth and cardiac muscle. Although many of the same principles of contraction apply to these various muscle types, skeletal muscle will be the focus here. Skeletal muscle not only enables bones to move at the joint but also provides strength, stability, and protection of the skeleton by distributing loads and absorbing shock.

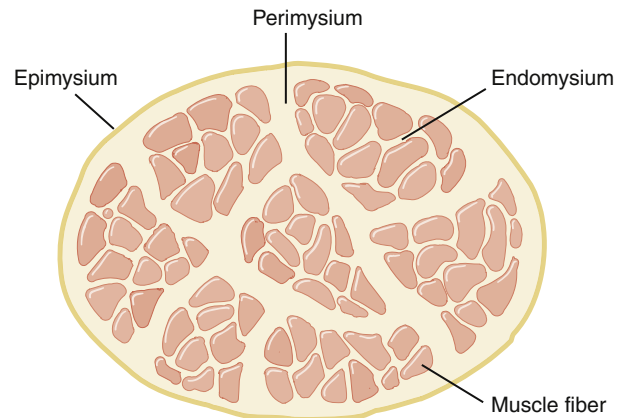

FIGURE 50-21 Muscle fiber.

### Composition

The structural unit of skeletal muscle is the muscle fiber (Figure 50-21). A skeletal muscle is composed of thousands of muscle fibers. Each fiber is a single muscle cell, or myofibril, enclosed in a membrane called the **sarcolemma**. Muscle fibers are grouped together in bundles called **fasciculi**. Individual muscles are composed of many fasciculi. The sarcolemma of an individual muscle fiber is surrounded by connective tissue called the **endomysium**. Connective tissue surrounding the fasciculi is called the **perimysium**. Connective tissue surrounding the entire muscle is called the **epimysium**. The epimysium tracks continuously with the endomysium and the perimysium (Figure 50-22, A). Tendons are attached to bones by Sharpey fibers, which are continuous with the perimysium.

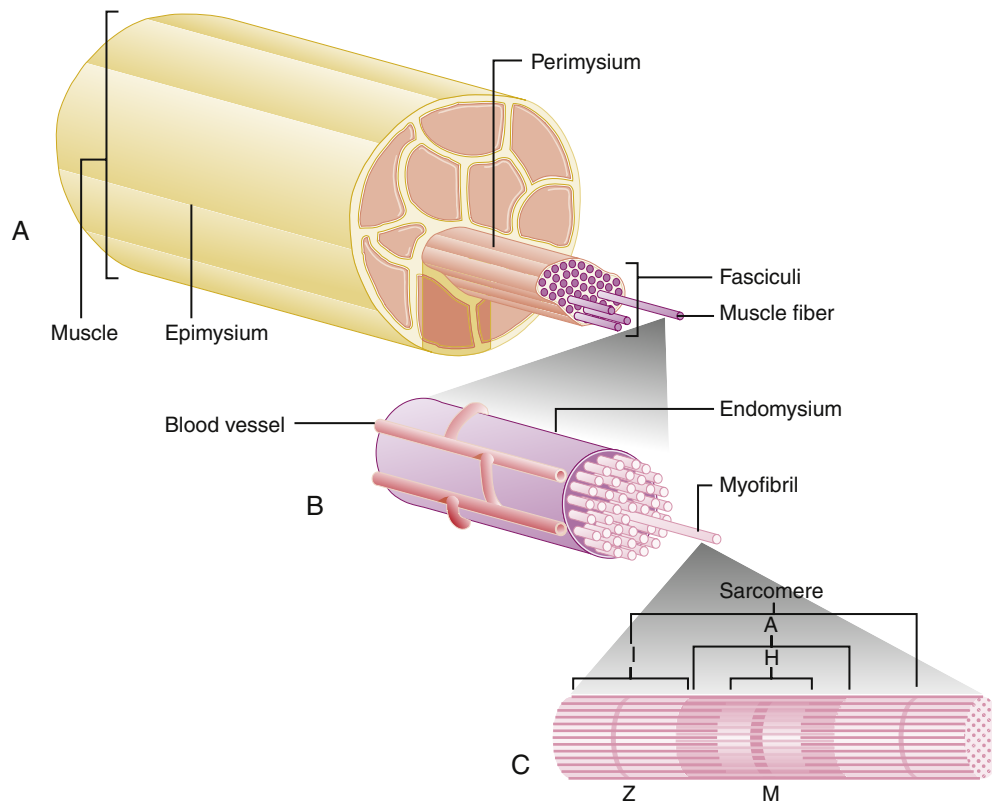

The arrangement of fasciculi varies among muscles and can present a specific visual effect of the muscle (Figure 50-22, B). Fasciculi that lie parallel to each other are often found in muscles that function to generate larger range-of-motion joints. Muscles designated as strap or spiral have fibers situated in parallel arrangements. Fibers situated in an oblique pattern relative to the long axis of the muscle are called **unipennate**, **bipennate**, or **multipennate** muscles. Pennate (Latin for “feather”) muscles usually contain a large number of muscle fibers and can transmit a large amount of force to the muscle tendon. Examples of pennate muscles include the gastrocnemius (a bipennate muscle), the deltoid (a multipennate muscle), and the flexor pollicis longus found in the forearm and serving the thumb (a unipennate muscle).

The cytoplasm of the muscle fiber is called the **sarcoplasm**. Structures composing the sarcoplasm include ribosomes, glycogen, and mitochondria, which are required for cell metabolism. Muscle contraction is accomplished by protein filaments of the contractile apparatus.

### Contractile Apparatus

Microscopic inspection of a skeletal muscle cell reveals a typical pattern of banding called **striation**. This striated appearance is due to an organized structure of proteins (myofibrils) of the contractile apparatus (Figure 50-22, C). The contractile proteins actin and myosin are called filaments because they are long and narrow. **Myosin** filaments are larger and are referred to as thick filaments. Thin filaments are actually composed of three different types of proteins bundled together. **Actin** is the primary constituent of thin filament, with smaller amounts of the proteins tropomyosin and troponin bound to it.

Thick and thin filaments are specifically arranged in contractile units called **sarcomeres** (Figure 50-23). Sarcomeres are defined by dark bands called **Z lines** that lie perpendicular to actin and myosin

**FIGURE 50-22** Structure of muscle fiber. **A**, The epimysium extends continuously with the endomysium and the perimysium. **B**, The arrangement of fasciculi varies among muscles. **C**, The banding pattern apparent on microscopic inspection of a muscle cell results from the organized structure of the proteins (myofibrils) of the contractile apparatus.

**FIGURE 50-23** Thick and thin filaments are organized into contractile units called sarcomeres.

filaments. A sarcomere extends from one Z line to the next. Thin actin filaments are attached to Z lines and extend from them. The **I bands** (isotropic) are light in color and correspond to the position of thin actin filaments extending in both directions from the Z line. Thick myosin filaments lie parallel to and between the thin filaments. Each myosin filament is actually surrounded by six thin filaments. The dark **A band** corresponds to an area where actin and myosin filaments overlap. An **M line** marks the center of the A band and the midpoint of

myosin filaments. One other zone, the **H zone**, corresponds to a region occupied solely by myosin filaments with no actin filament overlap. An efficient, synchronized contraction is enhanced by this precise arrangement of contractile elements. (See Chapter 17 for a detailed description of contractile filament structure.<sup>8</sup>)

#### KEY POINTS

- Muscles are composed of bundles of muscle fibers called fasciculi.
- A single muscle fiber is one elongated muscle cell packed with contractile proteins and cytoplasmic organelles.
- Connective tissue encases each fasciculus (endomysium) and the muscle as a whole (perimysium).
- Tendons that attach muscle to bone are continuous with the perimysium.
- The arrangement of fibers within a muscle may be parallel or oblique.
- A parallel arrangement occurs in muscles having greater range of motion.
- Oblique patterns occur in muscles with large force potential.
- Skeletal muscle is striated because of an orderly arrangement of contractile proteins in muscle cells.
- Myosin is the primary component of the thick filament. Thin filaments are composed mainly of actin, with smaller amounts of the regulatory proteins troponin and tropomyosin.

#### MECHANICS OF MUSCLE CONTRACTION

To accomplish the powerful shortening, or contraction, of a muscle fiber, several processes are necessary. Contraction allows muscle tissue to pull on bones and thus body movement is possible. The molecular

basis of muscle contraction is described by the sliding filament, or cross-bridge, theory.

### Sliding Filament Theory

The **sliding filament**, or **cross-bridge**, theory of muscle contraction is suggested by the anatomic configuration of the sarcomere. Muscle shortening is accomplished by increasing the amount of overlap of actin and myosin filaments. The Z lines at the ends of the sarcomere move closer together as interdigitating actin and myosin filaments slide past one another. Myosin head groups grip binding sites on actin filaments and pull the thin filaments toward the sarcomere's center. Each time a myosin head binds an actin bead, it forms a **cross-bridge**. Flexible myosin heads move in a ratchet-like manner to tug on actin filaments. Myosin heads bend back and forth, binding and pulling on actin filaments in a steplike fashion. Actin filaments are prevented from slipping back to their original position because some myosin-actin bonds are forming while others are breaking. Formation and subsequent breaking of each actin-myosin cross-bridge requires one molecule of adenosine triphosphate (ATP). Consequently, tremendous quantities of ATP are hydrolyzed with each muscle contraction.

The three energy-producing processes for ATP production are: (1) the ATP-phosphocreatine system in which energy for resynthesis of ATP is derived from one compound, phosphocreatine; (2) anaerobic glycolysis, which generates lactic acid but provides some ATP from the partial degradation of glucose or glycogen without oxygen; and (3) the aerobic system, which uses oxygen and has two parts: part A, in which oxidation of carbohydrates is completed, and part B, in which fatty acids and some amino acids are oxidized.

ATP is the immediate source of energy for muscle contraction. Glucose, obtained from glycogen in the muscles and liver, is the primary source of energy for muscle contraction. When enough oxygen is present, glucose is oxidized to carbon dioxide and water. The energy released is partly used to form more ATP. Some energy is wasted in heat. When enough oxygen cannot be supplied via the respiratory and vascular systems, as during intense exercise, glucose is converted to lactic acid. The smaller amount of energy liberated by this anaerobic reaction contributes to the formation of additional ATP. Lactic acid is basically a poison to muscle and oxygen is needed to remove it, so the muscle is said to have accumulated an oxygen debt. Resting muscle receiving enough oxygen uses the oxygen to re-form glucose and glycogen from lactic acid and oxidize the lactic acid to carbon dioxide and water.<sup>1</sup>

### Role of Calcium

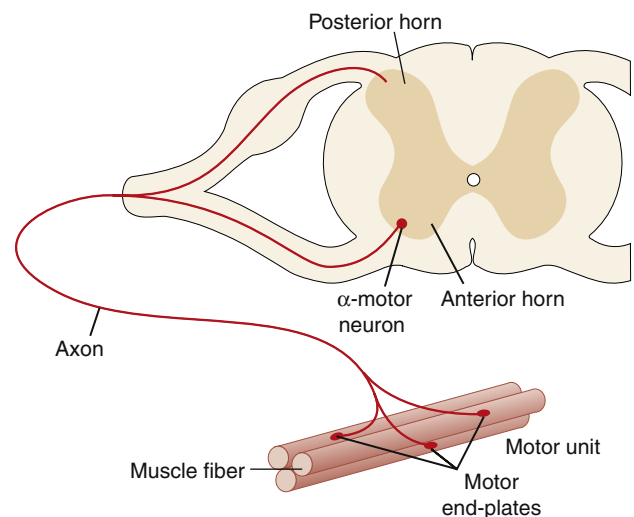

Muscle contraction depends on an adequate amount of calcium ion in the cytoplasm. In the absence of free intracellular calcium, no muscle contraction will take place even though myosin head groups have high affinity for actin binding sites. This phenomenon can be explained in the following way. Myosin heads are prevented from binding to actin by **tropomyosin proteins**, which lie on top of actin binding sites. The position of tropomyosin protein is controlled by **troponin**. When calcium is absent, troponin induces tropomyosin to cover the actin binding sites. When calcium is present, troponin allows tropomyosin to move and uncover the binding sites (Figure 50-24). Cross-bridge formation immediately ensues because myosin heads have a high affinity for these sites in the relaxed state.

### Electromechanical Coupling

The nerve impulse that a muscle fiber receives to begin contraction is transmitted through the  $\alpha$ -motor neuron (Figure 50-25). The neuron's cell body is located in the anterior horn of the spinal cord. The axon extends from the cell body to the muscle and divides into many small

**FIGURE 50-24** The proteins troponin and tropomyosin regulate the ability of actin and myosin to form cross-bridges. **A**, In the absence of calcium, tropomyosin covers the binding sites on actin and inhibits cross-bridge formation. **B**, In the presence of calcium, troponin induces the tropomyosin to uncover the actin binding sites and allows cross-bridge formation.

**FIGURE 50-25** Relationship of the  $\alpha$ -motor neuron to the motor unit of muscle. The nerve impulse that a muscle fiber receives to begin contraction is transmitted through the  $\alpha$ -motor neuron. All muscle fibers innervated by a single motor neuron are part of one motor unit.

branches. Each branch ends in a structure called a **motor end-plate**. The end-plate is positioned near the sarcolemma of a single muscle fiber. All muscle fibers innervated by a single motor neuron are part of one motor unit (see Figure 50-25).

After the nerve impulse is transmitted from the cell body, it passes along the axon to the motor end-plate. Acetylcholine is released into the neuromuscular synapse and diffuses across to bind with receptors

on the skeletal muscle cell. More than enough acetylcholine is released with a single action potential to ensure depolarization of the muscle cell. Acetylcholine binding opens channels in the membrane that allow sodium ions ( $\text{Na}^+$ ) to flow into the cell. Depolarization of the motor end-plate area to threshold then opens voltage-gated channels and produces an action potential. An enzyme (acetylcholinesterase) in the synapse quickly degrades acetylcholine to stop receptor activation. The sarcolemma is depolarized, and an action potential spreads along the surface of the sarcolemma and into the interior of the fiber through the transverse tubules (T tubules). The **sarcoplasmic reticulum**, a calcium-storing structure, fills the space between myofibrils and forms sacs. The sacs, the terminal cisternae, are positioned close to the T tubules. When the action potential passes down the T tubules, free calcium from the terminal cisternae is released into the myofibrils. Release of the calcium ions stimulates the actin-myosin cross-bridge, thereby causing muscle tension. After depolarization, or when the sarcolemma becomes electrically stable, calcium ions rebind in the sarcoplasmic reticulum and the muscle fiber relaxes.

The motor unit is the functional unit of skeletal muscle and consists of the  $\alpha$ -motor neuron and all of the muscle fibers that it innervates. When stimulated, all of the muscle fibers innervated by a motor unit will respond as one. This response is called the **all-or-none response**, which means that the motor unit will contract to its maximum or it will not contract at all. The size of the contraction of the muscle depends on the number of motor units recruited. The greater the demand placed on the muscle or the more stimuli provided, the greater the number of motor units firing. Fibers of each motor unit are not in contact with each other but are dispersed throughout muscle and intermixed with other fibers. If a single motor unit is stimulated, a large section of muscle visibly contracts. If additional motor units of the nerve are stimulated, the muscle can contract with greater force. **Recruitment** is the term used for calling in more motor units in response to an increase in stimulation of the motor nerves.

## Types of Muscle Contraction

**Electromyography** is used to evaluate muscle contraction. With electromyography, aspects of the contractile process such as time relationships between the beginning of electrical activity and the actual contraction of the muscle may be studied. The mechanical response of a muscle to electrical stimulation causes movement in the joint, control of joint motion, or joint stabilization.

### Twitch Contraction

The fundamental unit of recordable muscle activity on electromyography is the muscle twitch. A **twitch** is the mechanical response to a single stimulus of a motor unit. After stimulation, a latency period follows before tension in muscle fibers begins to increase. This **latency period** is the time required for elastic structures to tighten to prepare for the development of tension. The time from initial tension development to peak tension is called the **contraction time**. The period between peak tension and zero tension is the **relaxation time**.

An action potential in a muscle lasts only a fraction of a second. It is possible for a series of action potentials to be initiated before completion of the first twitch. The mechanical response to repetitive stimuli is known as **summation**. The period before a second stimulus can induce a twitch during the latency period of the first muscle twitch so no additional response of the muscle occurs is termed the **refractory period**.

The frequency of motor unit stimulation is quite variable. The greater the frequency of stimulation, the greater the tension produced in the muscle. A muscle may achieve higher levels of work when it shortens immediately after being stretched. The elastic components of muscle do not entirely account for this phenomenon. Some energy

must be stored in the contractile component of muscle. If the stimulus is so great that the ability of the muscle to increase tension is exceeded, the muscle is said to be “in tetanus.” In this situation, the speed of stimulation is faster than the contraction-relaxation time of the muscle. Little relaxation occurs before the next contraction.

The variable grade of contraction demonstrated by muscles is important. Repetitive twitching of all recruited motor units develops as a summation of contractions of the muscle, which is responsible for the smooth movements of skeletal muscle.

Based on the mechanical activity that they exhibit, muscles can be divided into two groups: **slow twitch** (type I, red) and **fast twitch** (type II, white). Slow-twitch fibers contract and relax more slowly. They support high levels of oxidative metabolism instead of using glycolytic processes to produce energy. Continual energy is provided by large amounts of myoglobin, which potentiates the action of stored oxygen. Slow-twitch fibers are modified for either prolonged or continuous muscle activity such as in the case of endurance marathon running and maintaining posture. These muscles have a high content of myoglobin.

Fast-twitch muscle fibers depend on energy released from the glycolytic process. Type II fibers are used for fast muscle contractions such as in sprinting, eye blinking, or jumping. Because of the lack of myoglobin in their fibers, they are white. Fast-twitch fibers fatigue more easily than slow-twitch fibers.<sup>8</sup>

### Concentric, Eccentric, and Isometric Contractions

Contraction of a muscle exerts a force that causes a torque, or turning, effect on the joint involved. When muscle force generates sufficient tension to overcome the resistance of a limb, the muscle will shorten and joint movement occurs. This shortening contraction is called a **concentric contraction**. Lifting a cup of water to one’s mouth is an example of concentric contraction of the biceps muscle. If the load is greater than the amount of tension that the muscle is able to generate, the muscle will lengthen even though it is contracting. A lengthening contraction is termed an **eccentric contraction**. Walking down stairs is an example of an eccentric contraction of the quadriceps muscles. A third type of contraction is an **isometric contraction**. No movement occurs, and the muscle maintains its specific length. Holding a weight in the hand with the elbow flexed is an example of an isometric contraction.

Combined actions of concentric, eccentric, and isometric contractions provide the body the ability to control movement and function in the environment. Walking, eating, and lifting require the interaction of various types of contractions to provide for smooth and coordinated activity. In a rehabilitative situation, it is interesting to note that isometric contractions generate greater tension than concentric contractions. Eccentric contractions may generate more tension than isometric contractions. When using strengthening programs in rehabilitation settings, a working knowledge of strengthening and tolerance of traumatized tissue is imperative to ensure safe reconditioning.

### Mechanical Principles

The amount of tension that a muscle can generate is dictated by a number of mechanical concepts or principles of relationship. These principles include the length-tension relationship, the load-velocity relationship, the force-time relationship, and the effects of muscle temperature change and muscle fatigue. Muscle tension, fatigue, and prestretching are other important factors in muscle force production. A brief review follows.

#### Length-Tension Relationship

Maximal tension is produced when muscle is at its usual resting length because this position allows actin and myosin filaments to overlap and

provide the maximal number of cross-bridges between filaments. At a short resting length, little tension or muscle shortening is possible inasmuch as myosin filaments abut the Z line. If muscle fiber is held at lengths beyond the resting length, tension decreases because actin and myosin do not overlap and therefore no active tension is present.

### Load-Velocity Relationship

The velocity of shortening of a muscle contracting concentrically is inversely related to the weight of the applied load. The lower the weight, the higher the velocity of contraction. The greater the weight, the slower the contraction of the muscle. An isometric contraction occurs when the load equals the amount of force that the muscle exerts. If the load exceeds the force generated by the muscle, an eccentric contraction occurs. Greater load leads to faster eccentric lengthening.

### Force-Time Relationship

The longer the time of contraction, the greater the force that the muscle can generate until the muscle reaches its point of maximal tension. An increase in the duration of force allows higher levels of tension to be produced by the contractile structures.

### Effects of Temperature Change

Conduction velocity across the sarcolemma increases with a rise in muscle temperature. Temperature elevation increases the enzymatic activity of muscle metabolism and the elasticity of collagen in elastic components. For example, the warm-up exercises performed by athletes increases muscle temperature as a result of the increased blood flow and heat generated by metabolism. Both of these changes increase the amount of force that a muscle can produce.

### Effects of Fatigue

The availability of ATP determines muscles' ability to contract and relax. Prolonged activity of muscles can be sustained only when the muscle has an adequate supply of nutrients and oxygen to synthesize ATP. If the activity is of sufficient intensity to deplete ATP faster than it can be replaced, muscle tension will gradually weaken and at some point drop to zero. When muscle returns to its original state, creatine phosphate, a major storage form of energy in muscle, must be resynthesized and glycogen stores replaced. This revitalization process requires energy, so the muscle will continue to consume oxygen at high rates even after termination of activity. Heavy, rapid breathing continues after a period of strenuous exercise to provide adequate oxygen for ATP synthesis. This oxygen is also essential for removing lactic acid from muscle. Resting muscle uses oxygen to re-form glucose and glycogen from lactic acid and to oxidize the lactic acid to carbon dioxide and water.

### Response to Movement and Exercise

Early mobilization may prevent muscle atrophy after surgery or injury. With early motion, muscle fibers position themselves in a more parallel alignment as opposed to the fibers in an immobilized individual. With movement, capillarization occurs more rapidly and tensile strength improves more quickly. With immobilization, the cross-sectional area of muscles decreases and oxidative enzyme activity is reduced. Early mobility prevents atrophy. Afferent impulses from the muscle spindles are increased, thus improving the stimulation of some muscle fibers.

Physical training and conditioning increase the cross-sectional area of muscle fibers. An increase in area coincides with an increase in muscle bulk and strength. In addition, stretching exercises are effective in preventing injury and improving performance, as well as increasing muscle flexibility, maintaining and improving joint motion, and enhancing the elasticity and length of the musculoskeletal unit.

### KEY POINTS

- The fundamental unit of muscle contraction is the sarcomere.
- A sarcomere extends from one Z line to the next and consists of interdigitating thick and thin filaments.
- Muscle contraction occurs when myosin head regions bind to sites on the actin filament to form cross-bridges.
  - After binding, myosin tugs on the actin filament, which causes thick and thin filaments to overlap more.
  - Myosin then releases and proceeds to bind at another point farther along the actin filament. Each cross-bridge cycle requires one molecule of ATP.
- For contraction to occur, the cytoplasm must have sufficient calcium ions.
  - In the absence of calcium, tropomyosin covers binding sites on the actin filament and prevents cross-bridge formation.
  - Another regulatory protein, troponin, controls the position of tropomyosin.
  - When calcium is bound to troponin, tropomyosin is moved to expose binding sites on actin, and cross-bridge formation ensues.
- Calcium ions are stored in the sarcoplasmic reticulum and released into the cytoplasm when the muscle cell depolarizes during an action potential.
- A group of skeletal muscle cells innervated by a single motor neuron is called a *motor unit*. All of the cells in the unit contract simultaneously when the motor neuron depolarizes.
  - An action potential in the  $\alpha$ -motor neuron releases acetylcholine at the motor end-plate. Acetylcholine binds to receptors on the muscle cell membrane and triggers an action potential in the cell. To generate more force in the muscle, a greater number of motor units can be activated, a process termed *recruitment*.
- Activation of a motor unit by a single action potential results in a brief twitch contraction.
- A train of action potentials in the motor neuron results in a sustained contraction, in which calcium is released into the cytoplasm faster than it is removed.
- Sustained contraction in response to repetitive stimulation is termed *summation*.
- Muscle contraction does not always result in muscle shortening.
  - Isometric contraction refers to contraction with no change in muscle length.
  - Eccentric contraction occurs when the muscle lengthens while contracting (because of a high load).
  - Muscle shortening with contraction is termed *concentric*.
  - Isometric contraction generates greater tension than concentric contraction; eccentric contraction may generate the highest amount of tension.
- The behavior of contracting muscle is governed by several mechanical principles:
  - Length-tension relationship: Up to a point, a greater resting length of the muscle generates a greater force of contraction. Optimal actin-myosin overlap occurs at about the usual resting muscle length.
  - Load-velocity relationship: The velocity of muscle shortening is inversely related to the weight of the applied load.
  - Force-time relationship: A longer contraction is associated with a greater force of contraction.
- Creatine phosphate is a storage form of energy that is quickly converted to ATP when cellular ATP levels fall.
- Fatigue results when energy and nutrient supply are insufficient.
- A higher rate of muscle oxygen consumption occurs during and for a period after muscle activity.
- Lack of muscle use (disuse) leads to a reduction in muscle mass and slowing of oxidative enzyme activity.
- Early activity after injury is associated with quicker recovery of tensile strength, less atrophy, and better circulation.

## GERIATRIC CONSIDERATIONS

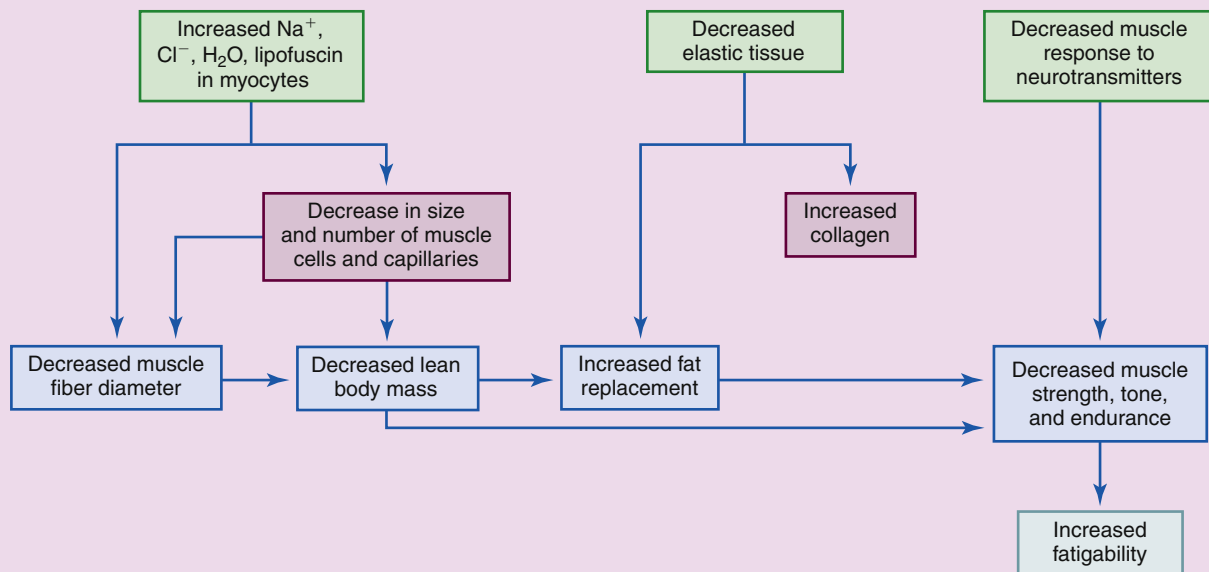

**Changes in the Muscular System**

With aging, the size and number of muscle cells decrease. The remaining muscle cells undergo atrophy, resulting in decreased muscle fiber diameter and reduced amount of elastic tissue. These changes result in reduced muscle mass. Within muscle cells, amounts of extracellular sodium, chloride, water, and lipofuscin pigment increase, with diminished intracellular potassium concentration. The loss of muscle protein may not be obvious because of increased collagen and fat replacement.

Because fewer capillaries are available to supply the muscles, removal of metabolites is decreased. Hormonal stimulation of muscle by testosterone, somatotropin, and thyrotropin is decreased, in addition to reduced muscle uptake of glucose during exercise.

Muscle response to nervous system stimulation is decreased with reduced amounts of muscle norepinephrine. Muscles are also less responsive to neurotransmitters, including acetylcholine at the myoneural junction, and cholinesterase activity is decreased as well.

The muscle, neural, and hormonal changes of aging that affect the muscular system lead to a functional decrease in muscle strength of 30% to 50%, reduced muscle endurance, diminished muscle tone, and increased fatigability. Muscular decline rises with increasing age and usually occurs earlier in men; however, the extent of muscular system decline varies. An elderly individual with good nutritional balance and protein intake combined with adequate active exercise maintains muscle function and strength.<sup>9</sup>

**SUMMARY**

The musculoskeletal system provides movement for the body. Alterations in function of the musculoskeletal system that decrease the efficiency of movement can often magnify the stress placed on uninvolved structures and increase the potential for degeneration, joint laxity, and pain.

A sound knowledge base of the anatomy, physiology, and mechanics of movement makes the diagnosis of aberrant movement and function easier and thus aids in planning the necessary care and education of patients. Too often, in attempts to provide relief for patients with musculoskeletal dysfunction, the tissue involved or the mechanism of activity causing the injury is not properly identified. Short-lived relief of pain may be provided through the use of analgesics. However, return to activity exacerbates pain and the restriction of movement present before medical care.

Familiarity with the musculoskeletal system also allows health care providers to identify basic tissues involved in injury or disease. Such awareness empowers the clinician to provide relief of pain as well as to address quality-of-life issues. Determination of the type of activity that creates the problem and identification of segments of the musculoskeletal system affected provide the basis to achieve positive long-lasting improvement. Weakness, instability, or decreased motion of structures involved in the dysfunction must be identified. Analysis of physical limitations can lead to patient education and referral to sources that can reduce the impact of physical limitations. In addition, use of recommended exercises, modification of living and working environments, and education of family members will help affected individuals achieve optimal motor function and prevent further injury. The effects of aging on the muscular system are described in Geriatric Considerations: Changes in the Muscular System.

A smoothly functioning musculoskeletal system facilitates a complete range of human actions, including walking, talking, running, breathing, and a myriad of voluntary physical activities. Any abnormality in the musculoskeletal system decreases the efficiency of movement and increases mechanical stress. Ballistic requirements of many sports and occupations, such as skiing and driving an automobile, have increased the potential for trauma. Diseases also disrupt the integrity of the musculoskeletal system. Infectious processes, genetic abnormalities, immune-mediated inflammatory disorders, and nutritional deficiencies may all affect movement.

Clinicians who work with patients experiencing dysfunctions of the musculoskeletal system must have a solid background in evaluation and management of such disorders. Without this preparation, interventions will not be sufficient to promote maximal functional return. This chapter discusses disorders particular to the musculoskeletal system as they affect the soft tissues, skeletal frame, and muscles.

**SOFT-TISSUE INJURIES**

In addition to injuries of the bony skeleton, soft tissue may also be traumatized. At times it is difficult to differentiate among the types of soft tissue. In an attempt to differentiate the exact site of a lesion, Cyriax<sup>1</sup> described two types of soft tissue: contractile and inert. **Contractile** tissue is composed of structures involved in the contraction of muscle and includes not only the muscle belly but also the tendon and bony insertion, called an enthesis. Although not involved in a pure contraction, as is the muscle belly, the tendon and its insertion into bone are mechanically linked to tension generated by the muscle. **Inert, or non-contractile**, tissue possesses no ability to contract or relax. Inert soft tissues include joint capsules, ligaments, bursae, fasciae, dura mater, and nerve roots. Passive stretching provokes pain from inert tissue. Evaluation of inert tissue lesions requires identification of all structures involved: the capsule of a joint, a section of a ligament or a nerve, or the mechanical displacement of the meniscus.

**INERT SOFT-TISSUE INJURIES****Ligament Injuries**

A **ligament** is a dense connective tissue with parallel-fibered collagenous tissues designed to connect bone to bone. Ligaments contribute to mechanical stability of the joint, guide motion, and prevent excessive motion. Injuries to ligaments occur when loading exceeds the physiologic range of motion. Microfailure precedes total failure of the

ligament. With total failure of a ligament, damage to surrounding soft tissue occurs. Ligament injuries are classified by the extent of tear and may be described as mild, moderate, or severe.

Grade 1 (mild) = stretching injury without instability

Grade 2 (moderate) = severe injury with instability but some ligament fibers still intact

Grade 3 (severe) = complete disruption of ligament<sup>2</sup>

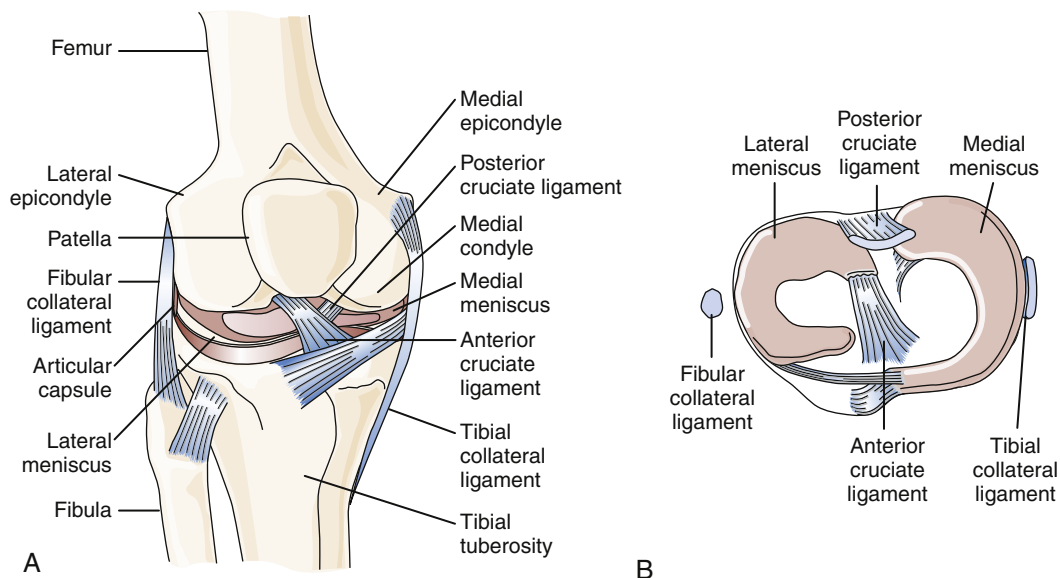

**Clinical manifestations.** A common site of ligament injury, particularly among athletes, is the anterior cruciate ligament of the knee (Figure 51-1). Symptoms may include a sudden “tearing” sensation or “popping” in the knee followed by pain with weight bearing and often acute swelling of the knee. Another common site for ligament injury is the anterior ankle (talofibular ligament).

**Treatment.** Treatment is geared primarily toward relief of symptoms, and recovery is usually complete. A moderate ligament injury is a definite tear in some component of the ligament with loss of strength. The fibers are not widely separated. Treatment is primarily protection of the ligament. With a severe ligament injury, the ligament is completely torn and no longer functions. Potentially the fragments are widely separated. Treatment may require surgical restoration of ligament continuity, when possible.

**Joint Capsule Injuries**

Another inert structure that is intimately involved in stabilization of a synovial joint is the **joint capsule** (Figure 51-2). The joint capsule is composed of an inner layer and an outer layer. The inner layer is highly vascularized but has minimal innervation. It synthesizes the hyaluronic acid component of synovial fluid, produces matrix collagen, and is essential for joint nutrition.<sup>3</sup> The outer layer of the capsule is attached to the periosteum of the bones through Sharpey fibers. The capsule is reinforced by ligaments and musculotendinous structures. The outer layer of the capsule is poorly vascularized but richly innervated by joint receptors. Joint receptors are able to detect the rate and direction of motion, proprioception, compression and tension, vibration, and pain.<sup>3</sup>

After injury to the joint capsule, the ensuing increase in vascularity and development of fibrous tissue lead to a thickening of the capsule. Any effusion into the joint cavity may lead to stretching of the capsule and its associated ligaments. The joint capsule, like ligaments, provides joint stability. The capsule, however, has an interesting mechanical adaptation: capsular redundancy. An example of the importance of the redundancy has been identified by Hettinga<sup>4</sup>: “The inferior medial portion of the shoulder joint capsule is a loose, redundant sac that becomes tense only when the shoulder is fully abducted or flexed.

**FIGURE 51-1** The principal structures of the interior of the knee joint. **A**, From the front. **B**, From above with the femur removed.

**FIGURE 51-2** Joint capsule.

The posterior capsule of the knee is loose in flexion but so tight in extension that it becomes an important stabilizer.”

Capsular redundancy provides for a stable joint at the end ranges of movement. Any injury or edema in the joint that causes scarring in the lax section of the capsule prevents full range of motion. Prolonged immobilization of a joint causes loss of mobility and extensibility of the capsule, with subsequent loss of motion. Immobilization of a joint causes an alteration in the flow of synovial fluid and contracture of the joint capsule and periarticular muscle. The altered flow of synovial fluid prevents fluid diffusion into and out of cartilage and causes compression and distention of cartilage. Nutrition of the joint components stagnates, leading to degenerative changes in the joint that become permanent. Contracture of the joint capsule and periarticular muscle results when fatty tissue proliferates in the joint space. This increase in the amount of connective tissue leads to adhesions that limit joint motion. The increase in connective tissue is due to failure to keep the latticework of tissue stretched open, which usually occurs by normal flexion and extension of muscle. The muscles bridging the immobilized joint also shorten.

### Adhesive Capsulitis

An example of such a restriction is loss of function in the shoulder after even a minor injury, leading to a “frozen shoulder,” also called adhesive capsulitis. With an injury to any component of the shoulder complex, inflammation occurs in the joint along with swelling and distention of the joint capsule. With prolonged immobilization, thickening of the capsule may ensue possibly attributable to proliferation of fibroblasts and capsular contraction. Capsular tightness leads to a loss of movement and an increase in pain, especially at night. Excessive joint motion may cause a tearing of the capsule, similar to a ligamentous tear, and render the joint unstable. Conservative treatment of the frozen shoulder is usually recommended with intraarticular corticosteroid injections, gentle stretching and physical therapy, and anti-inflammatory medication. Prevention of adhesive capsulitis involves avoiding prolonged or excessive immobilization of the shoulder after minor injuries and performing early, gentle stretching.<sup>3</sup>

### Internal Joint Derangement

Internal joint derangement may be caused by injury to inert soft-tissue structures. Meniscal tears at the knee, labrum tears at the glenohumeral joint, and disk tears in the temporomandibular joint all cause restrictions of the joint and may lead to soft-tissue dysfunction in the form of weakness, loss of motion, or pain. Tears of the medial and lateral menisci in the knee are common causes of knee pain, with the medial meniscus being torn more often. A meniscal tear is usually the result of a twisting motion.

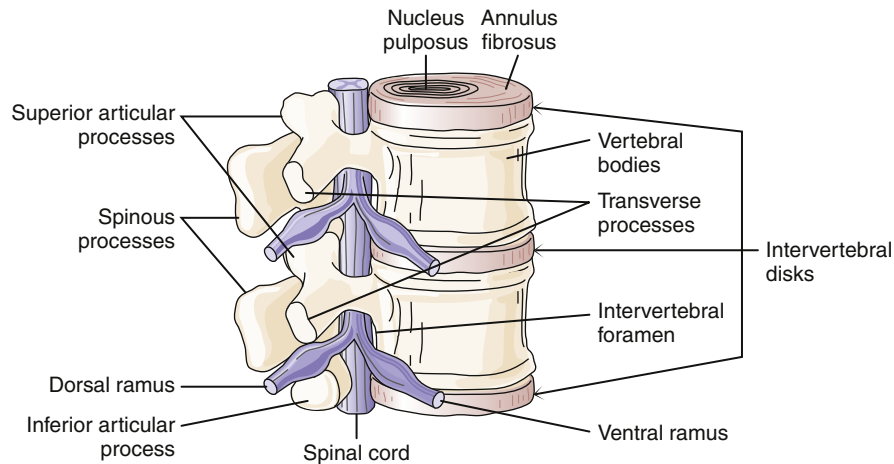

The anterior and posterior cruciate ligaments prevent anterior and posterior displacement of the tibia relative to the femur, respectively (see Figure 51-1). These ligaments can be torn in varying degrees of severity. Injury to either ligament leads to some degree of instability in the knee joint.

### Injuries to Fasciae and Bursae

Fasciae and bursae may also be causes of pain and restriction of movement of the musculoskeletal system.

### Fasciae

When connective tissues of the body are arranged in sheaths that envelop muscles, they are designated **fasciae**. Individual muscles are

**FIGURE 51-3** Lateral view (somewhat superior) of a segment of the lumbar part of the vertebral column.

surrounded by a thin fascia called the **perimysium**. Trauma to fascia, as with any soft tissue, may cause edema and scarring. Restrictions in fascia movement cause a restriction in joint function.

### Bursae

In many locations between muscles or between muscle or tendon and bone, connective tissue forms a pocket lined with synovium that contains fluid. These pockets are identified as **bursae**. Bursae are located in areas of high friction and are designed to dissipate some of the stress. With faulty mechanics of the joint, repetitive movement, or direct trauma, the bursal sac may become inflamed (bursitis) and extremely painful. Bursitis, because of its strategic position at stress points of muscle function, causes major disruption of movement. An inflamed bursa may restrict any movement of the joint and lead to restriction in capsular function or muscle dysfunction as a result of edema. Some of the more common sites of bursitis include the trochanteric bursa (lateral hip), subacromial bursa (shoulder), pes anserine bursa (medial knee), and olecranon bursa (elbow).

### Injuries to Nerves, Nerve Roots, or Dura Mater

Trauma to any soft tissue may lead to adhesive constriction of the nerve, nerve root, or dura mater. Irritation or entrapment of a nerve causes pain that radiates along the structures innervated by that nerve. Pain, altered sensation (numbness and tingling), motor weakness, and diminished reflexes may result from trauma to these essential soft-tissue components of the musculoskeletal system.<sup>5</sup>

An example is trauma to vertebrae in the lumbosacral area with nerve root impingement. Components of the intervertebral disk can herniate and cause pressure on nerve roots (Figure 51-3). The intervertebral disk is a shock absorber located between vertebrae. The center is a gelatinous-like material, the nucleus pulposus, which has a high water content. The nucleus pulposus is surrounded by the fibrous annulus fibrosus. Trauma to the back can cause unequal pressure on the disk leading to herniation. Common sites of disk problems are at L3 to L4, which affects the L4 nerve root; L4 to L5, which affects the L5 nerve root; and L5 to S1, which affects the S1 nerve root.

## CONTRACTILE SOFT-TISSUE INJURIES

### Injury to Tendons

Injury to tendons occurs along a continuum from a minor strain, in which a few fibers of the tendon are torn, to a complete tear or

rupture. The sheath in which a tendon slides may also be traumatized. Inflammation of the tendon within the sheath is called **tendinitis**. This inflammation may be due to infection, direct injury, or injury from repetitive motion. Tendons are injured when the stress placed on them is greater than the fibers can tolerate. Muscle tendons that are subjected to high tensile stress or compression are more prone to injury. Frequently injured tendons include the following: extensor pollicis brevis and abductor pollicis longus of the thumb (de Quervain disease), rotator cuff of the shoulder, biceps brachii tendon, tendons of the patellar complex, quadriceps tendon, hamstring tendon, Achilles tendon, and posterior tibialis tendon.

### Muscle and Tendon Strains

Muscle trauma compromises the contractile unit. As in the case of injury to a tendon, tears in a muscle may range from a minor tear to complete rupture. Most injuries to muscle are due to abnormal muscle contraction. Muscle and tendon strains are often categorized by the severity of injury in a scale similar to that used for ligament injuries: mild, moderate, and severe, with the latter term applying in the setting of total rupture of the contractile structure.

### Blunt Trauma

A soft-tissue contusion or crush injury also compromises the contractile structure. Any blunt trauma that causes bleeding into the muscle belly may lead to an inability to contract the muscle. Hemorrhage in a muscle belly has the potential to coagulate and calcify. This abnormal calcification in a muscle results in a painful condition called **myositis ossificans**. Calcification prevents a normal and strong contraction of the muscle involved.

### Compartment Syndrome

**Compartment syndrome** is due to trauma to soft tissue caused by the unyielding structure of inert tissue. Causes of compartment syndrome may be divided into three categories: decreased compartment size, increased compartment content, or externally applied pressure. With an injury, edema causes an increase in pressure within the compartment. Because volume is expanding in a confined area, pressure reduces capillary flow. Muscle and nerves become ischemic, with a resultant excruciating pain and tissue damage. For a more detailed discussion of compartment syndrome, see the Complications of Fractures section later in this chapter.

**FIGURE 51-4** Edema formation. With trauma, increased capillary permeability and dilation cause leaking into tissue space. Initially clear, the exudate in the tissue space becomes more viscous with an increase in the amount of plasma protein.

### Soft-Tissue Healing After Trauma

Trauma to soft tissue results in disruption of the circulatory and lymphatic systems. Hemorrhage, fluid loss, and cell death result. Blood vessels at the site of trauma constrict, which limits blood loss from the affected area. Norepinephrine mediates this initial constriction response, which may last a few minutes. Serotonin (from mast cells of connective tissue) and platelets prolong vasoconstriction. These processes may also contribute to vasodilation in inflamed tissue.

Platelets adhere to collagen fibers and release serotonin and adenosine diphosphate, which causes platelets to adhere to the traumatized endothelial wall and form a platelet plug that temporarily decreases bleeding. Trauma to the endothelial surface triggers release of an enzyme that initiates clotting by converting prothrombin to thrombin, which converts fibrinogen to fibrin. The endothelial surfaces of small vessels are also compressed, thereby ensuring that vessels remain closed after vasoconstriction has ceased. In the early stages of inflammation, the endothelial margins of the venules may be covered with neutrophilic leukocytes, a process called neutrophilic margination. At this point the release of histamine from mast cells, basophils, and platelets causes vasodilation and increased permeability of venules. With the increase in permeability, serous fluid containing cells and plasma proteins accumulates as edema in tissue spaces (Figure 51-4). This edema fluid contains fibrinogen, which forms fibrin through an interaction with thrombin. Fibrin seals damaged lymphatics and confines the inflammatory reaction to an area immediately surrounding the injury.

### Wound Repair

The inflammatory response prepares injured tissue to progress to the healing process of repair and reorganization. Figures 51-5 and 51-6 provide a summary of the phases of wound repair. The acute response lasts about 2 weeks, and the subacute phase lasts another 2 weeks. When the wound is clear of foreign substances, an infiltrate of macrophages and fibroblasts is noted. A matrix of collagen, hyaluronic acid, and fibronectin develops. Lymphatics form in the matrix, prevent additional edema, and assist in preventing infection. This granulation tissue develops in the wound space. Macrophages have an important role in wound repair.

Next in the process of wound repair is reepithelialization of the wound surface. Epidermal cells migrate over established epidermal cells until the defect is closed. The formation of basement membrane

follows. This membrane is first laid down at the wound periphery and then progresses to the center of the wound. A strong bond forms between epidermal cells and the newly formed basement membrane to complete reepithelialization (granulation tissue formation).

Wound tensile strength is a result of the deposition of collagen. Collagen production begins approximately 5 days after myofibroblast migration into the wound space. Hyaluronic acid, found in the extracellular matrix, assists glycosaminoglycans to stimulate fibroplasia. Myofibroblasts secrete an extracellular matrix, which induces cell migration and proliferation, and synthesize proteoglycans, which stimulate collagen formation and increase tissue resilience and tensile strength. By the end of the first month, tensile strength begins to increase, but several months are required to achieve the maximal level. Collagen reaches its maximal strength approximately 3 months after injury. Maximal tensile strength is only 70% to 80% of preinjury levels.

Revascularization (angiogenesis or growth of new blood vessels) must take place to ensure survival of the new tissue. Vascularization occurs through the development of new circulatory networks in the wound and reattachment of existing vessels. The formation of extracellular matrix, the development of endothelial cells, and the presence of lactic acid and heparin are a few of the factors that stimulate revascularization.

Wound closure or contraction is the final phase of healing in soft-tissue injuries. Contraction begins soon after injury and is completed in approximately 2 weeks. Myofibrils assist in wound closure. Interaction between extracellular matrix and granulation tissue results in a contractile unit called a *fibronexus*. Cytoplasmic actin binds to the fibronexus and draws tissue together to ensure a stable wound. As tension increases across the wound, collagen fibers are reoriented and collagen phagocytosis increases. Complete organization and concentration of collagen may require more than 40 weeks. In the case of rupture of soft-tissue structures, surgical intervention may be necessary to ensure that the traumatized tissue is in close enough proximity to allow healing.

#### KEY POINTS

- Soft-tissue injury refers to injuries of noncontractile elements (joint capsule, ligament, bursa, fascia, dura mater, and nerve root) and contractile elements (muscle and tendons).
- Ligament, tendon, and other soft-tissue injuries are classified on the basis of the severity of fiber disruption.
- Passive stretching causes pain in noncontractile tissue injury, whereas active contraction is painful in contractile injury.
- Noncontractile tissue injuries generally cause altered range of motion around a joint as a result of pain, edema, adhesion, or fibrosis.
- Contractile tissue injuries are characterized by decreased muscle strength.
- Compartment syndrome is a dangerous complication of soft-tissue injury that results from swelling of injured tissue within a restrictive fascia. Unless pressure is quickly reduced, compressed tissue may become ischemic and necrotic.
- Soft-tissue injury results in local inflammation and initiates the process of wound healing. Strength of the injured tissue is improved by the deposition of collagen. Normalization of collagen may require more than 40 weeks.

## BONE INJURIES AND INFECTIONS

### BONE AND JOINT TRAUMA

The skeletal system is subject to alterations in function from mechanical stress and infection. The purposes of the skeletal system are to protect internal organs, contribute to mineral homeostasis, produce blood cells, and provide muscle attachment sites and thus facilitate

body movement. Bone is one of the body's hardest structures, as well as one of its most dynamic and metabolically active tissues. Bone is vascular with a capacity for repair. It adapts to mechanical demands placed on it and alters its configuration in response to those mechanical stresses.

### Types of Bone

Two basic forms of bone are present in the human body: cortical bone and cancellous bone. **Cortical bone** forms the cortex, or outer shell, of the bone. Cortical bone is designed to tolerate compression and shearing forces, but tension forces may exceed the tolerance of cortical bone. Most fractures are due to tension failures in which bone is pulled apart. With bending, twisting, or straight tension, stress may exceed the bone's tolerance, and a fracture occurs on the convex side of the bend. **Cancellous bone**, which has a spongy or lattice-like appearance,

is found in the interior of bones. Unlike cortical bone, cancellous bone does not tolerate compression stress. Cancellous bone provides structural support to cortical bone and increases a bone's potential to withstand stress.

### Fracture

A **fracture** is a break in continuity of a bone, an epiphyseal plate, or a cartilaginous joint surface. Trauma generating enough energy to fracture a bone also produces force sufficient to traumatize adjacent soft tissue. With that concept in mind, the remainder of this section will address injury to the bony component of the musculoskeletal system.

### Types of Fracture

Fracture type reflects the type of tension stress placed on bone (Figure 51-7). A **transverse** fracture occurs in a straight line at approximately

**FIGURE 51-5** Steps in wound healing by first intention and second intention. In the latter, the resultant scar is much smaller than the original wound because of wound contraction. (From Kumar V et al: *Robbins basic pathology*, ed 9, Philadelphia, 2013, Saunders.)

a 90-degree angle to the longitudinal axis of the bone. **Spiral** fractures are the result of rotational forces and cause bone to separate in the form of an S around the bone. **Longitudinal** fractures split bone along its length. **Oblique** fractures result from a rotational force, but unlike spiral fractures, the break is along an oblique course (45-degree angle) and does not rotate around the entire bone. **Comminuted** fractures consist of more than one fracture line and more than two bone fragments. These fragments may be shattered or crushed. Comminuted fractures often present considerable treatment problems because of associated soft-tissue damage and multiple bone fragments. An **impacted** fracture is caused by excessive force that telescopes or drives one fragment into another. A **greenstick** fracture is an incomplete break in the bone with the intact side of the cortex flexed. It is usually seen in children. A **stress** fracture is a failure of one cortical surface of the bone, often caused by repetitive activity such as running. Without proper treatment, a stress fracture can become a complete fracture with two distinct fragments. An **avulsion** fracture is the separation of a small fragment of bone at the site of attachment of a ligament or tendon.

Of special concern are fractures at or near a joint line in children. This location of a fracture may suggest an epiphyseal growth plate fracture (Figure 51-8). With epiphyseal injuries, the potential for

disruption of growth of the long bones is present. Proper reduction and fixation are necessary to avoid growth disturbance in fractures through the growth plate. Crush injury to the epiphyseal plate commonly leads to premature growth cessation. Cancellous bone does not tolerate compression stress; it buckles and then cracks. Therefore, **crush** or **compression** fractures (Figure 51-9) are consistent with cancellous bone trauma. In children, a compression injury to cancellous bone of the metaphysis of a long bone is identified as a **buckle** fracture, where bone buckles and eventually cracks. In adults, compression fractures are often found in a vertebral body of the spine, especially in older individuals with osteoporosis.

**Extent of Fracture**

Fractures can be classified according to extent and depth. A **displaced** fracture is one in which the ends of fracture fragments are separated. In a **nondisplaced** fracture, the fracture fragments remain in alignment and position. With a **depressed** fracture, the fragment is displaced below the level of the surface of the bone, usually in the skull. A **complete** fracture is one in which the fracture line disrupts bone continuity through the whole thickness of the bone, including the cortex (Figure 51-10). In an **incomplete** fracture, the cortex of the bone buckles or cracks; however, bone continuity is not disrupted. Incomplete fractures tend to occur in the more flexible, growing bones of children. Fractures can also be classified as **open** (compound) or **closed** (simple) (Figure 51-11). An open fracture occurs when bone is broken and an external wound leads to the fracture site. These fractures present an increased risk of infection and are therefore difficult to manage. A closed fracture is a fracture in which the fragments do not extend through mucous membrane or skin and skin is not broken.

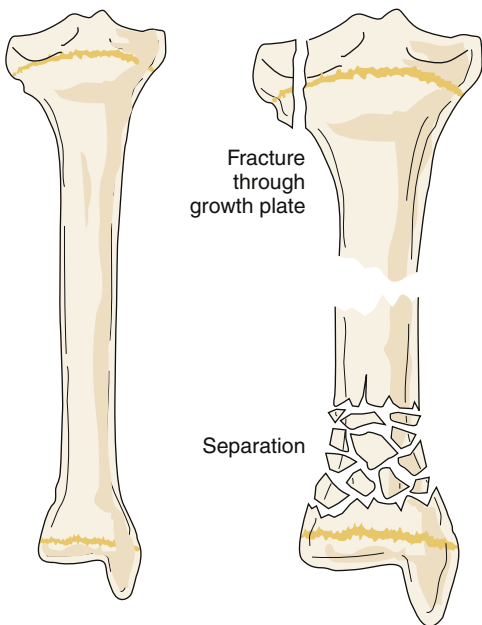

In cases of open fractures, a wound classification system may be used that ranges from type I to type IIIC in increasing degree of severity. Type I is a wound smaller than 1 cm, moderately clean with minimal contamination. The fracture is a simple transverse or an oblique fracture with a bone spike piercing the skin. Soft-tissue damage is minimal. Type II wounds are larger than 1 cm with moderate contamination. The fracture might be a moderate comminution or crush injury with moderate soft-tissue damage. Type III wounds have a high degree of contamination. The fracture is severely comminuted and unstable. It is accompanied by much soft-tissue damage involving muscle, skin, and neurovascular structures. Traumatic amputations would be classified here. With type IIIA wounds, soft-tissue coverage of the fracture is sufficient. Segmental or severely comminuted fractures occur with these wounds. Type IIIB wounds with open fractures include extensive injury or loss of soft tissue, as well as periosteal stripping and bone exposure. Fractures are severely comminuted. Massive contamination

is found with such wounds. Type IIIC wounds include any open fracture associated with arterial injury requiring repair regardless of the extent of soft-tissue injury.<sup>2</sup>

### Diagnosis of Fracture

In addition to a careful history and physical examination, diagnosing a fracture most often starts with plain radiographs of the skeletal area in question. It is essential to obtain views from at least two angles, preferably at 90 degrees from each other. Whenever possible, more than two views should be taken, which may increase the sensitivity of finding a fracture. Radiographs must be of optimal quality (proper exposure and angles) and include the entire bone or joint in question.

Occult nondisplaced fractures (including stress fractures) may not be seen on plain radiographs acutely. If a fracture is suspected but not easily seen, one may choose to immobilize the area as if a fracture was confirmed and then repeat the plain films in 1 to 2 weeks. Fine

**FIGURE 51-10** Comparison of complete and incomplete fractures.

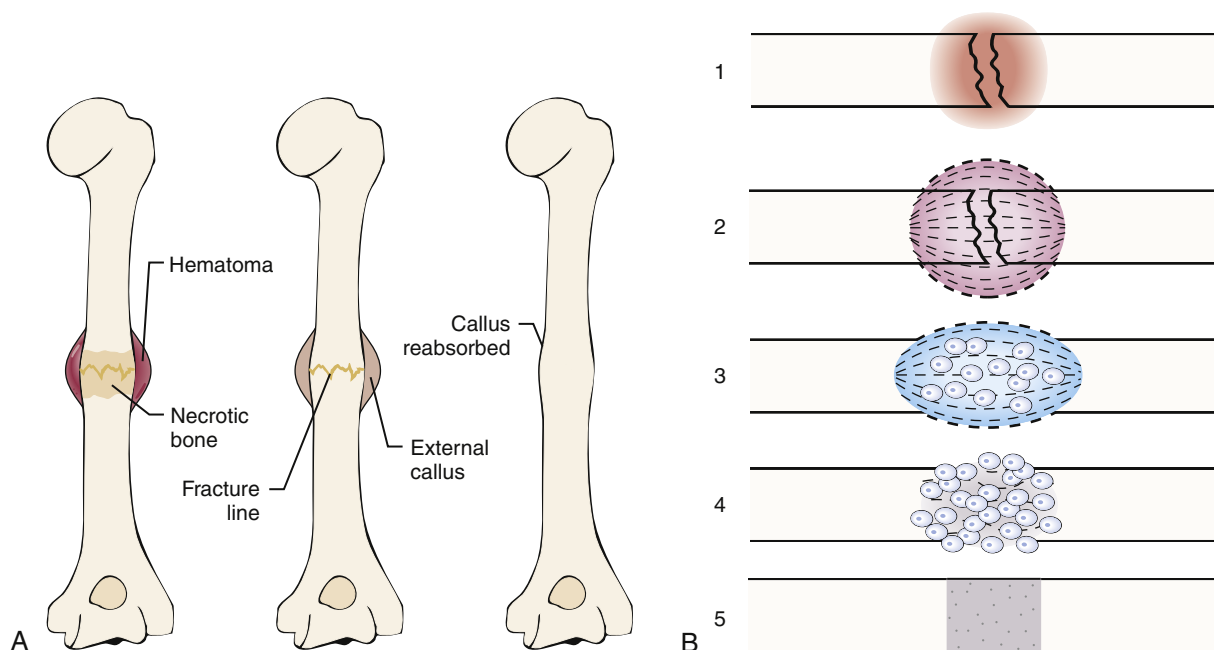

**FIGURE 51-11** Comparison of open and closed fractures.

fractures not seen on acute films may become evident on later studies. Alternatively, computed tomography (CT) or magnetic resonance imaging (MRI) can be very useful to reveal occult fractures or non-displaced fractures in areas not easily seen on plain films (such as the scaphoid of the wrist or the femoral neck).<sup>6</sup>

### Treatment of Fracture

Initial management of a simple fracture may include icing, elevating, and immobilizing the affected limb as soon as possible to minimize soft-tissue injury. Two main goals of treatment often include fracture reduction and immobilization. Fracture reduction means restoring the limb as close to the normal anatomic position as possible. This may need to be considered emergently if there are any concerns for

**FIGURE 51-12** **A**, Stages of healing of cortical bone. **B**, Bone healing (schematic representation). 1, Bleeding at broken ends of the bone with subsequent hematoma formation. 2, Organization of hematoma into fibrous network. 3, Invasion of osteoblasts, lengthening of collagen strands, and deposition of calcium. 4, Callous formation: new bone is built as osteoclasts destroy dead bone. 5, Remodeling is accomplished as excess callus is reabsorbed and trabecular bone is deposited. (**B**, From Lewis SM, et al: *Medical-surgical nursing*, ed 8, St Louis, 2011, Mosby.)

neurovascular compromise or potential for ischemia to the distal limb. The purpose of immobilization is to maintain the proper alignment of the reduced fracture until adequate bone healing occurs.<sup>7</sup>

Fracture immobilization may be accomplished through different means depending on the nature and severity of the fracture. For simple nondisplaced fractures, a hard cast may be the most useful. For injuries that involve considerable soft-tissue damage, splinting may be preferable over a cast because of the risk of compartment syndrome (see Complications of Fractures). Functional bracing can sometimes be used to allow joint movement while still securing the bone (such as in some types of humeral fractures).

In some circumstances, surgical intervention to reduce and immobilize the injured bone may be preferred or even required such as in cases of open fractures when debridement of the wound is needed or when multiple injuries are present. Intraarticular fractures often require surgical fixation to preserve joint motion and fractures with severely displaced bone may require surgical reduction and fixation. In other instances, when a rapid return to mobility is desired, surgical fixation may have an advantage over nonsurgical treatment.<sup>7</sup> Internal fixation may include plates and screws attached to bone or intramedullary nails placed within long bones. External fixation utilizes fixation devices applied temporarily until an injury or the patient is stabilized and a more permanent treatment initiated. This may be needed in the setting of multiple fractures, compromised blood supply, contaminated open fractures, or extensive surrounding tissue damage.

Further treatment options may also include bone grafting to bridge wider gaps in a displaced fracture or electrical bone stimulation, which utilizes negative current applied through the use of a bone stimulator to induce bone formation.

Other treatment considerations must include indications for antibiotic prophylaxis in the setting of open fractures, tetanus prophylaxis,

pain medication, and eventual rehabilitation of the soft-tissue structures surrounding the fracture.

### Healing Process

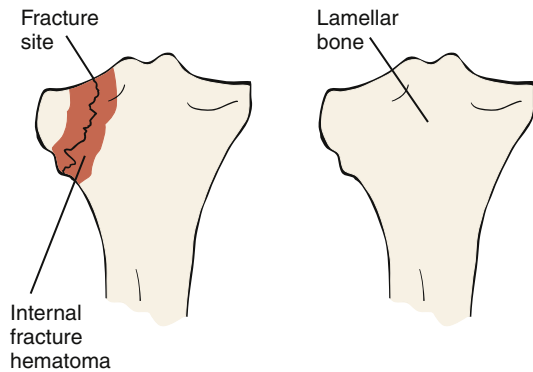

When a fracture occurs, the continuity of both cortical and cancellous bone is usually compromised. The five stages of fracture healing are described in Chapter 50.

**Healing in a cortical bone.** At the time of fracture in a cortical bone, blood vessels in the haversian systems are torn. After a period of bleeding, clotting occurs at the fracture site and for a short distance on both sides of the fracture. Because of lack of circulation, a small section of bone distal to the fracture site undergoes necrosis (Figure 51-12). The avascular bone eventually is replaced by living bone through resorption and bone deposition. The majority of bleeding occurs from arteries in the periosteal sleeve.

The hematoma that forms becomes the medium for early stages of healing. Osteogenic cells, which develop from the periosteum, form the external and internal callus. If the periosteum is severely torn, healing cells must proliferate from the mesenchymal cells of surrounding soft tissue. During the early stages of repair, the amount of osteogenic tissue is extensive. Within the first few weeks, the thick mass of osteogenic tissue has formed a fracture callus.

During the initial stages of **callus formation**, no bone cells are present within the matrix. The callus is quite soft but becomes progressively firmer. With consolidation of the fracture callus, new bone formation begins. Initially, new bone forms at the edges of the periosteum, where the blood supply is more substantial. Where blood supply is sufficient, osteogenic cells differentiate into osteoblasts and primary woven bone. Near the fracture site, where the blood supply is less adequate, osteogenic cells initially differentiate into chondroblasts (cartilage).

As both the external callus (which unites cortical bone) and the internal callus (which unites cancellous bone) harden from the cartilage

**FIGURE 51-13** Healing of cancellous bone.

stage through ossification, the fracture site becomes firm and stable. No movement is detected by the medical evaluator or patient. At this point the fracture is clinically united. Although stable, cartilage and primary woven bone may be found intermixed at the site of healing.

With time, the primary callus is replaced by mature bone, and any excess callus is reabsorbed. This phase is the remodeling (last) stage of bone healing. When all immature bone cells have been replaced by mature lamellar bone, the fracture is said to be consolidated (radiographic union).

**Healing in a cancellous bone.** Cancellous fracture healing occurs mainly through development of an internal callus. The rich blood supply present in cancellous bone prevents necrosis of bone at the fracture site. If the fracture is nondisplaced, the healing process is much more rapid than that of cortical bone. Osteogenic cells in the trabeculae form the primary woven bone in the internal fracture hematoma (Figure 51-13). The internal callus fills the open space of cancellous bone and crosses the fracture site. Woven bone develops and is eventually replaced by lamellar bone. As noted earlier, cancellous bone is susceptible to compression forces, and the majority of injuries incurred are compression-type fractures. With a compression fracture, fragments of bone are impacted together, which provides a more suitable environment for healing of cancellous bone. Rapid union occurs because fracture fragments move in unison.

### Complications of Fractures

**Delayed healing.** Fracture healing may not always progress smoothly without complications. Delayed union, malunion, and nonunion of the fracture are all complications that might occur. Delayed union is usually identified anywhere from 3 to 6 months after the fracture, when bone pain and tenderness are continuously increasing beyond the expected healing period for the wound type. Healing is slowed. The cause of delayed union might be either distraction of fracture fragments or the consequence of systemic causes such as infection. Bone healing can be delayed by additional factors such as smoking, malnutrition, use of corticosteroids, and poor vascular circulation to the area. Elderly patients or those with disease comorbidities, such as diabetes, coronary artery disease, peripheral vascular disease, or osteoporosis, are at particular risk.<sup>7</sup>

**Nonunion** occurs when a fracture has not healed after 6 months. Failure to heal is due to poor blood supply and repetitive stress on the fracture site, and can be the result of interposition of muscle, tendon, or soft tissue between fracture pieces; prolonged or excessive traction; poor immobilization that allows motion at the fracture site; poor internal fixation; or wound infection after internal fixation.

**Malunion** results when unequal stresses of muscle pull and gravity lead to improper alignment of fracture fragments. It often happens in

the case of fractures managed with cast immobilization after skeletal traction. Malunion may also occur if an ambulatory device is applied before the fracture is firm or if the extremity is subjected to weight bearing too early in the healing process. Primary features of malunion are external deformity and radiographic evidence of internal derangement. Prevention is adequate reduction and immobilization of the fracture and adherence to specific activity and positioning restrictions.<sup>7</sup>

**Osteonecrosis.** Osteonecrosis, also termed avascular necrosis, is a condition of compromised circulation to bone leading to ischemia and death of bone tissue. In the setting of a fracture, this can occur as a result of direct occlusion or injury of blood vessels because of fracture displacement or dislocations. Most common locations include the femoral head, proximal scaphoid, proximal humerus, and talar neck.<sup>7</sup>

**Osteomyelitis.** Osteomyelitis, a severe bone infection, can occur following an open fracture as a result of direct invasion of bacteria into bone from a nearby contaminated soft-tissue wound or direct penetration by a contaminated foreign body or contaminated surgical equipment (see Infections of the Bone for further discussion).

**Compartment syndrome.** Compartment syndrome is a result of the accumulation of pressure in a soft-tissue compartment that is restricted by unyielding fasciae. This process can occur as a result of any type of severe soft-tissue injury. Compartment syndrome may be classified as acute, chronic, or crush. In the case of severe soft-tissue damage surrounding a fracture, the acute classification is of concern because it is the most severe form and often requires surgery urgently.

A compartment is a portion of the body where muscles, nerves, and blood vessels are enclosed within tissue such as fasciae. Compartment syndrome can be triggered by injury to the tissues surrounding bone with soft-tissue inflammation, swelling, and, in some cases, hemorrhage into the area. This increase in edema causes an increase in pressure attributable to the restriction of the surrounding compartment fasciae. Decreased blood flow from arterial damage can also occur, which leads to hypoxia of the cells of capillary walls. Capillary integrity is diminished and colloid proteins and fluid escape into the extravascular tissues, causing further swelling and escalation of the intracompartmental pressures. If the tissue pressure exceeds the intravascular pressure, blood vessels will collapse, impeding blood flow and leading to further hypoxia and worsening edema. Intracompartmental pressures of 30 to 40 mm Hg can compromise microcirculation in muscle. The excessive compartment pressures lead to hypoxia, damage, and eventual necrosis of the soft tissue, especially muscles and nerves. Emergent decompression is needed to preserve limb viability. Compartment syndrome can also occur as a result of extrinsic compression, such as that of a cast on an injured, swollen limb.<sup>2</sup> Symptoms of compartment syndrome are pain out of proportion to the injury, paralysis, paresthesia, pallor, and pulselessness. Compartment syndrome is noted most often with injuries to the leg (anterior, deep posterior, superficial posterior, and lateral), forearm, upper arm (deltoid, biceps), hand (interosseus), and thigh (quadriceps).

**Fat emboli syndrome.** Fat emboli syndrome occurs when, following a fracture, fat particles are released from bone marrow (especially from the pelvis or long bones) into the bloodstream and lodge in the vasculature of the lungs. Often occurring within 24 to 72 hours of the trauma, fat emboli syndrome may be subclinical or may lead to respiratory failure and death. The patient may be noted to have shortness of breath, rapid breathing, hypoxemia, and a fine petechial rash (especially on the torso and neck area) as well as altered mental status or focal neurologic deficits. A plain chest x-ray may be normal and often a CT scan or ventilation-perfusion scan of the chest is more useful in diagnosis. Treatment is predominantly with ventilatory support. Early mobilization of fracture patients is advisable when possible to reduce the risk of this complication.<sup>2</sup>

**Deep venous thrombosis and pulmonary embolism.** Deep venous thrombosis and pulmonary embolism should be considered in a patient who develops chest pain, dyspnea, and hypoxemia more than 5 days after a fracture. This occurs when a thrombus forms in a distal extremity and clot fragments break loose to enter the circulation, thereby lodging in the lung circulation. Those with highest risk include patients with multiple traumatic injuries, patients with pelvic or long bone fractures who require more than 5 days immobilization in bed, obese patients, patients with a prior history of deep venous thrombosis, or patients with other risk factors for coagulation disorders. Diagnostic testing is similar to that of fat emboli syndrome and treatment includes ventilatory support as well as anticoagulation therapy. Prevention of thrombosis often includes administration of anticoagulation prophylaxis, implementation of intermittent pneumatic compression devices, and early mobilization of the patient whenever possible.<sup>2</sup>

**Neurovascular injury.** Neurovascular injury after a fracture may be due to either the fracture or the treatment for the fracture. Neurovascular damage occurring at the time of fracture may be the result of any of the following: the force causing the fracture, fracture fragments, hemorrhage, joint dislocation, or the body position assumed after trauma. Neurovascular damage related to treatment may be due to moving or splinting the fracture, manipulation at the time of reduction of the fracture, application of stabilizing devices such as a cast or splint, or the presence of hemorrhage or edema.

### Dislocations and Subluxations

Two additional mechanical alterations in the musculoskeletal system are dislocations and subluxations. A **dislocation** is displacement of a bone from its normal position to the extent that articulating surfaces completely lose contact.<sup>7</sup> A **subluxation** is displacement of a bone from its normal joint position to the extent that articulating surfaces partially lose contact.<sup>7</sup> A dislocation or subluxation can occur when forces cause one aspect of the joint complex to move beyond its normal anatomic limit. A considerable amount of tissue damage occurs in dislocation and subluxation, including possible ligament tear or rupture. With any dislocation, especially first-time dislocation, evaluation for a fracture is necessary. Although almost any joint may dislocate, some joints are more prone to dislocation than others. Joints most commonly dislocated are small joints of the fingers, the patella, and the shoulder. Symptoms of dislocation are pain, alteration in the normal contour of the joint, change in extremity length, and loss of normal mobility. Treatment must include consideration of local soft-tissue trauma and healing.

#### KEY POINTS

- Bones are subject to different types of fracture, depending on the type of tension stress imposed.
- Fractures can be classified according to the orientation of the break as transverse, longitudinal, oblique, or spiral.
- A comminuted fracture consists of more than one fracture line and more than two bone fragments.
- A greenstick fracture is an incomplete break.
- Fractures are classified as open or compound when the skin is penetrated and as closed or simple when the skin is not broken.
- Healing of fractured cancellous bone occurs more quickly than healing of cortical bone.
- Treatment goals of fractures are to minimize soft-tissue injury, maintain proper alignment until adequate bone healing can occur, and prevent complications as much as possible.

- Trauma causes hematoma formation, followed by callous formation; the callus is initially soft and cartilaginous; then it progressively ossifies to become firm and stable.
- Radiographically apparent union occurs when the callus has been completely replaced by mature bone.
- Delayed union, nonunion, and malunion are potential complications of a fracture that does not heal in a normal time period and with proper alignment.
- Compartment syndrome after a fracture can result when a buildup of pressure occurs in a soft-tissue compartment because of edema and inflammation within restrictive fascia layers. It is usually a surgical emergency.
- Symptoms of compartment syndrome include severe pain, pallor, paresthesias/paralysis, or pulselessness.
- Fat emboli syndrome and deep venous thrombosis with pulmonary emboli are two possible complications of a fracture that can lead to dyspnea, chest pain, hypoxemia, and respiratory failure.
- Complete separation of joint articulating surfaces is termed *dislocation*. Subluxation refers to partial separation. Soft-tissue damage is the primary problem.

## INFECTIONS OF THE BONE

### Osteomyelitis

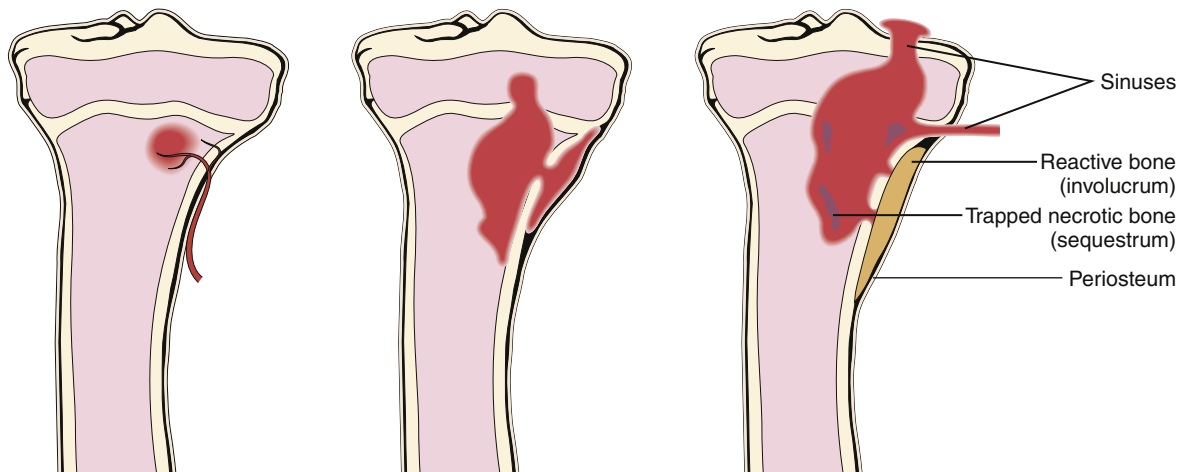

**Osteomyelitis** is a severe pyogenic infection of bone and local tissue that requires immediate treatment. Organisms may reach bone by one of three routes: (1) via the bloodstream (hematogenous osteomyelitis), (2) from adjacent soft tissue (contiguous focus), and (3) by direct introduction of the organism into the bone.

**Etiology and pathogenesis.** *Hematogenous osteomyelitis*, in which the infectious agent may be introduced by blood from infection elsewhere in the body, is the most common type of osteomyelitis. It occurs most often in children younger than 16 years (mean age of 6 years old) and elderly adults, intravenous (IV) drug users, and patients with indwelling central lines.<sup>8-9</sup> It involves bone rich in red marrow. In children as well as infants, these are long bones and the infection usually begins acutely in the metaphyseal region of the bone. Blood-borne bacteria reach the marrow space via the nutrient artery, or after blunt trauma a hematoma develops; thus a pathway for the organism to reach the bone is present (Figure 51-14).

**Clinical manifestations.** In children, acute hematogenous osteomyelitis manifests as a high fever and pain at the site of bone involvement. The infection may remain localized if it becomes enclosed by fibrotic tissue reaction, a condition referred to as a *Brodie abscess*. Muscle spasms, redness, and swelling are common, and the child may refuse to move the limb. In adults, hematogenous osteomyelitis is more difficult to detect. Symptoms are vague and may include fever, malaise, anorexia, night sweats, and weight loss. Pain at rest is common. The diagnosis may be supported by radiographic signs of bone destruction. The most common causative organism is *Staphylococcus aureus* followed by *Streptococcus pneumoniae*, with gram-negative bacillary infections increasing in frequency. In children between 2 months and 3 years of age, *Haemophilus influenzae* can also be a cause though this is quite rare since the development of a vaccination.<sup>9</sup>

Osteomyelitis secondary to an introduced or contiguous focus of infection can occur after burns, sinus disease, trauma, malignant tumor necrosis, periodontal infection, or an infected pressure ulcer. Again, *S. aureus* is the most common pathogen; however, some infections are polymicrobial and include gram-negative and anaerobic agents.

Direct invasion of the organism into bone can occur as a result of open fractures; penetrating wounds; surgical contamination; or

**FIGURE 51-14** Osteomyelitis. The bacteria reach the metaphysis through the nutrient artery. Bacterial growth results in bone destruction and formation of an abscess. From the abscess cavity, the pus spreads between the trabeculae into the medulla, through the cartilage into the joint, and through the haversian canals of the compact bones to the outside. These sinuses traversing the bone persist for a long time and heal slowly. The pus destroys the bone and sequesters parts of it in the abscess cavity. Reactive new bone is formed around the focus of inflammation. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

insertion of surgical instrumentation such as prostheses, metal plates, or screws. Infections caused by surgical instrumentation can act as a focus for bacterial reproduction.

During the acute stage of osteomyelitis, bacteria remain in bone and proliferate where the circulation is not optimal. Before puberty the bacteria grow in the metaphyseal sinusoidal vein, which leads to infection of the metaphysis near the growth plate. The loose attachment of overlying periosteum permits exudate to accumulate in the subperiosteal area. Uncontrolled infection can disrupt the cortex and lead to joint infection or septic arthritis, which can cause osteoarthritis to develop later in life. In infants, medullary infection can reach the epiphysis and joint surfaces via capillaries crossing the growth plate, and stunted growth and angular deformities can result. The growth plate in children is avascular, so infection is limited. The inflammatory reaction leads to pus formation, edema, and vascular congestion. Pus collects and is confined within bone, thus increasing pressure and adding to vascular occlusion, ischemia, and, finally, necrosis of bone. Volkmann and haversian canals allow a route for release of pus and thus spread of bacteria. Blood and therefore antibiotics cannot reach bone tissue when vascular system pressure equals arteriolar pressure. As a result, the course and virulence of the osteomyelitis are affected. Even after meticulous treatment, the organism can reappear years later in a context of trauma or immunosuppression.

**Healing complications.** If osteomyelitis is not managed or if the treatment is not sufficient, the resulting necrotic bone can separate from healthy bone into dead segments called *sequestra*. A sequestrum is then a medium for the continued bacterial proliferation described as chronic osteomyelitis. Sequestra can enlarge and extrude through bone into soft tissue, where it is possible that they might revascularize and resolve as a result of the body's defense mechanisms.

Osteoblasts may try to heal infected bone by isolating the dead tissue and forming an involucrum (a layer of new bone around old bone). Involucrum formation prevents successful effects of antibiotics and phagocytosis and leads to chronic infection.

Any type of osteomyelitis may become chronic, especially if the treatment was inadequate during the acute phase. It may be manifested months or years after assumed cure, especially after acute hematogenous disease. Drainage via a sinus tract to the skin can occur.

**Treatment.** Treatment usually includes 4 to 6 weeks of parenteral antibiotic therapy for acute osteomyelitis, although in children a typical course may be about 3 weeks in some cases. A shorter period of parenteral therapy followed by oral antibiotics can be effective if the infection is under control, the patient is afebrile, and a therapeutic blood level of the antibiotic can be maintained. Antibiotic choice is based on culture and sensitivity results.

If acute osteomyelitis is complicated by an abscess or extensive necrosis, the involved area is debrided and antibiotic therapy is instituted. If a prosthesis is involved, it is usually removed. After debridement, dead space is usually filled with packing, bone grafts, muscle pedicles, or skin grafts. In osteomyelitis associated with peripheral vascular disease, amputation is performed if antibiotic therapy is unsuccessful.<sup>2</sup>

## Tuberculosis

**Etiology and pathogenesis.** Bone and joint tuberculosis (TB) is an extrapulmonary form of TB that occurs after lymphohematogenous or sometimes contiguous spread from a primary lung lesion. It is estimated to occur in about 5% of patients with pulmonary TB worldwide.<sup>8</sup> As the incidence of TB increases in the United States, one can expect to see more cases of skeletal TB. Persons with skeletal TB may have a history of pulmonary TB, drug abuse, crowded and poor living conditions, diseases that depress the immune system, and immigration to the United States after 1991. Musculoskeletal TB is not communicable to others unless an open wound exists. *Mycobacterium tuberculosis*, the organism responsible for the destruction of bone and joint, is transmitted via the airborne route. Initially, infectious droplets are inhaled and infect lungs; then *M. tuberculosis* spreads hematogenously from lungs or lymphatic drainage to bone. The bacterium may lie dormant for a long time before it is detected.

**Clinical manifestations.** One of the more common sites of *M. tuberculosis*-infected bone (33% of skeletal TB cases) is in the vertebral column, particularly the lower thoracic and lumbar spine (called Pott's disease). Infection often begins at the anterior portion of the vertebral body and then spreads further into the bone, causing bony destruction, anterior wedging, and collapse. On x-ray, the appearance is of a lytic lesion in the bone without local sclerotic (new bone

formation) reaction. In about 50% of cases, the infection spreads to adjacent disks and paraspinous fluid may accumulate as a “cold abscess” that can be seen on CT or MRI of the spine.<sup>9</sup> Symptoms may include local pain, low-grade fever, and possible neurologic symptoms (weakness of lower extremities) attributable to local inflammation of nerve tissue and its surroundings as well as impingement.

Other common sites of skeletal TB or tuberculous arthritis include weight-bearing joints such as the hips, knees, and ankles, although any joint or bone could be involved.<sup>5</sup>

**Risk factors.** Persons most at risk for TB are those at extremes of age or individuals who are immunosuppressed or undernourished. Children are at higher risk for skeletal TB because of extreme vascularity. In acquired immunodeficiency syndrome (AIDS), knowledge of the patient’s human immunodeficiency virus status is critical to optimize the therapeutic plan for the patient.<sup>5</sup>

**Treatment.** Treatment for skeletal TB requires long-term combination antibiotic therapy. Agents such as isoniazid, rifampin, pyrazinamide, ethambutol, and others are used in combinations for at least 6 to 9 months with longer courses needed for certain drug combinations. Therapeutic response can be complicated by development of drug resistance. Surgical intervention may be indicated in cases of spinal TB when severe deformities or neurologic deficits are seen.<sup>9</sup>

**KEY POINTS**

- Bone infections may be from blood-borne organisms or direct traumatic infection.
- Osteomyelitis—organisms reach the bone by one of three routes: bloodstream (hematogenous osteomyelitis), adjacent soft tissue (contiguous focus), and direct introduction of the organism into the bone.
- *Staphylococcus aureus* and *Streptococcus pneumoniae* are the two most common organisms to cause bone infections in adults.
- Skeletal tuberculosis occurs when the TB infection spreads hematogenously or via the lung lymphatic drainage to bone and is most common in the vertebral bones, hips, and knees.
- Antibiotic therapy can help to reduce the progression of bone infection and is the first-line treatment; however, abscess formation and chronic infection may occur, requiring surgical intervention.

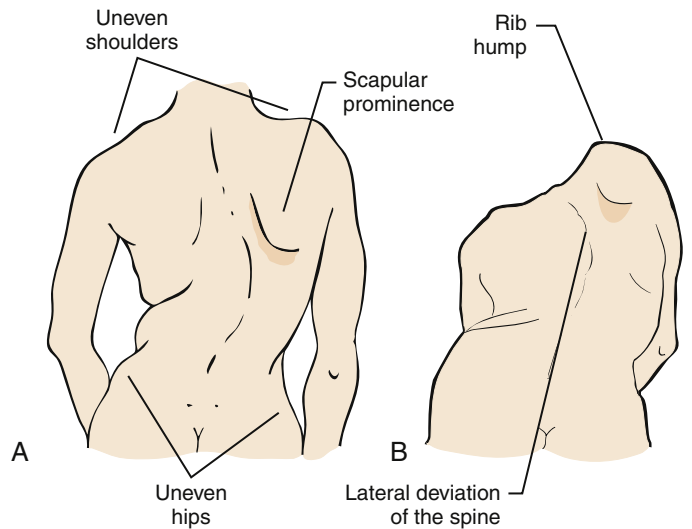

**ALTERATIONS IN BONE STRUCTURE AND MASS**

**BONE STRUCTURE DISORDERS**

**Scoliosis**

**Etiology and pathogenesis.** Scoliosis is a lateral curvature of the spine resulting in an S- or a C-shaped spinal column with vertebral rotation. Scoliosis can be a consequence of numerous congenital, connective tissue, and neuromuscular disorders. The majority of scoliosis cases are classified as idiopathic with an annual incidence in the general population of about 1%. The frequency is greater in children of women with scoliosis. The idiopathic form is more common in women.<sup>2</sup>

**Clinical manifestations.** Scoliosis may be described as either structural or nonstructural. Nonstructural scoliosis resolves when the patient bends to the affected side. No vertebral rotation or bony deformity of the vertebrae is present, and the condition is not progressive. When the patient bends laterally, the spine usually appears symmetric. The scoliotic curve will disappear on forward flexion. Nonstructural scoliosis may be related to postural problems, hysteria, nerve root irritation, inflammation, or compensation caused by leg length discrepancy or contracture (in the cervical spine).

**FIGURE 51-15** Structural scoliosis. **A**, The patient is standing erect, demonstrating the asymmetry of shoulder height as well as hip and scapular differences. **B**, The patient is bending forward at the waist, further emphasizing the spinal deviation and asymmetry of the shoulders and upper rib cage.

**Structural scoliosis, often called congenital scoliosis,** is a lateral curve of the spine that fails to correct itself on forced bending against the curvature and has vertebral rotation. This type of scoliosis is more serious and involves deformity of the vertebrae and asymmetric changes in hip, shoulder, and rib cage positions. The patient lacks normal flexibility, and side bending becomes asymmetric. This type of scoliosis is progressive, and the curve does not disappear on forward flexion. Severe structural scoliosis may require intensive therapy or surgical intervention to halt progression and correct deformities.<sup>2</sup>

Scoliosis is detected by typical asymmetric changes (Figure 51-15), including: (1) uneven shoulders or hips, (2) shoulder or scapular prominence, (3) rib or chest hump when bending over, and (4) a C- or S-shaped spine. A scoliometer can be used to assess the angle of trunk rotation when the patient is bent in a forward flexion position. Scoliosis is usually diagnosed after puberty because of a tendency for the curve to be accentuated during periods of rapid skeletal growth. The diagnosis is confirmed by radiographic examination of the spine. The degree of curvature is determined from radiographs and is classified as right or left, depending on the direction of convexity. Mild degrees of curvature may be managed conservatively with exercise and frequent reevaluation to assess progression to more significant deformity. Surgery is indicated for curvatures of 40 to 50 degrees or greater, or in cases of significant progression of scoliosis in spite of bracing and other conservative therapies.<sup>2</sup>

In addition to body image disturbances, scoliosis predisposes a patient to a number of physiologic problems. Respiratory difficulties from restricted expansion of the lungs may occur. Severe forms may be associated with significant pain. Gastrointestinal dysfunction can result from compression of abdominal organs. If uncorrected, scoliosis may progressively worsen with age owing to increased upper body weight and gravitational forces exacerbating the vertebral deformity. Over time, significant degenerative changes to the intervertebral disks can occur.

**Treatment.** Treatment for structural scoliosis is aimed at correcting spinal malalignment. Nonsurgical measures include primarily braces and exercises. Bracing applies constant pressure to the spinal convexity to straighten the curve. Braces must be worn for prolonged periods each day to be effective. Compliance is a major difficulty because the

**FIGURE 51-16** Micrographs of osteoporosis. On the left is normal bone. On the right is osteoporotic bone with decreased density and loss of trabeculae. (From Fillet HM: *Brocklehurst's textbook of geriatric medicine and gerontology*, ed 7, Philadelphia, 2010, Saunders. Courtesy of Professor A. Boyde, Department of Anatomy and Developmental Biology, University College, London.)

braces are stiff and uncomfortable. Spinal muscle strengthening should accompany brace therapy because trunk musculature loses tone after prolonged bracing.<sup>2</sup> Surgical intervention includes spinal realignment, fusion, and bracing with internal appliances, and most surgical procedures require prolonged body immobilization postoperatively.

Conditioning exercises to strengthen muscles and correct posture are used to treat nonstructural, or postural, scoliosis.

#### KEY POINTS

- Scoliosis is a lateral deformity of the spinal column that is detected from asymmetry of the shoulders, hips, and chest wall.
- Scoliosis may be described as structural or nonstructural.
- Severe scoliosis can compromise lung expansion and lead to a restrictive respiratory disorder.

## METABOLIC BONE DISEASES

### Osteoporosis

**Etiology and pathogenesis.** Osteoporosis, the most common metabolic bone disease, affects an estimated more than 10 million people in the United States and leads to more than 1.5 million osteoporotic fractures each year.<sup>8</sup> It occurs when the rate of bone resorption is greater than that of bone formation, osteoblastic and osteoclastic balance is disrupted, and the levels of mineral and protein matrix components are decreased (see discussion on Bone Remodeling in Chapter 50). The number of trabeculae is decreased and the width and mass of bone mass are reduced, which leads to fragile bone and thus fractures (Figure 51-16). Cancellous bone is lost faster than cortical bone, with fractures happening earlier in cancellous bone (vertebrae) than in cortical bone (femoral neck).

A current definition of osteoporosis is based on gradations of bone mineral density (BMD), which is most commonly measured by dual-energy x-ray absorptiometry (DXA). This yields a T score, which is the number of standard deviations the patient's BMD measurement is greater than or less than the young normal mean BMD value. A Z score is the number of standard deviations greater than or less than the mean BMD value of age-matched controls. The World Health Organization

(WHO) defines osteoporosis as bone mineral density (BMD) greater than or equal to 2.5 standard deviations below the mean peak BMD of young normal women (a T score less than  $-2.5$ ).<sup>8</sup> Osteopenia, which also carries an increased risk of fracture, is defined as a T score between  $-1.0$  and  $-2.5$ . Because hip fractures are not uncommon in women with BMD in the osteopenic range, other risk factors for fractures and progression to osteoporosis must be considered. The World Health Organization has developed a computer-based Fracture Risk Assessment tool (FRAX) that calculates a 10-year probability of hip fracture based on multiple variables, including age, body mass index, tobacco use, alcohol use, corticosteroid use, history of rheumatoid arthritis, and personal and parental history of fractures.

The specific cause of osteoporosis is not known. However, the rate of bone loss is influenced greatly by age, genetics, estrogen level, and risk factors. A family history of osteoporosis is a major risk factor. The normal bone loss that occurs with aging is accelerated during menopause, with the most rapid phase of loss occurring in the first 5 years because of the sudden decrease in estrogen concentration. The exact mechanisms of estrogen action are unclear, but estrogen derivatives may influence osteoblast activity and the production of local cytokines and growth factors that modulate the balance of bone resorption and formation. Estrogen deficiency increases the risk of osteoporosis by stimulating bone resorption over formation. Other risk factors include small frame, Caucasian or Asian race, early surgically induced menopause, high doses of thyroid hormone supplementation, use of corticosteroid drugs (such as prednisone), a diet low in sources of calcium and vitamin D, physical inactivity, and smoking or increased alcohol intake. Patients with chronic renal disease often have abnormal parathyroid function, as well as altered calcium and vitamin D metabolism, which can lead to a decline in bone mass. Furthermore, chronic inflammatory diseases, such as rheumatoid arthritis or systemic lupus erythematosus, can be associated with increased risk of osteoporosis, even independent of corticosteroid use (Box 51-1).<sup>8</sup>

**Clinical manifestations.** Evaluation of the patient must include an assessment of risk factors because osteoporosis is most often asymptomatic until a fracture occurs. On physical examination of someone with longstanding disease, the patient may have a Colles fracture, femoral or hip fractures, or vertebral compression fractures. Obvious kyphosis of the thoracic spine (dowager's hump) may be present. The patient often

**BOX 51-1 RISK FACTORS FOR OSTEOPOROSIS****Common Risk Factors**

Female gender  
 Ethnicity (Caucasian or Asian)  
 Family history  
 Increased age  
 Low calcium intake (<400 mg/day)  
 Low body weight  
 Smoking  
 Alcoholism  
 Prolonged immobilization

**Comorbid Diseases Increasing Risk**

Rheumatoid arthritis  
 Cushing syndrome  
 Hyperthyroidism and thyroid replacement therapy  
 Hyperparathyroidism  
 Anorexia nervosa or exercise-induced amenorrhea  
 Chronic obstructive pulmonary disease  
 Ankylosing spondylitis  
 Celiac disease  
 Hypogonadism  
 Type 1 diabetes

**Genetic Disorders Increasing Risk**

Osteogenesis imperfecta  
 Menkes syndrome  
 Ehlers-Danlos syndrome  
 Marfan syndrome  
 Homocystinuria

**Medications Increasing Risk**

Corticosteroids  
 Thyroid hormone supplements  
 Heparin  
 Antiepileptic agents  
 Gonadotropin-releasing hormone agents  
 Aromatase inhibitors  
 Cytotoxic/immunosuppressive drugs

Data from Klippel JH, Stone JH, Crofford LJ, White PH, editors: *Primer on the rheumatic diseases*, ed 13, New York, 2008, Springer.

has shortened stature, muscle wasting or spasms of back muscles, and difficulty bending over. The patient may complain of impaired breathing (because of deformities of the spine and rib cage) and poor dentition. Screening bone density measurement is also generally accomplished using DXA, assessing BMD of the hip (trochanter, femoral neck, and total hip), spine (L1 to L4 vertebral bodies), and sometimes the distal radius. Laboratory tests may show normal levels of urinary and serum calcium, phosphorus, and alkaline phosphatase but elevated serum osteocalcin levels. Radiographic and computed tomographic findings may show diffuse radiolucency of bones, sparse transverse trabeculae, normal vertical trabeculae, indistinct articular cortices, wedge-shaped thoracic vertebrae, biconcave lumbar vertebral bodies, and possibly old or new compression fractures.

**Treatment.** Treatment varies depending on the cause. Moderate, regular exercise such as walking or riding a stationary bicycle is valuable in prevention as well as treatment of osteoporosis. Physical therapy exercises for individuals who are immobilized or paralyzed are helpful as well.

**Calcium and vitamin D.** Both calcium and vitamin D are necessary for maintenance of bone mass. Calcium is needed as a constituent of bone and vitamin D is essential for increasing intestinal absorption of calcium and for calcium uptake into bone. In vitamin D deficiency states, calcium absorption can decrease from a normal rate of 30% to 40% to just 10% to 15%.<sup>10</sup> Vitamin D must be metabolized to its active form, 1,25-dihydroxyvitamin D<sub>3</sub>, which is also regulated by the kidneys. Although sun exposure can increase vitamin D production in skin, this source is often inadequate, even in warm climates. Recommendations for calcium supplementation vary but most experts recommend 1000 to 1200 mg daily—preferring calcium citrate, which does not depend on an acidic environment in the gut for absorption. Vitamin D deficiency can be detected by measurement of blood levels, with a goal of at least 20 mg/ml. Many believe a level of 30 mg/ml not only increases BMD but may also decrease risk of falls by a stimulatory effect on muscle function.<sup>10</sup> The recommended doses of daily vitamin D<sub>3</sub> are 400 to 1000 IU; also, in a deficient state 2000 to 4000 IU daily appears to be safe.

**Antiresorptive agents.** The most often used antiresorptive agents are the bisphosphonates (alendronate, risedronate, ibandronate, and zoledronate), which increase BMD and decrease fracture risk by inhibiting bone resorption by osteoclasts while osteoblast-related bone formation continues. These agents bind to hydroxyapatite in the bone, thus blocking the enzymes needed for osteoclast cell structure stability during resorption.<sup>11</sup> Questions about long-term use (>5 years) of bisphosphonates have arisen with the concern that the longevity of bisphosphonate binding into the bone may decrease bone's ability to repair microtrauma and be associated with atypical fractures. One such complication is osteonecrosis of the jaw, which, though very rare, has been reported particularly in patients receiving intravenous bisphosphonates for the treatment of bone cancer. Another rare complication under study is the atypical femoral fracture, which occurs below the level of the trochanter and also may be at slightly increased risk in patients taking bisphosphonates for prolonged periods. Ultimately, the risk of a fracture attributable to untreated osteoporosis is 7- to 10-fold higher than the risk of these rare complications. It is recommended that after 5 years of bisphosphonate therapy, a drug "holiday" of 2 years or more be considered with subsequent BMD testing being used to determine need for further treatment.<sup>11</sup>

Other agents for the treatment of osteoporosis include teriparatide, a recombinant human parathyroid hormone, which is the only true anabolic agent. Parathyroid hormone, when given at intermittent doses, increases BMD by stimulating bone turnover with the rate of bone formation exceeding that of resorption. It is approved for daily subcutaneous administration, but its use is limited to 2 years because rat studies have shown an increase in risk for osteosarcomas.<sup>11</sup> Denosumab is a monoclonal antibody that inhibits the receptor activator of nuclear factor κB ligand (RANKL). By binding and inhibiting RANKL, osteoclast activity is suppressed and bone resorption is decreased. This agent is given subcutaneously every 6 months.

**Other causes of osteoporosis.** Disuse osteoporosis may occur with prolonged bed rest, which leads to an increase in osteoclast activity and resorption of bone greater than osteoblast accumulation. Stress placed on bone as a result of weight bearing is necessary for osteoblast function. The stress of exercise stimulates new bone growth as a result of changes in electrical charges on the bone surface.

The loss of bone density following a period of reduced weight bearing may be restored upon return to normal activity, although recovery may not be complete. Osteoporosis may also occur when collagen formation is impaired in such conditions as scurvy, protein deficiency, or Cushing syndrome.

### Rickets and Osteomalacia

**Clinical manifestations.** Rickets and osteomalacia are characterized by deficits in mineralization of newly formed bone matrix either in the growing skeleton (rickets) or in the mature skeleton (osteomalacia) with resulting soft osteopenic bone. Deficiency of vitamin D prevents maintenance of normal levels of calcium and phosphorus. Children may have either vitamin D-resistant rickets or congenital hypophosphatasia. In rickets, cartilage in the growing epiphyses fails to calcify. Cartilage is not replaced by bone and continues to enlarge, leading to widening of epiphyseal plates and irregularity of the junction with the metaphyses. Bone is poorly calcified and less rigid. Kyphosis, genu valgum (“knock knee”), and genu varum (“bowleg”) are common deformities as well as growth retardation. Delayed eruption of the teeth, enlargement of costochondral junctions, and decreased muscle tone can all be seen.<sup>12</sup>

**Osteomalacia** is the adult counterpart of rickets with defects occurring after closure of epiphyseal plates. Osteomalacia is always due to an inadequate concentration of vitamin D, calcium, and/or phosphorus in the body as a result of any of the following factors: decreased intestinal absorption of vitamin D and calcium attributable to poor intake or malabsorption; poor vitamin D metabolism attributable to decreased sun exposure; renal disease (especially chronic renal failure or nephrotic syndrome); or a combination of these conditions.<sup>12</sup> In the case of vitamin D deficiency, calcification fails to occur and the bone is soft. Patients may complain of bone pain and muscle weakness, and plain x-rays may show bowing of bones and “pseudofractures.” All bones are affected, but weight-bearing structures may collapse and cause compression-type fractures.

**Treatment.** Treatment involves correction of the underlying deficiency with adequate intake of vitamin D supplementation (especially vitamin D<sub>3</sub>). Adequate intake of calcium and phosphate is also indicated by dietary adjustments or supplements.

### Paget Disease

**Paget disease of bone** (osteitis deformans) is a slowly progressive metabolic bone disease characterized by an initial phase of excessive bone resorption, mediated by osteoclasts, followed by excessive bone formation (Figure 51-17). The end product is a disorganized mosaic of bone matrix composed of woven and lamellar bone at affected sites of the skeleton. This new bone is less compact, more vascular, and more fragile, which accounts for the deformities and fractures of Paget disease.

**Etiology and pathogenesis.** The specific cause of Paget disease is unknown, but the disease has a familial tendency, suggesting a genetic component. It is prevalent in parts of northern Europe and the United States but rare in Africa or Asia.<sup>12</sup> It has also been theorized that a viral infection may affect osteoclastic function, leading to aberrant bone remodeling. Changes in certain cytokines produced in the local bone marrow environment may also influence the bone formation/resorption balance. In the United States, about 1% of individuals older than 40 years have Paget disease, with males being affected slightly more than females.<sup>8</sup>

**Clinical manifestations.** In the early stages the disease may not cause any symptoms; however, when pain develops, it can be severe and persistent bone pain. Fatigue and joint stiffness are also noted. In the initial stages of Paget disease, affected bones soften and tend to bend. As the disease progresses, irregular subperiosteal bone formation occurs and causes bone to become thick and hard. Thickening of cranial bones may cause compression of cranial nerves and result in vertigo, blindness, deafness (with or without tinnitus), headaches, and facial paralysis. Any bone can be affected, but the most common sites include the sacrum and spine (50%), femur (46%), skull (28%), and pelvis (22%).<sup>12</sup> Other complications may include hypertension, arthritis, calcific periarthritis, and pain.

**FIGURE 51-17** Diagrammatic representation of Paget disease of bone demonstrating the three phases in the evolution of the disease. (From Kumar V et al: *Robbins basic pathology*, ed 7, Philadelphia, 2003, Saunders, p 764.)

**Treatment.** During active stages of the disease, treatment focuses on preventing deformity and fracture, often with the use of calcitonin or bisphosphonates (such as alendronate, risedronate, or pamidronate, among others). These medications have been shown to decrease bone resorption, stabilize the fragile bone lesions, and reduce pain and the risk of fractures.<sup>12</sup>

#### KEY POINTS

- Bone density is a product of the rate of bone resorption and bone deposition.
- Osteoporosis occurs when the rate of bone resorption is greater than that of bone formation. A reduction in bone mass predisposes to fractures.
- Osteoporosis in women is defined by the WHO as a bone mineral density  $\geq 2.5$  standard deviations below the mean peak bone mineral density of young normal women.
- Hormone deficiencies (estrogen, androgen), poor calcium intake, and inadequate muscle use are common factors in the rate of bone loss.
- Treatment of osteoporosis should include adequate calcium and vitamin D supplementation along with a choice of antiresorptive agents (e.g., bisphosphonates), anabolic agents (e.g., teriparatide), or other inhibitors of bone resorption (e.g., denosumab) among others.

- Vitamin D deficiency is associated with rickets and osteomalacia, disorders characterized by soft, weak bones.
- Paget disease may be genetic. It has also been theorized that a viral infection may affect osteoclastic function, leading to aberrant bone remodeling. Painful deformities or bone fractures may result.

## BONE TUMORS

Neoplasms occurring in the musculoskeletal system can be benign or malignant with a relative incidence ratio of benign to malignant lesions of 200 to 1.<sup>2</sup> Benign tumors often are undiagnosed because they cause no pain. These lesions typically do not grow aggressively or metastasize; also, they do not tend to recur. Malignant neoplasms that originate in bone are referred to as *sarcomas*. These lesions can be very destructive, tend to regrow, and may metastasize.<sup>2</sup> More common than sarcomas are metastatic lesions, which have spread to bone from a primary tumor elsewhere. Primary carcinomas that most commonly metastasize to bone are breast, prostate, lung, and kidney carcinomas. Other malignancies that can metastasize to bone include cancer of the thyroid, bladder, uterus, colon/rectum, and vagina. Common sites of bone metastases are the vertebral bodies, pelvis, proximal ends of the femur and humerus, and ribs. Metastases occur via direct spread within a body cavity or by hematogenous or lymphatic spread.

Thus although the majority of bone tumors are metastatic, a number of primary tumors of bone can be identified. Some bone tumors are benign (Figure 51-18).

### Benign Tumors

#### Osteochondroma

**Etiology, pathogenesis, and clinical manifestations.** Osteochondroma is a common cartilage-forming benign tumor that is most often asymptomatic and may not be discovered until adulthood. Osteochondromas can be hereditary and are often found unintentionally.

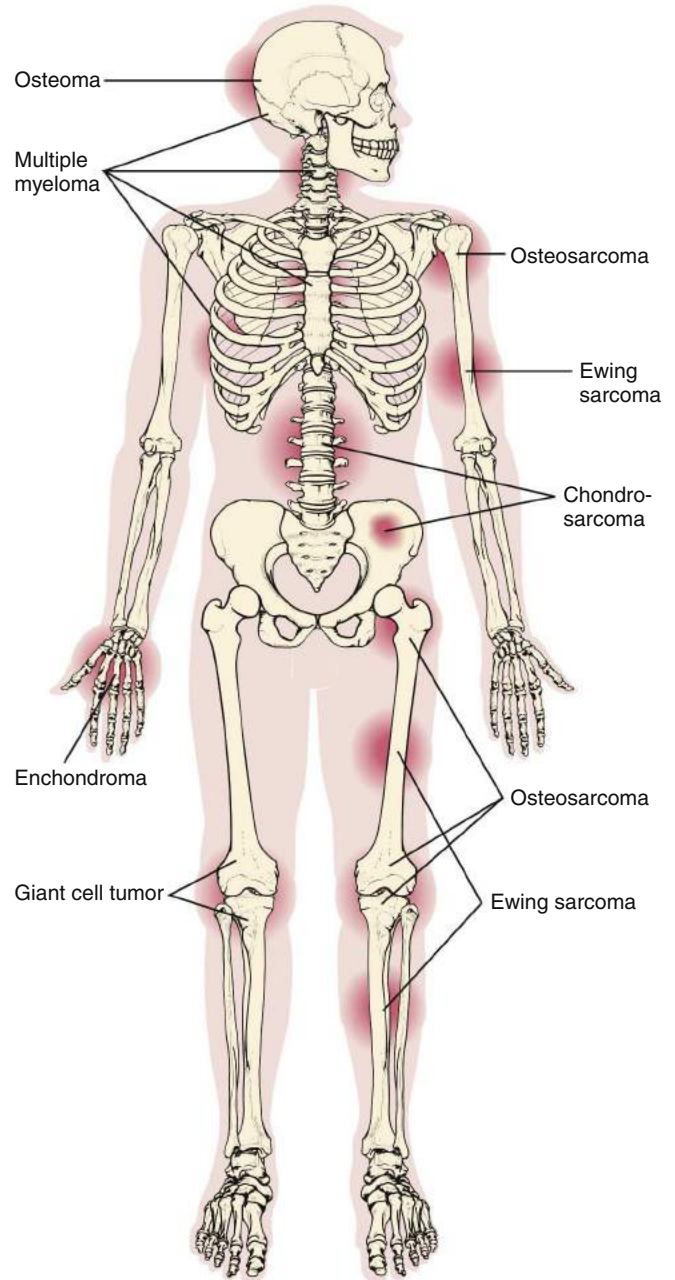

The lesion arises from a growth plate defect that can become pedunculated or sessile. Bony projections on the external surface of the bone are capped with cartilage. Pressure on surrounding soft tissue may cause pain. These tumors are usually located on the metaphyses of long bones such as the proximal end of the tibia and the distal part of the femur, the shoulder, and the pelvis (see Figure 51-18).<sup>2</sup>

#### Chondroma

**Chondroma** or enchondroma is a cartilage-forming tumor in bone that can be located in the medullary cavity or in the subperiosteal layers of bone.<sup>2</sup> It is believed to arise from remnants of epiphyseal cartilage. Chondromas develop most often in the small bones of the hands and feet but can be found in other areas. Tumor growth may erode the cortex of bone and expand the contour. Chondromas may be found incidentally, sometimes not until adulthood.

#### Osteoid Osteoma

**Osteoid osteoma** is one of the more common types of benign bone-forming tumor and accounts for approximately 10% to 13% of symptomatic benign lesions.<sup>2</sup> The patient often complains of persistent, dull pain, which is often worse at night and alleviated by aspirin or other nonsteroidal antiinflammatory drugs. This small lesion is often found in the cortex of the tibia and femur, but any bone may be involved. Radiographs show the lesion enclosed in a sclerotic shell. This tumor usually occurs in persons in their twenties.<sup>2</sup>

**FIGURE 51-18** Schematic presentation of the most common sites of origin of bone tumors. Most often, osteosarcomas originate in the metaphyses of long bones, chondrosarcomas arise in the axial skeleton, Ewing sarcomas develop in the diaphyses of long bones, and giant cell tumors originate in the epiphyses of long bones. Osteomas occur most often in the skull and enchondromas in the small bones of the hand. Multiple myelomas involve the calvaria, vertebrae, and ribs, but also other bones that contain hematopoietic bone marrow. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

#### Giant Cell Tumor

Many different tumors can contain giant cells but are not true giant cell tumors. A **giant cell tumor**, or osteoclastoma, is benign but aggressive with richly vascularized tissue consisting of plump spindle-shaped cells and numerous giant cells. These lesions account for about 5% to 10% of all primary bone tumors.<sup>2</sup> In some cases, giant cell tumors undergo transformation to sarcomas, a complication that is thought to

occur in less than 5% of cases. An increase in this transformation may be related to exposure to radiation therapy. The cells can metastasize without malignant transformation, in particular to the lung. Giant cell tumors commonly occur during the third decade of life and are slightly more common in females.<sup>2</sup> The area of development includes the distal end of the femur, proximal part of the tibia, distal part of the radius, and proximal end of the humerus (see Figure 51-18). Pain is the initial complaint.

## Malignant Bone Tumors

### Osteosarcoma

**Etiology and pathogenesis.** Osteosarcoma, an extremely malignant bone-forming tumor, is the most common primary malignant bone tumor (aside from multiple myeloma) and accounts for 20% of all primary malignant bone cancers. The majority of patients are adolescents and young adults 20 to 30 years of age, although cases can be seen in adults 60 to 70 years old. It develops in the metaphyseal region of long bones and is characterized by the formation of bone or osteoid by tumor cells. The most active epiphyseal growth areas—the distal end of the femur, proximal end of the tibia, fibula, and proximal end of the humerus—are common sites of involvement (see Figure 51-18). Lesions can also be seen in flat bones of the pelvis, skull, scapula, ribs, or spine.<sup>6</sup>

**Clinical manifestations.** Osteosarcoma grows rapidly and is quite destructive; destruction of the cortex of the metaphyseal region predisposes it to pathologic fracture. Metastasis to lungs is noted early in disease development. Pain may occur very early in the disease and become consistent and progressively more intense. Joint function may be compromised as a result of the proximity of the metaphysis.

**Treatment.** Although radical amputation was the only treatment previously employed, conservative surgery and chemotherapy are currently providing positive results, with studies showing 5-year disease-free survival rates between 70% and 85%.<sup>2</sup>

### Chondrosarcoma

**Pathogenesis.** A **chondrosarcoma** is a malignant cartilage-forming tumor most often diagnosed in adults 30 to 60 years old. These tumors usually develop slowly and have a higher cellularity and greater pleomorphism than a chondroma.

Secondary chondrosarcomas arise from benign lesions such as osteochondroma or multiple enchondromatosis, which undergo malignant transformation. These tumors develop in the pelvis and proximal ends of the femur and humerus in individuals between 20 and 40 years of age. Evidence of malignant transformation may include pain, an irregular border, or an increase in the proximal end of long bones after patient growth is complete.<sup>2</sup>

**Clinical manifestations.** Because of the slow growth of the tumor, pain is not usually a prominent clinical symptom. Even with a slow rate of development, the tumor will eventually metastasize, typically to the lung. Chondrosarcomas tend to develop in the pelvic and shoulder girdles as well as the ribs and the proximal ends of long bones such as the femur (see Figure 51-18).<sup>2</sup>

### Ewing Sarcoma

**Pathogenesis.** Ewing sarcoma is the third most common primary sarcoma of bone and is characterized as a rapidly growing malignant round cell tumor. This tumor most often develops in the bones of children and young adults between the ages of 5 and 25 years. Ewing tumor is composed of densely packed small cells with round nuclei. It arises in the medullary canal of bone and perforates the cortex of the shaft, producing a painful soft-tissue mass (with a central lytic area) overlying the involved bone. The tumor favors pelvic bones followed

by long tubular bones, such as the femur, tibia, humerus, or scapula (see Figure 51-18).<sup>2</sup>

**Clinical manifestations and treatment.** Ewing sarcoma metastasizes quite early in its development to the lungs and other bones, with 15% to 25% of cases being metastatic at diagnosis.<sup>2</sup> Because of the rapid rate of growth, pain is a dominant symptom that increases in severity. Ewing sarcoma is often confused with osteomyelitis because patients often appear systemically ill and may develop fever, anemia, leukocytosis, and an increased sedimentation rate.<sup>2</sup> Treatment with local resection and chemotherapy of an isolated lesion can have a 5-year survival approaching 70%. In patients with metastatic disease at diagnosis, 5-year survival drops to 30% even with surgery and radiotherapy or chemotherapy.<sup>2</sup>

### Multiple Myeloma

**Etiology and pathogenesis.** Multiple myeloma is a slowly growing bone marrow malignancy with neoplastic proliferation of a single clone of plasma cells. The annual incidence is approximately 4 per 100,000 and represents about 1% of all malignant cancers.<sup>13</sup> It is usually a disease of elderly adults.

**Clinical manifestations and treatment.** Although multiple myeloma is not a sarcoma, its symptoms and radiographic findings are similar. On radiographs, evidence of bone destruction by a lytic, or bone-destroying, process and bone marrow involvement can be seen. Homogeneous immunoglobulin is also present in urine or serum. Because multiple myeloma is a slow-growing lesion, it takes a long time to become symptomatic. Bone pain is the most common symptom, particularly of the chest and back, and is related to excessive accumulation of abnormal plasma cells in the bone marrow (Chapter 11). Although it can affect any bone, multiple myeloma most commonly occurs in the thoracic and lumbar vertebrae. Patients experience hypercalcemia and pathologic fractures where bone has been destroyed. This disease can also cause kidney dysfunction, lung or pleural involvement, and neurologic symptoms attributable to nerve compression. Treatment often requires aggressive combination chemotherapy, although at times local radiation may be useful for refractory bone pain.

#### KEY POINTS

- Primary tumors of the bone are not common. Osteochondroma, chondroma, osteoid osteoma, and giant cell tumors are benign, primary bone tumors.
- Malignant bone tumors include osteosarcoma, chondrosarcoma, and Ewing sarcoma.
- Multiple myeloma is a slow-growing bone marrow malignancy in which plasma cells proliferate. This disease affects the kidneys and the immune and circulatory systems.

## DISEASES OF SKELETAL MUSCLE

Skeletal muscle, the most abundant tissue in the human body, accounts for approximately 40% of total body weight.<sup>3</sup> Skeletal muscle performs dynamic work (locomotion) and static work (posture). As with other tissue of the musculoskeletal system, muscle atrophies in response to disuse and immobilization, and hypertrophies when subjected to increased stress.

## MUSCULAR DYSTROPHY

**Muscular dystrophy** comprises a group of genetically determined myopathies characterized by progressive muscle weakness and degeneration as muscle tissue is replaced by fat and fibrous connective tissue.

The dystrophies are classified by their pattern of inheritance, age of onset, and distribution of muscular weakness.

### Duchenne Muscular Dystrophy

**Etiology and pathogenesis.** Duchenne muscular dystrophy, the most common and most severe form of muscular dystrophy, is inherited as an X-linked trait and therefore afflicts only males. The incidence is 1 in 3500 male births. Because of a genetic mutation, muscle cells are deficient in the protein dystrophin, a deficiency that weakens the cell membrane and allows extracellular fluid to leak into the cell. Proteases and inflammatory processes are activated, leading to muscle fiber necrosis and muscle degeneration.<sup>14</sup>

The disease begins at birth and is usually apparent by the age of 3 years, with initial involvement of the pelvic girdle and progression to the shoulder girdle.

**Clinical manifestations.** The calf muscles of an individual with Duchenne muscular dystrophy are noticeably enlarged because of the infiltration of fat cells and degeneration of muscle fibers. Distal muscle involvement leads to frequent falling by the age of 5 or 6 years, and by age 12 to 14 years most children are confined to a wheelchair. Some muscles, such as those in the hands, face, jaw, pharynx, larynx, and eyes, are spared to the end. Survival to age 20 is rare. Cardiac failure or pulmonary infection is the usual cause of death.<sup>14</sup>

**Treatment.** Treatment of muscular dystrophy is focused on appropriate education for the patient and family, preservation of physical function as long as possible, and prevention of contractures. In some cases, corticosteroid therapy may be useful to delay loss of muscle strength and prolong independent ambulation, but eventual steroid-induced osteoporosis is a risk. Immunosuppressive therapies have also been tried but with limited success.

### Becker Muscular Dystrophy

**Etiology, pathogenesis, and clinical manifestations.** Becker muscular dystrophy is a milder form of inherited muscle degeneration, somewhat less common than the Duchenne type. The genetic mutation leads to production of a reduced amount of an abnormal dystrophin protein and a slower muscular degeneration. Calf hypertrophy is still prominent and often painful with progressive loss of strength and ability to ambulate. The mean age of symptom onset is somewhat later (older than 5 years and even into adulthood) with patients requiring a wheelchair by the age of 30 years.<sup>14</sup>

### Facioscapulohumeral Muscular Dystrophy

**Etiology and pathogenesis.** Facioscapulohumeral muscular dystrophy is an inherited autosomal dominant trait that affects the muscles of the shoulder girdle and the face. It is rare with an annual incidence of 1 in 20,000. The onset of disease can occur at any age, but it usually begins in the second decade. Facial muscles are involved early, with later involvement of scapular and upper arm musculature. It progresses slowly with periods of arrest and can ultimately involve more distal muscles of the upper and lower extremities. Both males and females are affected, and most live to a normal age.<sup>14</sup>

## OTHER DISORDERS OF MUSCLE

### Myasthenia Gravis

**Myasthenia gravis** is a chronic autoimmune disease affecting the neuromuscular function of voluntary muscles and characterized by profound muscle weakness and fatigability. Its peak onset in females occurs at 20 to 30 years of age although onset later in life is becoming more widely recognized. Women are affected more often than men with a prevalence

of 15 per 100,000. Characteristically, weakness begins with ocular and cranial muscles, and then limb muscles can also be involved. During times of emotional stress, respiratory muscles may be included.<sup>14</sup>

In myasthenia gravis, acetylcholine receptor antibodies are produced that destroy or block acetylcholine receptors of the muscle end-plate of the neuromuscular junction. These antibodies impair the transmission of acetylcholine across the junction. The result is the muscle weakness and fatigability so prevalent in this disease.

**Treatment.** Anticholinesterase inhibitors (e.g., pyridostigmine bromide, neostigmine) may be used to inhibit breakdown of acetylcholine in the neuromuscular synapse. Increased synaptic acetylcholine enhances the activation of postsynaptic receptors and improves skeletal muscle contraction force. Because myasthenia gravis is an autoimmune disorder, corticosteroids, intravenous immunoglobulin, plasmapheresis, and immunosuppressive agents may be used to regulate the immune system. In severe cases, respiratory muscle fatigue may necessitate mechanical ventilation. Thymectomy is often recommended when patients fail to respond well to medications, particularly in patients less than 45 years old.<sup>14</sup>

Myasthenia crisis can be due to insufficient medication, emotional stress, trauma, infection, or surgery. A sudden increase in blood pressure and pulse rate is noted. Other symptoms include cyanosis from hypoxia, absent cough and gag reflexes, restlessness, increased secretions and lacrimation, diaphoresis, decreased urine output, bowel and bladder incontinence, dysarthria, and respiratory distress.

Cholinergic crisis is usually due to excessive medication. Patients experiencing such a crisis will have fasciculations, especially around the mouth; difficulty chewing, swallowing, and speaking; advancing muscle weakness approximately 1 hour after anticholinesterase medication; nausea and vomiting; cramps and diarrhea; increased secretions (salivary, perspiration, lacrimal, bronchial); headache; confusion; irritability and anxiety; syncope; and respiratory distress leading to respiratory arrest.

## CHRONIC MUSCLE PAIN

### Fibromyalgia Syndrome

**Etiology and pathogenesis.** The cause of **fibromyalgia syndrome** (FMS) is unknown. No laboratory abnormalities have been found, muscle biopsy findings are nonspecific, and patients are usually normal on psychological testing. The condition is not an inflammatory process but rather a “pain syndrome,” with recent studies suggesting that changes in the central nervous system may lead to amplification of pain fiber impulses, a theory called *central sensitization*. This generalized increase in pain sensitivity may involve both ascending and descending neural pathways and a variety of neurotransmitters and neuropeptides.<sup>15</sup>

FMS is characterized by chronic pain in muscles and surrounding structures often of months’ or years’ duration. Additional symptoms include fatigue, sleep dysfunction, headache, numbness and tingling (i.e., paresthesia), joint pain, memory and concentration difficulties, irritable bowel syndrome, depression, edema of the hands, and sensitivity to cold. Patients either may have no other musculoskeletal disease or may have rheumatoid arthritis, osteoarthritis, Lyme disease, or sleep apnea. FMS is characterized by a strong female preponderance, with an estimated prevalence in the United States of more than 45% of the general population.<sup>15</sup>

**Clinical manifestations.** Patients with FMS complain of widespread musculoskeletal pain, stiffness, and fatigability. Joint pain and swelling may be perceived by the patient, but the swelling, if present, is usually soft-tissue “puffiness” and not a true inflammatory process. Complaints of muscle pain and weakness are expressed without objective demonstration. In addition to pain and fatigue, sleep disturbances are a common complaint. The examination of a patient with FMS is characterized by an excessive number of reported symptoms with

minimal objective findings other than muscular tenderness. Proposed criteria for the diagnosis of FMS established by the American College of Rheumatology include widespread pain in combination with tenderness of at least 11 of 18 (9 bilateral sites) specific tender-point sites, especially of the cervical, paraspinal, trapezius, and parascapular muscles, as well as gluteal and trochanteric areas among others. However, these criteria were not meant to be used for diagnosis and FMS is diagnosed on a clinical basis. Although the specific tender points are the most common and are included in the criteria for fibromyalgia, in actuality, nearly any muscle in the human body could be tender to palpation.<sup>8</sup>

**Treatment.** FMS is a chronic pain condition that is not life threatening nor does it lead to destruction of musculoskeletal tissues. Because the cause of FMS is unknown, treatment focuses on maintaining functionality and reducing symptoms. Patient education is important and may be associated with improved outcomes and better prognosis. An exercise regimen is essential and should include regular stretching; improvement in physical conditioning via low-impact aerobic exercise (biking, swimming, walking); and measures of pacing, muscle protection, and relaxation. Because pain and fatigue may be aggravated by stress and other psychological factors, counseling may be helpful.<sup>16</sup>

Blinded, randomized, placebo-controlled studies of amitriptyline, cyclobenzaprine, zolpidem, and alprazolam administered at bedtime have indicated that all are effective FMS therapy. Treatment begins at the lowest possible doses and increases as tolerated, with the goal being to improve quality of sleep without drug side effects, such as daytime somnolence or excessive dry mouth. Other medications under investigation in FMS are meant to lower pain sensitivity. The selective serotonin reuptake inhibitors that have been studied in FMS

include fluoxetine, sertraline, and citalopram. Although their efficacy as monotherapy is modest at best, they may prove beneficial in combination with other agents. Most recently, pregabalin (an anticonvulsant agent) has been shown to be effective in reducing pain and is the first FDA-approved drug for the treatment of FMS. Additional medications that may have a role include venlafaxine and duloxetine (both serotonin-norepinephrine reuptake inhibitors), and tramadol (an opioid-like analgesic) among many other agents being investigated.<sup>8,16</sup>

#### KEY POINTS

- Muscular dystrophy comprises a group of genetic disorders characterized by degeneration of skeletal muscle.
- Duchenne muscular dystrophy is inherited as an X-linked disorder and affects only males.
- Becker muscular dystrophy is a milder form of inherited muscle degeneration, somewhat less common than the Duchenne type. The genetic mutation leads to production of a reduced amount of an abnormal dystrophin protein and a slower muscular degeneration. Calf hypertrophy is still prominent and often painful with progressive loss of strength and ability to ambulate.
- Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder in which degenerating muscle fibers are replaced by connective tissue such that muscles may increase in bulk even though muscle strength is lost.
- Myasthenia gravis is an autoimmune disorder characterized by progressive weakness as the muscles are used. Antibodies against acetylcholine receptors in the motor end-plate interrupt neuromuscular transmission.
- FMS is a poorly characterized chronic disorder associated with generalized pain, stiffness, sleep dysfunction, and fatigability.

## SUMMARY

A solid working knowledge of the anatomy, physiology, and biomechanics of movement is extremely important when dealing with any type of alteration in the musculoskeletal system. With a grasp of the mechanics involved in function, the clinician is able to approach each aberration with an awareness of the time requirements for healing, stress tolerances, and expected management outcomes.

The injuries and diseases discussed in this chapter are a small representation of the many dysfunctions that may afflict the musculoskeletal system. An ability to determine the specific type of tissue involved (contractile or inert) allows the clinician to be cognizant of activities

that would aggravate trauma, types of injury that require supportive devices, and injuries that respond to medical intervention.

An awareness of the tissue response to healing enhances the clinician's evaluative skills and provides a signal regarding when intervention has achieved the expected results within an appropriate time frame. It is the responsibility of the practitioner to become knowledgeable about the variety of dysfunctions that occur. This knowledge base must continue to expand as technological advancements provide increasingly complex levels of information and new diagnostic tools become available.

Arthritis is the most common disabling musculoskeletal condition in the United States. The National Arthritis Foundation estimates that approximately 46 million people have arthritis with the numbers increasing yearly as the population ages. More than 150 defined rheumatologic diseases have been identified. This chapter discusses the more common rheumatologic diseases.<sup>1</sup>

### LOCAL DISORDERS OF JOINT FUNCTION

#### Osteoarthritis

**Osteoarthritis** (degenerative joint disease) is the most common arthritis worldwide. It is a progressive, noninflammatory disease of diarthrodial joints, especially those that bear weight. It is characterized

by a progressive loss of articular cartilage and by formation of thick subchondral bone and new bone at the joint margins. Osteoarthritis (OA) becomes more prevalent with increasing age. Individuals older than 70 years have the highest incidence. In postmenopausal women, the knees and hands are most frequently affected by OA.<sup>1</sup> It is difficult to estimate the exact prevalence of OA because of difficulties associated with diagnosis, lack of longitudinal data, and problems in defining disease onset.

**Etiology and pathogenesis.** The etiologic progression of OA varies widely. Development of OA may be related to factors that increase the likelihood of abnormal “wear and tear” on joints such as obesity, joint trauma, and congenital disorders (e.g., hip dysplasia, joint laxity, leg length discrepancy). Other predisposing conditions include lifestyle factors and occupation (stress to joints), genetic predisposition, and hormonal status (postmenopausal).<sup>1</sup>

Biomechanical, biochemical, inflammatory, and immunologic factors may all be involved in the development of OA (Figure 52-1). An initial injury causes release of proteolytic and collagenolytic enzymes from chondrocytes. A breakdown of the matrix of proteoglycan and collagen occurs. The decreased hydration of cartilage that occurs with aging can increase the likelihood of wear and damage. Collagen fatigue and microfracture occur with the stress of weight bearing. The ability of the structure to absorb shock is decreased as a result of subcortical bone and cartilage microfractures. Breakdown of joint integrity overloads the capacity for repair, with resultant degenerative changes.

Structural deterioration of the cartilage involves fissuring, pitting, and erosion. Erosion can become so extensive that the articular surface denudes the full thickness of the cartilage. Osteophyte spur formation, subchondral bone sclerosis, and cyst formation are also examples

of structural changes present in OA. Cartilage fragments may break off into joints and form “loose bodies” (Figure 52-2). Joint effusions are common in advanced cases. Synovium becomes inflamed and secretes an increased amount of synovial fluid, which causes the joint to distend.

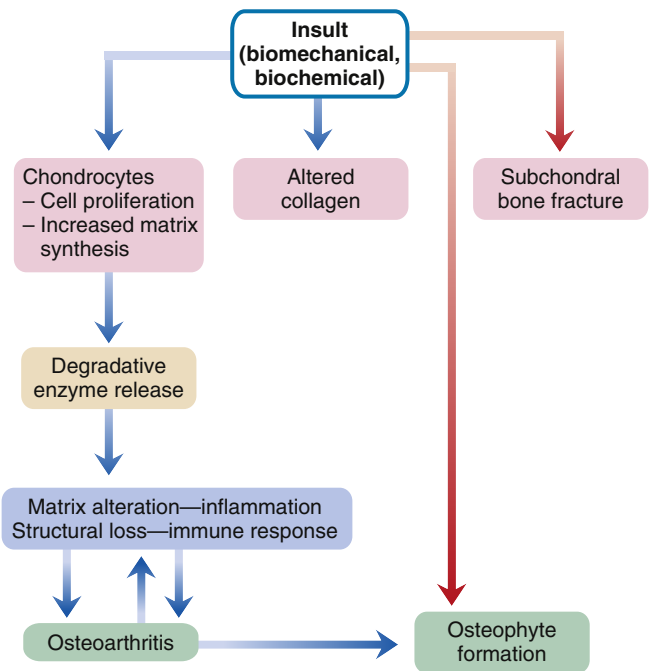

FIGURE 52-1 Pathogenesis of osteoarthritis.

FIGURE 52-2 Schematic presentation of the pathologic changes in osteoarthritis. Fragmentation and loss of cartilage denude the subchondral bone, which undergoes sclerosis and cystic change. Osteophytes form on the lateral side and protrude into the adjacent soft tissues, causing irritation, inflammation, and fibrosis. (From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

**Clinical manifestations.** Bony enlargement of joints, crepitus with movement, morning stiffness lasting less than 30 minutes (that improves with joint mobility), and pain with function are typical clinical manifestations of OA. These signs and symptoms are usually local. Although any joint may be affected, weight-bearing joints such as the hips and knees, cervical and lumbosacral joints, and interphalangeal joints are most frequently involved. Degenerative arthritis or OA may occur in an isolated joint, or multiple joints can be involved, especially in the hand. Mechanical dysfunction, anatomic anomalies, or trauma may cause breakdown of the joint surface. It is imperative to establish a differential diagnosis and to eliminate a systemic or medical problem. Although OA is localized, rheumatoid arthritis (RA) is a systemic autoimmune disorder that causes a highly inflammatory, symmetric, peripheral arthritis.

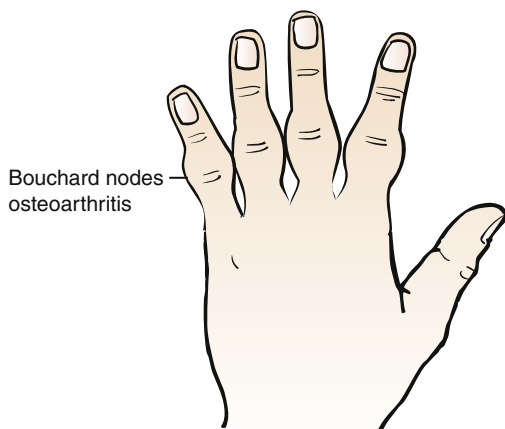

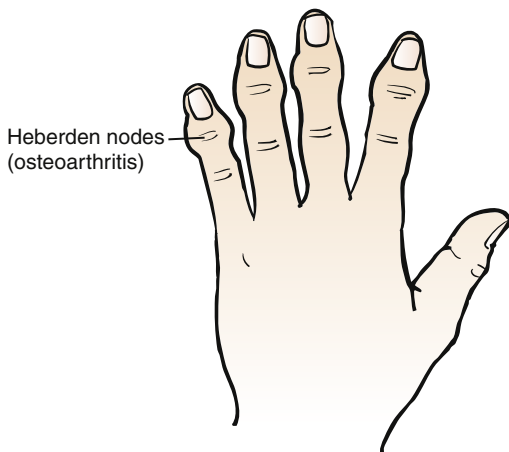

Radiologic abnormalities are normally consistent with clinical symptoms. Classic findings include bony proliferation at the joint margins (i.e., osteophytes or bone spurs), asymmetric narrowing of the joint space, and sclerosis of the subchondral bone. Later, malalignment of the joints and cyst formation in subchondral bone can also be seen. When significant synovial fluid accumulates in the joint, it is usually translucent noninflammatory fluid containing less than 2000 white blood cells per cubic millimeter.<sup>1</sup>

The most common deformity of the hands occurs in the distal interphalangeal (DIP) joints (Figure 52-3). Enlargement is caused by bone spurs (*Heberden nodes*) that form on the dorsolateral and medial aspects of the joint. Similar enlargements in the proximal

interphalangeal (PIP) joints are called *Bouchard nodes*. The knees and hips are also common locations for OA. Local pain over joint margins, tenderness, crepitus, and muscle atrophy are common findings. Loss of cartilage in medial or lateral compartments of the knee may lead to such structural changes as genu valgus or varus (Figure 52-4).

Pain is relieved by rest during initial stages, though stiffness can be a complaint after prolonged sitting. Because cartilage does not contain nociceptors (pain receptors), pain originates from intraarticular and periarticular structures. Although an acute inflammatory response is often the result of a specific traumatic incident and may cause synovitis in the joint capsule, acute inflammation is not commonly associated with OA. As breakdown in structure progresses, even light activity elicits discomfort, and pain at night is common.

**Treatment.** Initial treatment is designed to decrease stress on the joint and protect it from additional trauma. Acetaminophen is often the initial analgesic agent recommended for management of mild OA symptoms. Nonsteroidal antiinflammatory drug (NSAID) therapy decreases swelling and pain. Most NSAIDs are nonselective, but antiinflammatory agents that target the cyclooxygenase-2 (COX-2) enzyme have clinical benefit equal to traditional NSAIDs and may have potentially fewer gastrointestinal side effects. The only COX-2 inhibitor presently available in the United States is celecoxib (Celebrex). All NSAIDs (selective or nonselective) have the potential for renal toxicity and possibly even cardiovascular side effects. Visco-supplementation, the intraarticular injection of hyaluronan or its derivatives, may increase joint lubrication, reduce inflammation, and alleviate pain.

**FIGURE 52-3** Comparison of Heberden nodes with Bouchard nodes (seen in patients with osteoarthritis).

FIGURE 52-4 Genu varus and genu valgus.

These agents are currently only available for use in knee OA. Intra-articular corticosteroid injections can provide temporary pain relief, but too frequent usage (i.e., more than three injections per year in the same joint) may accelerate cartilage deterioration.

Physical therapy to improve range of motion, muscle strength, and joint conditioning as well as weight reduction can improve symptoms and prevent loss of function. Assistive devices, such as a cane or walker, afford mechanical relief of weight-bearing stress as can supportive shoe wear. Surgical intervention may be necessary if the joint surface loses enough integrity to prevent joint function. OA is the most common cause for total hip and total knee replacement.

### Infectious Arthritis

Infectious or septic arthritis may be defined as an invasion of the synovial membrane by bacteria or another pathogen, leading to a closed-space infection. A reported annual incidence of infection in a joint is 2 to 10 cases per 100,000, with much higher rates noted in patients with comorbid diseases such as rheumatoid arthritis, diabetes, osteoarthritis, chronic kidney disease, and others.<sup>2</sup> The pathogen can invade the joint space via a hematogenous route, by extension of an adjacent infection, or from direct inoculation following trauma or an invasive procedure. Infection causes both synovium and cartilage to deteriorate. Joints with underlying disease or inflammation are more susceptible to infection because of increased vascularity and defective barrier effects of the synovial tissue.

**Etiology and pathogenesis.** The basic cause of bone and cartilage destruction is the interaction of antigenic bacterial cell wall components, the toxic effects of bacteria, the destruction caused by the purulent inflammatory exudate, and the local immune-mediated synovial or cartilage response. If the bacterial infection is not managed, cartilage can be destroyed, and this can lead to ankylosis of the joint.

In most adults and neonates, *Staphylococcus aureus* is the most common causative organism followed by *Streptococcus pyogenes* and *Streptococcus pneumoniae*. Also in neonates, gram-negative bacilli can be cultured, including *Kingella kingae*, which is an oral flora. In young children, *Haemophilus influenzae* type B (HIB) was a frequent cause of infection but this agent is now rare since the development of the HIB vaccine.<sup>2</sup> *Neisseria gonorrhoeae* is a causative organism in some adults younger than 30 years of age.

**Clinical manifestations.** The patient with septic arthritis presents with joint pain, fever, chills, and leukocytosis. Fever may range from mild to high fever with shaking chills. A warm, red, and very swollen joint with limited range of motion attributable to pain is symptomatic

of any type of infectious arthritis. Usually only a single joint is involved, but polyarticular joint infections can occur in 10% to 20% of cases, most often in debilitated or immunosuppressed individuals. Synovial fluid analysis reveals a very high white cell count (often  $>50,000$  cells/mm<sup>3</sup>), and diagnosis is established by recovery of bacteria from synovial fluid. Blood cultures are also used to provide a medical diagnosis.<sup>2</sup>

**Treatment.** Treatment of a septic joint should include appropriate antibiotic therapy (often initially intravenous and then oral) with the average duration required being 4 to 6 weeks. This therapy is most effective when the bacteria can be isolated and identified from the synovial fluid and antibiotic sensitivities can be used to determine the most effective antibiotic to be used. In addition, the infected joint usually requires repetitive drainage to facilitate bacterial clearance, decrease pain, and prevent loss of function. This can be accomplished by repeated joint aspiration, arthroscopy with tidal lavage, or open surgical drainage.

**Joint prosthesis infection.** Any bacteria can lead to infection in a prosthetic joint via the hematogenous route. *S. aureus* is still common, but *Staphylococcus epidermidis* can also result in prosthetic joint infection and is rarely seen in a native septic joint. Generally, a prosthetic joint infection requires removal of the prosthesis followed by a rigorous course of intravenous antibiotic therapy, often for 6 weeks or longer. Antibiotic beads may also be placed in the wound. The prosthesis is replaced when cultures from the wound show no growth.<sup>2</sup>

#### KEY POINTS

- Osteoarthritis is a local degenerative joint disorder associated with aging and wear and tear from repetitive stress.
- OA is characterized by loss of articular cartilage, deterioration of underlying bone, and the formation of bone spurs. The process is noninflammatory. Weight-bearing joints are often affected.
- Signs and symptoms of OA are localized (not systemic) and include joint pain and crepitus with movement.
- Joint infection may be due to a variety of infectious agents, but bacteria are the most problematic. The route of infection is usually by way of the bloodstream. Signs and symptoms are due to localized infection and the systemic manifestations of inflammation.

## SYSTEMIC DISORDERS OF JOINT FUNCTION

### Immune-Mediated Disorders

#### Rheumatoid Arthritis

**Rheumatoid arthritis** is a systemic autoimmune inflammatory disease. In the United States, approximately 1% to 2% of the population is affected with a lower prevalence being reported in Asian countries.<sup>1</sup> Women are two to three times more likely to develop RA than men, with a peak incidence in the fourth and fifth decades. Gender difference disappears in older age. RA affects all races, and its prevalence is not affected by climate. RA occurs two to three times more often in women with a familial history of RA.<sup>1</sup>

**Etiology and pathogenesis.** The specific cause of RA is unknown. An infectious agent has long been sought as a cause, but reproducible evidence of a particular bacterium or virus has not been found. A more likely theory is that RA is caused by an abnormal autoimmune response (possibly triggered by a bacterial or viral antigen) occurring in individuals who have a genetic predisposition to the disease.

Current research suggests that susceptibility to RA is influenced by the structure of class II major histocompatibility complex (MHC) molecules of antigen-presenting cells.  $\beta$ -Lymphocyte alloantigen human leukocyte antigen DR4 (HLA-DR4) has been noted in 70% of adult Caucasian patients with RA (compared with 30% in control patients), although it is likely that several genes are involved.<sup>3</sup> These

genes possibly control humoral and cell-mediated immune mechanisms believed to contribute to the pathogenesis of RA. A particular amino acid sequence of the third hypervariable region of DR  $\beta$  chains (called the “shared epitope”) is seen more commonly in RA patients. The cause and type of stimulus of immunologic abnormalities are not known, but they might be due to an infectious agent, environmental influences, or other lifestyle factors (such as tobacco use). An increase in physical and/or psychological stress has also been associated with precipitating acute exacerbation of the disease.

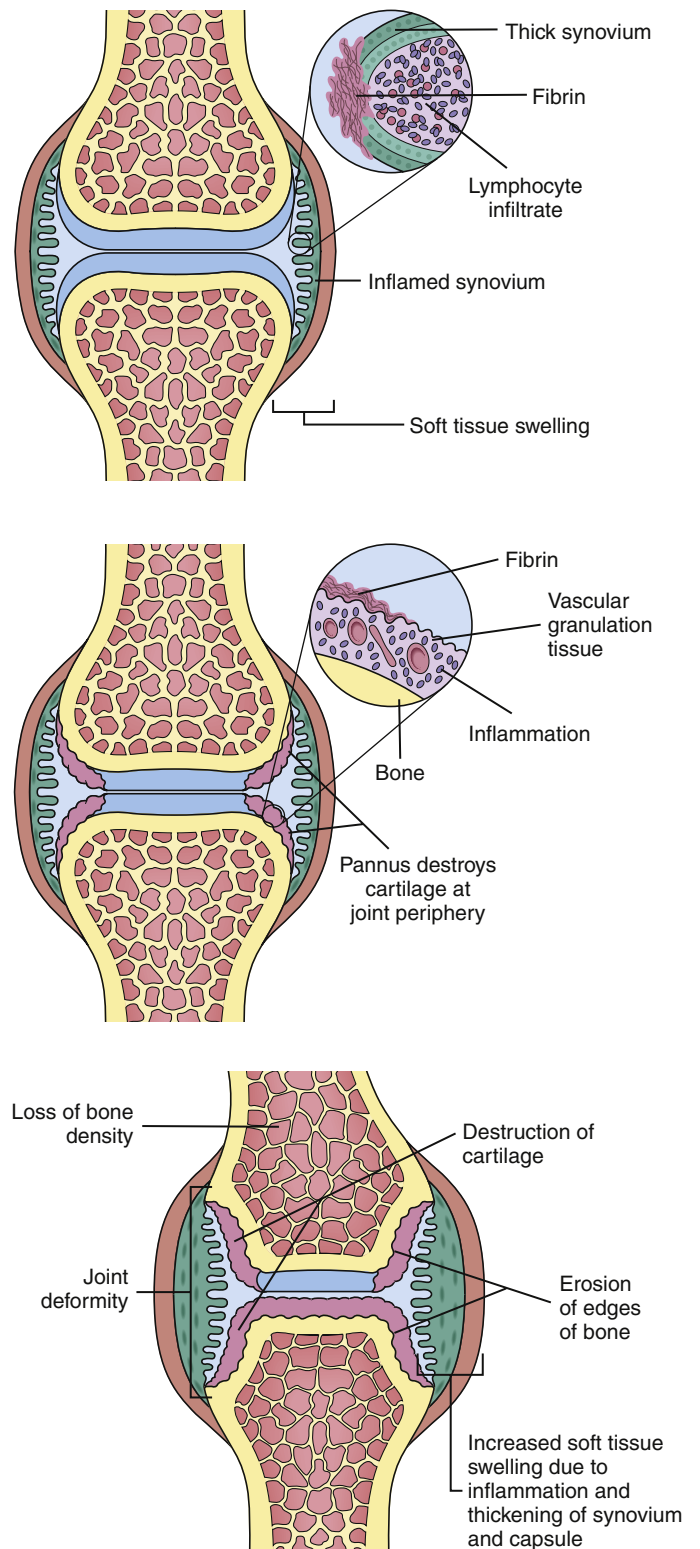

Initially, pathologic changes in RA occur when the immune response localizes in synovial tissue. Here lymphocytes (T and B cells) and macrophages are activated by an unknown antigen trigger. Activated B cells help to perpetuate the escalating inflammatory response by stimulating more lymphocytes and other immune cells. B cells also produce RF antibodies against immunoglobulin G (IgG) as well as anti-cyclic citrullinated peptide (anti-CCP) antibodies. Although immunoglobulins are natural human antibodies, the body produces an antibody (RF) against its own antibody (IgG). Anti-CCP antibodies target peptides modified by converting the amino acid arginine to citrulline.<sup>1</sup> Activated lymphocytes, macrophages, and antigen-antibody complexes activate the complement system, stimulate recruitment of other immune cells into the synovium, and produce an extensive array of inflammatory cytokines, metalloproteinases, and other mediators. These products of macrophages and lymphocytes are believed to be critical in RA pathogenesis because they stimulate and perpetuate the inflammation in the joint. Key proinflammatory cytokines demonstrated in the synovium include tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ); interleukin-1 $\beta$  (IL-1 $\beta$ ); and interleukins 6, 8, 15, 17, 18, and 23, although many more are thought to be involved. Newer biological therapies are designed to target these cytokines as well as activated inflammatory cells and cell costimulatory markers.

The escalating inflammatory response in the rheumatoid joint leads to accumulation of dense aggregates of immune cells and infiltration of the synovium. The cells produce more cytokines and growth factors, which also stimulate edema, neovascularization, and proliferation of the synovium (which expands in a tumorlike manner). This hypertrophied synovium invades such surrounding tissue as cartilage, ligaments, joint capsules, and tendons. Granulation tissue forms, covering articular cartilage and leading to pannus formation. Pannus is vascularized tissue composed of lymphocytes, macrophages, histiocytes, fibroblasts, and mast cells. Pannus can erode and destroy articular cartilage, resulting in bone erosion, bone cysts, and fissures (Figure 52-5). The expansion and destruction of joint structures can lead to inflammation, shortening, and even rupture of tendons as well as ligament laxity, joint subluxations, contractures, and deformities.<sup>1</sup>

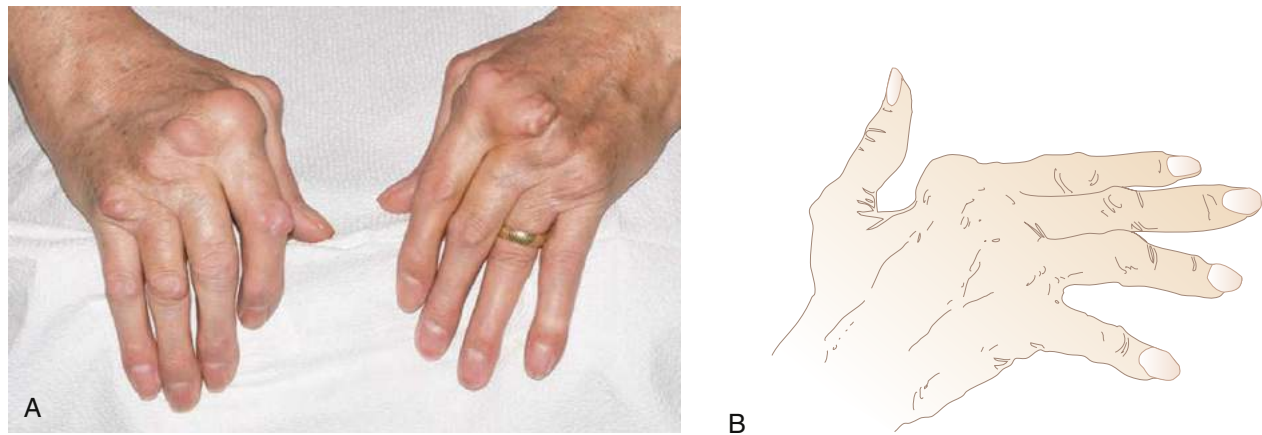

**Clinical manifestations.** RA has a wide range of clinical features, but the classic presentation is that of a bilateral symmetric polyarthritis involving smaller joints. Malaise, fatigue, and diffuse musculoskeletal pain are common manifestations during acute exacerbations of the disease. It is interesting to note that symmetric patterns involving the joints of the hands, wrists, elbows, and shoulders are evident. DIP joints are usually spared. This symmetry and the noninvolvement of the DIP joint assist in making the diagnosis of RA.

The hands, wrists, knees, and feet are most commonly involved. In the spine, the upper cervical area is most often affected. However, any diarthrodial joint is potentially at risk. The development of pannus followed by inflammatory destruction of the soft tissue leads to laxity of the ligaments and tendons and results in biomechanical dysfunction. This mechanical stress causes the typical deformities of RA.

Swelling in the hands is a typical sign of metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joint involvement. Pain is elicited on palpation of the joints. Gradually, progressive synovial damage leads to characteristic ulnar deviation in the MCP joint

**FIGURE 52-5** Schematic presentation of the pathologic changes in rheumatoid arthritis. The inflammation (synovitis) leads to pannus formation, obliteration of the articular space, and, finally, ankylosis. The periarticular bone shows disuse atrophy in the form of osteoporosis. (From Black JM et al: *Medical-surgical nursing: clinical management for positive outcomes*, ed 6, Philadelphia, 2001, Saunders.)

**FIGURE 52-6** **A**, Typical deformity of the hand seen in patients with rheumatoid arthritis. Note ulnar deviation involving the right hand. **B**, Schematic of ulnar deviation. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 2058. Courtesy Dr. Douglas White.)

(Figure 52-6). In advanced situations, a swan-neck deformity develops in the fingers. Swan-neck deformity is a hyperextension of the PIP joint with flexion of the MCP and DIP joints attributable to contractures of intrinsic muscles and tendons.<sup>4</sup> A boutonnière deformity, consisting of flexion of the PIP joints and hyperextension of the DIP joints, is also a common dysfunctional position caused by rupture or excess laxity of extensor tendons over the fingers (Figure 52-7). Loss of strength and the ability to achieve a strong pinch is frequently noted in the hand affected by RA. A rupture of tendons and loss of the ability to extend the fingers are common findings in later stages of the disease.

The wrist is commonly involved. The synovium around the wrist becomes boggy and affects the tendon sheaths. Limitation of movement, especially dorsiflexion of the wrist, is often noted. Proliferation of the synovium on the volar or palmar aspect of the wrist may cause compression of the median nerve and development of carpal tunnel syndrome. Flexion contractures and swelling of the elbow are other common manifestations; in later stages of the disease, shoulder involvement may occur. Typical signs of shoulder involvement are limitations of movement and pain on palpation in the area of the coracoid process. Dislocation, subluxation, or rupture of the joint capsule may occur as the disease progresses.

Involvement of the upper cervical vertebrae is another common finding. Destruction of structures of the atlantoaxial vertebrae (such as the transverse ligament) creates the potential for subluxation of this joint and endangerment of spinal cord compression. Laxity in the cervical region may also allow compression of the vertebral artery, leading to vertebrobasilar insufficiency. Limitation of motion (especially rotation), pain on palpation, and headache in the occipital region are common.

Abnormalities in gait and limitations of movement are signs noted when RA affects the hip. Groin pain attributable to capsular involvement may be present. If synovitis of the hip becomes extensive, severe pain may be noted on evaluation. RA involvement in the knee is often extensive. Effusion, quadriceps atrophy, contractures, and synovitis of the semimembranous bursa (Baker cyst) may be observed. Destruction of the articular surface, bone, and soft tissue may result from joint instability. One common clinical sign of involvement of the foot is retrocalcaneal bursitis. Other features of foot involvement include swelling of joints, a cocking-up of the toes attributable to subluxation of the metatarsal heads (claw toes), and lateral deviation of the first through fourth toes.

**Boutonnière deformity**

**Swan-neck deformity**

**FIGURE 52-7** Boutonnière and swan-neck deformities. (From Black JM, Hawks JH: *Medical-surgical nursing: clinical management for positive outcomes*, ed 8, Philadelphia, 2009, Saunders, p 2058.)

These clinical manifestations may develop rapidly or progress over many years. Usually symptoms develop over weeks and months. Initially, the patient may feel fatigued or chronically tired and may complain of systemic aching in the musculoskeletal system. Specific joint pain, tenderness, swelling, redness, and nodules are quite common.

Prolonged inactivity, such as sitting, initiates complaints of stiffness and swelling. As the disease progresses, walking, climbing stairs, opening jars or doors, and precise movement of the digits become quite

**FIGURE 52-8** Rheumatoid arthritis. Radiographs of deformities of the feet, including bone erosions, osteopenia, lateral deviation, and subluxations, especially at the metatarsophalangeal joints. (Courtesy Dr. Douglas White.)

difficult. Weight loss, depression, and a low-grade fever often are noted in these patients.

Unlike OA, RA is a systemic autoimmune disease. It is imperative that a definitive differential diagnosis be developed. RA may be confused with a number of disease entities such as Lyme disease, systemic lupus erythematosus (SLE), gout, and other inflammatory conditions. RA may also cause subcutaneous nodules and be associated with cardiac, pulmonary, and ophthalmologic manifestations.

Cardiac manifestations may include pericarditis, myocarditis, mitral valve disease, and conduction system disease or complete heart block. Pulmonary manifestations may occur as pleuritis, pulmonary fibrosis, pleural effusions, or pulmonary nodules. Ophthalmic manifestations might include episcleritis, scleritis, or secondary Sjögren syndrome (dry eyes and mouth).

A positive RF is found in the sera of approximately 75% to 85% of patients with RA. The titer of the RF does not fluctuate with disease activity and is not essential for the diagnosis of RA. Antibodies against cyclic citrullinated peptide (anti-CCP antibody) can be found with a sensitivity of 70% to 80% and a high specificity of 90% to 95% for RA. The presence of both RF and anti-CCP antibodies in a patient may signify a risk of more aggressive disease. Inflammatory markers (sedimentation rate, C-reactive protein) are often elevated. Other laboratory features may include hypergammaglobulinemia, thrombocytosis, and hypochromic microcytic anemia.<sup>1</sup>

Radiography may demonstrate structural damage caused by RA. Typical findings include erosions on the bony margins of joints, joint space narrowing, periarticular osteopenia, and eventual malalignment and subluxation of the bones (Figure 52-8).

**Diagnosis.** In 2010 the American College of Rheumatology (ACR) in collaboration with the European League Against Rheumatism (EULAR) published new guidelines for the classification and diagnosis of rheumatoid arthritis (Table 52-1). The criteria require the patient have at least one documented swollen joint, the absence of an alternative diagnosis that better explains the joint swelling, and a total

**TABLE 52-1 2010 ACR/EULAR CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS**

CRITERION	POINTS*
<b>Joint Distribution (0-5 points)</b>	
1 large joint	0
2-10 large joints	1
1-3 small joints	2
4-10 small joints	3
>10 joints (at least 1 small joint)	5
<b>Serology (0-3 points)</b>	
Negative RF <i>and</i> negative ACPA	0
Low-positive RF <i>or</i> low-positive ACPA	2
High-positive RF <i>or</i> high-positive ACPA	3
<b>Symptom Duration (0-1 point)</b>	
<6 weeks	0
≥6 weeks	1
<b>Acute-Phase Reactants (0-1 point)</b>	
Normal CRP <i>and</i> normal ESR	0
Elevated CRP <i>or</i> elevated ESR	1

Data from Aletaha D, Neogi T, Silman AJ, et al: 2010 Rheumatoid arthritis classification criteria, *Arthritis Rheum* 62(9):2574, 2010.

\*A score ≥6 points indicates definite rheumatoid arthritis.

ACPA, Anti-citrullinated protein/peptide antibody; ACR, American College of Rheumatology; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; EULAR, European League Against Rheumatism; RF, rheumatoid factor.

score on the criteria scale of 6 or more (out of 10). The diagnosis takes into account the number and size of the swollen joints, the presence or absence of the RF antibody or CCP antibody, and the level of the patient's markers of inflammation (sedimentation rate and C-reactive protein). The goal of these new criteria is to aid in the diagnosis of RA at an earlier stage of disease.<sup>5</sup>

**Treatment.** Goals of therapy should include alleviation of pain and swelling, prevention of structural damage, and preservation of function. Initial therapy with antiinflammatory medications may include NSAIDs, COX-2 inhibitors, or corticosteroids (oral, parenteral, or intraarticular injections). Corticosteroids are potent antiinflammatory agents, effective at quickly controlling the pain, stiffness, and swelling of RA activity; however, every effort is made to avoid long-term steroid use because of adverse consequences such as steroid-induced osteoporosis, diabetes mellitus, cataracts, and more.

Disease-modifying antirheumatic drugs (DMARDs) are used to achieve long-term control of RA activity and are recommended very early in the course of disease to minimize later damage. The most common first-line agent used is methotrexate (oral or subcutaneously once weekly), which is a folate analogue. Within cells, methotrexate (MTX) may exhibit its antiinflammatory and immunoregulatory effects by inhibiting several different enzymatic pathways, leading to decreased RNA and DNA synthesis (via decreased pyrimidine synthesis) and accumulation of intracellular and extracellular adenosine (which is a potent antiinflammatory agent). Leflunomide is another immune modulator that may work via decreased pyrimidine synthesis, although the mechanism of action of this agent is not well understood.<sup>3</sup>

Sulfasalazine and antimalarial drugs (especially hydroxychloroquine) have inhibitory effects on inflammatory cell function and may be useful in milder cases of RA or in combinations with methotrexate. Older immunosuppressive agents, such as azathioprine, gold (oral or intramuscular), or cyclosporine, are still available for management of RA but are much less commonly used.

In the last 10 years or more, the research into the use of biological agents in rheumatic disease, especially RA, has yielded a number of new and effective agents for controlling RA inflammation as well as preventing erosive and destructive mechanisms. Tumor necrosis factor- $\alpha$  is a central and potent stimulator of inflammation in the rheumatoid joint, and there are currently five TNF- $\alpha$  inhibitors available in the United States. Etanercept is a soluble TNF- $\alpha$  receptor fusion protein, whereas adalimumab, golimumab, and certolizumab are monoclonal antibodies or modified fragments of antibodies that can bind and inhibit TNF- $\alpha$ . These agents are all self-administered injections given once weekly to once monthly depending on the agent. Infliximab is a chimeric monoclonal antibody against human TNF- $\alpha$  and is given as an intravenous (IV) infusion every 6 to 8 weeks.

Another biological agent available for treatment of aggressive RA is abatacept, which is a fusion protein that binds to CD80/CD86 on the surface of antigen-presenting cells. This binding prevents CD80/86 from binding with CD28 on T cells, a process that is necessary for T-cell activation and increased activity in the inflammatory response. Abatacept is administered once every 4 weeks via IV infusion. Rituximab, a monoclonal antibody against the B-cell marker CD20, has been approved since 1997 for the treatment of non-Hodgkins lymphoma.<sup>1</sup> In RA, B cells are known to be active in several facets of the chronic inflammation and therefore the B-cell depletion caused by rituximab therapy can have very positive and sustained immunosuppressive effects. This agent is given as a series of two IV infusions administered 14 days apart every 6 months. The newest agent approved for RA is tocilizumab, a once monthly IV infusion, which binds the proinflammatory cytokine interleukin-6.

### Systemic Lupus Erythematosus

**Systemic lupus erythematosus (SLE)** is a chronic, multisystem, inflammatory, autoimmune disease. It is characterized by periods of exacerbations and remission, with multiple organ systems being affected at different times.

**Etiology and pathogenesis.** Genetic involvement has been demonstrated in familial occurrences of SLE.<sup>6</sup> Although SLE occurs in all races, it occurs more often in the United States among African Americans than Caucasians and yet is uncommon in Africa.<sup>6</sup> Environmental factors such as sunlight, thermal burns, and other types of physical stress may initiate the development of SLE. SLE is more common in women, with peak incidence between 15 and 40 years of age, suggesting that hormonal factors may influence onset.

SLE is the result of an abnormal immune reaction of the body against its own tissues, cells, and serum proteins—the body has a decreased tolerance to itself. One of the main mechanisms is B-lymphocyte overactivity leading to excessive autoantibody production. SLE patients can express a myriad of antibodies directed against many self molecules and antigens located in cell nuclei and cytoplasm. Among these antibodies, those directed against nuclear antigens (antinuclear antibodies, or ANAs) are found in more than 98% of SLE patients.<sup>6</sup> Antigen-antibody complexes form within the basement membranes of glomeruli in the kidneys, heart, skin, brain, and joints. Immune complexes then activate complement and trigger the inflammatory responses, which are responsible for tissue destruction.

**Clinical manifestations.** SLE typically affects multiple organ systems such as the kidneys, heart, skin, nervous system, joints, lungs,

and gastrointestinal tract. Not all systems are affected simultaneously. The characteristic clinical course is one of exacerbation and remission. A remission may last for many years.

Arthralgias and synovitis are common features of SLE with most patients noting joint pain at some time during the course of the disease. In lupus arthritis, swelling, tenderness, pain on movement, and morning stiffness are noted. Involvement of the capsule, ligaments, and tendons can be extensive, causing reducible deformities in hands and feet (called Jaccoud arthropathy). Deformities range from contractures of the fingers, to hyperextension of the interphalangeal joint of the thumb, to subluxation of the MCP joint of the thumb. With steroid therapy, tendon rupture is not uncommon.

Skin lesions may be quite extensive in SLE. Acute cutaneous lupus erythematosus often manifests with a classic butterfly (malar) rash, though some form of skin involvement can be present in 80% of patients.<sup>1</sup> The skin lesion may be exacerbated during systemic flare-up. Swelling and redness are noted, and sunlight or artificial ultraviolet light may initiate a response. Skin involvement may occur on the shoulders, upper arms, upper back, chest, and neck. Scales or plaques develop on the scalp, ears, face, and neck. A latticelike venular skin change (livedo reticularis) is a very common skin manifestation. Alopecia may also occur.

A number of systemic manifestations may also be present. Cardiac complications include pericarditis, valvular heart disease, and rarely myocarditis with congestive heart failure. Premature atherosclerotic heart disease is recognized as an important cause of morbidity and mortality. Lung and pleural involvement includes pleuritis or pleural effusion. More aggressive lung involvement may include acute interstitial pneumonitis, pulmonary embolus, or pulmonary hypertension. Renal involvement is common ( $\frac{1}{2}$  to  $\frac{2}{3}$  of lupus patients) and can vary in severity.<sup>1</sup> Glomerulonephritis (inflammation in the glomeruli of the kidneys) can be associated with proteinuria, hematuria, and progressive renal failure. Central nervous system involvement has also been recognized (ptosis, diplopia, ataxia, seizures, psychosis).<sup>6</sup> Lymphadenopathy or Raynaud phenomenon (small vessel vasospasm in response to cold) may also be noted at some time in the course of the illness.

When SLE involves autoantibodies against blood elements, laboratory testing can reveal hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia. Renal disease often causes proteinuria, hematuria, or cellular casts on microscopic urinalysis. Although many autoantibodies cannot be measured by conventional laboratory methods, testing for the ANA class of antibodies is most important in screening for SLE, although a positive ANA test result can be seen in about 2% of healthy young women and in an even higher number of elderly individuals.<sup>1</sup> Also found in the sera of some SLE patients are autoantibodies against double-stranded DNA and other extractable nuclear antigens such as SSA (Ro), SSB (La), Smith (Sm), and RNP. Complement levels (C3 and C4) can be low in the setting of active SLE because the complement proteins are “consumed” in the antigen-antibody-mediated immune activation.

**Treatment.** The choice of therapeutic agents often depends on disease manifestations. Application of topical corticosteroids, avoidance of the sun, and use of sunblock can help control skin disease. NSAIDs and/or antimalarial medications are useful for the management of arthritis and serositis. For more aggressive disease, including renal, hematologic, or neural involvement, oral or parenteral corticosteroids may be needed for initial control followed by immunosuppressive medications, such as azathioprine, methotrexate, mycophenolate mofetil, cyclophosphamide, and others. New biological therapies targeting activated B lymphocytes, cell costimulatory molecules, and cytokines are under investigation. The most recent agent to be FDA approved for the treatment of SLE is belimumab, which is a humanized

monoclonal antibody that inhibits BLys (B-lymphocyte stimulator). Inhibition of BLys leads to a decreased number of activated B cells and lowered levels of autoantibody production (such as antibodies against double-stranded DNA).<sup>7</sup>

### Scleroderma

**Scleroderma** is a multisystem inflammatory connective tissue disease characterized by skin thickening and a deposition of large quantities of collagenous tissue, which results in severe fibrosis.<sup>3</sup> Skin, blood vessels, synovium, skeletal muscle, and microvasculature of internal organs are all affected. Scleroderma may occur in a localized form that only involves areas of skin without any internal organ involvement, or it can be a systemic disease. Two major types of systemic scleroderma are limited systemic sclerosis (LSS) and diffuse systemic sclerosis (DSS). It affects women three to four times more frequently than men. Onset is most common between 30 and 50 years of age.

**Etiology and pathogenesis.** The cause of scleroderma is unknown. Early in the disease, inflammation and immune cell infiltration can be found in skin, lungs, and other tissues. Widespread vasculopathy is seen with proliferation of smooth muscle cells within vessels causing vascular wall thickening and eventual lumen obliteration, especially of small arteries, arterioles, and capillaries. Tissue ischemia results followed by diffuse tissue fibrosis. Increased amounts of collagen and other connective tissue components are produced by fibroblasts that are stimulated by local cytokines and mediators.<sup>1</sup>

**Clinical manifestations.** Clinical manifestations often begin with Raynaud phenomenon (blanching of the digits in response to cold) and puffiness of the fingers, which can precede the development of other clinical features by many months. Polyarthritides involving small joints of the hands is common early in the disease but can resolve later. Evaluation of the skin discloses initial bilateral swelling of the fingers, hands, and, periodically, feet. After a few weeks or months, edema is replaced by thick, tight skin that usually begins distally and progresses proximally, a feature called *sclerodactyly*. This tightening can eventually lead to severe contractures of the digits, skin ulceration at the tips, and severe loss of function. Skinfolds are lost, and a shiny appearance is noted. Hyperpigmentation or hypopigmentation may occur. In limited systemic sclerosis, the *sclerodactyly* involves just the distal extremities (below elbows and knees) with or without changes to the face, and other internal organ features can still occur. Diffuse systemic sclerosis involves the skin of proximal and distal extremities and can spread rapidly to the face and trunk. These patients are far more likely to have internal organ involvement early in the disease course. Tenosynovial involvement may be seen with tendon friction rubs, carpal tunnel syndrome, and very severe flexion contractures.

Patients with scleroderma may experience disuse atrophy of muscle because muscular motion is limited by involvement of skin and joints. A low-grade inflammatory myositis can be seen but this is uncommon. Gastrointestinal involvement is present in a majority of patients. Musculature of the esophagus is involved, with dysmotility leading to difficulties in swallowing. Involvement of the esophageal sphincter musculature may result in reflux of gastric contents and development of peptic esophagitis. Malabsorption problems may also result from gastroparesis, intestinal dysmotility, and bacterial overgrowth. Constipation related to hypomotility of the large colon can be severe.

Pulmonary involvement, particularly pulmonary fibrosis, is the leading cause of death in systemic sclerosis. Pulmonary arterial hypertension can also develop as a result of vasculopathy of the pulmonary vasculature or from cardiac dysfunction. Manifestations of myocardial involvement include congestive heart failure, pericarditis, and atrial or ventricular dysrhythmias. Renal involvement used to be the predominant cause of death before the availability of angiotensin-converting

enzyme inhibitors. In scleroderma *renal crisis*, sudden malignant arterial hypertension may rapidly progress to oliguric renal failure without immediate treatment.

A form of limited systemic sclerosis, abbreviated CREST, refers to calcinosis (deposits of calcium in tissues); Raynaud phenomenon; esophageal dysmotility; sclerodactyly; and telangiectasias (capillary dilation that causes formation of vascular lesions on the face, lips, and fingers). Some patients with CREST syndrome develop pulmonary hypertension and intestinal malabsorption, often resulting in death.

**Treatment.** Treatment for scleroderma is largely organ-specific because systemic disease-modifying agents have had disappointing results. Raynaud phenomenon is managed with avoidance of cold exposure and use of vasodilator medications such as calcium channel blockers or, in severe cases, intravenous iloprost. Symptoms from gastrointestinal disease may be controlled with antacids, H<sub>2</sub> antagonists, proton pump inhibitors, and promotility agents. Previously associated with very high mortality, acute renal crisis (renal failure with malignant hypertension) can now be successfully managed with angiotensin-converting enzyme inhibitors. Pulmonary arterial hypertension is often managed with intravenous epoprostenol or treprostinil, which are two prostacyclin analogues. In some cases, an endothelin receptor antagonist (such as bosentan) can be tried.<sup>1</sup>

### Ankylosing Spondylitis

**Ankylosing spondylitis (AS)** literally means fusion (ankylosis) of inflamed vertebra (spondylitis). It is arthritis of the sacroiliac joints that involves the axial skeleton and, in some cases, peripheral joints. The disease often begins in the spine of young males in their late teens or early twenties. The male to female incidence ratio is 2:1, with symptoms being somewhat more variable in women.<sup>1</sup>

**Etiology and pathogenesis.** A strong genetic component likely plays a role in the development of AS, because 90% to 95% of patients are positive for the HLA-B27 marker and the frequency of this arthritis in different ethnic groups roughly parallels the frequency of HLA-B27 presence.<sup>4</sup> The role of the HLA molecule in the pathogenesis of this arthritis is not clear, although antigen presenting cells (expressing these HLA markers) may interact with certain bacterial or environmental factors and cross-react with self antigens found in joint tissues. Activation of immune-mediated inflammation occurs within the sacroiliac joints of the pelvis and the ligaments supporting the vertebral column. This leads to persistent back pain, stiffness, and gradual loss of mobility.

**Clinical manifestations.** Clinical features include the insidious onset of low back pain that improves with exercise but is not relieved by rest and the presence of severe morning stiffness for more than 3 months. Back pain in the night is common. Initial evaluation of the spine suggests an increase in muscle tone, and a loss of normal lumbar lordosis that progresses to a marked limitation of mobility noted in both anterior and lateral planes. With this limitation of movement and a position of spinal flexion, the hips and knees must compensate, creating lower extremity joint degeneration and deformities. Because of restricted postural position and decreased chest expansion, tidal volume may be diminished. A typical postural position for advanced ankylosing spondylitis is shown in [Figure 52-9](#).

Asymmetric peripheral arthritis with swelling of knees, ankles, or toes can also occur along with enthesitis (inflammation at the sites of ligament attachment to bone), with the plantar fascia and Achilles tendon being the most common sites. Persistent diffuse swelling of individual toes (called dactylitis or “sausage toes”) can last weeks to months. Other organ systems that may be affected include the eyes (anterior uveitis, iritis), heart (aortitis, aortic valve insufficiency), and nervous system (nerve root or spinal cord impingement related to spinal deformities or fractures).

**FIGURE 52-9** Typical posture of a patient with ankylosing spondylitis.

**Treatment.** The primary objectives of treatment are to relieve pain, decrease inflammation, and strengthen and maintain posture and function. Regular stretching and range-of-motion exercises are often recommended. Medication options include NSAIDs to reduce pain and swelling, or in severe cases, short-term corticosteroids. Disease-modifying agents, such as sulfasalazine or methotrexate, can be used. Agents that inhibit TNF- $\alpha$  (etanercept, adalimumab, golimumab, or infliximab) have been shown to slow disease progression.

### Polymyositis and Dermatomyositis

**Polymyositis** and **dermatomyositis** are idiopathic inflammatory myopathies. With these diseases there is focal or extensive degeneration of muscle fibers attributable to inflammatory infiltrates of lymphocytes and macrophages.<sup>3</sup> Necrosis of muscle fibers occurs. Possible triggers of this immune-mediated inflammation include viruses, bacteria, parasitic organisms, neoplasms, drugs, vaccinations, and stress. A viral cause has been proposed because various researchers have noted virus-like inclusion bodies in muscle tissue of dermatomyositis patients.<sup>3</sup>

Proximal limb and neck weakness and associated muscle stiffness are clinical signs of these illnesses. Muscle pain is often mild. Most patients initially complain of hip and leg weakness and difficulty with climbing stairs and rising from a chair. Later in the progression of the disease, weakness in the arms prevents functional overhead activity. Anterior neck weakness makes lifting the head from the pillow very difficult. When classic skin changes occur with polymyositis, the disease is classified as dermatomyositis. Inflamed, injured skeletal muscle leaks several enzymes (creatine kinase, aldolase, aspartate aminotransferase) into the bloodstream and are found at high levels on laboratory testing.

**Clinical manifestations.** During the physical examination, manual muscle testing reveals weakness in the proximal limb muscles. Contractures are not usually present, but they may develop later. Facial and ocular muscle weakness seldom occurs, distinguishing myositis from

myasthenia gravis. Diagnosis of myositis can be detected by electromyography and confirmed on skeletal muscle biopsy.

In dermatomyositis, cutaneous manifestations may develop with muscle involvement. Common findings are flat-topped papules overlying the dorsal surface of the small joints of the hands (Gottron papules). A more common finding is development of an erythematous smooth or scaly patch over other joints such as the elbow, knees, or medial malleoli areas (Gottron sign). Other skin changes may include the heliotrope rash (violaceous edema of the eyelids) or a dry erythematous rash over the anterior chest wall (V-sign) or the upper back and shoulders (shawl sign).

Cardiac involvement may occur but is often mild and asymptomatic. Dysrhythmias can occur, but development of congestive heart failure or pericarditis is less common. Weakness of the respiratory muscles can cause dyspnea as can interstitial lung disease, which can be severe in rare cases.

**Treatment.** Initial therapy with corticosteroids is usually used to decrease muscle inflammation and preserve function. Immunosuppressive agents, such as methotrexate, azathioprine, or mycophenolate mofetil, may be helpful in severe cases. Physical therapy is also important and should include passive range-of-motion activities, followed by assisted and then active strengthening exercises.

### Postinfectious Systemic Disorders Reactive Arthritis (Reiter Syndrome)

Historically, **Reiter syndrome** consisted of the triad of arthritis, urethritis, and conjunctivitis. Currently terminology renames this reactive arthritis (ReA), and it is defined as a seronegative arthritis preceded by urethritis, cervicitis, or dysentery. Additional problems may include inflammatory skin lesions, oral ulcers, and keratoderma. The onset is most common between 20 and 40 years of age. Onset following a gastrointestinal tract infection is equally common in males and females, but young men are more frequently affected following a sexually transmitted infection.<sup>6</sup> ReA is linked to the prevalence of HLA-B27. It develops in individuals who are genetically susceptible following an infection by bacteria such as *Chlamydia trachomatis* in the genitourinary tract, or *Salmonella*, *Shigella*, *Yersinia*, or *Campylobacter* in the gastrointestinal tract. It is thought that persistence of bacterial antigens and cross-reactivity of immune cells with these antigens trigger the inflammation seen in joints and tendons of persons affected by this syndrome.

**Clinical manifestations.** Clinically, oligoarthritis typically appears 2 to 6 weeks after the onset of the infectious episode. This acute arthritis onset predominantly affects knees and ankles. Three additional features of musculoskeletal manifestations are typical: diffuse swelling of toes (dactylitis); swelling at the Achilles tendon insertion or plantar fascia (enthesitis); and low back pain, especially associated with inflammation of the sacroiliac joints.

The most common eye involvement in ReA is noninfectious conjunctivitis in up to one third of patients.<sup>6</sup> Acute anterior uveitis (unilateral or bilateral) occurs in approximately 20% of cases and could lead to impairment of vision.<sup>1</sup>

Cutaneous lesions related to ReA include development of small, shallow, painless ulcers on the glans penis and urethral meatus (circinate balanitis). A hyperkeratotic skin lesion (keratoderma blennorrhagicum) may form on the soles of the feet and palms of the hands. Hyperkeratosis (thickening beneath the nails) can occur.

ReA patients may have elevated inflammatory markers (sedimentation rate, C-reactive protein) as well as a mild normocytic anemia, transient leukocytosis, and thrombocytosis. RF test results are usually negative.

**Treatment.** Antiinflammatory medications, particularly NSAIDs, are usually effective at controlling pain and swelling, although

intraarticular corticosteroid injections may also help. Second-line immune-regulating agents, such as sulfasalazine or methotrexate and others, can be used in refractory cases.

### Acute Rheumatic Fever

**Acute rheumatic fever (ARF)** is an inflammatory disease that follows a  $\beta$ -hemolytic group A streptococcal pharyngeal infection. The incubation period, or latent period from infection to onset of the disease, ranges from 2 to 6 weeks. The prevalence of ARF has been estimated at more than 15 million cases worldwide and may be increasing.<sup>1</sup> This might be due to the reappearance of heavily encapsulated, highly virulent rheumatogenic streptococcal strains and/or to the decrease in awareness of the disease and less stringent adherence to disease control measures, especially prevention.

**Etiology and pathogenesis.** One theory of disease occurrence is the cross-reactivity of a patient's immune cells within the lymphoid tissue of the pharynx. Lymphocyte activity and antibody production are stimulated by streptococcal antigens, and then these cells cross-react with proteins in the target organs such as joints, heart, skin, and nervous system, leading to inflammatory reactions in these areas.<sup>1</sup>

**Clinical manifestations.** The clinical aspects of ARF depend on the age of the affected individual. Peak incidence is between ages 5 and 15 years. Children and teenagers present with polyarthritis and carditis. Polyarthritis is usually the only manifestation in the adult. Fever is present in most patients.

Polyarthritis is the most common presenting symptom noted in patients with ARF. Pain may be quite severe over the initial few days to 1 or 2 weeks and then gradually subside. Synovial effusions and erythema may be noted. The knees, ankles, elbows, and shoulders are affected most often. Hips, wrists, and small joints of the hands and feet may also be compromised. Onset may be monoarticular with spread to numerous other joints. Joint symptoms usually respond rapidly to treatment with antiinflammatory medications, especially salicylates.

Children and teenagers with ARF are more likely than adults to develop carditis, with the youngest children (younger than 3 years) being the most likely affected. The signs of carditis include murmurs, cardiomegaly, congestive heart failure, and pericarditis. Mitral valve regurgitation is the most common murmur, followed by aortic regurgitation. Evidence of rheumatic heart disease may not be apparent for many years after the acute incident.

A rash is noted in less than 2% of individuals affected by ARF.<sup>1</sup> The rash, called *erythema marginatum*, begins as a pale erythematous, blanching macular rash over the trunk and proximal regions of the extremities. Painless nodules may cover the extensor surfaces.

Throat cultures may be negative by the time the symptoms of ARF are recognized, but certain antibody tests (antistreptolysin O, anti-DNase B) can be useful to aid in diagnosis.

**Treatment.** The most common therapy is NSAIDs, especially aspirin, and response can be rapid. Corticosteroids may be required in cases of severe cardiac involvement. Antibiotic therapy, including long-term prophylaxis in some cases, is generally recommended.

### Postparasitic Disorders

#### Lyme Disease

**Lyme disease** is a complex illness caused by the *Borrelia burgdorferi* tick-borne spirochete. It is commonly carried by the deer tick, although other species serve as vectors as well. The process by which the presence of the spirochete leads to the later chronic clinical symptoms of Lyme disease is unclear. Theories suggest that persistent antigenic fragments of the dead or inactivated organism trigger the inflammatory responses, or the initial infection stimulates an autoimmune inflammatory response.

**Clinical manifestations and treatment.** The tick bite produces a red macule or papule that may expand to form an annular lesion. The lesion may expand and become quite red. The lesion is warm to the touch but not painful and is often accompanied by a flu-like illness, headache, neck stiffness, fever, chills, myalgia, arthralgia, malaise, and fatigue. Systemic involvement may consist of lymphadenopathy, splenomegaly, hepatitis, nonproductive cough, testicular swelling, and conjunctivitis.

Musculoskeletal symptoms occur early in the illness and follow a pattern of migratory pain in joints, tendons, bursae, muscles, or bones. More than half of patients develop frank arthritis with involvement of the large joints. The knee is a particularly common site of Lyme arthritis and can be associated with large effusions. A persistent arthritis develops in about 10% of patients.

Neurologic abnormalities suggest meningeal irritation. Neurologic abnormalities may include meningitis, cranial neuritis, motor and sensory radiculoneuritis, and chorea.

Cardiac involvement may be noted, including atrioventricular blocks, left ventricular dysfunction, or cardiomegaly. Although cardiac involvement lasts only a few weeks, it can be fatal.

Treatment is with oral or parenteral antibiotics.

#### KEY POINTS

- A number of immune-mediated systemic connective tissue diseases result in joint dysfunction, including RA, SLE, and scleroderma. Most are classified as autoimmune disorders of unclear cause. The signs and symptoms of systemic joint disorders are generalized but involve multiple joints and usually other connective tissue structures.
- Differentiation among types of systemic joint disorders is based on patterns of joint dysfunction, immunologic factors (e.g., rheumatoid factor), and related lesions (e.g., the butterfly rash of SLE).
- Joint destruction in some systemic joint disorders is inflammatory in nature and involves the synovial membrane, cartilage, joint capsule, and surrounding ligaments and tendons.
- Rheumatic fever and Lyme disease are inflammatory joint disorders associated with a known organism.
- Rheumatic fever–related arthritis is a sequela of group A streptococcal infection. Lyme disease is associated with a spirochete carried by ticks.

### JOINT DYSFUNCTION SECONDARY TO OTHER DISEASES

#### Psoriatic Arthritis

**Psoriatic arthritis (PA)** is an inflammatory arthritis associated with psoriasis occurring in 0.04% to 0.1% of individuals in the United States. Peak age of onset is 30 to 55 years of age, and the arthritis can occur in patients who have had psoriasis for many years.<sup>6</sup>

**Etiology and pathogenesis.** Studies have shown a strong familial tendency for psoriatic arthritis, suggesting that genetic factors may cause an increased predisposition to the disease. Environmental factors, such as infection or physical trauma, may trigger the onset of the arthritis. Immunologic features also have a dominant role, with activated T lymphocytes and macrophages infiltrating skin and joint tissue and producing multiple inflammatory cytokines (TNF- $\alpha$ , IL-1, and IL-15, among others). These immune reactions cause proliferation of synoviocytes within joints, angiogenesis (new blood vessel formation), and expansion of inflammatory tissue. In the skin, keratinocytes are stimulated and will proliferate extensively.

**Clinical manifestations.** The pattern of joint involvement seen clinically varies. The majority of patients have peripheral joint involvement in the form of asymmetric oligoarthritis. Fewer patients have

a polyarthritis that is difficult to distinguish from RA. In some PA patients, the DIP joints of the hands can be affected, which is different from RA. Sacroiliac and spinal involvement can also occur.

Commonly, PA is characterized by a combination of soft-tissue and peripheral joint disease. Inflammation occurs in the joints as well as the periosteum, along the tendons, and at tendon insertions in bone (enthesitis). Fusiform swelling of the digits (dactylitis) is common.

Evidence of skin or nail changes, typical of psoriasis, is noted in psoriatic arthritis. These skin changes typical for psoriasis include erythematous papular lesions with characteristic scales. Nail involvement includes pitting and onycholysis (raised transverse thickening and longitudinal ridging). Subungual hyperkeratosis and oil droplet discoloration suggest psoriasis.

Inflammatory markers may be elevated, and rheumatoid factor (RF) and anti-cyclic citrullinated peptide antibody (anti-CCP) are usually negative. Radiographs may show minimal changes; however, some cases involve aggressive disease with bone erosion, fluffy new bone formation (periostitis), and marked loss of joint spaces.

**Treatment.** Psoriasis may respond to topical corticosteroids, emollients, and keratolytic agents. Light therapy, utilizing ultraviolet A radiation, can also be effective. Management of the arthritis centers on NSAIDs or corticosteroids to control pain and swelling, but in many cases, more aggressive immunosuppressive therapy is needed, including methotrexate, cyclosporine, or TNF- $\alpha$  antagonists (etanercept, adalimumab, infliximab).

### Enteropathic Arthritis

**Enteropathic arthritis** refers to articular manifestations of two inflammatory bowel diseases (IBDs): **ulcerative colitis** and **Crohn disease**. A peripheral or axial arthritis can occur in 10% to 22% of patients with IBD, and in some cases the arthritis can precede the onset of gastrointestinal symptoms.<sup>1</sup>

As in the case of the other spondyloarthropathies, the cause of enteropathic arthritis is unclear, but it is postulated to be associated with immune cross-reactivity with bacterial antigens. In the setting of IBD, inflammation of the gut lining may permit entrance of bacteria from the bowel lumen into the lymphoid tissue and bloodstream, stimulating an autoimmune response that can target joints.

**Clinical manifestations.** Articular manifestations include peripheral arthritis, spondylitis, and involvement of muscle and bone. Peripheral arthritis is most commonly asymmetric and pauciarticular, usually in the knees and ankles. Synovial inflammation may be mild to severe, and in mild cases may be transient but prone to relapse. In severe cases, a chronic and potentially erosive arthritis can develop. In spondylitis, there is inflammation in the spinal ligaments and sacroiliac joints, similar to features seen in patients with ankylosing spondylitis. Like other spondyloarthropathies, enthesitis can also be noted.

Various cutaneous and ocular manifestations can occur in IBD. Skin lesions, such as erythema nodosum (painful inflamed nodules under the skin) or leg ulcers (pyoderma gangrenosum) may also be associated with the disease. Ocular manifestations, particularly acute anterior uveitis, occur in 3% to 11% of patients.<sup>6</sup> Amyloidosis with involvement of major organs can be observed in Crohn disease.

Anemia is common in IBD as well as leukocytosis. In the setting of arthritis, elevated inflammatory markers are often seen and HLA-B27, when positive, may identify patients at higher risk of developing spondylitis.

**Treatment.** Treatment focuses on management of the gastrointestinal disease with immunosuppressive agents. Control of the arthritis can be pursued with use of NSAIDs (when tolerated by the gut), COX-2 inhibitors, or corticosteroids. In severe cases, second-line medications may be required for treatment of the arthritis as well as

the bowel disease, particularly the use of TNF- $\alpha$  antagonists as in the setting of Crohn disease.

### Neuropathic Osteoarthropathy

Commonly called *Charcot joint*, **neuropathic osteoarthropathy** is a neurologic disease that leads to bone and joint abnormalities. The mechanism is not clear, but because of a loss in normal proprioception and pain responses, damage occurs to the joint. The mechanics of disease development are probably a combination of neurovascular and neurotraumatic processes. Peripheral nerve injuries, diabetes mellitus, pernicious anemia, alcoholism, and multiple sclerosis can lead to Charcot joint.<sup>1</sup> Motor neuron involvement can affect both upper and lower motor neurons. Diabetes, tabes dorsalis, and syringomyelia are the three most prevalent disease processes that lead to neuropathic osteoarthropathy.

**Clinical manifestations and treatment.** Clinically, the patient presents with a swollen, deformed, and unstable joint. Radiographs reveal advanced joint destruction and pathologic fractures. Management requires protection of the involved joint through immobilization and less weight bearing. Surgical intervention has shown poor results attributable to nonunion, dislocation, or infection.

### Hemophilic Arthropathy

Bleeding into joints, as noted in hemophilia, causes extension of the joint capsule and a limitation of movement. Hemorrhage stimulates a synovial proliferative response, chronic inflammation with a release of degradative proteinase, and changes in cartilage composition with less resistance to stress.<sup>6</sup> Chronic synovitis alters the synovial lining and eventually leads to joint destruction.

**Clinical manifestations.** Three stages of hemophilic arthropathy are described. The acute stage manifests with bleeding in the joint and occurs as the child begins to walk. Bleeding into the confined area of the capsule causes the joint to be positioned in flexion and increases stress to articular structures. Atrophy of muscles around the joint predisposes it to further hemarthrosis. The second stage is due to repetitive hemorrhages into the joint, resulting in chronic synovitis. The joint is edematous and warm but painless. The third stage is characterized by destruction of joint integrity.<sup>3</sup>

Larger joints are affected more frequently than smaller joints.eldom are structures of the wrist involved. Elbows, hips, and knees are subject to major destruction. Muscle hemorrhage (iliopsoas, forearms, gastrocnemius), muscle cysts, and pseudotumors (attributable to osseous hemorrhage) may develop.<sup>3</sup> Medical treatment to enhance clotting is imperative. Education and prevention of joint deformity are essential in the management of hemophilia.

### Gout

**Gout** is a heterogeneous disorder in which disturbance of uric acid metabolism leads to deposition of monosodium urate salts in articular, periarticular, and subcutaneous tissue (Figure 52-10). It is also characterized by hyperuricemia and urate crystal-induced arthritis. Gout arises in humans because of a lack of the enzyme uricase and subsequent inability to oxidize uric acid to a soluble compound. Uric acid is a normal waste product of purine metabolism and therefore must be filtered primarily by the kidneys. When production of uric acid exceeds removal, hyperuricemia results and the possibility of deposition of crystalline sodium urate increases. The acute attack is often triggered by a traumatic event, a surgical procedure, an acute illness, or use of alcohol or medications.

**Clinical manifestations.** The incidence of gout has been reported to be approximately 5.9%.<sup>6</sup> Risk of developing gout increases with age and with an increase in serum urate concentrations. Clinically, acute

**FIGURE 52-10** **A**, Gout. **B**, Gouty arthritis. Deposits of uric acid crystals in the connective tissue have a chemotactic effect and cause exudation of leukocytes into the joint. The inflammation most often affects the metatarsophalangeal joint. (**A**, From Frazier MS, Drzymkowski JW: *Essentials of human diseases and conditions*, ed 5, Philadelphia, 2013, Saunders. **B**, From Damjanov I: *Pathology for the health professions*, ed 4, Philadelphia, 2012, Saunders.)

gouty arthritis is the form most frequently observed. Gouty arthritis is common in middle-aged men and postmenopausal women. A familial tendency is often noted.

Manifestations of gout include recurrent episodes of articular and periarticular inflammation (acute gouty arthritis), accumulation of tophi (crystalline deposits) in bony and connective tissue, impairment of the renal system, and the presence of uric acid calculi. There are four phases in gout: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout.

**ASYMPTOMATIC HYPERURICEMIA.** Hyperuricemia has been estimated at highly variable rates in Americans, from 2% to 40% who are asymptomatic.<sup>6</sup> In this phase, there are no clinical signs; however, the serum urate level is elevated. In the male, hyperuricemia can begin at puberty. In women, hyperuricemia usually does not appear before menopause. No treatment is required at this stage.

**ACUTE GOUTY ARTHRITIS.** Gouty arthritis is the most common early clinical sign. Weight-bearing joints are usually affected and are warm, red, and tender to palpation. The metatarsophalangeal (MTP) joint of the great toe is most often involved. Ankle, tarsal, and knee joints are often affected, although attacks can occur in hands, wrists, and elbows. The first attack of acute gouty arthritis is often sudden onset with an intense pain that can awaken the patient from a sound sleep. Diffuse periarticular erythema often accompanies the attack. Diagnosis relies on classic clinical presentation, hyperuricemia, and the demonstration of urate crystals in synovial fluid of the involved joint.

Initial attacks subside within 1 or 2 days or may last 1 to 2 weeks, after which the patient is symptom free until the next episode. Later attacks tend to become more frequent, and mild arthralgia may occur between episodes.

**INTERCRITICAL GOUT.** Intercritical gout, the name for the disease in the intervals between acute attacks, presents no symptoms. Even during asymptomatic periods, urate crystals can be aspirated from involved joints.

**CHRONIC TOPHACEOUS GOUT.** This is an advanced stage of gout. Tophi begin to appear approximately 10 years after initial onset of gout. Tophi occur commonly in the synovium, subchondral bone, olecranon bursa, and infrapatellar and Achilles tendons. Tophi have been noted in walls of the aorta, valves of the heart, ear cartilage (pinna), corneas, sclerae, and kidneys.<sup>1</sup>

As a result of deposition of crystals and chronic inflammation, deforming arthritis can develop. Development of tophi in tendon sheaths of the hand and wrist can cause a trigger finger or carpal tunnel syndrome.

Patients with gout may have involvement of the kidneys and develop renal malfunction. These individuals have a higher incidence of arterial hypertension, diabetes mellitus, and cardiac and cerebral atherosclerosis. Hypertriglyceridemia occurs more frequently in the patient diagnosed with gout.

**Treatment.** Management of an acute gouty attack usually requires aggressive antiinflammatory medication such as NSAIDs or

corticosteroids (oral, parenteral, or intraarticular). Colchicine may also be used early in the course of an attack or in lower doses as a prophylactic agent. Medications to correct hyperuricemia and prevent gout exacerbation may target uric acid excretion by the kidneys (uricosuric agents) or uric acid production (allopurinol or febuxostat). Pegloticase is a porcine uricase enzyme recently approved for treatment of patients with refractory gout. It is administered as an intravenous infusion every 2 weeks and has a number of side effects, such as infusion reactions, worsening gout flare-ups, gastrointestinal side effects, and congestive heart failure. The practical usefulness of pegloticase is still uncertain and may be best reserved for those with chronic, severe active gout that is not responsive to other treatment options or in patients in whom other agents are contraindicated.<sup>8</sup>

### Adult-Onset Still Disease

Adult-onset Still disease is a form of seronegative (i.e., negative RF) polyarthritis with a number of symptoms similar to those of systemic-onset juvenile rheumatoid arthritis (JRA) in children (see the Pediatric Joint Disorders section in this chapter). Adult-onset Still disease may follow diagnosis of RA. Its cause is unknown.

**Clinical manifestations and treatment.** Clinical features include high-spiking fever, a rash on the trunk and extremities, and, possibly, a sore throat. Polyarthritis usually affects the PIP and MCP joints of the hands, but can also involve the wrist, knees, hips, and shoulders. Visceral involvement includes hepatic insufficiency, chronic respiratory failure, cardiac tamponade, congestive heart failure, and splenomegaly. Laboratory features may include anemia, leukocytosis, elevated sedimentation rate, thrombocytosis, and elevated liver enzymes.

Some patients respond well to high-dose aspirin or NSAIDs during the acute illness, although in severe cases corticosteroids are used.

#### KEY POINTS

- Psoriatic arthritis differs from rheumatoid arthritis in that PsA is more often asymmetric, is associated with psoriasis in the skin, and is not associated with autoantibody (RF or CCP) production. It can, however, lead to joint erosions and damage.
- Neurovascular, hematologic, and metabolic disorders may lead to associated disorders of joint function. Diabetes, for example, results in neurovascular changes that desensitize the joint and predispose it to traumatic joint dysfunction. Hemophilia predisposes to intraarticular bleeding.
- Altered uric acid metabolism leads to deposition of uric acid crystals in joints, causing inflammation and gouty arthritis.

## PEDIATRIC JOINT DISORDERS

Pediatric rheumatic diseases include more than 100 illnesses associated with arthritis and musculoskeletal syndromes. Soft-tissue pain and restrictions constitute a major proportion of the complaints presented to pediatric rheumatologists.

### Nonarticular Rheumatism

“Growing pain” or **nonarticular rheumatism** is a common soft-tissue syndrome in children. Nocturnal pain, usually occurring in the calves, shins, and thighs, is the most common symptom. Although this problem seems to be benign, medical consultation and education concerning the problem are essential.

### Hypermobility of Joints

Hypermobility of joints is a common cause of complaints of pain in the joints. Mobility may be excessive in any joint, but it is most apparent in

passive apposition of the thumb to the forearm, hyperextension of the fingers parallel to the forearm, and excessive extension (greater than 10 degrees) of the knees and elbows.

### Juvenile Idiopathic Arthritis

**Juvenile idiopathic arthritis** (JIA; also called juvenile rheumatoid arthritis [JRA]) is a chronic, inflammatory childhood disease that sometimes resolves by the time the child reaches adulthood. However, residual joint damage remains. JIA begins with synovial inflammation of unknown cause and affects approximately 57 to 220 per 100,000 children under the age of 16 years.<sup>1</sup> JIA may be defined as arthritis in one or more joints (pain, redness, swelling, warmth, and limited range of motion). The duration of the arthritis is at least 6 weeks. JIA may present with one of three general types of onset, which is classified during the first 6 months of the disease: (1) systemic, (2) polyarticular, and (3) pauciarticular (oligoarticular).<sup>1</sup> The classification of JIA, however, is being expanded to include many other subtypes of childhood inflammatory arthritis.

**Clinical manifestations.** Systemic-onset JIA is noted in approximately 2% to 17% of children with JRA with peak onset at 1 to 6 years of age.<sup>1</sup> Clinical manifestations include spiking fevers (103° to 104° F), daily or twice daily and usually in the afternoon with return to baseline without antipyretics; transient, pale pink rash; lymphadenopathy; hepatosplenomegaly; and pericardial or pleural effusions. Fatigue, muscle atrophy, and weight loss can be severe. Anemia, leukocytosis, and thrombocytosis are common. RF is usually negative. Musculoskeletal findings in the early stages of the disease include recurrent arthralgia, myalgia, and transient arthritis, which are concurrent with fever spikes. Polyarthritis can develop weeks to months after the onset of the disease. Severe chronic arthritis may continue after the systemic symptoms subside.

A **polyarticular onset** of JIA (i.e., involving five or more joints) is seen in approximately 10% to 28% of patients (somewhat less when including only those who are RF positive), with peak onset at age 8 to 16 years. The female to male ratio is 3:1.<sup>1</sup> RF positivity is also more common in girls with later onset of disease that can resemble adult RA. These patients are at a higher risk of developing progressive bone erosions, nodules, and poor functional outcome. Malaise, growth retardation or weight loss, low-grade fever, and anemia are other clinical manifestations.

By definition, a child with **pauciarticular (oligoarticular) onset** of JIA has arthritis in four or fewer joints. One subset of this form of JIA includes patients who are very young at disease onset (1 to 5 years of age), can have a positive ANA test result, and are most often girls (female to male ratio is 4:1). Patients with a positive ANA test result are at highest risk for developing inflammatory ocular disease, a complication that may start with minimal or no symptoms yet can lead to severe irreversible vision impairment. A second group of patients with pauciarticular JIA have later disease onset. These children are more commonly boys, may be HLA-B27 positive (50%), and often develop large joint disease (hips, knees, shoulders, or spine). These patients may also develop eye inflammation, but this is less likely than in the early-onset group.

**Treatment.** All forms of JIA can cause general growth retardation, although it is more of a risk in children with systemic or polyarticular onset of disease. Inflammation close to the epiphyseal plates can result in altered growth of long bones. It is therefore imperative to achieve early diagnosis and implement appropriate treatment to minimize deformity and disability. Education and counseling are also important. Relief of symptoms and maintenance of joint position and muscle function are immediate goals of treatment.

Pharmacologic intervention is an important component of the treatment regimen. Drug therapy is instituted to decrease pain and

arrest progression of the disease. The following categories of drugs are used: (1) antiinflammatory analgesics (aspirin or NSAIDs), (2) corticosteroids, (3) disease-modifying drugs (methotrexate, sulfasalazine, leflunomide), and (4) biological disease-modifying agents (such as the TNF- $\alpha$  inhibitors etanercept, adalimumab, and infliximab). An additional biological agent that can be used in severe JIA is tocilizumab, which inhibits activity of interleukin-6. Biological agents targeting other inflammatory cytokines, such as interleukin-1 (anakinra), have also shown some efficacy in JIA as well. Physical and occupational therapy assessment and treatment plans are important, and daily

activity should be an integral part of the child's lifestyle. Joint support and physical activity help prevent joint contracture.

### KEY POINTS

- JIA has three subtypes: systemic onset (which has more systemic manifestations, including rash, high fever, lymphadenopathy, splenomegaly, fatigue, and polyarthritis); polyarticular arthritis (in which symptoms are primarily localized to five or more joints); and pauciarticular arthritis (which involves four or fewer joints).

## SUMMARY

This chapter has provided an overview of major rheumatic disorders. Broadly speaking, interventions must assist in controlling disease activity, managing pain, minimizing deformity, and maintaining or restoring function. Depending on the stage of the disease, correct intervention must be implemented using knowledge of joint physiology biomechanics and pathologic changes resulting from the disease.

The challenge to the health professional is to ensure that an inflammatory response is not exacerbated while the body structures are being stimulated to increase strength, enhance nutrition, and improve tolerance to stress. Long periods of immobilization, bed rest, and sedentary behavior are counterproductive in the patient with arthritis. Lack of

activity poses particular problems in people with arthritis. Deleterious effects on muscle strength, reflexes, connective tissue extensibility, and cardiovascular fitness are identifiable in the immobilized arthritic patient. It is imperative that the health professional look beyond disease-specific interventions and prescribe a well-developed exercise program for patients with arthritis. Achievement or retention of as much function as possible is the ultimate goal for an individual with arthritis. Every level of intervention must be directed to achievement of specific performance goals cooperatively developed by clinician and patient.

This chapter focuses on altered structure and function of the integumentary system. The etiologic factors, pathogenesis, and clinical manifestations of selected skin disorders as well as general considerations regarding treatment modalities and their therapeutic application are described.

**AGE-RELATED CHANGES**

The skin undergoes dramatic changes from birth through the mature years. Healthy infants and young children have relatively smooth and unwrinkled skin characterized by elasticity and flexibility. Because skin tissues are in an active phase of new growth, healing of skin injuries is often rapid and efficient. Young children and elderly individuals have fewer sweat glands than adults do, so their bodies rely more on increased blood flow to maintain a normal body temperature.

As adulthood begins at puberty, hormones stimulate the development and activation of sebaceous glands and sweat glands. After the sebaceous glands become active, especially during the initial years, they may overproduce sebum and thus give the skin an unusually oily appearance. Sebaceous ducts may become clogged or infected and form acne pimples or other blemishes on the skin. Activation of apocrine sweat glands during puberty causes increased sweat production, an ability needed to maintain an adult body properly, and also

the possibility of increased “body odor.” Body odor is caused by wastes produced by bacteria that feed on the organic compounds found in apocrine sweat and on the surface of the skin.

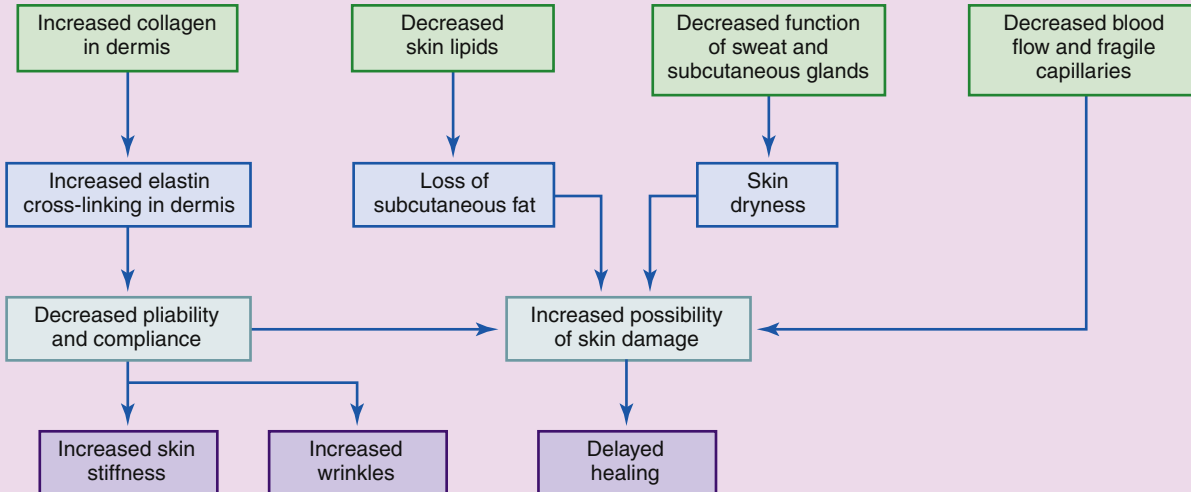

Past early adulthood and into middle age, the sebaceous and sweat glands become less active. Although this can provide relief to those who suffer from acne or other problems associated with overactivity of these glands, it can affect the normal function of the body. For example, the reduction in sebum production can cause the skin and hair to become less resilient.

Changes in the appearance and function of the skin, perhaps more than in any other organ, reflect the continual aging process (see Geriatric Considerations: Changes in the Integumentary System). One need only look at a person to determine an approximate age. Evidence of advancing age includes wrinkling and sagging skin, gray hair, and baldness. Aging changes are also linked to environmental influences, genetic makeup, and other bodily changes (Figure 53-1).

Exposure to sunlight is one of the greatest factors in age-related skin changes. The result of such exposure can be seen in people who work outdoors in sunlight. Results are also evident when skin exposed to sunlight is compared with unexposed skin. Skin that is usually covered shows little change with age. Blue-eyed, fair-skinned individuals are more susceptible to solar skin damage than are people with darker, more heavily pigmented skin.

## GERIATRIC CONSIDERATIONS

## Changes in the Integumentary System

With aging, the skin's protective functions decline. Although the thickness of the stratum corneum remains the same, the properties of the water and chemical barriers in this layer of the integument are less effective. In the epidermis, mitosis decreases and cellular variation increases. The thickness of the epidermis is unchanged. The number of melanocytes decreases in Caucasians, with declining function. The melanocytes are less efficient and lack uniformity in pigment production with sun exposure.

There is a decrease in both the thickness and the amount of subcutaneous fat in the dermis, and there is an increase in the amounts of collagen and elastin with cross-linking and calcification of elastin fibers. These changes cause a loss of skin pliability, compliance, and resiliency. There is an accompanying

escalation in skin stiffness and an increase in wrinkling of the skin. Sebaceous and sweat gland function declines, resulting in drier, less oily skin. The number of sensory nerves and blood vessels in the skin declines, resulting in decreased sensation and loss of effective vasoactivity by dermal arterioles.

Nail and hair growth declines. The nails may become yellowed and thickened. Graying of the hair is due to the loss of melanocytes at the hair follicle base. The degree and pattern of hair loss are affected by genetic and endocrine factors. Body hair patterns change, with thinning of leg, axillary, and pubic hair.

The cumulative effect of these skin changes is loss of the regulatory, secretory, and excretory properties of the skin. The skin becomes injured more easily, and, once injured, heals more slowly.

**FIGURE 53-1** Physiologic signs of aging human skin. (Photo by Lee-Ellen C. Copstead.)

## Epidermis

The epidermis shows a generalized thinning with advancing age, although there may be some thickening in sun-exposed areas. Although there is an increased variation in epidermal thickness, the average number of cell layers remains unchanged. The prickle cells of the inner layer of the epidermis show greater variation in nuclear and cytoplasmic size with a less orderly arrangement of cells. Cells reproduce more slowly and are larger and more irregular; however, exposed epidermal cells may divide more frequently than unexposed cells.

## Dermis and Subcutaneous Tissue

The dermis contains blood vessels, nerves, hair follicles, and sebaceous glands, but the major portion is composed of collagen and elastin. The elasticity of the skin is largely due to dermal elastin. Decreased skin strength and elasticity with aging are attributed to a decreased amount of elastin and a proportionate increase in the collagen-to-elastin ratio. Collagen fibers change with age, becoming cross-linked and rearranged into thicker bundles. This condition is called **elastosis** and is closely associated with exposure to sunlight (**solar elastosis**). It produces a weather-beaten or tanned appearance.

Aging also produces a decrease in the vascularity of the dermal skin, as evidenced by decreasing numbers of epithelial cells and blood vessels. There is greater vascular fragility, leading to the frequent appearance of hemorrhages (senile purpura); cherry angiomas; venous stasis; and venous lakes on the ears, face, lips, and neck. The decreased vascularity and circulation in the dermis and the underlying subcutaneous tissue also have an effect on drug absorption. Drugs administered

subcutaneously are absorbed more slowly, thus prolonging their half-life. The amount of subcutaneous fat tissue also decreases, especially in the extremities, so that arms and legs appear to be thinner.

## Appendages

### Hair

The most obvious change in aging hair is its color. Half of the population over age 50 years has at least 50% gray body hair, regardless of gender or hair color. Gray hair is determined by an autosomal dominant gene and results from a decreased rate of melanin production by the hair follicle. Hair color generally darkens with age, but this process is reversed with the onset of graying. Graying usually begins at the temples of the head and extends to the vertex of the scalp. It may not occur in the axilla, especially in women, and occurs to a lesser extent in the presternum or the pubis.

Changes in hair growth and distribution are also associated with aging. The amount and distribution of hair are determined by racial, genetic, and sex-linked factors; however, almost all older people have a diminution of body hair except on the face. Adults develop a full terminal hair pattern by age 40 years, and this is followed by a progressive loss of hair in reverse order of development. Postmenopausal Caucasian women lose trunk hair first, then pubic and axillary hair. Unopposed adrenal androgens produce coarse facial hair in 50% of Caucasian women older than 60 years, especially on the chin and around the lips.

Men also show a general thinning of hair distribution, with the hairs of the eyebrows, ears, and nose becoming longer and coarser. Baldness is often a concern, particularly in aging men, although women also tend to show some thinning of scalp hair. Frontal recession of the hairline occurs in 80% of older women and 100% of older men. Baldness in men is inherited from the mother and occurs only in the presence of testosterone. Onset is variable and is manifested by an M-shaped pattern of hair loss on either side of the midline or by a thinning patch over the vertex.

In general, the hair of both men and women changes from darker, thicker, and more numerous to lighter, thinner, and less numerous with aging. Hair changes begin in midlife and become highly noticeable in later life, especially after age 60 years. Women seem to manifest more hair loss on the trunk and extremities, whereas men have greater hair loss on the head.

### Nails

With aging, nails become dull, brittle, hard, and thick. Most nail changes are due to a diminished vascular supply to the nail bed. There is approximately a 30% to 50% decrease in the growth rate of fingernails, from 0.1 mm/day in 30 year olds to 0.07 mm/day in 90 year olds. Aging nails show an increase in longitudinal striations, which can cause splitting of the nail surface.

Toenails are particularly prone to hyperkeratosis and resultant thickening. Pressure and trauma from poorly fitting footwear may be a significant factor, but onychomycosis, which affects approximately 20% of individuals over age 60, is the primary factor.<sup>1</sup>

### Glands

Sebaceous glands show little atrophy or histologic change with age; however, their function tends to diminish, as evidenced by a decrease in sebum secretion. In men the decrease is minimal, but in women there is a gradual diminution in sebum secretion after menopause, with no significant changes after the seventh decade. There are fewer sebaceous glands in older individuals, which appear related to the loss of hair follicles. The decrease in sebum secretion and in the number of sebaceous glands results in the drier, coarser skin associated with aging.

Sweat glands generally decrease in size, number, and function with age. In the eccrine glands, the secretory epithelial cells become uneven

## BOX 53-1 MORPHOLOGIC FEATURES OF AGING HUMAN SKIN

EPIDERMIS	DERMIS	APPENDAGES
Flat dermoepidermal junction	Atrophy	Graying of hair
Variable thickness	Fewer fibroblasts	Loss of hair
Variable cell size and shape	Fewer blood vessels	Conversion of terminal to vellus hair
Occasional nuclear atypia	Shortened capillary loops	Abnormal nail plates
Loss of melanocytes	Abnormal nerve endings	Fewer glands

From Gilchrist BA: Skin. In Rowe JW, Besdine RW, editors: *Health and disease in old age*, Boston, 1982, Little, Brown, p 383.

in size, ranging from normal to small, and there is a progressive accumulation of lipofuscin in the cytoplasm. In the very old, the secretory coils of many eccrine glands are replaced by fibrous tissue, which drastically diminishes their capacity to produce sweat. The thermal threshold for sweating is raised, so that the amount of sweat output at a body temperature of 38° C (100.4° F) decreases. This may be due to the fact that there are fewer blood vessels and nerve cells around the glands that enable the body to respond to temperature changes. Apocrine glands do not decrease in number or size, but they do decrease in function. An accumulation of lipofuscin has also been noted in apocrine glands. The diminished functioning of sweat glands in the elderly greatly impairs the ability to maintain body temperature homeostasis.

Box 53-1 summarizes the morphologic features of aging human skin, and Figure 53-2 summarizes the histologic changes associated with aging in normal human skin.

### KEY POINTS

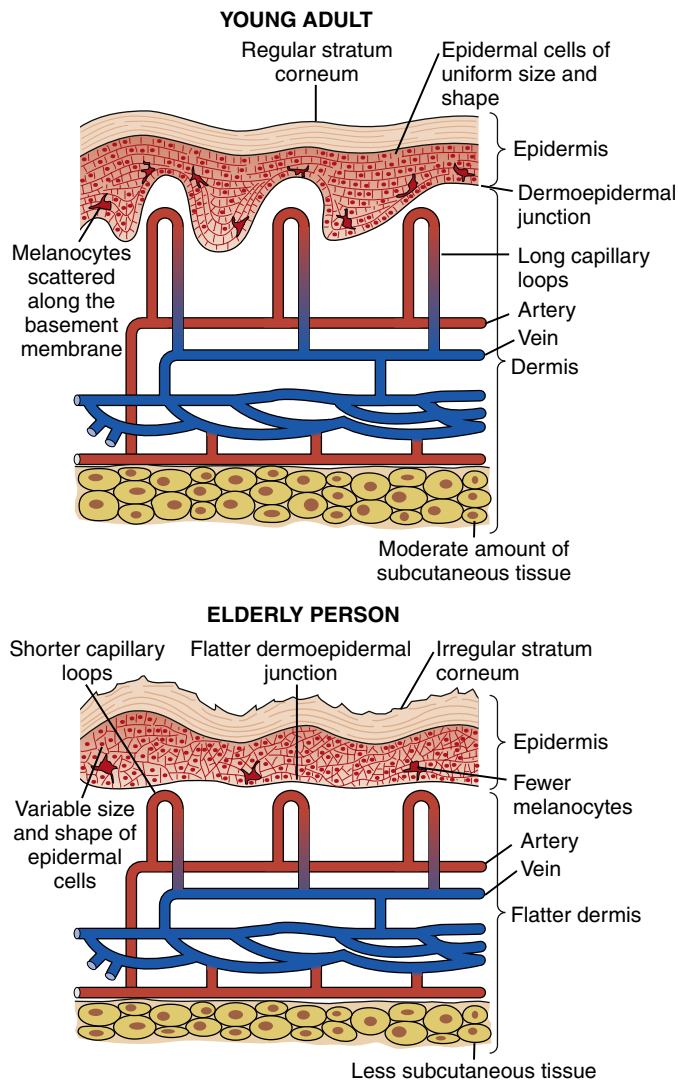

- The glandular function of skin varies considerably with age. Young children and elderly adults have fewer functional sweat glands and therefore less efficient evaporative heat loss capabilities. Sebaceous glands are particularly active during puberty, causing a predisposition to acne; they become less active with age, causing a predisposition to dry skin.
- The epidermis and dermis undergo degenerative changes with aging. The epidermis thins, and the dermis becomes less elastic and less vascular. The amount of subcutaneous fat decreases. Exposure to sunlight is an important factor in the development of aged skin.
- Graying of hair results from decreased melanin production by the hair follicle. After age 40 years, progressive hair loss occurs. Male pattern baldness is an inherited trait that is mediated by testosterone.

## EVALUATION OF THE INTEGUMENTARY SYSTEM

A careful examination of the skin yields valuable information that may aid in identifying a systemic disease or a specific problem of the skin or appendages. Diagnostic evaluations include a careful history, and Table 53-1 provides a general guide. A proper skin examination also describes the objective signs of dermatologic disease, including all types of lesions and their distribution.

### Primary and Secondary Lesions

Physical descriptions should include the lesions and their classification, generally **primary** (original appearance) or **secondary** (appearance modified by normal progress over time or by such external agents as scratching). Figure 53-3 shows clinical examples of primary and secondary lesions.

**FIGURE 53-2** Histologic changes associated with aging in normal human skin. Note the flattening of the dermoepidermal junction and the shortening of capillary loops in older skin. Variability in size and shape of epidermal cells, irregularity of stratum corneum, and loss of melanocytes are also apparent. Age-associated loss of dermal thickness and subcutaneous fat is also illustrated.

### Lesion Descriptors

After a skin lesion has been classified as primary or secondary, other features should be noted, particularly size, symmetry of color and shape, and distribution if more than one lesion is present. Skin lesions may assume a wide range of colors—red—salmon pink, brown—black, blue—purple, bone white—slate gray, and yellow, to name a few. Each color suggests certain diagnoses. Skin lesions may be solitary, few, or profuse. When more than one lesion is present, the distribution pattern may be important in suggesting the diagnosis. Look for the following common patterns: symmetric (affecting mirror-image portions of the body), sun-exposed (affecting skin sites that routinely receive solar irradiation), intertriginous (affecting warm, moist, apposed skin sites), acral (affecting the distal extremities, ears, and nose), genital, and flexor or extensor predominance. Additional descriptors are often used to further characterize and describe a skin lesion or the relationship between various skin lesions such as confluent or clustered. Table 53-2 lists common morphologic and configurational terms.

**TABLE 53-1** SUMMARY OF KEY ASSESSMENT ITEMS

ASSESSMENT ITEM	PURPOSE AND RELEVANT QUESTIONS TO ASK
Family history	Some skin diseases are familial or hereditary. When hereditary skin disease is ascertained, one may have the opportunity to both correct misconceptions and allay fears about the presence, absence, or prognosis of disease. What are the current familial dermatologic diseases?
Personal history	What was the age at onset of the problem? How has the patient adjusted to the problem? By social withdrawal? Cosmetic cover-up? Withdrawal from school athletic activities that require showers (e.g., football, tennis)? Does the problem threaten the patient's self-image of masculinity or femininity? What is the patient's ethnic origin? (Some skin diseases are more common in certain ethnic groups.)
Geographic origin and present abode	Length of time spent living in each area? Some skin diseases are indigenous, which may be important because of increased exposure. Occasionally, a contact of only 5 min is all that is necessary for acquisition of a disease.
Season	Seasonal occurrence of a problem? Pollen? Sunlight?
Occupation	Type of work? Skin contact material (e.g., chemicals, dust, gas), excessive heat and abnormal lighting, unhygienic surroundings, possible infective insects, other family members' occupational exposures?
Leisure activities	Does the problem occur only on weekends? After yard activities? Painting? Woodworking? Camping? Fishing? Hiking? In association with children's play?
Accompanying diseases	Collagen disease? Drug therapy for collagen disease? Other diseases and their drug therapy?
Previous treatment	Self-treatment? Other drugs prescribed?
Special history	Onset of skin lesions (abnormality)? Remissions, exacerbations, or recurrences? Site of onset? Character of lesions? Original character and subsequent changes? Course or extension? Symptoms? Itching? Ability to perform duties? Topical therapy? Self-treatment? Psychological factor? What does the patient associate with exacerbations of the problem (e.g., stress of a family argument, tax time, report time)?

Data from Rosen T et al, editors: *Nurse's atlas of dermatology*, Boston, 1983, Little, Brown.

### KEY POINTS

- Skin lesions may be categorized as primary or secondary.
- Primary lesions retain their original appearance, unmodified by time and external processes such as scratching.
- Secondary lesions are those whose appearance has been modified over time; they may look quite dissimilar to the original lesion. The differentiation of primary from secondary lesions aids in establishing a correct diagnosis.
- A description of lesion color, shape, number, and distribution is helpful in determining the cause of a lesion.

## CHAPTER 53 Alterations in the Integumentary System

### NONPALPABLE

### PRIMARY LESIONS (Original Appearance)

**Macule:** A spot, circumscribed, up to 1 cm; not palpable; not elevated above or depressed below surrounding skin surface; hypopigmented, hyperpigmented, or erythematous. **Example:** Freckles. Referred to as **patch** if greater than 1 cm. **Examples:** Café au lait spots, mongolian spots.

### PALPABLE, SOLID

**Papule:** A bump, palpable and circumscribed, elevated and less than 5 mm in diameter; may be pigmented, erythematous, or flesh-toned. **Example:** Elevated nevus (mole).

**Nodule:** A lesion similar to a papule, with a diameter of 5 mm to 2 cm; may have a significant palpable dermal component. **Examples:** Fibroma, xanthoma, intradermal nevi.

**Tumor:** Any mass lesion; generally larger than a nodule; may be either malignant or benign. **Example:** Lipoma.

**Plaque:** Usually well-circumscribed lesion with large surface area and slight elevation. **Examples:** Psoriasis, lichen planus.

**Wheal:** An elevation in the skin, with a smooth surface, sloping borders, and (usually) light pink color; caused by acute areas of edema in the skin; may appear, disappear, or change form abruptly within minutes or hours; size ranges from 3 mm to 20 cm. **Example:** Mosquito bite.

### PALPABLE, FLUID-FILLED

**Vesicle:** A small blister (up to 5 mm in diameter); fluid collection may be subcorneal, intraepidermal, or subepidermal. **Example:** Herpes simplex (early stages).

**Bulla:** A blister larger than 5 mm; fluid may be located at various levels. **Examples:** Pemphigus, pemphigoid.

**Pustule:** An elevated, well-circumscribed lesion containing purulent exudate. **Example:** Acne vulgaris.

*Continued*

**FIGURE 53-3** Characteristics of common skin lesions.

## SELECTED SKIN DISORDERS

Diseases of the skin are divisible into two broad etiologic categories: inflammatory/infectious and proliferative/neoplastic. Inflammatory disorders of the skin often occur in individuals who have hypersensitivity reactions to substances in the environment. Infectious agents ranging from viruses to insects may infect the skin. Proliferative conditions include psoriasis, seborrheic keratosis, cysts, warts, and papillomas.

Other benign tumors arise from other cells in the skin: nevi, lipomas, dermatofibromas, neuromas, and hemangiomas. Kaposi sarcoma is a malignant, opportunistic neoplasm that occurs in persons with preexisting immunodeficiency.

Skin cancer is the most common malignancy in the United States; however, with the exceptions of malignant melanoma and a few squamous carcinomas, skin cancers are not life threatening. Ultraviolet light damages sun-exposed skin and is a major factor in development

## SECONDARY LESIONS (Modification of Original Appearance)

## DAMAGED OR DIMINISHED SKIN SURFACE

**Erosion:** Loss of epidermis that does not extend into dermis. **Example:** Ruptured chickenpox vesicle.

**Ulcer:** Loss of skin through the epidermis; healing results in scar formation. **Example:** Stasis ulcer.

**Fissure:** A split in all epidermal layers of skin. **Example:** Athlete's foot.

**Atrophy:** Diminution of epidermal surface; skin looks thinner and more translucent than normal; atrophy of the dermal layers may result in wasting or depression of the skin surface. **Example:** Arterial insufficiency.

**Excoriation:** Loss of outer skin layers from scratching or rubbing. **Example:** Scratched insect bite.

## AUGMENTED OR INCREASED SKIN SURFACE

**Crust:** A collection of serous exudate and debris on the surface of damaged or absent outer skin layers. **Example:** Impetigo.

**Scale:** A compact portion of desquamating stratum corneum; may vary in size, thickness, and consistency. **Examples:** Psoriasis scale (compact and thick), pityriasis rosea scale (thin and small).

**Lichenification:** Epidermal thickening and roughening of the skin with increased visibility of skin surface furrows. **Example:** Chronic atopic dermatitis.

**Scar:** A collection of fibrous tissue that forms to replace lost epidermal and dermal tissue. **Examples:** Surgical scar, acne scar.

**Keloid:** Augmentation of scar tissue, creating a significant elevation on the skin surface after healing. **Examples:** Postsurgical scar, postacne scar.

FIGURE 53-3, cont'd Characteristics of common skin lesions.

TABLE 53-2 LESION DESCRIPTORS

TERM	DEFINITION
Confluent	Blending together
Diffuse	Generalized or widespread
Discrete	Remaining separate but close together
Eczematous	Vesicles with an oozing crust
Herpetiform	Closely grouped vesicles (herpeslike)
Linear	Set in a straight line
Localized	Found only in one area
Pedunculated	On a stalk
Reticulated	Netlike array
Round lesions	Annular (ring shaped, active edge, clear center)
	Arcuate (arc shaped, incomplete circle)
	Circinate (circular)
	Guttate (small droplet-like)
	Iris (concentric circles such as a bull's eye)
	Nummular (coin shaped)
	Ovoid (oval shaped)
Serpiginous	Wandering, snakelike
Telangiectatic	Characterized by dilated surface vessels
Verrucous	Rough, wartlike surface
Zosteriform	Similar to shingles, following along a nerve root dermatome

Data from Sauer GC: *Manual of skin diseases*, ed 6, Philadelphia, 1991, Lippincott.

of skin cancer. Although many of the disorders described in the following section are not life threatening, they can affect the quality of life.

## INFECTIOUS PROCESSES

## Viral Infections

## Verrucae

**Etiology and pathogenesis.** Verrucae, or warts (Figure 53-4), are common benign papillomas caused by DNA-containing papillomaviruses. Although warts vary in appearance depending on their location, the histologic characteristics of all lesions are similar. A wart is actually an exaggeration of normal skin composition, with the stratum corneum being irregularly thickened. The human papillomaviruses, the subgroup of papovaviruses that causes human warts, are not found in other animals and invade only the skin and mucous membranes of humans.

Warts may resolve spontaneously if immunity to the virus develops, but the immune response can be delayed for years and is not reliably activated in every case. In 95% of cases, untreated warts will resolve within 5 years,<sup>2</sup> but they may multiply into hundreds of lesions and can involve any body site. Current surgical treatment may be directed at removal of the wart by laser. Liquid nitrogen or acid chemicals, cryotherapy, and salicylic acid paint or plasters have also been effective medical treatments. Topical blistering agents, immunomodulators, and intralesional injections of various agents may also be effective treatment modalities.

**FIGURE 53-4** Plantar warts. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 92.)

### Herpes Simplex Virus

**Etiology and pathogenesis.** Herpes simplex virus (HSV) infections of the skin and mucous membranes are common (Figure 53-5). Two types of herpesviruses infect humans: type 1 and type 2. Most HSV-1 infections occur above the waist.<sup>3</sup> HSV-1 may result when external infection is spread to the other parts of the body through the occupational hazards that exist in professions such as dentistry and medicine and some athletics. HSV-2 is responsible for most infections in the genital region.<sup>3</sup>

Herpesvirus lesions usually begin with a burning or tingling sensation. Vesicles and erythema follow and progress to pustules, ulcers, and crusts before healing. The lesion is most common on the lips, face, and mouth. Pain is common, and healing takes place in 10 to 14 days.<sup>4</sup> After the initial infection, the herpesvirus persists in latent form in the trigeminal nerve and other ganglia. Recurrent lesions are common and may be precipitated by stress, sunlight exposure, menses, or injury.<sup>5,6</sup> The vast majority of patients have at least 1 episode of herpesvirus reactivation, and some individuals may have 10 or more outbreaks per year. Recently, concern has arisen over the identification of infectious viral shedding in the absence of symptomatic lesions.<sup>5</sup>

**Treatment.** No cure for herpes simplex is known, and most treatment measures are palliative. Lidocaine (Xylocaine) or diphenhydramine (Benadryl) application and aspirin administration help relieve pain. Cold compresses help in the acute stages. Acyclovir, famciclovir, or valacyclovir is recommended to shorten the duration of active disease outbreaks; in certain situations, these drugs may be used for daily prophylaxis.

### Herpes-Zoster Virus

**Etiology and pathogenesis.** Herpes zoster (shingles) is an acute localized inflammatory disease of a dermatomal segment of the skin (Figure 53-6). It is caused by the same herpesvirus that causes chickenpox (varicella-zoster virus). It is believed to be the result of reactivation of a latent varicella-zoster virus that has been present in the sensory dorsal ganglia since childhood infection. During an attack of shingles, the reactivated virus travels from the ganglia to the skin of the corresponding dermatome.

**Clinical manifestations.** The clinical manifestations of shingles include the eruption of vesicles with erythematous bases that are restricted to skin areas supplied by sensory neurons of a single or associated group of dorsal root ganglia. Eruptions generally follow a unilateral dermatomal distribution and most often occur on the thorax,

trunk, and face. In immunosuppressed persons, the lesions may extend beyond the dermatome. New crops of vesicles erupt for 3 to 5 days along the nerve pathway.<sup>3</sup> Lesions are deeper and more confluent than those of chickenpox. The vesicles dry, form crusts, and eventually fall off. Lesions usually clear in 2 to 3 weeks.<sup>3</sup> Severe pain and paresthesias are common. In the elderly, herpes-zoster virus is a particularly serious condition that may be long lasting. Pain reports from elderly individuals indicate an increased severity and lengthy episodes of up to 1 year.<sup>3</sup> Systemic treatment with acyclovir, famciclovir, or valacyclovir should be initiated as soon as possible, preferably within the first 48 to 72 hours.

**Postherpetic neuralgia** is the most important complication occurring in people older than 50 years.<sup>3</sup> Eye involvement can result in permanent blindness.

**Treatment.** Management of shingles includes oral antiviral drugs; acyclovir (Zovirax) is one example. Topical agents such as Burow compresses or aqueous alcohol shake lotions may also be used. Pain medication may be indicated in severe cases. Systemic corticosteroids have also been effective in healthy persons older than 50 years with severe pain, but their use remains controversial. High doses of interferon, an antiviral glycoprotein, have been used in persons with cancer when the herpetic lesions are limited to the dermatome.<sup>7</sup>

Additionally, vaccination is becoming an important tool in preventing herpes zoster (e.g., Zostavax).

### Fungal Infections

#### Superficial Fungal Infections

Three genera of fungi (**dermatophytes**) commonly infect human skin: *Microsporum*, *Trichophyton*, and *Epidermophyton*. These organisms can cause an infection termed **tinea** in any cutaneous area, including the hair and nails. Infections in different locations are named after the location: tinea capitis (scalp) (Figure 53-7, A), tinea barbae (beard), tinea faciei (face) (Figure 53-7, B), tinea corporis (trunk) (Figure 53-7, C), tinea manus (hand), tinea cruris (groin), and tinea pedis (foot).

**Clinical manifestations.** The clinical signs of superficial fungal infection vary depending on the physical location and the host's response to the invading organism. Often fungal infections are manifested as erythematous macules or plaques with peripheral scaling and some central clearing. Vesicular lesions often accompany the dry scaling on the feet. Because of the variability of signs and symptoms, superficial dermatophytosis must be considered when evaluating even a weeping, crusted area more suggestive of eczema or impetigo. Dermatophyte infection of the nails, or onychomycosis, is usually seen as a white or yellow opaque discoloration that often progresses to a thickened, crumbed, or deformed nail (Figure 53-8).

**Treatment.** Topical management of localized superficial dermatophyte infections is very effective. Among the topical antifungal preparations available in cream and solution form are miconazole nitrate, clotrimazole, econazole nitrate, ciclopirox olamine, and terbinafine. A 4-week course of twice-daily applications will usually clear the symptoms. For more extensive infections involving the hair, nails, or resistant organisms, systemic therapy (e.g., griseofulvin or itraconazole and terbinafine) is required. Treatment duration ranges from 3 or 4 weeks (tinea corporis) to 12 months (onychomycosis).

#### Yeast Infections

The yeast *Candida albicans* is another common source of superficial infection (Figure 53-9). It is manifested in newborns as the white lesions of **thrush**, in infants and bedridden patients as **intertrigo**, and in immunosuppressed individuals as the systemic disorder **mucocutaneous candidiasis**. Mucocutaneous candidiasis may actually be the

**FIGURE 53-5** Herpes simplex virus (HSV), types 1 and 2. **A**, Herpes simplex labialis—recurrent lesions. **B**, Herpetic whitlow: herpes simplex infection of the finger. **C**, Vaginal primary herpes simplex virus. **D**, Penile lesions of recurrent herpes simplex infection. **E**, Recurrent blistering on the elbow of this patient was treated as recurring impetigo before being correctly diagnosed as HSV infection. **F**, The histopathologic appearance of HSV reveals an intraepidermal bulla with bizarre multinucleated balloon cells. **G**, A positive Tzanck smear from a herpes simplex blister. (**A-E**, From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 92. **F** and **G**, From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 168.)

**FIGURE 53-6** Herpes zoster. **A**, Recurrent infection with the varicella-zoster virus. The eruption is usually dermatomal but can become generalized. **B**, Disseminated herpes zoster. **C**, Herpes-zoster ophthalmicus. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 92.)

presenting sign in an individual with a previously undiagnosed immunodeficiency disorder.

Localized yeast infections such as oral candidiasis (thrush) may be managed with nystatin mouth rinse or clotrimazole troches (throat lozenges). The topical antifungal medications mentioned earlier may also be used in the management of localized yeast infections. Widespread or systemic infections respond well to oral ketoconazole or fluconazole (Diflucan).

## Bacterial Infections

### Impetigo

**Etiology and clinical manifestations.** Impetigo is an acute, contagious skin disease characterized by the formation of vesicles, pustules, and yellowish crusts (Figure 53-10). The most common cause of

infection of the skin, impetigo is caused by staphylococci or streptococci. Approximately 5% of the population each year sustains staphylococcus infections of a severity sufficient to require medical attention.<sup>8</sup> Approximately 20% of adults are chronic carriers of the bacterium *Staphylococcus aureus*, and another 60% are intermittent carriers.<sup>8</sup> The bacterium is carried in the nasal area and may pass onto the skin and produce disease. Staphylococcal infections are a special problem for hospitalized patients, who may become infected from the infected hospital staff.

**Treatment.** Treatment for impetigo includes topical application of 2% mupirocin ointment (Bactroban) or 1% retapamulin (Altabax) ointment. If a large area of skin is involved or if the person is febrile, impetigo may be managed systemically with oral dicloxacillin, cephalixin, or erythromycin.

**FIGURE 53-7** Tinea infections. **A**, Tinea capitis, localized patch. **B**, Tinea faciei. **C**, Tinea corporis. Annular scaly plaques in superficial basal cell epithelioma. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, pp 89, 106.)

**FIGURE 53-9** *Candida albicans* infection of the tongue in chronic mucocutaneous candidiasis. (From Berger TG et al: *Andrews' diseases of the skin: clinical dermatology*, ed 9, Philadelphia, 2000, Saunders, p 385.)

**FIGURE 53-10** Impetigo. (From Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2010, Saunders, p 785.)

TABLE 53-3 COMPARISON OF CHRONIC DISCOID WITH SYSTEMIC LUPUS ERYTHEMATOSUS

PARAMETER	CHRONIC DISCOID LE	SYSTEMIC LE
Primary lesions	Red, scaly, thickened, well-circumscribed patches with enlarged follicles and elevated border	Red, mildly scaly, diffuse, puffy lesions; purpura also seen
Secondary lesions	Atrophy, scarring, and pigmentary changes	No scarring; mild hyperpigmentation
Distribution	Face, mainly in the "butterfly" area, but also on the scalp, ears, arms, and chest. May not be symmetric.	Face in "butterfly" area, arms, fingers, and legs; usually symmetric
Course	Very chronic with gradual progression; slow healing under therapy; no effect on life	Acute onset with fever, rash, malaise, and joint pains; most cases respond rather rapidly to steroid and supportive therapy, but prognosis for life is poor
Season	Aggravated by intense sun exposure or radiation therapy	Same
Gender incidence	Almost twice as common in females	Same
Systemic pathology	None obvious	Nephritis, arthritis, epilepsy, pancarditis, hepatitis, etc.
Laboratory findings	Biopsy characteristic in classic case LE cell test negative, as are other laboratory tests	Biopsy less useful

From Sauer GC: *Manual of skin diseases*, ed 6, Philadelphia, 1991, Lippincott, p 253.  
LE, Lupus erythematosus.

### Syphilis

**Etiology and clinical manifestations.** A variety of sexually transmitted diseases caused by bacteria can infect the genitalia. The most serious is **syphilis**, which is caused by *Treponema pallidum*. If the person remains untreated, three stages can occur. In primary syphilis, a chancre (ulcer) generally occurs as a single lesion on the genitalia; the spirochetal microorganism that causes syphilis can be seen in a scraping of the chancre. Secondary syphilis is characterized by a disseminated rash that cannot be clearly distinguished from other rashes. Both the primary and the secondary stages of syphilis are contagious.

**Treatment.** Studies to detect serum antibodies against syphilis (such as the Venereal Disease Research Laboratories [VDRL]) and examination of the pustules for the spirochete are required to achieve a diagnosis. Penicillin is very effective in eradicating syphilis in the primary and secondary stages, but unfortunately damage caused by tertiary syphilis to the cardiovascular and central nervous systems is permanent.

### Leprosy

**Leprosy** is a chronic infectious disease of the skin caused by the intracellular bacillus *Mycobacterium leprae*. Approximately 11 million people worldwide have leprosy.<sup>8</sup> The diagnosis is made with a skin biopsy. Leprosy has a low rate of infectivity and is usually responsive to sulfone drugs such as dapsone. For chronic deformities, corrective orthopedic surgery may be required.

## INFLAMMATORY CONDITIONS

### Lupus Erythematosus

Lupus erythematosus (LE) is an inflammatory disease that has cutaneous manifestations. Systemic LE and chronic discoid LE are clinically dissimilar but basically related diseases. The two diseases differ with regard to characteristic skin lesions, subjective complaints, other organ involvement, LE cell test findings, response to treatment, and eventual prognosis. Discoid lupus presents with scaly red plaques with scarring that involve sun-exposed skin. Classically, systemic lupus presents with a butterfly-shaped erythema involving the cheeks and nose; discoid lesions may be seen as well. A comparison of the two conditions is found in Table 53-3. Figure 53-11 illustrates characteristic skin lesions of both conditions.

### Seborrheic Dermatitis

**Clinical manifestations and treatment.** Seborrheic dermatitis (Figure 53-12) is a papulosquamous skin disease manifested by various

degrees of scaling and erythema in areas of high oil gland concentration such as the scalp, eyebrows, glabellae, eyelids, nasolabial folds, pinna and posterior sulcus of the ears, sternum, axillae, umbilicus, and anogenital area. Common manifestations of this disease are cradle cap in newborns and dandruff in adolescents and adults.

Although seborrheic dermatitis is not curable, it may be controlled with topical medication. The regular use of tar, zinc, selenium sulfide, or salicylic acid shampoos often clears the symptoms and signs of seborrheic dermatitis in the scalp; mild topical corticosteroids (e.g., 1% hydrocortisone) clear lesions on the face and ears.

### Psoriasis

**Etiology and clinical manifestations.** Psoriasis is a common chronic skin disease characterized by papules and plaques with an overlying silvery scale. The specific cause of psoriasis is unknown, but it appears to be a multifactorial inherited condition in which minor aberrations of the immune system promote inflammation and hyperproliferation within the skin. The disease may affect, with varying degrees of severity, people of all ages. Lesions can appear on any area of the body; however, they seem to have a predilection for the knees, elbows, lower part of the back, scalp, and nails (Figure 53-13). Disease progression is unpredictable, and the patient may periodically experience spontaneous exacerbations or remission.

**Treatment.** No cure for psoriasis is known. Treatments, both topical and systemic, are directed at clearing and controlling the lesions. Therapies include topical corticosteroids (most commonly used), a vitamin D derivative (calcipotriene ointment [Dovonex]), ultraviolet light exposure, topical tar preparations, and combinations of ultraviolet light with topical tar or systemic psoralen. Systemic therapies with methotrexate and hydroxyurea are also effective in clearing psoriasis but carry considerable risk of toxicity. Newer, highly effective biological agents are now available for use by injection but are very expensive and also carry risks of significant side effects.

### Lichen Planus

**Etiology and pathogenesis.** Lichen planus is a relatively common, chronic, pruritic disease involving inflammation and papular eruption of the skin and mucous membranes. Idiopathic lichen planus is of unknown cause but can be stimulated by a variety of drugs and chemicals in susceptible persons. The characteristic lesion is a shiny, white-topped, purplish, polygonal papule. Lesions appear on the wrists, ankles, and trunk (Figure 53-14). Mucous membrane

**FIGURE 53-11** **A** and **B**, Discoid lupus erythematosus. Round or oval cutaneous lesions occurring in patients with lupus erythematosus. **C**, Subacute cutaneous lupus erythematosus. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, pp 15, 16.)

**FIGURE 53-12** Annular seborrheic dermatitis of the ear. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 246.)

lesions are white and lacy and may become bullous. Pruritus is severe, and new lesions develop as a result of scratching (Koebner phenomenon). Nails are affected in approximately 10% of people with lichen planus.<sup>9</sup>

**Treatment.** In the majority of people, lichen planus is a self-limiting disease. Treatment measures include discontinuation of all medications, followed by the administration of topical corticosteroids and occlusive dressings. Systemic corticosteroids may be indicated in severe cases, and antipruritic agents are helpful in reducing the pruritus.

**FIGURE 53-13** Psoriasis vulgaris. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 280.)

### Pityriasis Rosea

**Etiology, pathogenesis, and treatment.** Pityriasis rosea is a rash of unknown origin that primarily affects young adults. The incidence is highest in the spring and fall seasons. It has been speculated to be viral in origin, but to date no virus has been isolated. The characteristic lesion is a macule or papule with surrounding erythema. The lesion spreads with central clearing, much like tinea corporis. This initial lesion is a solitary lesion, called the herald patch, and is usually located on the trunk or neck. As the lesion enlarges and begins to fade away

**FIGURE 53-14** Linear lichen planus as a result of Koebner phenomenon. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 249.)

(2 to 10 days), successive crops of lesions appear on the trunk and neck.<sup>10</sup> The extremities, face, and scalp may be involved, and mild to severe pruritus may occur. The disease is self-limiting and usually disappears within 2 to 10 weeks.<sup>10</sup> Treatment is palliative and includes topical steroids, antihistamines, and colloid baths. Systemic corticosteroids may be indicated in severe cases. Systemic antibiotics, especially erythromycin, may also shorten the course.

### Acne Vulgaris

**Etiology and pathogenesis.** Acne, an extremely common disease of the pilosebaceous unit, affects up to 90% of all individuals and produces unsightly lesions and sometimes permanent scarring and disfigurement<sup>11</sup> (Figure 53-15). Etiologically, acne involves multiple factors such as sex hormones, heredity, bacterial flora of the skin, stress, mechanical occlusion, and cosmetics' use. Acne arises when sludging of sebaceous oils and deposition of loose epithelial cells cause an obstruction of the follicular canal. Continued oil production and bacterial growth in this obstructed follicle may cause rupture of the wall or sebaceous gland and result in an inflamed lesion.

**Treatment.** No cure for acne is known. Treatment modalities are directed to clearing the lesions and maintaining a clear complexion. Topical therapy is effective for most patients. Such medications are designed to cause increased peeling of the stratum corneum and loosening of the follicular plugs.

Many products are available to achieve this goal. Soaps, lotions, and gels containing sulfur, resorcinol, salicylic acid, or benzoyl peroxide all enhance drying and peeling. Astringents, which are liquids primarily composed of alcohol with acetone, are used as solvents to remove the surface lipid and loose skin cells, as well as to enhance drying. Topical retinoids, of which there are several, are a mainstay of treatment. Retinoic acid, a derivative of vitamin A, is one example of this class of drugs.<sup>4</sup> Retinoic acid is an exfoliative agent and is very useful in dealing with open comedones and papules. Topical antibiotics are also available, the most effective being liquid preparations of erythromycin and clindamycin (Cleocin T) with an alcohol base.

For cases characterized by inflammatory lesions, pustules, or nodules, systemic therapy can be useful. Antibiotics, especially tetracycline and erythromycin, have long been used in such treatments. Concerns that continued use of systemic tetracycline group antibiotics may result in colonization with tetracycline-resistant *Staphylococcus aureus* have not been supported. This is significant because tetracycline group antibiotics are currently one of the primary options for outpatient

**FIGURE 53-15** A and B, Acne vulgaris with papules and pustules. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 151.)

treatment of methicillin-resistant *S. aureus* (MRSA).<sup>12</sup> In cases that are resistant, minocycline, sulfamethoxazole-trimethoprim, and sulfones are occasionally used. Isotretinoin, a vitamin A derivative, is effective in the management of nodular and cystic acne.<sup>12</sup> Birth control pills, especially the estrogen-dominant type, can be of value in managing severe recalcitrant acne in females. However, androgen-dominant contraceptives can aggravate or precipitate acne.

As with any medication regimen, both systemic and topical acne treatments can produce unwanted side effects in sensitive patients. Systemic tetracycline may cause gastrointestinal upset, nausea, diarrhea, and vaginal *Monilia* overgrowth. Tetracycline should not be used in children because their unerupted teeth may be severely and permanently discolored. Topical antibiotics can cause irritant or allergic contact dermatitis.

Other useful acne treatments include corticosteroid injection into cysts and nodules and surgery, which involves extraction of the comedones and drainage of fluctuant cystic lesions.<sup>6</sup>

### Pemphigus

A group of related disorders (**pemphigus group** of vulgaris, vegetans, foliaceus, and erythematosus) is characterized by bullous eruptions (blisters). These disorders are thought to be caused by autoimmune reactions. Patients show antibodies against keratinocytes and basement membranes. The autoantibodies perhaps cause the keratinocytes to separate from one another to form blisters. Of the group of related diseases, **pemphigus vulgaris** has the worst prognosis (Figure 53-16). Bullae can erupt on the skin and mucous membranes (e.g., esophagus), and toxemia and infection can cause death if proper treatment (cortisone) is not administered.

**FIGURE 53-16** Pemphigus vulgaris. **A**, Bullae are transient in this disorder; erosion is more characteristic. **B**, The blister is suprabasilar within the epidermis. Individual cells are unattached within the bulla (acantholytic cells). **C**, Deposition of IgG in the intercellular areas of the epidermis is characteristic of pemphigus. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 163.)

## ALLERGIC SKIN RESPONSES

### Atopic Dermatitis

**Etiology and clinical manifestations.** Atopic dermatitis is a complex genetic disease that results from gene-gene and gene-environment interactions. Genetic defects in the epidermal barrier protein filaggrin have been cited as a major cause of atopic dermatitis. It is suggested that the trait is inherited via a maternal gene located on chromosome 11. The stratum corneum layers of those individuals with loss-of-function mutations in the filaggrin gene have lower levels of natural moisturizing factor and also are deficient in extracellular lipids including ceramides. Repair of barrier function has become one of the important developments in treatment of atopic dermatitis; these treatments include emollients that contain ceramides.<sup>13</sup> **Atopy**, or **allergy**, is indicated by a personal and sometimes family history of asthma, allergic rhinitis, or the most commonly seen manifestation, eczematous dermatitis (Figures 53-17 and 53-18). The highest incidence of atopic dermatitis occurs in children, with most cases developing in those younger than 5 years.<sup>13</sup> The characteristic features depend on the age at onset, but pruritus is always present. In infants, the disease characteristically appears on the face, scalp, or extensor surfaces of the extremities; the predominant lesion is an oozing, crusting, coalescent papule. The disease in children is most often manifested as erythema, papules, and lichenification of the flexor surfaces of the extremities, especially the antecubital

and popliteal areas, the wrists, and the nape of the neck. Older children and young adults have thickening of the skin, or lichenification, along with fine, dry scaling and some papules. These changes are again seen on the flexor surfaces of the extremities and the scalp, face, and upper chest. Retrospective studies show that in nearly half of all patients with childhood atopic dermatitis, the disease improves or clears with age.<sup>14</sup>

**Treatment.** Treatment of atopic dermatitis is usually conducted on an outpatient basis. The most important considerations are moisturization of the skin and prevention of continued drying and water loss. The drying and scaling that are characteristic features of atopic dermatitis impair the skin's ability not only to retain moisture but also to repel such external invaders as chemical irritants and surface bacteria. Milder cases of atopic eczema can be managed conservatively by decreasing the frequency of bathing, using tepid water in baths, eliminating alkaline soaps, and using moisturizing creams (especially after baths and washing). In more severe cases that involve an inflammatory response to skin breakdown, topical steroids are an important part of therapy. Short courses of systemic antibiotics such as erythromycin have also been helpful in controlling the severity of atopic eczema by reducing the concentration of cutaneous bacterial flora. Even after all these measures have been executed, some patients with severe atopic dermatitis are hospitalized for application of continuous wet dressings and topical steroids.

An important feature of all atopic dermatitis cases that must be addressed is pruritus. The topical treatments mentioned previously

**FIGURE 53-17** Atopic dermatitis. An extremely pruritic condition. **A**, Multiple excoriations, vesiculation, and marked lichenification are seen in this patient. **B**, Minute excoriations with marked lichenification in the antecubital fossa. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 192.)

**FIGURE 53-18** **A**, Papular eczema. **B**, Chronic eczema of the feet. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 192.)

are helpful in reducing pruritus. If additional measures are needed, systemic antihistamines (e.g., hydroxyzine and diphenhydramine) are effective.

### Contact Dermatitis

**Etiologies and clinical manifestations.** Contact dermatitis is a cutaneous reaction to topical irritation or allergy. Irritant contact

dermatitis develops in any person exposed to a sufficiently high concentration of the irritating agent. Some of the more active irritants are acids, alkalis, and hydrocarbons.

**Allergic contact dermatitis** indicates delayed acquired hypersensitivity to a specific allergen. Dermatologic problems may appear after years of asymptomatic exposure to the precipitating agent. Chromates, nickel, ethylenediamine, paraphenylenediamine, neomycin, formaldehyde, and lanolin components may cause allergic contact dermatitis.

Aside from reactions to various industrial chemicals, the most common type of allergic contact dermatitis reaction is to plants. **Rhus dermatitis** encompasses allergy to poison ivy, poison oak, and poison sumac. Clinically, rhus dermatitis begins within 48 hours of contact. The first symptom is pruritus, followed by erythema and vesicle formation, sometimes in linear fashion (Figure 53-19). As long as the allergen remains on the surface of the skin, it can be spread to nonexposed areas. Therefore, thorough washing can help prevent spread by hand contact. Exposure to blister fluid does not prevent poison ivy lesions.

**Treatment.** Contact dermatitis from exposure to poison ivy can range from mild to severe. For the mildest cases, application of topical steroids or cooling shake lotions of camphor and menthol may effectively decrease discomfort. Severe cases may require hospitalization for cooling baths and wet dressings, which dry the lesions and decrease the tense, pruritic blisters. Discomfort and generalized edema often respond to systemic steroids administered over a 10- to 14-day period.

### Drug Eruptions

**Etiology and clinical manifestations.** Adverse or undesirable reactions to medically administered drugs are common, yet cutaneous reactions are uncommon (0.1%) within the overall prescription-taking population.<sup>15</sup> Cutaneous reactions to medication usually begin within a week of drug exposure, although reactions to penicillins may occur later. Women experience more cutaneous drug eruptions than men. The drugs that most frequently result in adverse cutaneous eruptions are ampicillin, penicillin, cephalosporins, and barbiturates. Blood transfusions also occasionally produce cutaneous reactions identical to those of a drug eruption.

The most common type of adverse cutaneous drug eruption is an erythematous maculopapular exanthem (rash). These often pruritic lesions are usually widely dispersed, and clearing is gradual and continues for several weeks after the drug has been discontinued. Other common drug reactions include urticaria (i.e., hives), erythema multiforme (including Stevens-Johnson syndrome), exfoliative dermatitis, photosensitivity, vasculitis, and fixed-drug eruption.

**FIGURE 53-19** Rhus dermatitis with the characteristic linear groups of vesicles. (From Berger TG et al: *Andrews' diseases of the skin: clinical dermatology*, ed 9, Philadelphia, 2000, Saunders, p 101.)

Exanthem-type eruptions can be caused by such medications as barbiturates, griseofulvin, penicillin, thiazides, and sulfonamides. Urticarial eruptions may result from the use of barbiturates, penicillin, chloramphenicol, phenolphthalein, salicylates, sulfonamides, or tetracycline. Erythema multiforme is seen with erythromycin, penicillin, phenolphthalein, salicylate, diphenylhydantoin, and thiazides. Exfoliative dermatitis can be caused by barbiturates, gold, penicillin, phenothiazides, and sulfonamides, and photosensitivity is seen with chlorthalidone, fluoroquinolones, griseofulvin, phenothiazines, sulfonamides, tetracycline, and thiazides. Cutaneous vasculitis may be triggered by iodines, erythromycin, penicillin, quinidine, sulfonamides, and thiazides. A fixed-drug eruption (Figure 53-20) is a round to oval, violaceous macule or slightly palpable plaque that is often recurrent, especially in previously affected sites, on reexposure to the irritating medication. This effect can be caused by barbiturates, gold, phenolphthalein, sulfonamides, and tetracycline. These drug lists are not inclusive, and several substances are known to cause multiple adverse cutaneous reactions.<sup>16</sup>

**Treatment.** Management of drug eruptions includes discontinuation of the offending drug and administration of oral antihistamines

**FIGURE 53-20** Fixed-drug eruption. An early lesion may be manifested as an urticarial plaque. This lesion frequently resolves with macular hyperpigmentation. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 217.)

and antipruritic lotions of hydrocortisone, menthol, camphor, or other proven substances for relief of pruritus. For more severe eruptions, a 2- to 3-week course of systemic corticosteroids should be considered. In addition, the patient should be counseled regarding use of the offending medication and an appropriate notation placed in the patient's medical record.

### Vasculitis

**Etiology.** When antigen and antibody react in blood vessels in the skin, severe **necrotizing inflammation (vasculitis)** can appear. This condition can be caused by drug allergies; disorders such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and glomerulonephritis; and certain infectious diseases such as hepatitis B. **Polyarteritis nodosa** is a form of systemic vasculitis that can cause inflamed arteries in visceral organs, brain, and skin.

**Treatment.** Immunofluorescent studies reveal antigens and serum immunoglobulins trapped in the wall of the blood vessel that is inflamed by neutrophils. Acute vasculitis can cause damage not only to skin but also to the brain and visceral organs. When the vasculitis is severe, systemic corticosteroids may be administered in high doses.

## PARASITIC INFESTATIONS

### Scabies

*Sarcoptes scabiei* is a mite, and infestation with this mite in humans is called **scabies**. Scabies begins with eggs laid in the stratum corneum. These eggs hatch into larvae within 3 to 4 days and grow to adulthood within 2 months. Scabies is usually contracted after close personal contact with an infested individual.

Clinically, scabies lesions are small (1 to 4 mm), erythematous papules, some with an overlying dry scale or crust (Figure 53-21). In some cases, linear burrows are seen. Scabies mites have a predilection for the finger webs, wrists, umbilicus, and groin area. The history related by most patients is an intensely pruritic eruption that spreads over a period of weeks from a single area of the body to other areas.

Scabies treatment consists of topical permethrin cream (Elimite),  $\gamma$ -benzene hexachloride (Lindane), or crotamiton (Eurax). For infants, 5% to 6% precipitated sulfur in petrolatum applied twice daily for 1 week is usually adequate.

### Fleas

Three types of flea commonly bite and cause cutaneous reactions in humans: the human flea (*Pulex irritans*), the cat flea (*Ctenocephalides*

**FIGURE 53-21** **A**, Scabies. **B**, An extremely pruritic infestation. **C**, Crusted (Norwegian) scabies. (**A**, From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, pp 170, 283.)

**FIGURE 53-22** Insect bites (fleas) led this patient to scratch. (From Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2010, Saunders, p 178.)

*felis*), and the dog flea (*Ctenocephalides canis*). Flea bites may appear as small erythematous macules, erythematous papules, wheals, or a vesicle (Figure 53-22).

Diethyltoluamide or pyrethrin insect repellents are effective in preventing flea infestation. Indoor carpeting, an ideal environment for fleas, should be treated with an appropriate insecticide.

The milder papular form of flea bites can be managed with soothing shake lotions of menthol and camphor or with topical steroids.

More severe reactions (e.g., vesicles or bullae) may require a course of systemic steroids.

### Lice

*Phthirus pubis* (crab louse), *Pediculus humanus* var. *capitis* (head louse), and *Pediculus humanus* var. *corporis* (body louse) are the types of lice most often found on humans. They are surface dwelling, unlike the burrowing scabies mite, and they usually can be seen without magnification. Control and eradication are possible with one of the following: permethrin cream rinse or pyrethrin and piperonyl butoxide liquid, gel, or shampoo.

### Chiggers

Chiggers are mites that reside in grass and bushes. They are common in the southern United States but can be found as far north as Canada. Puncture of the skin by the mite to obtain nourishment produces pruritic papules commonly seen wherever it encounters resistance, such as at the top of socks, at the belt line, or around the neckband area (Figure 53-23). Secondary lesions are excoriations from scratching that have become infected by bacteria. Treatment is palliative, and the use of insect repellent is encouraged for prevention.

### Bedbugs

The common bedbug, *Cimex lectularius*, is a reddish-brown insect 3 to 6 mm long that turns purple after feeding. Like most parasites, bedbugs feed on human blood. Importantly, they can also alternate between human and animal hosts, and they live up to and sometimes beyond 1 year.<sup>8</sup> When not feeding, bedbugs stay hidden in the cracks and crevices

**FIGURE 53-23** Chigger bites. (From Berger HL et al: *Andrews' diseases of the skin: clinical dermatology*, ed 9, Philadelphia, 2000, Saunders, p 569.)

of furniture, mattresses, wallpaper, picture frames, baseboards, flooring, door locks, or any darkened area. Unless their source is eliminated, recurrence is inevitable. Professional extermination is advised because of their many hiding places. Bedbugs have been known to feed on animal populations when forced from their living quarters. On rehabilitation in the same quarters, the bedbug can easily return to human hosts.

They are nocturnal feeders, and, when crushed, they emit a foul odor. The bedbug bite is painless and produces a pruritic oval or oblong wheal with a small hemorrhagic punctum at the center. Bullous lesions are not uncommon. Usually, lesions are multiple and arranged in rows or clusters on the face, neck, hands, and arms. No area is exempt. The wheal is probably a type 1 sensitivity reaction to the anticoagulant saliva of the bedbug. Secondary excoriation and bacterial infections may occur.

The diagnosis depends on the time of the day when the lesions appear. Because of the painless bite, it is not uncommon for the victim to awake with one or several pruritic papules. Topical antipruritics are used as treatment.

### Mosquitoes

Most people have experienced mosquitoes and are familiar with their bites. The typical lesion is a raised wheal on an erythematous base, accompanied by pruritus within 45 minutes of the bite. A second type of reaction is the delayed response: 8 to 12 hours after the bite, the lesion becomes raised, erythematous, and indurated, with extensive pruritus or pain. This reaction peaks 24 to 72 hours after the bite.<sup>9</sup> The saliva of the mosquito is believed to be the source of the skin reaction. Although severe skin reactions are possible, they are rare. Insect repellents are recommended for prevention; local antipruritics are used for treatment.

### Blood Flukes

Bathers in the freshwater lakes of Wisconsin, Michigan, and Minnesota are prone to periodic attacks of inflammatory, papular, urticarial,

and vesicular eruptions on the uncovered areas of the body, mainly the legs. This pruritic eruption, commonly called “swimmer’s itch,” usually subsides within a week and is caused by invasion of the skin by cercariae (larvae) of the schistosomes (worms) of ducks and mammals. The life cycle of these various species of schistosomes includes the snail as an intermediate host. On invasion of the abnormal definitive host, the human skin, the cercariae die, and the resulting skin eruption is the skin’s reaction in ridding itself of the foreign bodies. Repeated attacks are met with stronger resistance, and the dermatitis becomes increasingly severe. Secondary infection, edema, and lymphangitis can occur.

Swimmer’s itch is best prevented by destruction of the snails through careful addition of a combination of copper sulfate and hydrated lime to the lake water. Rapid drying of the swimmer with a towel apparently prevents penetration of the cercariae. Active therapy is directed to relief of the itching and prevention of secondary infection.

### Ticks

Ticks are insects that live in woods and underbrush. They attach to human and animal hosts and burrow in the epidermis, where they feed on blood. The tick bite itself is not problematic, but the infectious bacteria or viruses that ticks carry to human hosts create problems. Many tick-borne illnesses are known, including Central European encephalitis, Q fever, babesiosis, relapsing fever, Rocky Mountain spotted fever (RMSF), and Lyme disease. Both RMSF and Lyme disease are relatively common in the United States.

### Rocky Mountain Spotted Fever

**Etiology, pathogenesis, and clinical manifestations.** Rocky Mountain spotted fever (RMSF) is caused by a tick that carries *Rickettsia rickettsii*. In the past RMSF was localized to the Rocky Mountain area, but by 1982 most states had reported a case of RMSF.<sup>8</sup>

The initial tick bite appears as a papule or macule, with or without a central punctate area. The tick burrows into the host and enlarges as it feeds. The tick must be attached to the human host for 4 to 6 hours before the rickettsiae are activated by the blood.<sup>8</sup> Rickettsiae are found in the tick feces and body parts. The rickettsiae then enter the bloodstream and multiply in body tissues. Within 4 to 8 days the patient experiences fever, headache, muscle aches, nausea, and vomiting.<sup>8</sup> A rash then appears on the wrist or ankle. The characteristic rash is a macular or maculopapular one that spreads to the rest of the body. Other symptoms include generalized edema, conjunctivitis, petechial lesions, photophobia, lethargy, confusion, and cranial nerve deficits.

**Treatment.** Treatment for RMSF requires hospitalization and antibiotic therapy. The most important measure is to prevent tick bites by using insect repellents while engaged in activities in wooded areas. Once a tick has attached itself, it is important to remove all the tick’s body parts to limit the possibility of infection. One can remove ticks by dousing them with mineral oil or alcohol before slowly pulling them out with tweezers. The practice of applying a hot match to the end of the tick is not an effective method for removal because the tick may regurgitate into the open wound.<sup>8</sup>

### Lyme Disease

**Etiology.** Lyme disease is caused by the bite of a tick that carries the spirochete *Borrelia burgdorferi*. White-tailed deer and white-footed mice are the main reservoirs of this disease-causing spirochete. Lyme disease causes multiple symptoms affecting the skin, nervous system, heart, and musculoskeletal system.

**Pathogenesis, clinical manifestations, and treatment.** The disease has three clinical stages. Stage I usually occurs in the summer and

early fall with single or multiple erythematous papules that may itch, sting, or burn. The thighs, groin, and axillae are particularly common sites of involvement. This disease is often accompanied by flulike symptoms (fatigue, headache, chills, fever, sore throat, stiff neck, nausea, myalgias, and arthralgias). If the patient remains untreated, stage II Lyme disease appears weeks to months later. This stage is characterized by meningitis, cranial nerve palsies, and peripheral neuropathy; occasionally, cardiac involvement is noted. In stage III, oligoarticular arthritis occurs. In early Lyme disease, treatment includes administration of antibiotic therapy such as doxycycline, amoxicillin, or erythromycin for 10 to 21 days. Neurologic disease, arthritis, or cardiac

disease is managed with doxycycline or amoxicillin for 1 month or with intravenous penicillin for 10 to 14 days.

## OTHER DISORDERS OF THE DERMIS

### Scleroderma

**Scleroderma** is characterized by massive collagen deposition with fibrosis accompanied by inflammatory reactions and vascular changes in the capillary network. The process by which these changes occur is not known but may represent an autoimmune mechanism or primary vasculopathy.

The two forms of scleroderma, localized and diffuse, are clinically dissimilar except for some common skin histopathologic features. Localized scleroderma (morphea) is a benign disease; diffuse scleroderma (progressive systemic sclerosis) is serious, progressive, and fatal.

#### Localized Scleroderma

Localized scleroderma has an unknown etiology, no systemic involvement, and no known treatment. Disability is confined to the area involved. Lesions tend to involute (shrink) slowly and spontaneously. Relapses are rare. Primary skin lesions are single or multiple, violet colored, firm, inelastic macules and plaques that enlarge slowly. The progressing border retains a violet hue while the center becomes whitish and slightly depressed beneath the skin surface. Bizarre lesions occur, such as long linear bands on extremities, “saber cut” lesions in the scalp, or lesions involving one side of the face or the body. Secondary lesions include mild or severe scarring after healing, permanent hair loss from the scalp lesions, and, rarely, ulceration. The trunk, extremities, and head are most frequently involved (Figure 53-24).

#### Diffuse Scleroderma

Diffuse scleroderma is a rare systemic collagen disease of unknown cause characterized by a long course of progressive disability resulting from lack of mobility of the areas and the organs affected. The skin becomes hardened like hide, the esophagus and the gastrointestinal tract semirigid, the lungs and heart fibrosed, the bones resorbed, and the overlying tissue calcified. Figure 53-25 illustrates the “hideliike” skin on the face of a woman with diffuse scleroderma.

Another rare collagen disorder, **dermatomyositis** is characterized by the acute or insidious onset of muscle pain, weakness, fever, arthralgia, and, in some cases, a puffy erythematous eruption that is usually confined to the face and the eyelids. Progression of the disease results in muscle atrophy and contractures, skin telangiectasias (vascular lesions formed by blood vessel dilation) and atrophy, and generalized organ involvement. Death occurs in 50% of cases.<sup>12,17</sup>

**FIGURE 53-24** Extensive morphea (localized scleroderma). (From Berger TG et al: *Andrews' diseases of the skin: clinical dermatology*, ed 9, Philadelphia, 2000, Saunders, p 195.)

**FIGURE 53-25** Hideliike skin on the face of a woman with diffuse scleroderma (progressive systemic sclerosis). (From Berger TG et al: *Andrews' diseases of the skin: clinical dermatology*, ed 9, Philadelphia, 2000, Saunders, p 197.)

TABLE 53-4 CLINICAL DESCRIPTION OF PRESSURE SORES

GRADE/STAGE	DESCRIPTION
1	Acute inflammatory response primarily in epidermis with minimal soft-tissue swelling and warmth; erythema of intact skin; is erythematous and, unless abraded, erythema will blanch; blanchable erythema (reactive hyperemia) can be expected to be present for 30-45 min following exposure to pressure; is usually very discretely bordered; reversible with intervention
2	Pressure sore representing an inflammatory and fibroblastic response extending through epidermis into dermis; is partial thickness or superficial skin loss involving epidermis and/or dermis; may present as blistering with erythema and/or induration; ulcer may also present as abrasion or shallow crater; wound base is moist and pink; wound is painful but free of necrotic tissue
3	Pressure sore clearly penetrating subcutaneous layers; often there is exposed muscle, fat, and tendons; full-thickness tissue loss extends through dermis to involve subcutaneous tissue; damage or necrosis of dermis may extend down to, but not through, underlying fascia; ulcer presents clinically as deep crater with or without undermining of adjacent tissue; stage may also include sinus tract formation, exudates, and/or infection; wound base is usually painful
4	Pressure sore extending beyond deep fascia, almost always to bone; deep-tissue destruction occurs, extending through subcutaneous tissue and fascia; is full-thickness skin loss with extensive tissue necrosis and damage to muscle, bone, and supporting structures (tendons and joint capsules); undermining sinus infection may be present; wound base is usually not painful

## Sunburn and Photosensitivity

### Effects of Sunlight

Sunlight is an extremely harmful environmental agent because it produces the short ultraviolet wavelength that is responsible for sunburn, thickening of the stratum corneum, suntan, and increased melanin production. Sunlight produces direct local effects on the skin in the form of elastotic syndromes, keratoacanthomas, premalignant diseases, basal cell epitheliomas, and squamous cell epitheliomas. Both indirect and direct effects can produce malignant melanomas.<sup>18</sup>

Sunburn is initially manifested as erythema, pain, heat, and occasionally blistering, edema, and tenderness. In severe sunburn, these symptoms may also be accompanied by the constitutional symptoms of chills, fever, nausea, and generalized discomfort.

The most effective treatment is to avoid or limit exposure to sunlight. Wearing protective clothing is effective; sunscreens are also quite useful in preventing sunburn and the chronic solar changes of the skin. *Para*-aminobenzoic acid is the most widely used sunscreen. People sensitive to *para*-aminobenzoic acid may use cinnamates and benzophenones as substitutes. Opaque screens such as zinc oxide and titanium dioxide also work well. However, these white preparations are not cosmetically elegant. Recently, titanium dioxide has been incorporated into foundation makeup for women.

Sunburn can be managed symptomatically with cold water baths or compresses; topical steroids are often effective in relieving the discomfort of localized severe burns. For widespread sunburn, a 10- to 14-day course of systemic steroids may suppress the symptoms.

### Ulcers

An unfortunate problem for a bedridden person may be the development of **pressure sores**, or **decubitus ulcers**. Because thinning epithelial cells and blood vessels have a slower rate of repair in older adults, the incidence of decubitus ulcers is higher and the ulcer more severe in elderly individuals, and healing of damaged skin is slower.

Pressure sores are localized areas of cellular necrosis resulting from prolonged pressure between any bony prominence and an external object such as a bed or wheelchair. The tissues are deprived of blood supply and eventually die. Areas frequently affected in older persons include the heels, greater trochanter, sacrum, dorsal (especially in thin kyphotic persons) and scapular regions of the spine, and elbows. Long-term pressure increases vulnerability to decubitus ulcer development. High pressure maintained for a short time is less dangerous than low pressure continued for a long time. Predisposing factors include poor nutrition, aging, immobility, superficial sensory loss, and disturbed autonomic function (loss of bowel and bladder control).<sup>19</sup> Older people

with dementia are particularly prone to the development of pressure sores because of arteriosclerotic changes in the vessels, loss of subcutaneous tissue and tissue elasticity, and clouding of the sensorium.<sup>19</sup>

Pressure sores can be evaluated clinically using the staging system described in Table 53-4. Pressure sores are superficial (benign) or deep (malignant). Superficial sores are reddened areas involving only the outer skin layers. They are less dangerous than deep sores and are caused by friction, shearing stresses, trauma, infection, and saturation with urine or other wet agents. The lesions are frequently painful but are easily treated and prevented. Treatment consists of keeping the area clean, dry, and free from infection or further pressure; covering the lesion with a nonstick dressing also promotes healing. Measures such as performing frequent body position changes (every 2 hours), transferring the person out of bed and into a chair, ensuring the vulnerable areas are clean and dry, and keeping the weight of the bed coverings off the feet are most effective in the prevention of superficial pressure sores.

Deep sores develop quickly as a result of thrombosis of the vessels in deep tissue overlying bony prominences. Muscle and fat layers are more vulnerable than the dermis, and involvement of these layers causes deep, large ulcers. The sore begins as a reddening of the skin with unobservable necrosis in the deep underlying tissue. In 1 to 2 days, the lesion bursts through the skin like an abscess to reveal a deep cavity full of black or infected slough, which may penetrate the bone.<sup>19</sup> Skin loss from such a large area results in extensive scarring. The development of deep pressure sores with an illness can delay recovery and may even be fatal.

Prevention is more difficult with deep pressure sores, especially in the elderly. The risk of these lesions developing is greatest during the 10 days after the onset of illness or admission to the hospital, which coincides with the period of greatest immobility.<sup>19</sup> A sore that develops early and penetrates deeply is most dangerous to an older person. Early signs of deterioration include apathy, loss of appetite, and incontinence. Some measures that can help prevent deep pressure sores are described in Box 53-2.

Treatment consists primarily of reinforcing preventive measures, including maintenance of fluid and protein stores that are lost through serous and purulent discharge, repair of tissues by administration of vitamin supplements, avoidance of general infections such as pneumonia or cystitis, and remediation of anemia. The lesions should be cleaned and dressed, with care taken to manage local infection. To promote granulation and healing, the wound should be irrigated with warm saline daily. Irrigation washes out the debris, reduces the growth of anaerobes, promotes separation of the slough, and decreases the pocketing of infection in deeper tissues. Infection must be eradicated and the slough must separate before healing can take place.

**BOX 53-2 PREVENTION OF DEEP PRESSURE SORES**

Change position every 2 hours.  
 Do not oversedate or undersedate.  
 Avoid or correct malnutrition.  
 Avoid dehydration; maintain blood pressure and cardiac output.  
 Use an alternating-pressure airbed or waterbed.

Data from Rosen T et al, editors: *Nurse's atlas of dermatology*, Boston, 1981, Little, Brown.

**FIGURE 53-26** Ichthyosis. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 14. Courtesy Donald Hazelrigg, MD, Evansville, IN.)

**Altered Cell Growth: Epidermal Proliferation**

Keratinocytes produce keratin. Rare, inherited defects in keratinocytes can occur, and the inherited disease **congenital ichthyosis** is characterized by an excessive growth of keratinocytes and keratin, which gives the skin a fish-scale appearance (Figure 53-26).

**Corns** and **calluses** result from **hyperkeratosis**. Stimulation of the epidermis by intermittent pressure elicits hyperkeratosis (corn and callous formation). By contrast, **atrophy** of the epidermis can arise from a decreased blood supply.

Benign or malignant **neoplasms** commonly arise from keratinocytes. **Warts** (verrucae), for instance, are caused by a virus that provokes a benign proliferation of keratinocytes. **Squamous cell carcinomas** (arising from keratinocytes) often occur in areas of skin excessively exposed to sunlight.

**Tumors**

Each cell type of the skin can give rise to either benign or malignant tumors. Benign tumors, including squamous papillomas, arise from keratinocytes, common moles (**nevi**) from melanocytes, lipomas from

**FIGURE 53-27** A and B, Cryptococcosis associated with HIV infection. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 229.)

adipose cells, vascular tumors (hemangiomas) from blood vessels, dermatofibromas from fibroblasts, and neuromas from nerves.

Kaposi sarcoma arises from reticulocytes and is multifocal, metastasizing, and malignant. Kaposi sarcoma is classified as an opportunistic neoplasm because it occurs in persons with preexisting immunodeficiency, for example, in individuals with primary immunodeficiency, persons who undergo therapeutic immunosuppression, and persons with human immunodeficiency virus (HIV) infection. Figures 53-27 and 53-28 show some of the cutaneous diseases associated with HIV infection.

**FIGURE 53-30 A and B**, Squamous cell carcinomas. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 367.)

## Cancer

Cancer of the skin is common. Most skin cancers are slowly progressive, but certain types can be rapidly lethal. Excessive exposure to sunlight by a person with fair skin often leads to skin cancer. In addition to sunlight, exposure to irritating chemicals, recurrent trauma, and irradiation are associated with a high risk of skin cancer.

Basal cell carcinomas are the most common skin tumors and the most benign<sup>20</sup> (Figure 53-29). Squamous cell carcinomas are the second most common skin malignancy<sup>20</sup> (Figure 53-30). They can occasionally metastasize. By contrast, melanoma is rare but can be highly malignant (Figure 53-31). Melanoma is notoriously unpredictable; however, the prognosis is based on size, depth of invasion of the tumor, and the presence of metastasis.<sup>21</sup> Lumps that increase rapidly in size, change color, ulcerate, or bleed should undergo biopsy and be examined microscopically to rule out malignancy. Complete surgical excision is the treatment of choice for skin cancers.

## Pigmentation Alterations

### Vitiligo

**Vitiligo (leukoderma)** is a condition in which pigment disappears from a patch of skin. The onset is sudden and may be associated with pernicious anemia, hyperthyroidism, and diabetes mellitus.

Vitiligo is a concern to darkly pigmented individuals of all races. It also affects light-skinned individuals, but not as often. The lesion is a depigmented patch with definite borders on the face, axillae, neck, or extremities (Figure 53-32). The borders are smooth. Size varies from small to large macules involving large areas of the skin surface. The large macular type is much more common. Depigmented areas, which burn in sunlight, appear bone colored or grayish blue.

Vitiligo appears at any age, in men and women alike, and usually occurs before the age of 21.<sup>22</sup> Its incidence has been increasing in India, Pakistan, and Far Eastern countries.<sup>22</sup> Although the cause is unknown, inheritance and autoimmune factors have been implicated. Affected areas spread over time.

Treatment may consist of various topical immunomodulating agents as well as the use of various types of ultraviolet light. Cosmetics such as Dermablend may be used to camouflage the areas of depigmentation.

### Albinism

**Etiology and pathogenesis.** Melanocytes produce melanin. A partial or total absence of melanin arises as an inborn error in metabolism in individuals with **albinism**. Albinism, also termed

**FIGURE 53-31** **A** and **B**, Superficial spreading malignant melanoma. **C**, Cross-section through a melanoma. Note the nests of melanoma cells in the dermis. (From Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2010, Saunders, pp 160-161.)

**FIGURE 53-32** Vitiligo. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 282.)

*oculocutaneous albinism*, is characterized by a generalized lack of pigmentation of the skin and the hair. In addition, the eyes may show nystagmus and a lack of pigmentation of the fundi and translucent irises. The condition is recessively inherited. Biochemically, albinism occurs because of impaired or absent melanin synthesis. The long-term consequences of albinism may include solar keratoses and basal and squamous cell cancers.

**KEY POINTS**

- Skin infections may be caused by viral, fungal, or bacterial organisms.
- Viruses are associated with warts (human papillomavirus), cold sores (herpes simplex), and shingles (herpes zoster). Warts are painless. They may be surgically removed but often resolve spontaneously. Herpes simplex lesions are painful, may be managed symptomatically, and often recur in times of stress. Herpes zoster inhabits sensory dorsal ganglia neurons and causes pain along a dermatome.
- Superficial fungal infections (tinea, ringworm) are often characterized by central clearing and peripheral scaling. They may be effectively managed with topical antifungals. Yeast infections tend to occur in moist areas such as mucous membranes and are managed with systemic or topical drugs.
- Impetigo is caused by staphylococcal or streptococcal infection and is characterized by yellowish pustules and crusts. It responds to antibiotic therapy.
- The cause of noninfectious inflammatory diseases is usually unknown. Lupus erythematosus, seborrheic dermatitis, psoriasis, lichen planus, pityriasis rosea, and acne are in this category. Treatment is aimed at reducing inflammation rather than cure. Antibiotics may be used to prevent or manage lesion superinfections.

- Skin allergies are associated with substances that cause erythema and pruritus. Atopic dermatitis (eczema), commonly seen in young children, may be aggravated by substances to which the individual is allergic. Contact dermatitis can occur in anyone exposed to a sufficiently high concentration of an irritating substance. Drug reactions are allergic responses manifested as widely dispersed, often pruritic rashes. Antigen-antibody reactions within cutaneous blood vessels can result in severe necrotizing vasculitis.
- The skin is subject to invasion by a number of different bugs, ticks, and parasites. Lesions tend to be singular or grouped and in areas exposed to the particular pest. Scabies commonly occurs on the hands and wrists and may appear as linear burrows. Bites from fleas, mites, bedbugs, and mosquitoes often induce pruritic macules or papules. Tick bites are usually painless but may be problematic because ticks may carry diseases such as RMSF and Lyme disease.
- Scleroderma is a collagen disease of unknown cause. It may be localized to the skin or produce systemic involvement. The skin is discolored, thick, and hardened.
- Ultraviolet rays in sunlight are associated with acute damage to the skin (sunburn) and also increase the long-term risk of skin cancer.
- Pressure ulcer is a significant problem of immobility caused by prolonged pressure on bony prominences. Superficial sores are reddened areas involving the outer skin layers. Deep sores are due to thrombosis of vessels deep in tissue. Deep sores may be unnoticed initially and then burst through the skin like an abscess.
- Abnormalities of skin cell growth may result in such benign processes as corns and calluses or the more serious consequence of cancer. Basal cell and squamous cell carcinomas are slowly progressive and generally amenable to surgical excision. Malignant melanoma is more prone to metastasis and carries a poorer prognosis.
- Abnormal pigmentation may occur in response to skin injury, infection, or inflammation or may be genetically determined. Albinism is due to lack of melanin production. Vitiligo is a depigmented patch of skin that is most noticeable in dark-skinned individuals. The cause of vitiligo is unknown.

Education regarding the use of sunscreens and clothing for protection against ultraviolet light-induced damage is indicated. Sunglasses and magnifiers are beneficial for the ocular symptoms.

### SPECIAL CHARACTERISTICS OF DARK SKIN

A number of disorders of the skin exclusively affect people with dark skin. Pigmentary disturbances from many causes, both hypopigmentation and hyperpigmentation, are common. Postinflammatory hyperpigmentation, for example, may occur in African-American individuals when melanocytes are stimulated by inflammation. Hyperpigmentation in any person with dark skin can occur after traumatic injury, skin infection, or inflammatory skin disease. Patchy areas of depigmentation (vitiligo), described earlier, are more noticeable in persons with dark skin because of the color contrast. Some lesions, such as those causing erythema, may show no visible color change in darkly pigmented individuals. For example, petechiae, which cause pinpoint purplish red lesions, are usually observable only on the oral mucosa or conjunctiva.

Disorders such as seborrheic dermatitis and keloids are seen with greater frequency in African Americans.<sup>23</sup> The custom of tightly plaiting the hair or using hot oil and tension on the scalp leads to gradual damage to hair follicles, hair thinning, and, eventually, hair loss. Known as **traumatic alopecia**, this condition is also seen with greater frequency in African Americans (Figure 53-33).

Conversely, many skin disorders that affect light-skinned people, such as squamous cell or basal cell carcinoma, senile keratoses, and psoriasis, only rarely affect darker-skinned persons.

Psoriasis is rare among the African-American population. If present, it may be difficult to detect. The typical bright red color is not present. The plaques assume a blue or violet hue because of stimulation of melanocytes. The characteristic silvery scale is often absent.

Literature related specifically to abnormalities of dark skin is also rare. Normal variants such as the Mongolian spot in infants, Fletcher

**FIGURE 53-33** **A**, Traction alopecia from tight braiding and use of a hot comb. **B**, Hot comb damage resulting in scarring alopecia. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, pp 363, 366.)

or Voigt lines, and linear nail pigmentation are frequently mistaken for disorders. Box 53-3 presents tips for assessing dark skin.

#### KEY POINTS

- Certain skin disorders are manifested differently or appear in greater or lesser frequency in individuals with dark skin. Normal variants such as the Mongolian spot in infants, Futch or Voigt lines, and linear nail pigmentation are frequently mistaken for disorders.
- Disorders such as seborrheic dermatitis and keloids are seen more often in African Americans.
- Traumatic alopecia occurs more often in African Americans because of tight plaiting of the hair or the use of hot oil and tension on the scalp.
- Squamous cell or basal cell carcinoma, senile keratoses, and psoriasis only rarely affect darker-skinned persons.

### INTEGUMENTARY MANIFESTATIONS OF SYSTEMIC DISEASE

The skin reflects the status of many organ systems. For example, the endocrine, cardiovascular, renal, respiratory, and hepatic systems all have possible dermal manifestations. Metabolic disorders and internal malignancies also cause cutaneous alterations. Certainly, skin manifestations of internal malignancy can be obvious. The late-appearing features of **cachexia** (wasting), pallor, and cutaneous metastases are obvious signs of malignancy. Abnormalities in endocrine function also produce a myriad of cutaneous changes. In general, systemic disease states are expressed through altered color, sensation, texture, and temperature of the skin; altered growth, texture, color, and lubrication of the hair; and changes in nail shape, color, and texture.

## SKIN

### Color

Color changes in the skin can signal the presence of systemic disease. The entire color spectrum (red, orange, yellow, green, blue, indigo, and violet) is represented through possible coloration changes in the skin.

Redness (**erythema**) may be generalized, as with carbon monoxide poisoning, or localized, as with rashes or on the palms. Although erythema

is often visible in lighter-skinned individuals, it may be less apparent in those whose skin is dark; however, the affected part may become an even deeper shade of brown. Redness may accompany inflammation.

When inflammation is suspected in a dark-skinned person, other parameters can be assessed by palpation, among them increased skin temperature, tight skin suggestive of edema, induration of deep tissue or blood vessels, and tenderness. Because the dorsal skin surface of the fingers is more sensitive to subtle skin temperature differences than the palmar surface, the examiner should use the dorsal portion of the fingers to move from one skin area to another for comparison. The patient's family and friends are also helpful in validating color change, particularly when it has occurred gradually.

Orange discoloration can occur from the deposition of carotene. Protein-calorie malnutrition can cause hypopigmentation in African-American children, with the hair and skin appearing orange.

Yellow discoloration can occur locally when lipids are deposited in skin secondary to a metabolic defect in blood lipids. More commonly, a generalized yellow (jaundiced) appearance arises because of liver disease. Bilirubin accumulates in blood and saturates the tissues. **Jaundice** is observed in the usual sites (e.g., mucous membranes, nail beds). Because many factors can alter these findings, one single positive finding should not be held as conclusive. Other parameters, such as environmental temperature, drug use, smoking, amount of hemoglobin, and the color of urine or stool, can support a description of cyanosis or jaundice. In both dark-skinned and light-skinned individuals, yellow sclerae may indicate jaundice, but other factors can cause yellow scleral pigmentation; fatty deposits that contain carotene are a common finding in dark-skinned individuals. To determine whether the yellow sclerae signify jaundice, observe the hard palate in bright daylight. Jaundice can be detected in this location quite early (i.e., when serum bilirubin level is 2 to 4 mg/100 ml) if the palate does not have heavy melanin pigmentation.<sup>24</sup> If the hard palate does not show jaundice when the sclerae are yellow, the pigmentation may be due to some other factor, such as carotene accumulation. All these factors support the importance of repeated observation and accurate description of what is seen. As often as possible, the same individual should perform the entire examination and confirm specific findings in one area with additional data from other areas.

When jaundice is severe, **biliverdin** also accumulates. A person with obstructed bile ducts can become green-yellow because of biliverdin.

### BOX 53-3 TIPS FOR ASSESSING DARK SKIN

Skin color should be observed in the sclerae, conjunctivae, buccal mucosa, tongue, lips, nail beds, palms, and soles.

Inspection should be accompanied by palpation, especially if inflammation or edema is suspected.

Findings should always be correlated with the patient's history to arrive at a diagnosis.

**Pallor** in brown-skinned patients may appear as a yellowish brown tinge to the skin. In a black-skinned patient the skin will appear ash gray. Pallor can be difficult to determine. In dark-skinned individuals it is characterized by absence of the underlying red tones in the skin.

**Jaundice** may be observed in the sclera but should not be confused with the normal yellow-pigmented sclera of a dark-skinned black patient. The best place to inspect is in the portion of the sclera that is observable when the eye is open. If jaundice is suspected, the posterior portion of the hard palate should also be observed for a yellowish cast, which is most effective when done in bright daylight.

The **oral mucosa** of dark-skinned individuals may have a normal freckling of pigmentation that may also be evident on the gums, the borders of the tongue, and the lining of the cheeks.

The gingiva may normally have a dark blue color that may appear blotchy or be evenly distributed.

**Petechiae** are best observed over areas of lighter pigmentation—the abdomen, gluteal areas, and volar aspect of the forearm. They may also be seen in the palpebral conjunctiva and buccal mucosa.

To differentiate petechiae and ecchymosis from erythema, remember that pressure over the area will cause erythema to blanch but will not affect either petechiae or ecchymosis.

**Erythema** is usually associated with increased skin temperature, so palpation should also be used if an inflammatory condition is suspected.

**Edema** may reduce the intensity of the color of an area of skin because of the increased distance between the external epithelium and the pigmented layers. Therefore, darker skin would appear lighter. On palpation the skin may feel "tight."

**Cyanosis** can be difficult to determine in dark-skinned individuals. Familiarity with the precyanotic color is often helpful. However, if it is not possible to determine cyanosis from the skin, close inspection of the nail beds, lips, palpebral conjunctiva, palms, and soles should show evidence of cyanosis.

**Rashes** may be assessed by palpating for changes in skin texture.

Blueness of the skin (**cyanosis**) often occurs on the tips of the fingers, toes, nose, and lips in individuals with cardiac or respiratory problems that prevent oxygenation of blood. Localized blueness with pain of the fingers on exposure to cold is termed *Raynaud disease*. It frequently arises from the presence of cryoglobulins, which solidify in the cold, and is also associated with disorders of the immune system, such as lymphoma and acquired immunodeficiency syndrome.<sup>25</sup>

Indigo discoloration occurs locally, as in gangrene of the toes from severe generalized arteriosclerosis. The skin can darken from increased melanin synthesis, as in chronic adrenal insufficiency. Also, silver poisoning can make the skin dusky. Violet-colored palms (palmar erythema) can be seen in some individuals with liver disease and occasionally in pregnant women as a response to hyperestrogenism.

Shades of violet occur on the legs as a result of vascular insufficiency or when cardiopulmonary function is compromised.

The primary sites for assessing skin **pallor** are the nail beds, lips, and conjunctivae. When observing the lower eyelid (inferior palpebral conjunctiva) for pallor, the examiner should lower the lid sufficiently to see the conjunctiva near not only the outer canthus but also the inner canthus because the former is often darker. Greater perception is necessary when assessing a darkly pigmented individual for pallor because the changes are subtle. Red tones may be absent; a brown-skinned person may appear more yellowish brown, and a black-skinned person may appear ash gray. This variability supports the need for accurate baseline data for comparison.

## Sensation

Sensory innervation is generally responsible for the itching (**pruritus**) and **pain** that accompany most skin diseases. *Itching* is often the initial symptom in such conditions as atopic eczema, allergic contact dermatitis, scabies, dermatophytosis, psoriasis, and varicella. It can also be associated with systemic disorders, including carcinoma, diabetes, thyroid disease, uremia, and obstructive biliary disease. Other dermatologic conditions, such as herpes simplex, aphthous stomatitis, herpes zoster, furuncles, and cellulitis, produce considerable *pain*.

## Texture

Normal aging produces an alteration in the texture of skin. Loose and wrinkled skin that lacks tone may also indicate **dehydration** (an abnormal finding). Dehydration may also be apparent through inspection of the oral cavity. On inspection, a dry, leathery appearance of the tongue is *not* a reliable indicator of dehydration inasmuch as mouth breathing frequently makes the tongue look dry even when the individual is well hydrated. A more reliable method of assessing hydration of the oral cavity is to palpate the mucous membranes along the area of the gum and cheek where the membranes approximate. If the membranes are dry and the finger does not slide easily, dehydration is evident.

To evaluate **fluid excess**, palpate the skin over the hands, feet, ankles, and sacrum. If the skin is firm and indents easily (pitting edema) on moderate pressure from the fingertips, fluid excess is present.

Feeling the deeper portions of the skin may reveal areas of **induration** (hardness) such as those resulting from multiple intramuscular or subcutaneous injections of medication. **Lipodystrophies** consist of smooth, large depressions in the skin that indicate atrophy of the subcutaneous fat layer, which has a spongy consistency. Both induration and lipodystrophy are often seen at sites of repeated insulin injections.

## Temperature

If the skin feels warm and dry in a person who is febrile (feverish), the blood temperature is probably rising, an indication that the thermoregulatory mechanism of sweating may not be functioning. Likewise, if the skin is warm and wet, the temperature can be expected to fall owing to the cooling mechanism of sweating.

Sweating can also occur when the blood glucose concentration falls rapidly with a resultant rise in the blood epinephrine level. Hypoglycemic sweating can usually be distinguished from other causes of sweating because of the additional symptoms of weakness, tachycardia, hunger, headache, and “inward nervousness” manifested as mental irritability and confusion.

Because skin temperature depends on the amount of blood circulating through the dermis, decreased localized blood flow (resulting in coolness), often to the feet, may indicate a peripheral vascular dysfunction. Generalized skin coolness may indicate decreased metabolism such as that occurring after administration of a general anesthetic. If the temperature is very low, signs of shock may be evident.

On the other hand, an increase in skin temperature may indicate a **hypermetabolic state**, such as that occurring in hyperthyroidism and after sun exposure or sunburn.

## HAIR

Disturbances in body function are often reflected in changes in growth pattern, amount, texture, color, and lubrication of the hair.

### Growth

The high speed of growth of the scalp hair makes it more susceptible to damage from systemic disease, toxic drugs, radiation, and stress. The rate of growth varies with general health and age, and hair growth is dependent on circulating hormonal factors (primarily testicular or adrenal androgens). Thus hormonal imbalances or shifts (e.g., those accompanying childbirth) may also result in disturbances in the hair growth cycle. Nutritional factors, although often promoted in the non-medical literature, have little effect on hair growth except in cases of severe malnutrition.

### Amount

Alterations in the amount of body hair can be extremely anxiety provoking for both males and females. In females with hypertrichosis, or **hirsutism**, hair growth is intensified on the upper lip, chin, cheeks, and chest; around the nipples; and from the pubic crest to the umbilicus (along the linea alba); the downy hair on the arms, legs, and back becomes coarse. The pubic hair often assumes the upright triangular distribution typical of the male as opposed to the female’s usual inverted triangle. An endocrine malfunction such as excess androgen production may sometimes be associated with hirsutism, but ethnic background (Mediterranean groups predominantly) may also be responsible for the excessive hair growth. This propensity is especially true of the hair on the arms, legs, back, and face. Other ethnic group members such as full-blooded African-American females and male Native Americans rarely have facial hair. Distribution of the hair in family members and ethnic background are thus important considerations in ascertaining hair growth.

**Hypertrichosis lanuginosa** is typically a congenital, autosomal dominant disorder in which excessive hair is distributed over the entire body throughout life. The condition is usually associated with other congenital anomalies such as spina bifida.<sup>26</sup> In some cases, such as with certain internal carcinomas, hypertrichosis lanuginosa is an acquired disorder; the degree of hairiness is variable and usually involves the face.

### Color

Perhaps the most common color change in the hair is the generalized graying that accompanies the aging process.

### Texture

Normal aging also produces a decrease in hair thickness. Disturbances of the thickness of scalp hair are common. Baldness (**alopecia**) or

**FIGURE 53-34** Male pattern baldness (androgenetic alopecia) in a woman. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 365.)

thinning of the hair that is generalized or creates a receding hairline is often genetically determined (Figure 53-34). Some rare genetic defects in the hair shaft itself may produce breaking of the hairs and be erroneously diagnosed as alopecia. Generalized and localized baldness may result from treatment modalities such as radiation therapy or chemotherapy. In addition, various types of scalp diseases (e.g., fungal, lupus) and telogen effluvium (transient hair loss occurring 2 to 3 months after general anesthesia, febrile illness, or giving birth) can cause hair loss. Other traumatic types of hair loss may result from pulling of the hair because of a nervous habit, wearing hair styles such as tight braids or ponytails, or donning constrictive apparel such as a hat.

### Lubrication

Hyperfunction of the sebaceous glands is associated with androgen stimulation such as occurs with the excessive scalp oiliness and facial acne in adolescence. Dry, brittle hair is commonly the result of excessive washing or the application of chemical agents (coloring, bleach, or detergent shampoos) to the hair.

In addition to direct observation of the scalp and face, correlation of the findings with data from the patient history helps determine dysfunctional states of health.

## NAILS

Because nails are derived from a highly active tissue, they may be affected by any serious systemic illness. Moreover, any local skin disease that affects the epidermis may also affect the nail matrix (epidermal cells that give rise to the nail plate) and lead to an abnormal (**dystrophic**) nail. By measuring the distance between abnormalities (pits, grooves, and lines) and the proximal nail border, one may estimate the time of initial illness.

### Shape

Transverse furrows (**Beau lines**) in the nail indicate that nail growth has been disturbed (Figure 53-35). These furrows can result from infection, systemic disease, or injury. Nails with a concave curve are known as spoon nails, or **koilonychia**. This may signal a form of iron-deficiency anemia and is also associated with other disorders such as coronary disease, syphilis, or the use of strong soaps. Destruction of the nails (**onycholysis**) may accompany a great variety of unrelated conditions ranging from the application of false nails to hyperthyroidism, fungal nail infection, or psoriasis (Figure 53-36). Certain medications may also cause onycholysis (Figure 53-36, D). **Splinter hemorrhages** may

**FIGURE 53-35** Beau lines. This patient had major surgery 5 months previously. (From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, p 334.)

be linked to bacterial endocarditis and trichinosis. These red or brown splinters or streaks run parallel to the finger in the nail bed (Figure 53-37). **Clubbing** of the fingers is characterized by a flattening of the angle of the base of the nail. It may occur in association with cardiovascular disease, subacute bacterial endocarditis, and pulmonary disease.

### Color

Nail color indicates the amount of blood oxygenation. Bluish or purplish discoloration of the nail beds occurs with **cyanosis**, whereas **pallor** often indicates anemia. To compare color of the nail beds, apply slight pressure on the free edge of the second or third fingernail. The blanching that results is then compared with the normal color of the nail. The rate of color return also indicates the quality of peripheral vasomotor function.

### Texture

Thickening of the nail may result from nutritional disturbances, repeated trauma, inflammation, and local infection. Along with thickening, toenails may become discolored and grooved, and debris may accumulate under the nail. This condition may be exacerbated as the distal portion of the nail works free from the underlying nail bed and more debris is accumulated; fungal infections may also follow. Treatment usually consists of periodic debridement of the nail plate; however, a return to normal nail structure rarely occurs after thickening.

### KEY POINTS

- Many systemic diseases are associated with alterations in skin, hair, and nails. Skin reflects systemic inflammation and fever as erythema. A rising fever is manifested as warm, dry skin, whereas warm, moist skin indicates a fever beginning to decline. Poor oxygenation and circulation may be manifested by cyanosis, pallor, or coolness. Jaundice indicates altered bilirubin metabolism, usually caused by liver or biliary disease. Fluid balance may be manifested in the skin as decreased turgor or edema. Sympathetic activation may be indicated by cool, pale, diaphoretic skin.
- Hair growth, strength, texture, and color are affected by systemic diseases such as endocrine abnormalities, extreme malnutrition, and drugs. Excessive androgen may result in hirsutism. Alopecia may result from chemotherapeutic drugs or radiation therapy.
- Abnormalities of nail growth (pits, grooves, lines) occur as a result of nearly any serious systemic illness. Certain nail defects are characteristic of particular diseases: spoon nails may indicate iron-deficiency anemia; clubbing is associated with cardiopulmonary disease. Nail color is commonly assessed to determine the adequacy of oxygenation and perfusion.

## TREATMENT IMPLICATIONS

A distinct advantage in treating the skin is the ease of direct observation of the pathologic process and the effects of treatment. Culture, macroscopic examination of skin scrapings, and biopsy also facilitate diagnosis. A correct diagnosis can help prevent complications from improper therapy but does not lessen the importance of choosing an appropriate delivery system.

## TOPICAL TREATMENT

### Wet Dressings

Wet dressings, the application of a liquid in compress form, are a very important part of the dermatologic therapy delivery system. The applied liquid can be plain water or water with additives (e.g., sodium, magnesium, or aluminum salts).

Wet dressings are a versatile, even paradoxical therapeutic approach in that they can dry or hydrate as necessary. Intermittently applied, they serve as an effective astringent for the weeping, oozing lesions that accompany stasis and decubitus ulcers and impetigo. Vesicular lesions, including those seen in dyshidrotic eczema, herpes zoster, and pemphigus, also respond nicely to treatment with intermittent wet dressings. By drying disease-related lesions, intermittent dressings help speed recovery.

Continuous wet dressings, on the other hand, are effective in rapidly hydrating the skin. This technique, used most often in severe cases of atopic eczema, normally requires hospitalization. Wet dressings of gauze soaked in tap water are applied directly to the skin and covered with an insulating agent such as towels, large thick gauze pads, or even long underwear to prevent evaporation. It is very important that the dressings remain moist. Therefore, they must be resoaked and changed every 3 hours around the clock throughout the course of treatment. Once the desired state of hydration has been achieved, the dressings can be discontinued and emollient creams used to prevent redrying of the treated area.

### Lotions

Shake lotions are mixtures of small suspended particles in a liquid vehicle such as water or alcohol. These are especially useful for application

directly to moist or exudative processes such as rhus dermatitis. As the liquid phase dissipates, the evaporative effect cools and dries the skin.<sup>27</sup>

Emollient lotions are a mixture of oil in water and have a slightly greasy consistency. These preparations are useful when skin moisturization is needed such as in xerotic conditions. Lotions are often used as a vehicle for other medications such as topical steroids that must be applied over large areas of skin.<sup>27</sup>

### Gels

Most gels are clear, colorless, volatile substances. They generally penetrate better than creams. Gels are very convenient to use on wet lesions because of their astringent tendencies. Because they do not leave the white or oily residue of creams and ointments, they are appropriate for use on scalp lesions.

### Creams

Creams are the most widely used dermatologic delivery system. Many different bases are used in creams, but the “vanishing” type is most common and allows application with no surface residue. Creams penetrate well and have some moisturizing capability. They are used most frequently in the management of dry to slightly moist dermatoses.

### Ointments

The medication in most ointments is carried in a petrolatum-type base, which facilitates penetration into the upper skin layers. Ointments are frequently used on skin lesions that have overlying dry scaling and crusting, but they are also very effective on severe dermatoses requiring an increased medication dosage. Ointments are semiocclusive and often not appropriate for use on lesions that are oozing and discharging a transudate or exudate.

### Aerosols and Foams

Aerosols, fine particle sprays of medication usually delivered by gas under pressure, are a cosmetically elegant way of treating dermatoses, especially on hairy areas of the body. Many topical medications are now available as foams that can be used in a similar fashion.

## INTRALESIONAL INJECTION

Intralesional injection, or the deposition of medication directly into the lesion, can be done with a conventional needle and syringe or with an instrument (Dermojet) that injects fine particles of medication through the skin with air pressure. This delivery form is especially useful in delivering higher concentrations of corticosteroids to lesions (usually with deep dermal components) that do not respond to topical medication.

## SELECTION OF A DELIVERY SYSTEM

Delivery system selection depends on the disease being treated, the type of lesions clinically present, and the practitioner’s preferred medication routine. For instance, weeping exudative lesions require drying (wet dressings) and perhaps corticosteroids. Initial delivery as a gel would increase the drying tendency; as the lesion dries, a cream may be used to prevent overdrying and fissure formation.

In a disease state such as chronic atopic eczema with lichenoid or thickened skin, the prescriber may choose an ointment to enhance penetration of the medication into the lesion. The ointment’s occlusive nature reduces moisture loss from the skin.

Seborrhea and psoriasis in the scalp may be treated with aerosols, which are quick and easy to use and are associated with a high degree of patient compliance. Patients often find them cosmetically superior to the identical medication in cream form. Keloids, which require highly

concentrated medication to be delivered to a small area, are ideal candidates for intralesional injection of corticosteroids.

## CORTICOSTEROIDS

Corticosteroids are a very important tool in the practice of dermatology. Dermatologists administer steroids systemically and topically. Steroids may be characterized as short acting (cortisone or hydrocortisone), intermediate acting (prednisone, prednisolone, methylprednisolone, or triamcinolone), or long acting (dexamethasone or betamethasone).

### Systemic Steroids

Administration of systemic steroids in dermatologic disease is usually oral. Intermediate-acting steroids (prednisone, prednisolone, methylprednisolone) are used most often. The greatest benefit of oral administration is the ability to adjust dosage schedules quickly if required. Once-daily doses, divided daily dosage, or alternate-day regimens are all effective.

Intramuscular administration of corticosteroids is also common. Preparations such as triamcinolone acetonide are used most often. These drugs, which may reduce inflammation for more than 4 weeks, ensure that an unreliable patient will receive appropriate doses of medication.

Systemic corticosteroids are generally used for relatively short periods. Therefore, the complications commonly associated with corticosteroid use are not usually seen in dermatologic treatment. However, the long-term use of corticosteroids in diseases such as pemphigus and SLE often results in cushingoid features such as a round, puffy face and a “buffalo hump.” Additional adverse effects include fatigue, weakness, and acne.

### Topical Steroids

Corticosteroids can also be applied topically to suppress inflammation. Although this approach does not cure the disease, the reduction in erythema, edema, and pruritus promotes healing. Topical steroids are available in a variety of forms. Based on their capacity to cause cutaneous vasoconstriction, topical steroids are divided into seven groups, with group 1 being the most potent (augmented betamethasone dipropionate [Diprolene AF] and clobetasol dipropionate [Temovate]) and group 7 being the least potent (1% hydrocortisone).

#### KEY POINTS

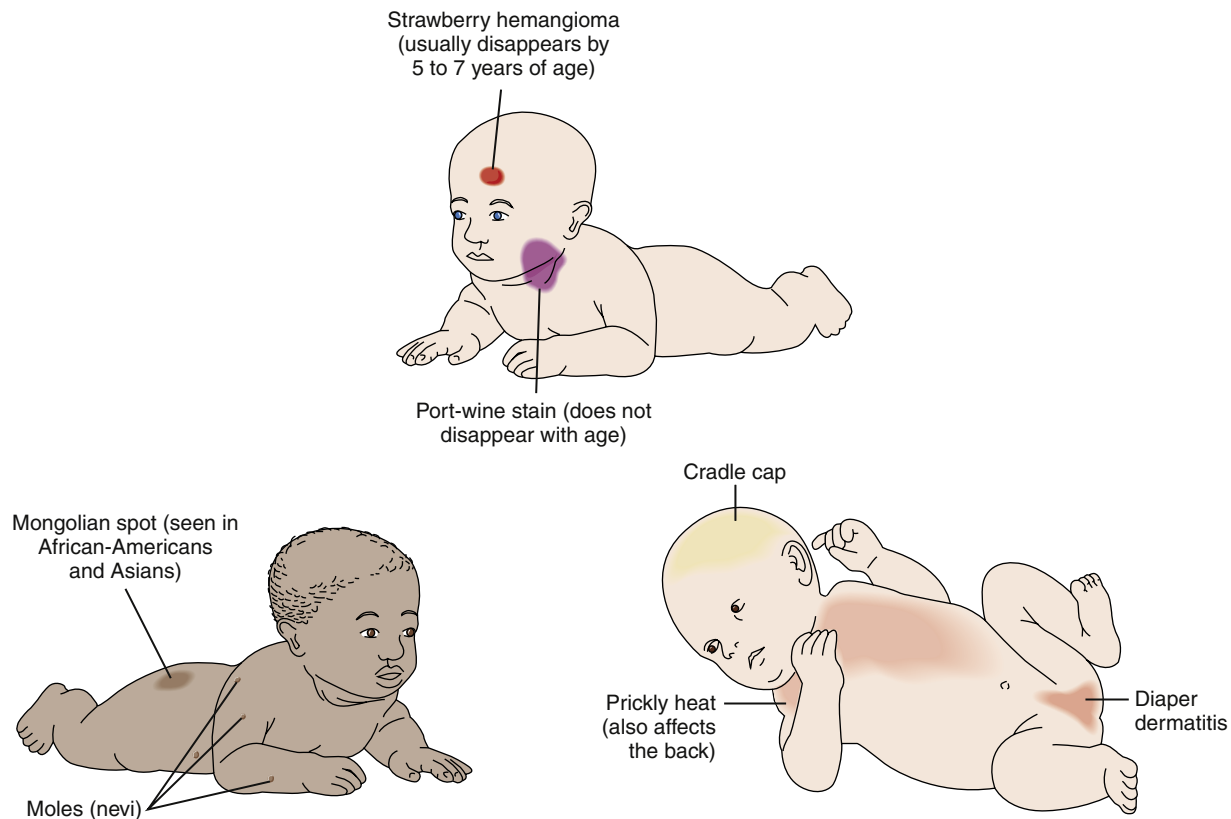

- Selection of topical treatment depends largely on whether the goal is to moisturize or dry the affected area. Continuous wet dressings, lotions, creams, and ointments tend to be moisturizing. Intermittent wet dressings and gels tend to be astringents for weeping, oozing lesions.
- Corticosteroids are commonly administered to reduce inflammation. They may be given topically, intralesionally, or systemically.

## DEVELOPMENTAL CONSIDERATIONS

The skin and the skin problems of special groups warrant consideration. Certain skin problems are seen only in infants and children (e.g., cradle cap and diaper rash) (Figure 53-38). Other dermatoses are seen in both children and adults, but in children these dermatoses may appear different from the adult counterpart. Still other dermatoses affect primarily older individuals.

## INFANCY

Infancy connotes soft, flawless skin. In general, this is a true image. Several congenital skin lesions, such as Mongolian spots, hemangiomas, and nevi (moles), are nevertheless associated with the early neonatal period.

## CONGENITAL DERMATOSES

## IRRITATIVE AND INFLAMMATORY DERMATOSES

**FIGURE 53-38** Sites of common dermatoses in infants and small children.

**Mongolian spots** are caused by selective pigmentation. They usually occur on the buttocks or sacral area and are commonly seen in Asian Americans or African Americans.

**Hemangiomas** are vascular disorders of the skin. Two types of hemangiomas are commonly seen in infants and small children: bright red, raised *strawberry hemangiomas* and flat, reddish purple *port-wine stain hemangiomas*. Strawberry hemangiomas begin as small red lesions shortly after birth. They may remain as small superficial lesions or extend to involve subcutaneous tissue. Strawberry hemangiomas usually disappear before the child reaches 5 to 7 years of age without leaving an appreciable scar.<sup>28</sup> Port-wine stain hemangiomas are rare, usually occur on the face and neck, and can be quite disfiguring. They do not disappear with age and no satisfactory medical treatment is available, although laser surgery may be effective in some cases. Coverage using cosmetic makeup such as Dermablend may sufficiently conceal their disfiguring effects.

**Nevi** may vary in shape or size, and they may be present at birth or develop later in life.

Infant skin is also exquisitely sensitive to irritation, injury, and extremes of temperature. Prolonged exposure to a warm humid environment can lead to **prickly heat**, and too frequent bathing can cause excessive dryness. Soiled diapers, left unchanged, can lead to **contact dermatitis** and bacterial infections. **Cradle cap** is a harmless and usually self-limited scaly condition of the scalp. **Figure 53-38** illustrates common skin problems of infants and small children.

The primary factor in preventing infant skin disorders is careful and meticulous skin care. Baby lotions are helpful in maintaining skin moisture, whereas baby powder acts as a drying agent. Both are helpful aids when used selectively and according to the nature of the skin problem (excessive moisture or dryness).

Baby powders containing talc can cause serious respiratory problems if inhaled; therefore, containers should be kept out of the reach of small children. Corn starch is preferable to talc, and baby powders containing corn starch are readily available. Unnecessary bathing should be avoided, and clothing should be comfortable and appropriate for environmental conditions.

**Diaper rash** results from the ammonia and alkaline by-products of urine breakdown. Disposable diapers or diapers washed in gentle detergent and thoroughly rinsed to remove all traces of ammonia and alkali help prevent diaper rash. Treatment includes frequent diaper changes with careful cleansing of any irritated areas, especially in hot weather. Exposing irritated areas to air is also helpful. The use of plastic pants should be discouraged.

**Prickly heat** is caused by mid-epidermal obstruction and rupture of the sweat glands from prolonged exposure to a warm and humid environment. Treatment includes removing excessive clothing, cooling with warm water baths, drying with powders, and avoiding hot, humid environments.

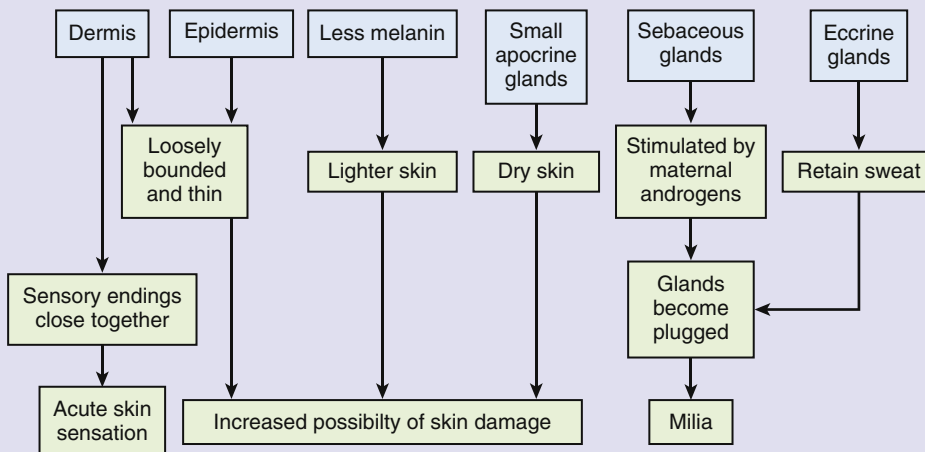

**Cradle cap** is usually managed with mild shampooing and gentle combing to remove the scales.

## CHILDHOOD SKIN DISORDERS

As infants grow and develop into active young children, they become susceptible to the many skin disorders affecting people of all age groups who encounter environmental agents. Children, because of their physiologic development and playful nature, may also be more prone to accidents that result in major skin trauma such as lacerations or burns. (See Chapter 54 for further discussion of burn injury.) Careful activity supervision helps prevent such accidental trauma.

**PEDIATRIC CONSIDERATIONS**

**Integument in the Newborn**

The integument in the newborn has sensory endings in the dermis that are closer together than seen in mature skin, creating more sensitive skin sensation. As the child develops the skin receptors begin to become more dispersed, decreasing skin sensitivity. There are several factors that lead to increased possibility of skin damage. The dermis and epidermis are present and functional at birth but the layers are thinner. The layers are loosely connected because rete pegs, which anchor the epidermis and dermis together, are not developed at birth. Therefore the dermis and epidermis are susceptible to skin damage with minimal friction. As a toddler, the dermis and epidermis become more closely linked. Another factor is that the newborn has less melanin at birth. The newborn will have lighter skin than he or she will have as a child. This lack of melanin makes the infant more susceptible to

harmful rays from the sun, increasing skin damage. The newborn also has small, nonfunctional apocrine glands. These glands, located on hair follicles, do not develop until puberty. The lack of functional glands can lead to dry skin.

Several other glands in the newborn help create milia—small, white acne found on newborns. The sebaceous glands can be found on the scalp, face, and genitalia of the newborn. The sebaceous glands are activated by maternal androgens in the fetus, producing vernix at birth, and becoming plugged and producing milia after birth. The eccrine glands respond to heat and emotional stimuli to create sweat that can obstruct the sebaceous glands and create milia. The eccrine glands will be activated at a higher temperature than in adults and are most active in the palms of newborns.

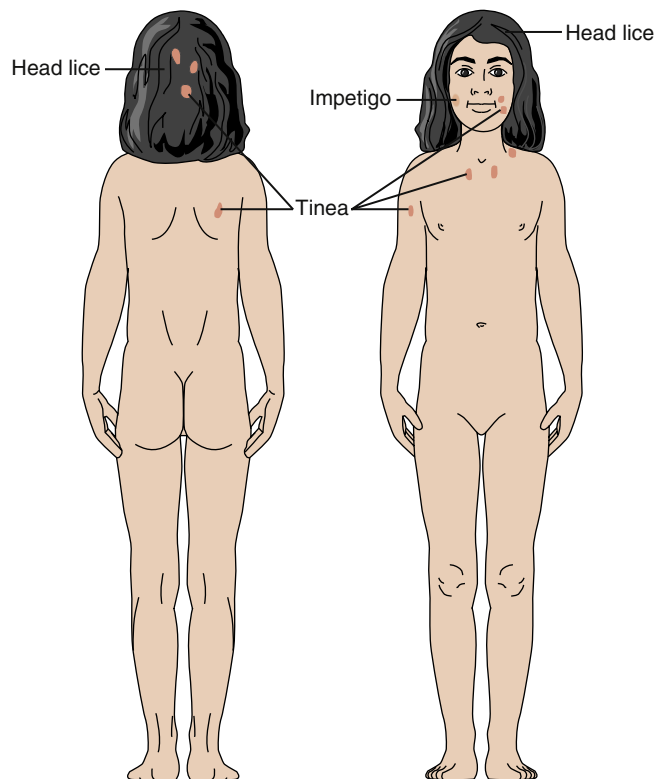

Besides interacting with the environment, children are frequently in close contact with other children. As a result, communicable diseases such as head lice, tinea capitis, and impetigo are more frequently seen in children (Figure 53-39). Epidemiologically, the incidence of rubella, roseola, rubeola (measles), chickenpox, and scarlet fever is also highest in this age group.

**Rubella**

**Etiology, pathogenesis, and clinical manifestations.** Rubella (3-day measles, German measles) is a childhood disease caused by the rubella virus. It is characterized by a diffuse punctate, macular rash that begins on the trunk and spreads to the arms and legs. Mild febrile states occur; generally the child's temperature is less than 100° F.<sup>28</sup> Postauricular, suboccipital, and cervical lymph node adenopathy is common. Coldlike symptoms usually accompany the disease in the form of cough, congestion, and coryza (profuse nasal mucous membrane discharge). Treatment is based on symptoms.

Rubella generally has no long-lasting sequelae; however, transmission of the disease to pregnant women early in the gestation period may result in severe teratogenic effects in the unborn fetus. Among the teratogenic effects are cataracts, microcephaly, mental retardation, deafness, patent ductus arteriosus, glaucoma, purpura, and bone defects.<sup>25</sup>

**Prevention.** Most states require immunization to prevent the transmission of rubella to pregnant women. Immunization is with a live virus vaccine called measles-mumps-rubella (MMR). One injection during infancy is followed by one booster dose when the child enters kindergarten or first grade or when the child enters middle school or junior high school. Administration of these two injections is considered adequate to prevent rubella. Cases of rubella in immunized children are rare.

**FIGURE 53-39** Sites of selected common communicable dermatoses affecting children.

**FIGURE 53-40** Varicella (chickenpox). **A**, Typical “dewdrop on a rose petal.” **B**, Multiple stages of lesions exist. (From Callen JP et al: *Color atlas of dermatology*, Philadelphia, 1993, Saunders, p 170.)

### Roseola Infantum

**Pathogenesis and clinical manifestations.** Roseola infantum is a contagious viral disease that generally affects children younger than 4 years and usually children about 1 year of age.<sup>28</sup> It produces a characteristic maculopapular rash covering the trunk and spreading to the appendages. A rapid rise in temperature to 105° F and the appearance of coldlike symptoms accompany the disease.<sup>28</sup> Unlike rubella, no cervical or postauricular lymph node adenopathy occurs. The symptoms usually subside within 3 to 5 days.<sup>28</sup> Roseola infantum is frequently mistaken for rubella, which can usually be ruled out by the age of the child, as well as by the absence of lymph node adenopathy. Generally, rubella does not develop in children younger than 6 to 9 months because of the presence of maternal antibodies.<sup>28</sup> Blood antibody titers may be assayed to determine the actual diagnosis. In most cases, no long-term effects from this disease are noted.

**Treatment.** Management of roseola infantum is palliative. As with rubella, antipyretic drugs such as acetaminophen (Tylenol) and cooling baths are used to reduce the fever. Ensuring sufficient rest and administering fluids are recommended for recuperation and body rehydration. Pruritus may rarely accompany the other symptoms. If severe, pruritus can be managed with topical lotions such as Caladryl.

### Measles

**Etiology, pathogenesis, and clinical manifestations.** Hard measles, or 7-day measles (rubeola), is a communicable viral disease caused by the *Morbillivirus*. The characteristic rash is macular and blotchy; sometimes the macules become confluent. The rubeola rash usually begins on the face and spreads to the appendages. Accompanying symptoms are a temperature of 100° F or greater, Koplik spots (small, irregular red spots with a bluish white speck in the center) on the buccal mucosa, and mild to severe photosensitivity.<sup>29</sup> Coldlike symptoms and general malaise and myalgia are often present. In severe cases, the macule may hemorrhage into the skin tissue or to another body surface, a condition called *hemorrhagic measles*. Measles is more severe in malnourished children. Complications include otitis media, pneumonia, and encephalitis. For a positive diagnosis, most states require antibody titer determination. Blood titers are usually determined during the disease process and 6 weeks after disappearance of the symptoms.

**Prevention and treatment.** Measles is preventable by vaccine (MMR), and immunization is required by law in most states. Immunization is accomplished by the MMR schedule (see discussion under Rubella).

Management of measles is based on symptoms. Children are kept in darkened rooms. Antipyretic medications are given to reduce the fever, and rest and fluids are recommended.

### Chickenpox

**Etiology, pathogenesis, and clinical manifestations.** Chickenpox (varicella) is a common communicable childhood disease. It is caused by the varicella-zoster virus, which is also the causative agent in shingles. The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab (Figure 53-40). The macular stage is characterized by the rapid development (within hours) of macules over the trunk of the body that spread to the limbs, buccal mucosa, scalp, axillae, upper respiratory tract, and conjunctivae. During the second stage, the macules vesiculate (blister) and may become depressed or umbilicated (raised blisters with depressed centers). The vesicles burst, and a scab forms during the third stage. Crops of lesions occur successively, so all three forms of the lesion are usually visible by the third day of illness. Mild to extreme pruritus accompanies these lesions and can be a complicating factor by leading to scratching and the subsequent development of secondary bacterial infection. Other symptoms that accompany chickenpox are coldlike symptoms, including cough, coryza, and sometimes photosensitivity. Mild febrile states usually occur. Complications such as pneumonia, sepsis, and encephalitis may occur but are rare among healthy children. Disease severity is age dependent, and the risk of visceral involvement is considerably higher in adults.

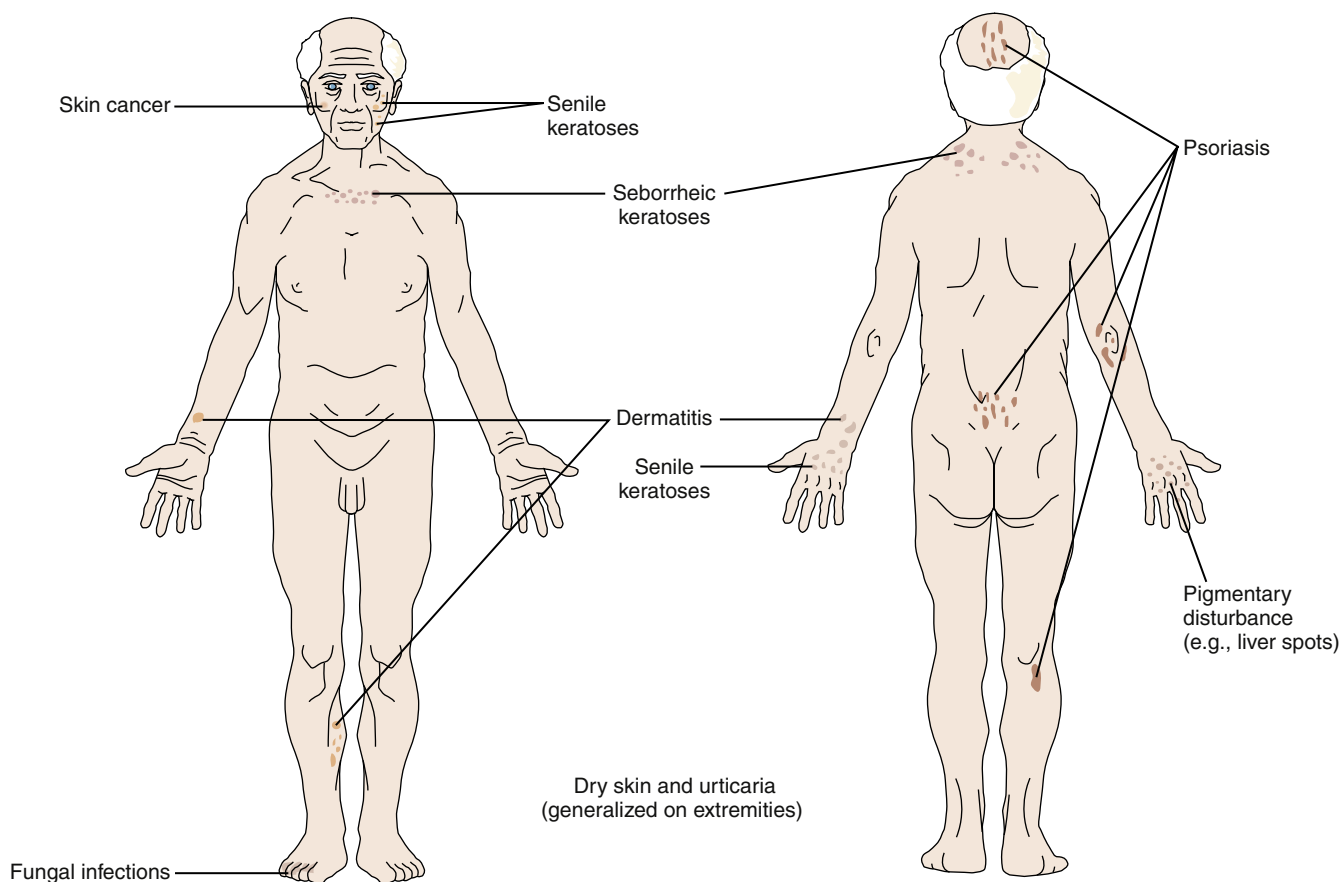

**Prevention and treatment.** Treatment is based on symptoms. Antipyretic drugs such as acetaminophen are given for fever reduction; they may also relieve local discomfort. Pruritus is relieved with lukewarm baths. Oral administration of diphenhydramine (Benadryl) or other antihistamines may be prescribed to alleviate itching. Application of topical antipruritics such as Caladryl lotion is also helpful. However, in young children, care must be taken to avoid topical preparations of Caladryl containing diphenhydramine to circumvent possible overdose of this agent through systemic absorption. (This consideration is especially important if the young child is also taking oral Benadryl.) Home remedies such as baking soda baths also relieve pruritus, and rest and fluids are important in recuperation and rehydration. Some authorities recommend acyclovir, an antiviral agent, for the management of chickenpox.<sup>30,31</sup>

Varicella-zoster immune globulin provides passive immunity against chickenpox and is recommended after exposure, especially for high-risk groups. A vaccine against chickenpox that will provide active immunity is also available. Vaccination is currently recommended for all children and sometimes required for school entrance.

### Scarlet Fever

**Etiology, clinical manifestations, and treatment.** Scarlet fever is a systemic reaction to the toxins produced by group A  $\beta$ -hemolytic streptococci. It occurs when the individual is sensitized to the toxin-producing variety of streptococci. Scarlet fever frequently occurs in

**FIGURE 53-41** Sites of common dermatoses of the elderly.

association with streptococcal sore throat (strep throat), but it may also be associated with a wound, skin infection, or puerperal infection. Scarlet fever is characterized by a pink punctate skin rash on the neck, chest, axillae, groin, and thighs. When palpated, the rash feels like fine sandpaper. Flushing of the face with circumoral pallor is evident. Other symptoms include high fever, nausea and vomiting, strawberry- or raspberry-colored tongue, and skin desquamation. Complications of scarlet fever include otitis media, peritonsillar abscess, rheumatic fever, acute glomerulonephritis, and cholera. Penicillin is the treatment of choice.

## ADOLESCENCE AND YOUNG ADULTHOOD

The most common skin disorder of adolescence and young adulthood is **acne vulgaris**. The increased production of sex hormones and oils contributes to the development of acne. Childhood diseases are less common in adolescence; however, chronic skin diseases may be exacerbated.

## GERIATRIC CONSIDERATIONS

Skin disorders are so common in elderly individuals that it is difficult to distinguish normal from abnormal. More than 90% of elderly individuals have some kind of skin disorder<sup>32,33</sup> (Figure 53-41). The most common skin disorders in the elderly are keratoses and skin cancers, followed by fungal infections, dermatitis, pigmentary disturbances, psoriasis, and urticaria (hives). Other skin disorders frequently seen in the elderly are comedones (blackheads), asteatoses (scaling), cherry angiomas (small, red, benign tumors), nevi (moles), skin tags (pedunculated fleshy growths), and lentiginos (“liver spots”). In addition, the incidence of senile purpura and senile warts (papillomas) significantly increases, especially among the very old. Senile purpura is related to loss of the

subcutaneous tissue that supports the skin capillaries. Minor trauma can cause small bruises or ecchymotic lesions, which largely occur on the extensor surface of the forearms. Approximately 40% of older men and 77% of older women show evidence of senile purpura.<sup>34</sup> Senile papillomas are small yellow, brown, or black warts located on the trunk, limbs, and face; 63% of all older individuals have some senile papillomas.<sup>35</sup>

Figure 53-42 illustrates several of the common skin lesions associated with aging. Most of these lesions are considered normal concomitants of aging and cause little discomfort. The greatest concern regarding body image is the appearance of the skin, which tends to look mottled and spotty. Disorders of the skin that tend to cause the most physical discomfort are pruritus, keratoses, epitheliomas, malignant melanomas, herpes zoster, psoriasis, and pressure sores.

### KEY POINTS

- Certain skin disorders are more common in particular age groups.
- Infants are prone to irritating lesions, including prickly heat, contact dermatitis, and cradle cap. Altered areas of pigmentation are first noticed in infancy, including Mongolian spots, hemangiomas, and nevi.
- Children are prone to skin injuries and communicable diseases. A number of viral infections, including rubella, roseola, measles, and chickenpox, are associated with characteristic skin rashes. Fever and malaise are usually present. Treatment is symptomatic. Vaccinations are available to prevent rubella, measles, and chickenpox. Scarlet fever is due to a bacterial infection and is managed with antibiotics. Children are often exposed to superficial infections and infestations, including head lice, ringworm, scabies, and impetigo.
- Acne is the most common skin disorder of adolescents.
- Elderly skin is prone to a number of problems, including psoriasis, angiomas, and skin tags. Cancerous and precancerous lesions are common and require careful screening examination.

**FIGURE 53-42** Common skin lesions associated with aging. **A**, Cherry angioma. **B**, Acrochordons (skin tags). **C**, Senile lentigines (liver spots) in an 87-year-old woman. Note the well-demarcated brownish black macules. **D**, Senile purpura. (**A** and **B**, From Callen JP et al: *Color atlas of dermatology*, ed 2, Philadelphia, 2000, Saunders, pp 83, 304. **C** and **D**, From Swartz MH: *Textbook of physical diagnosis*, ed 6, Philadelphia, 2010, Saunders, pp 807, 808.)

## SUMMARY

In systemic diseases, the color, texture, and composition of the skin mirror and participate in widespread pathophysiologic events. For example, internal disease states such as acquired immunodeficiency syndrome; collagen diseases such as scleroderma and dermatomyositis; diabetes; gout; malignancies; neurologic diseases; liver disease; muscle weakness; and vascular, inflammatory, and metabolic disorders all exhibit cutaneous manifestations. Because the skin mirrors the interior condition of the body, it is important in the diagnosis of disease. Cutaneous manifestations may be caused by bodily changes such as

pregnancy or obesity. They may also be caused by external factors such as climate, industrial contamination, indoor heating systems, clothing, plant life, and toxic or allergic reactions to drugs and cosmetics.

A distinct advantage in treating individuals with skin disease is the ability to observe the pathology and the effects of treatment. In addition to a careful history, a culture, skin scraping, or biopsy provides good diagnostic information. A correct diagnosis can help prevent complications from improper therapy, but it does not lessen the importance of choosing an appropriate delivery system.

Burns are injuries to tissues caused by contact with dry heat (flame or hot surfaces), moist heat (steam or hot liquids), electricity (current or lightning), chemicals (corrosive substances), friction, or radiant and electromagnetic energy. Approximately 450,000 individuals seek medical attention for burn injuries annually in the United States, with

10% necessitating acute hospitalization.<sup>1</sup> In recent decades, associated mortality rates have decreased significantly, with most patients achieving excellent functional and cosmetic outcomes. Improved outcomes have been attributed to the delineation of pathophysiologic mechanism of burns, advances in management, and the development of a

comprehensive, treatment-oriented approach to care.<sup>2-4</sup> The American Burn Association in conjunction with the American College of Surgeons Committee on Trauma has been instrumental in promoting the development of burn centers.<sup>5</sup> Advanced burn life support prehospital and provider courses have also been developed to provide evidence-based guidelines for the assessment and treatment of burn victims.<sup>6</sup> To facilitate appropriate treatment decisions and recognize potential complications, an understanding of the pathophysiologic processes associated with the burn injury is vital.

## THERMAL INJURY

### Etiology, Incidence, and Mortality

Thermal injuries are burns caused by contact with or exposure to extremes of temperature. Over the past 6 decades the incidence of burn injuries in the United States has steadily decreased, with approximately 450,000 currently occurring annually,<sup>1</sup> resulting in approximately 40,000 hospitalizations and 3120 deaths.<sup>7-10</sup> The fire loss record in the United States is the worst in the industrialized world, with the fire-related mortality double that of most countries on a per capita basis. From 2005 to 2009, residential fires resulted in nearly \$7 billion per year in property damage.<sup>11</sup>

A half century ago, burns over 50% of the total body surface area (TBSA) resulted in a greater than 50% mortality in pediatric patients.<sup>12</sup> Currently, most children survive burns of this size, and more than half survive burns of more than 90% of their TBSA.<sup>13</sup> Early mortality generally occurred as a result of inadequate initial resuscitation. As vigorous resuscitation protocols were developed, a significant reduction in mortality occurred. Additionally, many advances have also contributed to decreasing thermal burn-related mortality, including: a better understanding of the pathophysiologic mechanisms of burns, implementation of a multidisciplinary team-oriented approach, improvement of resuscitation strategies and infection control measures, use of early surgical excision and skin-grafting techniques, application of advances in skin substitute development, and employment of improved rehabilitation strategies.<sup>14-18</sup>

Unfortunately, the reduction in mortality was replaced by an increased number of survivors with wound sepsis. The development of improved topical and systemic antimicrobial agents, recognition of the importance of maintaining proper nutrition, and adoption of early wound excision and grafting techniques have resulted in a significant reduction in mortality. As a result of these advances, acute mortality in patients with thermal injuries remains relatively low. The primary cause of death in this population now occurs in the subacute setting as a result of pulmonary sepsis, often developing secondary to inhalation injury. More than 80% of patients sustaining burns have involvement of less than 20% of their TBSA and are treated on an outpatient basis. Despite burn degree, the associated physical and emotional sequelae are often extensive and prolonged. As a result, this unique population requires vigilant follow-up care.

### Risk Factors

The U.S. Centers for Disease Control and Prevention (CDC) has identified the following groups as being at high risk for fire-related injuries and deaths: children younger than 4 years; adults 65 years and older; Native Americans and African Americans; economically challenged individuals; people living in rural areas; and those residing in manufactured homes or substandard housing. Children younger than 15 years old account for one third of all admissions to burn units and one third of all deaths from burns and burn-related injuries.<sup>8</sup> Scald injuries, primarily secondary to accidental spills, or in up to 20% from an element of abuse or neglect, account for up to 65% of all burn injuries.<sup>4,12,19</sup> See Figure 54-1 illustrating an abuse burn.

**FIGURE 54-1** All burns in children must be carefully evaluated with a consideration for nonaccidental or intentional injury. This 2-year-old boy was immersed by his father in a bathtub of hot water and sustained burns over 55% of his total body surface area. One feature that characterizes abuse burns is a clear demarcation between burned and unburned skin and the absence of drip, spill, or splatter marks. (Courtesy Michael Peck, MD, University of North Carolina Burn Center, Chapel Hill.)

The population older than 65 years of age accounts for approximately 29% of all burn/fire-related deaths in the United States.<sup>20</sup> Burns in the elderly carry a high mortality rate as a result of preinjury disability, age-related immunosuppression, and impaired healing responses (Table 54-1).<sup>8</sup> Environmental and lifestyle factors influence the frequency and magnitude of thermal burn injuries. Alcohol and drug abuse contributes to approximately 40% of all residential fire-related deaths. Neurologic and psychiatric disorders have also been found to increase the risk of accidental burn injury, with one study finding 3% of patients admitted to the burn unit had thermal injuries associated with neurologic disorders.

### Integument Effects

The skin is the largest organ of the body and constitutes approximately 20% of the total body weight. It consists of two layers, the epidermis and dermis, which rest on the hypodermis (or subcutaneous layer). The epidermis contains two main cell types, melanocytes and keratinocytes, as well as multiple appendages such as hair, nails, and glands (sweat and sebaceous). The appendages, although originating from the epidermal layer, are anatomically located in both the epidermis and the dermis. Keratinocytes synthesize keratin, and melanocytes scattered throughout the basal layer (stratum germinativum) produce melanin, a pigment that shields deeper structures of the skin from sunlight. Apocrine glands, the large sweat glands, are rudimentary structures with no known useful purpose. They respond to autonomic nerve stimulation rather than thermal stimulation to produce an odorless, viscous, milklike droplet from the hair shaft. Apocrine glands are more numerous in women and are located in the axilla, areola of nipples, groin, perineum, and perianal and periumbilical regions. Eccrine glands are small sweat glands distributed over the body that act as true secretory glands and produce the sweat responsible for heat regulation. At environmental temperatures greater than 31° or 32° C (90° F), sweating occurs over the entire body; at lower temperatures, microscopically visible droplets are secreted periodically as part of the total insensible water loss from the body. Sweat normally provides skin with an acid mantle (average pH, 5.7 to 6.4) that retards growth of the many bacteria that reside in the keratin layer, glands, and hair follicles.

TABLE 54-1 PHYSIOLOGIC CHANGES ASSOCIATED WITH AGE

BODY SYSTEM	PEDIATRIC	ELDERLY
Cardiovascular	<p><b>Symptoms of shock:</b>            Increased heart rate            Decreased blood pressure            Decreased urine output            Cardiac output dependent on heart rate            Decreased myocardial compliance            Stroke volume plateaus at lower filling pressures</p> <p><b>Peripheral cyanosis:</b>            Neonates: a normal finding            Children: decreased cardiac output            Small trachea is easily obstructed</p>	Increased chronic disease processes Decreased vascular elasticity results in increased systolic blood pressure Decreased cardiac output Decreased $\beta$ -adrenergic responsiveness Decreased cardiac stress response Decreased intrinsic heart rate Decreased blood flow Decreased vascular permeability Increased myocardial irritability Decreased myocardial perfusion Increased dysrhythmias Conduction system changes
Pulmonary	Neck hyperextension leads to epiglottal or tracheal obstruction At <8 yr, cricoid cartilage is narrowest airway point At <8 yr, no cuff is needed on endotracheal tube Hypoxemia leads to decreased heart rate in neonates Hypoxemia leads to decreased heart rate in children Diaphragmatic breathing Lower airways are easily obstructed Decreased O <sub>2</sub> reserve	Increased need for ventilatory support Increased incidence of inhalation injury Increased pneumonia Decreased lung elasticity Decreased chest wall muscle Decreased oxygen saturation Decreased tidal volume Decreased vital capacity Decreased pulmonary capillary circulation
Thermoregulation and metabolism	Increased resting metabolic rate Increased resting O <sub>2</sub> consumption Increased BSA in relation to body weight Increased hypothermia Increased heat loss from evaporation and convection At <6 mo, inability to shiver to increase body heat Stress leads to hypoglycemia Glycosuria is a sign of infection At <2 yr, buffering capacity is decreased Increased metabolic demands of growth	Increased burn wound infection Increased sepsis Poor or delayed wound healing Increased preexisting malnutrition Decreased febrile response Increased hypothermia
Gastrointestinal and renal	Decreased endogenous calorie stores Increased diarrhea with fluid and calorie deficits At <2 yr, gastric emptying is delayed At <2 yr, increased gastric distention At <30% TBSA burn, can take sufficient caloric supplementation At >30% TBSA burn, requires caloric supplementation At <12 mo, poor renal filtration and absorption	Increased volume sensitivity Decreased nutritional status Increased likelihood of hypotensive or hypertensive renal damage Increased incidence of type 2 diabetes mellitus Decreased creatinine clearance
Neurocognitive	Increased incidence of cerebral edema with fluid resuscitation Increased irritability Increased regressive behavior Increased risk-taking behavior Immature judgment	Decreased brain mass Decreased cerebral nerve cells Decreased brain cortex layer Decreased cerebellar cortical cells Decreased nerve conduction velocity Decreased memory Decreased electroencephalographic activity Slower reaction time Decreased taste Decreased smell Decreased vision Decreased hearing Increased pain threshold Decreased judgment and cognitive abilities
Immune	Immature immune system Decreased immunocompetence	Decreased number of leukocytes Decreased immunocompetence Decreased T-cell response

 BSA, Body surface area; mo, month(s); TBSA, total body surface area; yr, year(s).

Sebaceous glands secrete sebum, a complex mixture of lipids that is emptied into the hair shaft. The rate of production of sebum and its location depend on androgens, which initiate and continue production. During the hypermetabolic state that follows major thermal injury, production of sebum is decreased, leading to the dry skin conditions commonly found after recovery.

Thermal injury to the integument occurs in two phases: (1) immediate, which is a result of direct cellular injury and (2) delayed, which occurs as a result of progressive dermal ischemia.

The duration of exposure and the temperature, or the amount of energy, to which the skin is exposed primarily determines the degree of tissue/cellular injury, which is characterized by three zones (from inner to outer): (1) zone of necrosis; (2) zone of stasis, which is a region with decreased blood flow that either can be returned to its normal state with appropriate resuscitation or can be converted to a necrotic state in the case of dehydration, infection, or decreased perfusion; and (3) zone of hyperemia, which is minimally injured tissue that usually recovers normal function within 1 week.<sup>21</sup>

In response to thermal injury, keratinocytes develop from cells in the basal layer of the epidermis and progress upward from the stratum germinativum to the stratum corneum over a 14-day period. During this time the wound develops a light pink or reddish coloration, with normal skin color restored in a delayed fashion by the melanocytes. Regeneration of hair and nails is dependent on viability of the hair follicle and nail matrix. With intact follicles, hair generally regrows at approximately 1 cm per month. New nail formation is often irregular and of abnormal thickness as regrowth occurs.

### Depth Classification

Depth of burn injury is divided into four classifications: first-degree burns, also known as superficial burns, second-degree burns, also known as superficial and deep partial-thickness, third-degree burns (full-thickness), and fourth-degree burns (full-thickness with bone or muscle involvement), based on criteria established by the American Burn Association (Table 54-2).<sup>22</sup>

*First-degree burns (also known as superficial burns)* involve only superficial tissue destruction in the outermost layers of the epidermis, with no associated compromise of the function of the skin (see Table 54-2). These burns are often associated with local discomfort, erythema, and mild systemic responses such as headache, chills, nausea, and vomiting. Erythema, a thermovascular response that occurs in first-degree burns in the absence of direct trauma to the dermis, is probably related to the release of tissue contents into the superficial circulation. First-degree burns are generally self-limiting, require no fluid resuscitation, and are therefore not included in estimates of the percentage of TBSA burned. However, in infants and elderly adults, first-degree burns may lead to systemic dehydration, necessitating intravenous resuscitation. Therapy generally includes simple analgesia. These injuries typically heal in 3 to 6 days without scarring or pigmentation changes.

*Second-degree (superficial partial-thickness) burns* involve the epidermis to the level of the dermis and appear red to pale ivory. Moist, thin-walled blisters often form within minutes of the injury (Figure 54-2). Pain is a major clinical feature of this depth of injury because tactile and pain sensors remain intact (see Table 54-2). Injuries typically heal in 7 to 21 days in the absence of wound infection. The amount of scarring that follows is a genetically determined trait, with some groups of people tending to scar excessively (African Americans and Caucasians with red hair) or minimally (Native American and Asian groups). Hair follicles remain intact and will regrow hair in the area of injury. Hair usually reappears 7 to 10 days after injury.

*Second-degree (deep partial-thickness) burns* may involve the entire dermis and leave only the epidermal skin appendages located in the hair follicles. The area of injury has a mottled appearance, with large areas of waxy-white tissue surrounded by light pink or red tissue. The surface is generally dry, and blisters tend to resemble flat, dry tissue paper rather than the fluid-filled raised areas seen with superficial partial-thickness injury. Tactile and pain sensors are either absent or greatly diminished in the area of deepest tissue destruction, but this area is usually surrounded by margins of lesser depth of injury in which pain and tactile sensors remain intact. Deep partial-thickness

TABLE 54-2 BURN WOUND CLASSIFICATION

DEGREE OF BURN	CAUSE OF INJURY	DEPTH OF INJURY	WOUND CHARACTERISTICS	TREATMENT COURSE
First-degree burn	Prolonged ultraviolet light exposure, brief exposure to hot liquids	Limited damage to epidermis, skin intact	Erythematous, hypersensitive, no blister formation	Complete healing within 3-5 days without scarring
Superficial partial-thickness burn: second degree	Brief exposure to flash, flame, or hot liquids	Epidermis destroyed, minimal damage to superficial layers of dermis, epidermal appendages remain intact	Moist and weepy, pink or red, blisters, blanching, hypersensitive	Complete healing within 21 days with minimal or no scarring
Deep partial-thickness burn: second degree	Intense radiant energy, scalding liquids or hot semiliquids (e.g., tar) or solids, flame	Epidermis destroyed, underlying dermis damaged, some epidermal appendages remain intact	Pale, decreased moistness, blanching absent or prolonged; intact sensation to deep pressure but not to pinprick	Prolonged healing (often longer than 21 days), may require skin grafting to achieve complete healing with better functional outcome
Full-thickness burn: third degree	Prolonged contact with flame, scalding liquids, steam; hot objects; chemicals; electrical current	Epidermis, dermis, and epidermal appendages destroyed; injury through dermis	Dry, leatherlike; pale, mottled brown, or red; thrombosed vessels visible; insensate	Requires skin grafting
Full-thickness burn: fourth degree	Electrical current, prolonged contact with flame (e.g., unconscious victim)	Epidermis, dermis, and epidermal appendages destroyed; injury involves connective tissue, muscle, and possibly bone	Dry; charred, mottled brown, white, or red; no sensation; limited or no movement of involved extremities or digits	Requires skin grafting, amputation of involved extremities or digits likely

From Carrougher GJ, editor: *Burn care therapy*, St Louis, 1998, Mosby, p 138.

injury is visually and clinically indistinguishable from full-thickness injury at the time of injury. These wounds heal spontaneously in previously healthy individuals in about 4 weeks in the absence of secondary infection. As the length of healing time increases, so does the degree of scarring and depigmentation. As a result, these burns are often excised early and subsequently treated with a skin graft in an effort to diminish scarring and achieve early wound closure.

*Third-degree (full-thickness) burns* may also involve the entire epidermis, the dermis, and the underlying subcutaneous tissue. Immediately following injury, these areas appear white, cherry red, or black. Deep blisters may be present under a dry layer of dehydrated skin. Superficial blood vessels coagulated by the heat of injury may be visible through the skin as thrombosed veins. One of the physiologic characteristics of the skin that is lost (Box 54-1) is the elasticity of the dermis,

**FIGURE 54-2** This young child sustained a hot water scald burn on the heel of the right foot that resulted in a superficial second-degree burn. A superficial second-degree (partial-thickness) burn will reepithelialize within 3 weeks. These burns are characterized by loss of epidermis (blistering) and by a shiny, sensate, vascularized dermis. (Courtesy Michael Peck, MD, University of North Carolina Burn Center, Chapel Hill.)

resulting in a wound with a dry, hard, leathery texture. The massive edema that accompanies major burn injury combined with the loss of elasticity may result in a tourniquet-like effect when the injury occurs circumferentially around a limb or torso. This often necessitates escharotomies or, rarely, fasciotomies to restore distal circulation.

These burns are painless to touch, because all superficial nerve endings in the skin have been destroyed. However, as with partial-thickness injuries, rarely are burn injuries totally uniform, and an area of lesser injury in which pain and tactile sensors are intact is usually located on the periphery. Areas of full-thickness injury require skin grafting with the patient's own skin because all dermal elements have been destroyed, leaving no residual tissue for regeneration. However, small injuries often heal by secondary intention as a result of ingrowth of dermal elements from the margins of the wound.

*Fourth-degree (full-thickness) injuries* that extend beyond the dermis to involve muscle, bone, or both are often classified as fourth-degree. These injuries often occur in victims of high-voltage electrical injury or in persons who have had prolonged exposure to intense heat, such as unconscious fire victims.

### Extent of Injury

Extent of injury refers to the percentage of TBSA burned. Estimates can be calculated with the rule of nines (Figure 54-3) or the Lund and Browder chart (Figure 54-4). The rule of nines is commonly used in prehospital settings and emergency departments, and provides a rough estimate of TBSA involved. The Lund and Browder chart, or a variation of it, is generally used in burn centers and is more precise, particularly in assessing TBSA in children under the age of 10 years (see Figure 54-4).

### Severity Classification

The severity of a burn injury is determined by the extent to which the physiologic functions of the skin are disrupted beyond the body's normal ability to respond with compensatory mechanisms. The American Burn Association<sup>22</sup> classifies burn injury as minor, moderate, and major (Table 54-3). The severity of the burn injury and the eventual morbidity and mortality associated with it are related to a combination of factors: the patient's medical history, the extent and depth of

## BOX 54-1 NORMAL PHYSIOLOGIC FUNCTIONS OF THE SKIN ALTERED OR LOST AFTER THERMAL INJURY

### Protection

Barrier between the internal organs and the external environment  
Continuous with the mucous membrane at the external openings of organs of the digestive, respiratory, and urogenital systems  
Acidic skin (pH 4.2 to 5.6) and perspiration protect against bacterial invasion  
Thickened skin of palms and soles provides padding

### Percutaneous Absorption

Epidermis is relatively impermeable to most chemical substances; some may be absorbed through the epidermis or the orifices of hair follicles

### Sensory Processing

Receptor skin nerve endings allow constant monitoring of the environment by sensing warm and cold temperature, pain, touch, and pressure

### Production

Endogenous production of vitamin D<sub>3</sub>, which is necessary for synthesis of vitamin D

### Barrier

Skin prevents water and electrolyte loss, maintains moist subcutaneous tissues, and prevents water absorption during immersion

### Thermoregulation

Body continuously produces heat as a by-product of cellular metabolism; heat is dissipated through skin  
Internal body temperature is regulated by radiation, conduction, or convection  
Rate of heat loss depends primarily on the surface temperature of skin, which is a function of skin blood flow

### Immunologic

Major location of immune complexes is at the dermal-epidermal junction and the dermal vessels of skin  
Monocyte/macrophage system is mobilized by local tissue mediators

### Circulatory

Skin temperature depends on the rate of blood flow through the skin  
Circulatory system distributes pharmacologic agents to local tissues

### Aesthetic

Provides the individual identity of a person

the burn, the body area involved, the presence of concomitant trauma sustained at the time of the burn, and the patient's age.

**Acute Management**

The first priority in burn management is the elimination of the source; however, extreme caution must be exercised to ensure that the rescuer

does not become a victim. The fire should preferably be extinguished with water, because it not only eliminates the source of the heat but also enables cooling of the underlying skin. In the absence of water, flames may be smothered with a blanket, coat, or any other nonflammable covering that will aid in deprivation of the oxygen required for combustion. Once the flames are eliminated, the cover should

**FIGURE 54-3** The rule of nines is a commonly used assessment tool that permits a timely and useful estimate of the percentage of total body surface area burned.

**FIGURE 54-4** The Lund and Browder chart. The areas of the body are presented in sections, which permits a more accurate estimation of burn size.

**TABLE 54-3 AMERICAN BURN ASSOCIATION BURN SEVERITY CLASSIFICATION SCHEDULE**

CLASSIFICATION	ASSESSMENT CRITERIA
Minor burn injury	<15% TBSA burn in adults <40 yr old <10% TBSA burn in adults >40 yr old <10% TBSA burn in children <10 yr old <i>and</i> <2% TBSA full-thickness burn without risk of cosmetic or functional impairment or disability
Moderate burn injury	12-25% TBSA burn in adults <40 yr old 10-20% TBSA burn in adults >40 yr old 10-20% TBSA burn in children <10 yr old <i>and</i> 10% TBSA full-thickness burn without cosmetic or functional risk to burned area involving face, eyes, ears, hands, feet, or perineum
Major burn injury	>25% TBSA burn in adults <40 yr old >20% TBSA burn in adults >40 yr old >20% TBSA burn in children <10 yr old <i>or</i> >10% TBSA full-thickness burn (any age) <i>or</i> Injuries involving face, eyes, ears, hands, feet, or perineum likely to result in functional or cosmetic disability <i>or</i> High-voltage electrical burn injury <i>or</i> All burn injuries with concomitant inhalation injury or major trauma

Modified from American Burn Association guidelines. In Carrougher GJ, editor: *Burn care and therapy*, St Louis, 1998, Mosby, p 94. TBSA, Total body surface area.

be promptly removed to enable dissipation of the underlying heat, thereby minimizing injury depth. Scald injuries are best treated initially with cool water, which allows cooling of the scalding liquid as well as the underlying skin.

### Assessment

Initial management of patients with thermal burn injuries should focus on stabilizing the ABCs (airway-breathing-circulation).<sup>4</sup> Common signs of inhalation injury include cough, stridor, hoarseness, singed nasal hair, carbonaceous sputum, oropharyngeal edema, and blisters. These injuries generally evolve over time, often progressing to complete airway obstruction secondary to edema. Unfortunately, no clinical variables accurately predict which patients will progress to airway compromise; therefore consideration should be given early to bronchoscopy and endotracheal intubation.<sup>23</sup> Compromise of breathing in burn patients is often attributed to underlying inhalation injury or circumferential full-thickness burns resulting in impaired chest excursion; however, breathing difficulties may also arise from associated pneumothorax, hemothorax, or chest wall instability from multiple segmental fractures (flail chest). Vascular access is preferentially obtained peripherally through unburned tissue if possible. If no such sites are available, access may be established through burned skin. The patient is then evaluated by a complete head-to-toe examination for any other associated traumatic injuries, which are identified and

### BOX 54-2 BURN UNIT REFERRAL CRITERIA

Partial-thickness burns greater than 10% TBSA  
Burns that involve the face, hands, feet, genitalia, perineum, or major joints  
Third-degree burns in any age group  
Electrical burns, including lightning injury  
Chemical burns  
Inhalation injury  
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality  
Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality; in such cases, if the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn unit; physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols  
Burned children in hospitals without qualified personnel or equipment for the care of children  
Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

From American College of Surgeons Committee on Trauma: *Resources for optimal care of the injured patient*, Chicago, 1999, The College, p 55. TBSA, Total body surface area.

managed as required. TBSA is then determined using a standardized chart such as the Lund and Browder chart (see [Figure 54-4](#)). Fluid resuscitation requirements are subsequently determined and initiated while the patient is placed on clean sheets and the burned areas covered with dry clean sheets or dressings. Coverage with cool wet sheets should be avoided, because these quickly become cold wet sheets, and with the loss of the burned skin's ability to regulate body temperature, hypothermia can quickly ensue. Application of topical agents in the acute setting outside of a burn center is not recommended. A Foley catheter is also placed to monitor urine output during resuscitation, and in patients with burns greater than 20% of the TBSA, if possible, a nasogastric tube should be placed to allow for gastric decompression and to minimize the risk of abdominal bloating and aspiration. Transfer of patients to burn units or other facilities with appropriate resources is initiated during the course of the initial assessment. The American College of Surgeons Committee on Trauma has developed a set of burn unit referral criteria to assist initial evaluators in triage ([Box 54-2](#)).

### Burn Shock and Acute Resuscitation

Two different, but simultaneous mechanisms occur in cases of major burns: local wound pathophysiologic processes related to the loss of skin integrity and systemic pathophysiologic processes related to sequelae of the burn injury.

Within minutes of a burn injury, the cardiovascular system, which is normally a closed, semipermeable system, becomes an open system through which the patient's circulating volume leaves the circulatory system. This phenomenon, known as "capillary leak," occurs within a few minutes of injury and persists for 24 hours. Burn shock is not confined to the burn area but, rather, is a systemic process. While the capillary system throughout the body becomes leaky, fluid lost in the area of the burn leaks through the burn into the environment in an evaporative fashion, whereas fluid loss internally collects in the nearby soft tissues, producing extensive interstitial edema ([Figure 54-5](#)).

Restoration of the patient's circulating volume is an essential part of acute burn management. The rate and volume of fluids lost are related

**FIGURE 54-5** Direction of fluid and electrolyte shifts associated with burn shock. During burn shock,  $K^+$  is exiting the cell, and  $Na^+$  and  $H_2O$  are moving into the cell. After burn shock,  $K^+$  enters the cell while  $Na^+$  and  $H_2O$  exit it.

### BOX 54-3 PARKLAND FORMULA FOR FLUID RESUSCITATION IN BURN SHOCK

During the first 24 hours after a burn, administer intravenous LRS at the following rate:

$$4 \text{ ml LRS} / \% \text{ TBSA burn} / \text{kg body weight}$$

where

- Time is calculated from the time of burn injury.
- TBSA is total body surface area.
- Half of the total fluid is administered in the first 8 hr after burn.
- One fourth of the total is administered in the second 8 hr.
- One fourth of the total is administered in the third 8 hr or in quantities to maintain adult urine output at 30 ml/hr or child urine output at 1 ml/kg/hr.

Example of formula calculation in a 70-kg patient with a 50% TBSA burn:

$$4 \text{ ml} \times 70 \text{ kg} \times 50 \% \text{ TBSA burn} = 14,000 \text{ ml (14 L) LRS in 24 hr}$$

- Administer 7000 ml in the first 8 hr at 875 ml/hr.
- Administer 3500 ml in the second 8 hr at 437 ml/hr.
- Administer 3500 ml in the third 8 hr at 437 ml/hr.

Data from Baxter CR: Guidelines for fluid resuscitation, *J Burn Care Rehabil* 2:279-286, 1981.

LRS, Lactated Ringer solution; TBSA, total body surface area.

directly to the severity of burn. Therefore, the extent and depth of the burn injury must be ascertained during the initial clinical assessment.

The most widely used formula to guide fluid resuscitation within the first 24 hours of burn injury is the Parkland formula (Box 54-3). The formula utilizes lactated Ringer solution as the resuscitation fluid, because it most closely approximates the fluid it is replacing and thereby minimizes the profound electrolyte imbalances often seen with large-volume resuscitation (Box 54-4). The standardized formulas provide an excellent guideline for initiating fluid resuscitation but do not ensure adequacy of resuscitation. In Cartotto's series, 30 patients with mean TBSA burns of 27% received  $6.7 \pm 2.8$  ml/kg/% TBSA burn in the first 24 hours to ensure adequate resuscitation.<sup>24</sup> Adequacy of resuscitation is determined by the global response of the patient to the fluid administration and not by one single variable.<sup>25</sup> Markers commonly used to reflect adequacy of resuscitation include normalization

### BOX 54-4 PLASMA REQUIREMENTS AND EVAPORATIVE WATER LOSS AFTER BURN INJURY

#### Colloid Replacement

Twenty percent of blood volume given as fresh-frozen plasma or plasma expander

Adult males: 20% = 5 ml/kg body weight

Adult females and children: 20% = 8 ml/kg

#### Maintenance Fluids Until Wound Closure Is Achieved

Basal fluid requirements:

1500 ml of fluid/m<sup>2</sup> TBSA = 24-hr requirement

Evaporative water loss from burn wound until healed:

Adults:  $(25 + \% \text{ TBSA burn}) \times \text{m}^2 \text{ BSA} = \text{ml/hr requirement}$

Children:  $(35 + \% \text{ TBSA burn}) \times \text{m}^2 \text{ BSA} = \text{ml/hr requirement}$

Maintenance fluids equal basal fluid requirements plus evaporative water loss and may be administered intravenously, orally, or by nasogastric or jejunal tube, according to patient need.

BSA, Body surface area; TBSA, total body surface area burned.

of mental status, blood pressure, pulse rate, capillary refill time, arterial pH, and base deficit and maintenance of urine output at 0.5 to 1 ml/kg per hour for adults and 1 to 1.5 ml/kg per hour for children. In addition to the fluid volumes calculated by the standardized formulas, the patient should also receive appropriate maintenance fluid over the first 24-hour period.

Approximately 24 hours following the acute burn injury, the capillary leak syndrome begins to resolve as cardiovascular integrity is restored. At this time, a colloid solution such as albumin may be administered according to an appropriate formula, which differs by gender and age (see Box 54-4), in an effort to replace the protein lost during the acute burn shock phase. Resuscitation in the acute setting with colloid has been shown to decrease net volume of fluid administered and complications associated with large-volume resuscitation such as abdominal compartment syndrome.<sup>26</sup>

One of the major functions of intact skin is to serve as a barrier to water evaporation. With major burn injury, this ability of the skin to regulate evaporative loss is disrupted. In a classic study conducted in

**FIGURE 54-6** Cardiovascular and pulmonary effects of major burn injury within the first 24 hours after burn injury, during burn shock. *CO*, Cardiac output; *GFR*, glomerular filtration rate.

1962, Moncrief and Mason<sup>27</sup> attempted to determine the magnitude of such a loss and found that daily evaporative loss was in the range of 20 times normal during the early phase of burn injury, with gradual decreases as wound closure was achieved. Further studies revealed that the insensible water loss through burned skin is not caused by evaporation of water from sweat glands but rather by water vapor formed within the body and lost through the skin.<sup>28,29</sup> As the patient progresses to the subacute phase of resuscitation, it is imperative that attention be paid to these unaccountable losses.

Patients at the extremes of age groups require special considerations with respect to resuscitation. Table 54-1 summarizes the physiologic changes associated with age that increase the vulnerability of children and elderly persons.<sup>30-32</sup>

## Organ Dysfunction

### Cardiovascular Dysfunction

Burn shock is often accompanied by a precipitous drop in cardiac output that does not parallel the gradual reduction in blood volume and is refractory to restoration of the circulating volume. This finding of low cardiac output in the presence of vigorous intravenous fluid resuscitation and massive catecholamine release has led to the suggestion of a specific myocardial depressant factor.<sup>33-38</sup> The pathophysiologic mechanism behind this myocardial dysfunction is poorly understood. There appears to be no simple, specific myocardial depressant factor but rather a cascade of events involving metabolic and immunologic factors (Figure 54-6).<sup>19</sup>

### Respiratory Dysfunction

Respiratory dysfunction following burn injury generally is the result of obstruction, interstitial alterations, and metabolic changes. Obstruction may occur as a result of edema of the upper airway secondary to

direct injury, or more often is attributable to the generalized edema that occurs following fluid resuscitation in the face of an ongoing capillary leak syndrome that accompanies burn injuries. On occasion, burns of the oral cavity and upper airway occur as superheated air is inhaled or scalding water enters the mouth. The pulmonary system is extremely efficient at dissipating heat and prevents the inhalation of superheated air beyond the bronchi, but steam may permeate further into the lung parenchyma (see Figure 54-6).<sup>21,23</sup>

Airway obstruction secondary to edema generally has its onset within the first few hours following burn injury but tends to manifest clinically 2 to 4 hours later as resuscitation is undertaken. Endotracheal intubation is recommended prophylactically when impending airway obstruction is identified. The endotracheal tube is preferably secured with cotton twill tape that enables readjustment to allow for the increase in head and face circumference related to increasing facial and soft-tissue edema.<sup>39</sup>

Smoke or fume inhalation often leads to acute hypoxia that is refractory to oxygen administration. Inhalation injury directly results in the chemical denaturing of pulmonary tissue, and the subsequent edema results in increased distances over which oxygen must diffuse to the capillaries. This may progress to acute respiratory distress syndrome (ARDS), which usually occurs within the first week. Whether the actual inhalation injury causes susceptibility towards ARDS is still a subject of debate. However, it is clear that many factors play a role in this condition because of the intense inflammatory response to the burn in addition to contributions from sepsis, shock, pneumonia, multiple organ failure, and increasing duration of mechanical support. Current ventilatory strategies emphasize use of low tidal volumes and increased frequency of breaths, which have resulted in decreased mortality.<sup>36,40</sup>

Smoke inhalation is also responsible for the majority of cases of inadvertent carbon monoxide poisoning. Carbon monoxide is in

direct competition with oxygen for hemoglobin binding sites and has much greater affinity for the oxygen binding sites on hemoglobin. Once carbon monoxide has bound to hemoglobin, it becomes carboxyhemoglobin, which has decreased ability to off-load oxygen to peripheral tissues. It is also responsible for inactivation of cytochrome oxidase, an enzyme that aids in oxygen utilization. The vast range of clinical symptoms can include vague constitutional symptoms such as headache, nausea, and fatigue, or may be much more severe and lead to lactic acidosis, seizures, and coma. The degree of carboxyhemoglobinemia is largely dependent on the amounts of carbon monoxide and oxygen in the native environment, the duration of exposure, and the minute ventilation of the patient.

Carbon monoxide poisoning is diagnosed with a compatible history and physical in conjunction with the presence of elevated carboxyhemoglobin levels. Carboxyhemoglobin can be directly measured on arterial blood gas samples, although these levels may not correlate with the development of neurologic sequelae. In addition, pulse oximetry plays no role in monitoring patients with carbon monoxide poisoning because it cannot differentiate between oxyhemoglobin and carboxyhemoglobin.

Treatment involves removal of carbon monoxide from hemoglobin via its direct competition with oxygen. The normal half-life of carbon monoxide in a patient breathing room air is 300 minutes. If high-flow oxygen is delivered via face mask, the half-life can be decreased to 90 minutes. Therefore treatment involves removal of the patient from the source of inhalation and immediate institution of high-flow 100% oxygen via a nonrebreather face mask. In cases of severe poisoning manifested by a carboxyhemoglobin level greater than 25%, loss of consciousness, severe metabolic acidosis, or evidence of ischemic change in any organ system, the treatment should involve institution of hyperbaric oxygen therapy. This will reduce the half-life of carbon monoxide even further to approximately 30 minutes, and it also increases the amount of oxygen dissolved in the blood (unbound to hemoglobin) from 0.3 to 6 ml/dl. In addition to assisting with elimination of carbon monoxide, the addition of hyperbaric oxygen improves delivery of oxygen to peripheral tissues, even in the presence of elevated carboxyhemoglobin levels.<sup>41,42</sup>

### Renal Dysfunction

Acute renal failure (ARF) after burn injury can be classified as early or late. Early renal failure occurs during the first 5 days postburn, secondary to low intravascular volumes and rhabdomyolysis-associated myoglobinemia. The etiology of renal failure in rhabdomyolysis is twofold: first, the shift of fluid into damaged muscle from the intravascular space (i.e., third spacing) causes reduced blood volume and less flow to the kidneys, with direct nephrotoxic effects of myoglobin by-products and possible renal failure. Second, the by-products of myoglobin can be toxic to the kidneys and cause damage by precipitation into the renal tubules. Development of early renal failure can be minimized by adequate fluid resuscitation and decompressive fasciotomy for compartment syndrome that may contribute to further muscle damage. Late ARF, defined as occurring after 5 days postburn, is less of a result of the initial burn and is generally attributable to infectious or direct nephrotoxic factors such as medications. Most patients will require renal supportive therapy. Continuous venovenous hemofiltration (CVVH) has been used with success in treating ARF in burns and is associated with less vascular complications than arteriovenous hemodialysis.<sup>43</sup> The prognosis is generally poor for the burn patient who develops ARF. Mortality rates from 50% to 100% have been described.<sup>44</sup> Survival is dismal for patients with early-onset ARF associated with rhabdomyolysis. However, even in the face of severe ARF, renal function will generally recover over time in those patients who survive.<sup>45</sup>

### Metabolic Changes

The metabolic changes associated with major burn injuries primarily involve the sympathetic nervous system and are manifested as sustained tachycardia (120 to 140 beats/min range) and increased oxygen consumption (approximately 150% of normal). The hypermetabolic state generally persists until the burn wound is reduced to less than 20% of TBSA and poses a major challenge in the treatment of these patients. Modalities to attenuate the hypermetabolic response have included use of propranolol, administration of counterregulatory hormones such as insulin and insulin-like growth factor, and stimulation of anabolism using growth hormones and steroids (natural or synthetic). A study from Shriner's Burns Institute in Galveston, Texas, randomized 56 children with major burns to receive supplemental growth hormone, propranolol, or both. Propranolol markedly reduced resting heart rate and energy expenditure measured by indirect calorimetry and improved net muscle protein synthesis. Interestingly, the addition of growth hormone did not enhance these effects.<sup>31</sup> Muscle protein wasting appears to be caused primarily by accelerated protein breakdown. Although protein synthesis is also increased, it fails to keep pace with proteolysis and amino acid mobilization. Thomas and colleagues evaluated the effect of continuous infusions of insulin (to maintain blood glucose levels between 100 and 140 mg/dl) on preservation of muscle mass in a randomized controlled clinical trial in 18 children with major burns. Evaluation of each patient when the burn wounds were 95% healed showed that insulin-treated patients had improved lean body mass, diminished muscle wasting, and reduced length of hospital stay in comparison with controls.<sup>41</sup>

Gianotti and colleagues studied temporal fluctuations in insulin-like growth factor type I and its binding protein in a group of burn patients, and demonstrated that they both decline for the first 14 days after the burn, paralleling decreases in prealbumin and transferrin levels.<sup>46</sup> However, plasma levels of growth hormone remained unchanged. In a small study of burned children, administration of insulin-like growth factor type I and insulin growth factor binding protein appeared to exert widespread effects in ameliorating acute inflammation by reducing the synthesis of type 1 and type 2 acute-phase proteins and interleukin 6 (IL-6) while increasing the synthesis of constituted protein such as prealbumin and transferrin. Anabolic steroids, including testosterone and its analogues, such as oxandrolone, are widely used to ameliorate muscle wasting in patients with cancer and acquired immunodeficiency syndrome; however, they have had limited benefits in burn patients.

### Cellular Changes

Major burn injury affects the entire body, but survival ultimately depends on its effects at the cellular level. The cellular response to burn injury occurs as a metabolic and an immunologic pathophysiologic process. The basic pathologic condition, named the "sick cell syndrome" by Welt<sup>47</sup> in 1967, is a cell membrane transport defect related to an alteration in the steady-state composition, characterized by high intracellular concentrations of sodium. Entry of sodium into the intracellular space occurs simultaneously with entry of water, which leads to cellular edema and possibly rupture of the cell wall. Trunkey and coworkers<sup>48</sup> demonstrated a marked decrease in the level of primate muscle extracellular water and an increase in the levels of intracellular sodium and water during burn shock. An associated decrease in resting membrane potential occurs as the transmembrane potential is disrupted and results in a decrease in amplitude of the action potential and prolongation of the repolarization and depolarization times.<sup>49,50</sup> As sodium and water enter the cell, the sodium-potassium pump is disrupted and potassium moves out, thus further exacerbating the electrolyte imbalance intracellularly.<sup>51</sup> Calcium channel transport

is disrupted, along with a loss of intracellular magnesium and phosphate<sup>43</sup> and an increase in serum lactate dehydrogenase levels.<sup>44</sup> The cascade of events that occurs at the level of the cell membrane suggests impairments of basic cellular function as the underlying cause of the diminished membrane potentials. Although the pathophysiologic mechanism has not been completely described, data suggest a decrease in the efficiency of the sodium-potassium pump, a change that can be reversed over time with adequate fluid resuscitation.

Evidence suggests that the burn wound itself at least partially mediates the physiologic response to burn injury at both local and systemic levels. Burn tissue inflammation can lead to vasodilation, increased capillary permeability and edema, which are normal conditions that promote wound healing. Massive injury results in increased metabolic demands and consumption of inflammatory mediators by the wound, when the priority for survival should be transport of these mediators to healthy tissue.

The extensive evaporative water loss that accompanies burn injury is a heat-consuming process, with the energy need met in part by increased visceral heat production. This hypermetabolic state persists during rest, sleep, and external cooling. The increased oxygen consumption cannot be accounted for on the basis of elevated body temperature alone; thus, an increased basal metabolic rate, not a thermoregulatory drive, is responsible for the increased heat production.

### Immune Response

Local and systemic physiologic changes are primarily mediated by the release of cytokines from burn wounds.<sup>52</sup> Cytokines act directly on the burn wound and also activate other agents, including those that release oxidants, arachidonic acid metabolites, and proteases, thereby contributing to further local and systemic inflammation and, potentially, multisystem organ dysfunction. Recent studies have shown a relationship between decreased cellular cytotoxicity in burned patients and increased production of the cytokines IL-4 and IL-10. Administration of immunopotentiators such as IL-12 has also demonstrated increased survival and resistance to bacterial infection.<sup>53</sup>

A host of chemicals found in altered concentrations in burn plasma may also play a role in burn shock. These substances include vasoactive amines (histamine, serotonin), products of complement activation (C3a, C5a), prostaglandins, kinins, endotoxins, and metabolic hormones (catecholamines, glucocorticoids). A decrease in the complement components C3a and C5a in the circulation after burn injury suggests nonspecific activation of the complement system. Activation of the complement system in injured tissue results in an inflammatory response caused by the release of histamine and serotonin by C3a and C5a. Because both histamine and serotonin alter capillary permeability, some investigators propose this mechanism as a cause for burn shock because these vasoactive amines initiate the inflammatory response along with kinin polypeptides and other chemical mediators. As a result of these vascular changes, fluid and fibrinogen leave the dilated, permeable vessels.

### Elements of Burn Injury Survival

The emergent phase of burn care refers to the time between the end of burn shock and the closure of the burn wound to less than 20% of the TBSA. Three elements are essential for survival after a major burn injury: meticulous wound management, adequate nutritional support to establish positive nitrogen balance, and timely surgical excision and grafting of full-thickness wounds.

### Management of Wounds

Optimal wound management strategies center around measures to limit bacterial proliferation on the wound and adjacent tissue following loss of the first line of defense—the skin. Burn wounds are sterile

initially as a result of thermal decontamination; however, bacterial flora soon re-establish colonies on the burned skin, or eschar. This medium is favorable for pathogenic growth because of the necrotic tissue and warm environment that exist within the burn wound dressing. Benign microorganisms normally found on skin, in the gastrointestinal tract, and in the pulmonary system become lethal as they colonize the burn wound, often resulting in burn progression, invasive sepsis, and death.

The most common source of burn wound bacteria is the patient's own hair follicles, sweat glands, pulmonary tract, and gastrointestinal system, although poor hand-washing technique by staff members can contribute to infection through cross-contamination from other patients.

The goals of wound care are to cleanse and debride the wound of necrotic tissue and debris that promote bacterial growth, minimize further destruction of viable tissue, prevent cross-contamination, preserve body heat and energy, and promote patient comfort. The excision of blisters is controversial and varies among institutions. Some argue that the blister provides a moist and protective environment for healing, whereas others state that large tense blisters apply pressure on the underlying wound bed (which impedes healing) and the contained fluid may serve as a nidus for infection. The decision to debride a blister should take into consideration the size and type of the blister. Blisters less than 6 mm in diameter are unlikely to rupture or place pressure on underlying tissue and should not be debrided. Thick-walled blisters attributable to thick skin, particularly on the hands and feet, should be left intact because they are not likely to become infected and debridement often leads to limited mobility of the affected extremity. Large tense blisters or those with thin walls that are likely to rupture and become infected can impede wound healing, and debridement of these lesions should be considered.<sup>54</sup> This debridement may also allow for further evaluation of the depth of injury in the underlying wound bed. Additional wound care requires daily observation and management, which includes bathing the patient at least once each day with mild soap and water. Burn wounds are washed to remove accumulated bacteria and previously applied ointments and to debride necrotic tissue. Cleansing of wounds is the most stressful and painful experience that burn patients endure. Pain medication diminishes the pain only marginally because the most effective analgesics work best on visceral or deep pain rather than pain at superficial skin nerve endings. Benzodiazepines are often added to decrease anxiety and provide a degree of amnesia.

After the wound is clean, topical antibacterial agents are applied and covered with a light dressing (Table 54-4). Systemic antibiotics are not helpful in controlling burn wound flora because the burn eschar has no blood supply, limiting local antibiotic bioavailability. Topical burn agents penetrate the eschar, thereby inhibiting bacterial invasion of the wound. Systemic antibiotics are administered when the patient demonstrates signs of systemic infection and are used prophylactically at times of surgical procedures. Appropriate antibiotic selection is based on laboratory cultures of the patient's wound tissue to identify and deliver antibiotics to which the bacteria are sensitive.

Healing of burn wounds begins when white blood cells have surrounded the burn wound and phagocytosis begins. Necrotic tissue begins to slough. Fibroblasts begin to build matrices of the collagen precursors that eventually form granulation tissue. Kept free from infection, a partial-thickness burn will heal from the edges and from below in a process that occurs over a 14- to 21-day period. Full-thickness burns require autografting to achieve wound closure because no dermal elements are available to form new skin.

### Burn Surgery

The third element essential to survival after major burn injury is surgical excision of dead skin, or burn eschar, followed by skin grafting with the patient's own skin (autograft). Areas of full-thickness burn are

TABLE 54-4 TOPICAL ANTIBIOTIC THERAPY FOR THERMAL INJURY WOUNDS

DRUG	INDICATIONS FOR USE	ADVANTAGES	DISADVANTAGES	METHOD OF USE
Bacitracin	Bland ointment with minimal antibiotic properties used to promote comfort in patients with minor injury (<25% TBSA)	Prevents drying of wounds; keeps eschar soft and pliable; economical; works well on facial burns to promote healing and patient comfort without facial dressings; painless upon application	No major antibiotic properties; oil based, so it is difficult to remove	1. Apply to cleansed wound twice daily; cover with Adaptic and Kerlix 2. Apply to facial burns twice daily 3. Apply to recently grafted or healed areas twice daily; wrap with Adaptic and Kerlix
Silver sulfadiazine (Silvadene)	Partial- and/or full-thickness thermal injury (>25% TBSA); small wounds that require topical antibiotic therapy such as frostbite	Wide-spectrum bacteriostatic action and painless on application; organisms resistant to silver nitrate are usually sensitive to silver sulfadiazine; eschar remains soft and pliable; water-miscible base promotes ease of removal	Not effective against fungal organisms; can cause leukopenia and is expensive; sulfa component can produce allergic reactions in sensitive patients; resistance can emerge with prolonged use	Apply to cleansed wound 1-3 times daily; may leave wound open or cover with light dressing
Silver nitrate	Partial- and/or full-thickness burns (>25% TBSA), fungal infections, patients with sulfa allergy	Wide-spectrum bacteriostatic action; effective against fungal infections; comfortable and economical; no sensitivity reported; painless on application; no resistant organisms	Can cause severe electrolyte imbalances (hyponatremia and hypochloremia), which are corrected with oral and intravenous NaCl; poor penetration into wound; requires bulky dressing, thereby severely limiting motion; messy and time consuming to use	0.5% solution in distilled water applied to wet dressing every 2 hr; dressing changes twice daily
Mafenide acetate (Sulfamylon)	Electrical injury, ear burns, wounds colonized with organisms resistant to other topical agents because it penetrates eschar more deeply	Wide-spectrum bacteriostatic action; active penetration allows delayed therapy to be effective; requires no dressing, thereby promoting motion; resistant organisms do not develop with prolonged use; drug of choice for all burns	Causes severe metabolic alterations within 72 hr when used on >20% TBSA wounds; carbonic anhydrase inhibition with excretion and chloride retention; compensation is by hyperventilation with subsequent CO <sub>2</sub> decreased or depletion	Apply to cleansed wound 1-2 times daily; leave open because wrapping produces maceration

TBSA, Total body surface area.

excised. In some cases, it is difficult to assess the depth of the burn. In these cases, it may be appropriate to wait 7 to 10 days to allow the area to declare its depth. This is especially true in young children with scald burns. In burns involving the face, scalp, and ears, it may be appropriate to wait as long as 3 weeks for the area to declare itself. These sites are particularly dense areas of dermal appendages and may heal without grafting if given time. Current surgical management of burn wounds has evolved from daily bathing and mechanical debridement of necrotic tissue for months, to early surgical excision and grafting, with significant associated decreases in attendant morbidity and mortality.

### Excision and Grafting

Significant blood loss associated with burn excision traditionally resulted in local wound management until eschar separation, at which time grafting was undertaken. This often resulted in prolonged hospital stays of approximately 3 to 5 weeks, increased bacterial colonization of wounds, and subsequent higher incidences of sepsis and multiple organ failure. Current practice now favors early excision and grafting of wounds 2 to 7 days after injury. Although blood loss remains a concern with early excision, improvements in excision and hemostasis techniques have enabled a significant decrease in the degree of magnitude.

In tangential excision, eschar is removed in thin layers with an instrument called a *dermatome* until viable tissue is visible. Full-thickness excision using a surgical scalpel removes eschar to the level of fascia. Full-thickness excision often leaves an uneven contour post-excision, which is difficult to graft, with resultant poor cosmetic effects. After bleeding has been controlled in the area of excision, application of an autograft, skin substitute, or dressing follows. In some cases, the area may need to be covered with wet dressings soaked in antibiotic solutions for 24 hours with delayed autografting. Some studies have shown a benefit for use of a vacuum-assisted closure device to promote blood circulation in the wound bed, allowing for earlier placement of an epidermal graft.<sup>55</sup>

Ong and colleagues<sup>56</sup> conducted a meta-analysis of data from six randomized controlled trials published from 1966 through 2004 that compared early excision of burns with wound dressing and grafting after eschar separation. No difference in overall mortality was observed, except for a lower mortality in the subgroup without inhalation injury that underwent early excision. Early excision patients overall had higher blood transfusion requirements and shorter lengths of stay. No evidence of reduced sepsis or a better cosmetic or functional outcome was noted with early excision.

### Skin Substitutes

In patients with burns that do not permit initial autografting, temporary coverage may be achieved by use of any of the following skin substitutes: biological (homograft—skin harvested from cadavers, xenograft—skin harvested from pigs); synthetic; and amnion (amniotic lining of human placenta harvested from afterbirth following delivery). Application often enhances patient comfort while partially restoring the water vapor barrier, thereby minimizing evaporative losses. Grafts often consist of a bilayer membrane that provides a dermal matrix of bovine collagen and an epidermal or silicone layer to prevent desiccation (drying), or the dermal and epidermal components may be replaced separately.<sup>57</sup> Bioactive dermal components added to the graft help to stimulate healing and include elastin, fibronectin, growth factors, glycosaminoglycans, and hyaluronic acid. The composition of a permanent skin substitute often includes the patient's own cells in either the dermal or the epidermal layer. The dermal matrix allows ingrowth of capillaries and fibroblasts. This matrix is slowly degraded as a neodermis develops. The silicone layer acting as the epidermal barrier is then removed and autograft is applied over the neodermis.<sup>58</sup>

The unburned area of the patient from which skin is harvested in a paper-thin sheet is referred to as the *donor site*. Donor sites heal in about 5 to 7 days in the presence of adequate nutritional support and the absence of infection and can be reharvested at that time. Donor sites can be repeatedly harvested depending on graft thickness, enabling increased wound coverage, which thereby permits survival in some patients with TBSA injury as large as 90%. To expand the surface area that a sheet of autograft will cover, harvested skin is cut in a manner that resembles a net or mesh by using an instrument called a *skin mesher*. The skin may then be expanded, depending on the size of the mesh, to cover two, three, four, or more times its original size. This combination of repeated harvesting and meshing allows autografting of massive burn injuries over a period of a few weeks. After grafting, the areas must be protected from infection, pressure, shearing, and trauma that produce bruising or bleeding under the graft. Major causes of graft loss include infection, blisters, or hematoma underneath the graft that interferes with revascularization. Negative-pressure dressings or vacuum-assisted closure (VAC) devices placed over a graft improve the contact surface of the graft as well as prevent underlying accumulation of serum or blood. When compared to standard bulky dressings, use of these devices has demonstrated a decrease in loss of graft, a decreased need for secondary grafting procedures on the same wound, and a resulting decrease in hospital stay for these procedures.<sup>59</sup>

The greatest risk of infection is after postoperative day 3, when the bacteria begin to recolonize the area. Grafts are usually stable by postoperative day 4, at which time physical and occupational therapy may begin.<sup>10,60</sup>

Surgical wound management of elderly burn patients is determined by the philosophy of the burn center. Elderly patients do not generally tolerate any surgical procedure as well as younger patients; this knowledge has been applied to the management of burn wounds in some patients, and conservative, nonsurgical wound management for weeks after injury has produced acceptable survival rates in elderly patients.<sup>61</sup> Others report that early excision of eschar and early wound closure are associated with increased survival and decreased length of stay for older patients with burns.<sup>62</sup> Children younger than 2 years have a high mortality with major burn injury, but older children recover at a high rate with proper medical management.<sup>16,18,31</sup> Table 54-5 summarizes physiologic changes related to the aging process that can affect surgical outcome.

### Nutritional Support

One of the most significant advances in recent burn management is recognition of the critical importance of early nutrition to the

wound-healing process. The magnitude of nutritional support required by burn patients depends on two factors: the patient's preburn nutritional status and the extent of the TBSA burn. Patients with minor burns require no nutritional support beyond a regular diet, whereas those with moderate and large burns require additional carbohydrate and protein supplementation. Patients with poor preburn nutritional status are classified as having a critical injury regardless of the burn size because of the associated immune deficiencies and limited metabolic reserves. The most easily recognized and documented finding in the absence of adequate nutritional support after burn injury is massive loss of body weight. Maintenance of body protein is critical for healing, minimizing complications, and survival. A 10% loss of total body mass leads to immune dysfunction; 20%, to decreased wound healing; 30%, to severe infections; and 40%, to death.<sup>63</sup>

Patients with greater than a 40% TBSA burn demonstrate the maximal stress response within predictable ranges of body mass. In these hypermetabolic patients, providing early protein and caloric support of at least the predicted energy requirement is necessary for optimal outcome and may be essential for survival. Providing early nutrition in enteral form may also help by blunting the hypermetabolic response to thermal injury.<sup>64</sup> Weight loss after thermal injury is not an obligatory component of the response to trauma but rather a reflection of the difference between the total energy requirements and the ability to supply them in the form of adequate caloric intake.<sup>13</sup> Kao and colleagues demonstrated that enteral feeding should begin within 18 hours of admission with a Dobhoff feeding tube.<sup>65</sup> These feedings should be continuous and should not be stopped when the patient goes to the operating room. With vigorous nutritional support, erosion of total body mass and subsequent starvation leading to immunologic alterations are not inevitable in a massively burned patient.<sup>51,66,67</sup>

General formulas are used to estimate the caloric requirements of burn patients, all of which are based on either preburn body weight and % of TBSA burn or square meters of body surface area and % of TBSA burn. The two most widely used formulas are the Curreri formula for adults and the Polk formula for children. Curreri and colleagues<sup>68</sup> demonstrated that caloric requirements in adult burn patients could be expressed by the following formula:

$$(25) \times (\text{body weight in kg}) + (40) \times (\% \text{ TBSA burn}) = \text{Ideal 24-hour caloric needs}$$

The requirements in children<sup>69</sup> are predicted as follows:

$$(60) \times (\text{body weight in kg}) + (36) \times (\% \text{ TBSA burn}) = \text{Ideal 24-hour caloric needs}$$

If the ideal daily caloric intake can be maintained, then the amount of postburn weight loss could be minimized. It is important to emphasize that these formulas represent more than just total caloric intake; they are used to predict positive nitrogen balance for each patient. Thus, if the patient is losing tremendous amounts of nitrogen or is not absorbing glucose, the net caloric utilization will be much less than the intake, even though the adult patient may be receiving as much as 5000 kcal/day. Monitoring of daily nitrogen balance by indirect calorimetry is essential throughout the course of burn treatment to ensure a positive nitrogen balance (nonprotein kilocalorie to nitrogen ratio of 100:1 and at least 2 grams of protein per kilogram per day). The serum prealbumin concentration is a useful indicator of nutritional progress.

The routes for initiating caloric support after major burn injury are either enteral or parenteral. Any patient with a functioning gastrointestinal tract should receive enteral nutrition orally, by tube feeding, or by a combination of both. Early enteral nutrition has been shown

**TABLE 54-5** PHYSIOLOGIC CHANGES RELATED TO THE AGING PROCESS THAT CAN AFFECT SURGERY

PHYSIOLOGIC CHANGES	EFFECTS	POTENTIAL POSTOPERATIVE COMPLICATION
<b>Cardiovascular</b>		
↓ Elasticity of blood vessels ↓ Cardiac output ↓ Peripheral circulation	↓ Circulation to vital organs Slower blood flow	Shock (hypotension), thrombosis with pulmonary emboli, delayed wound healing, postoperative confusion, hypovolemia, decreased response to stress
<b>Respiratory</b>		
↓ Elasticity of lungs and chest wall ↑ Residual lung volume ↓ Forced expiratory volume ↓ Ciliary action Fewer alveolar capillaries	↓ Vital capacity ↓ Alveolar volume ↓ Gas exchange ↓ Cough reflex	Atelectasis, pneumonia, postoperative confusion
<b>Urinary</b>		
↓ Glomerular filtration rate ↓ Bladder muscle tone Weakened perineal muscles	↓ Kidney function Stasis of urine in bladder Loss of urinary control	Prolonged response to anesthesia and drugs, overhydration with intravenous fluids, hyperkalemia, urinary tract infection, urinary retention
<b>Musculoskeletal</b>		
↓ Muscle strength Limitation of motion	↓ Activity	Atelectasis, pneumonia, thrombophlebitis, constipation or fecal impaction
<b>Gastrointestinal</b>		
↓ Intestinal motility	Retention of feces	Constipation or fecal impaction
<b>Metabolic</b>		
↓ $\gamma$ -Globulin level ↓ Plasma proteins	↓ Inflammatory response	Delayed wound healing, wound dehiscence or evisceration
<b>Immune</b>		
Fewer killer T cells ↓ Response to foreign antigens	↓ Ability to protect against invasion by pathogenic microorganisms	Wound infection, wound dehiscence, pneumonia, urinary tract infection

to effectively deliver caloric requirements (resting energy expenditure [REE]) by postburn day 3; diminish the hypermetabolic response; decrease circulating levels of catecholamines, cortisol, and glucagon; and preserve gut mucosal integrity, motility, and intestinal blood flow, which serves to decrease bacterial translocation and lower the incidence of intestinal ischemia.<sup>70</sup> Postburn ileus primarily affects the stomach and colon.<sup>71</sup> Patients with severe burn injuries may be fed through enteral tubes to the small bowel (duodenum or jejunum) as early as 6 hours' postburn, independent of total gastroduodenal function.<sup>72</sup> In a large meta-analysis conducted in critically ill patients that included a small number of burned patients, a grade B evidence-based recommendation was made for the use of parenteral nutrition for patients in whom enteral nutrition cannot be started within the first 24 hours of hospital admission. A subgroup analysis attributed a mortality risk reduction to parenteral nutrition versus delayed (>24 hours) enteral nutrition, despite an association with increased infectious complications with parenteral nutrition.<sup>73,74</sup>

Hart and colleagues demonstrated that the catabolic response may persist for up to 12 months in adults and 24 months in children.<sup>75</sup> Given this information, the nutritional status and dietary habits of burn patients should be continually evaluated for many months after their discharge from the burn unit.

## Rehabilitation Phase

The rehabilitation phase begins when the burn size is reduced to less than 20% of the TBSA and the patient is capable of assuming some self-care. This phase may occur as early as 2 weeks or as long as 2 to 3 months after the burn and, in the case of a major debilitating or disfiguring injury, may last many years. Goals for this period are to assist the patient in resuming a functional role in society and to accomplish functional and cosmetic reconstruction.<sup>10,15,17</sup>

## Wound Healing

During the rehabilitation phase, the pathophysiologic mechanism of hypermetabolism and the impaired immune function have begun to normalize, although some changes will persist beyond discharge from the hospital. The major pathophysiologic process of this phase is related to the dysfunctional results of wounds healing in a manner that causes flexor contractures, excessive scarring, and keloid formation. The burn wounds have healed either by primary intention or by autografting. Layers of epithelialization begin rebuilding the tissue structure destroyed by the burn injury. Collagen fibers present in the new scar tissue help healing and add strength to weakened areas. After healing, the new skin appears flat and pink, even in dark-skinned people.

**FIGURE 54-7** Physical and occupational therapy is necessary from the time of injury. This 8-year-old girl was burned 4 years previously in a house fire. Inadequate follow-up care because of parental neglect led to severe scar contractures and hand disability. (Courtesy Michael Peck, MD, University of North Carolina Burn Center, Chapel Hill.)

In approximately 4 to 6 weeks the area becomes raised and hyperemic. If adequate range-of-motion exercises are not instituted early in the hospital course, the new tissue will shorten and a contracture will result (Figure 54-7).<sup>10,15</sup> Mature healing is reached in 6 to 12 months, when suppleness has returned and the pink or red color has faded to a slightly lighter hue than the surrounding unburned tissue. It takes longer for darker skin to regain its color because many of the melanocytes were destroyed, and often the skin never returns to its original color. The mesh pattern in meshed autograft fades with time, but in larger expansions such as 4:1 or greater the pattern may persist.

Scarring has two components: discoloration and contour. The discoloration of scars fades with time and can be covered with makeup on visible body surface areas. However, scar tissue tends to develop altered contours; that is, the skin is no longer flat but becomes raised above the contour of the surrounding area (also known as hypertrophic scarring). Areas of the face tend to scar in an even plane—a process that distorts the natural contours around the nose, chin, and mouth and thus greatly alters a patient's appearance. Scarring on the cheeks can contract and pull the lower eyelid down sufficiently to prevent closure and protection of the eye normally afforded by the eyelid—a condition called ectropion. Burns on the eyelid can also result in ectropion and must be corrected by reconstructive surgery. Pressure can help keep a scar flat if the pressure is slightly greater than capillary pressure and is continuous during the healing process. This knowledge led to the development of burn garments, which are custom-made for each patient to contour with pressure over the area of burn for about 12 to 18 months after burn injury. Except for bath times, the garments must be worn continuously; patient compliance often becomes an issue (Figure 54-8).

Excessive and sometimes debilitating discomfort from pruritus occurs in the healing burn wound and persists for many months. The exact pathophysiologic process is not known but is related to the absence of sebaceous glands in the area and to the hyperactivity of sweat glands. Topical lotions and orally administered antihistamines provide partial relief of symptoms, but tolerance to the drugs develops and patients often require a series of different medications over time. The newly formed skin is extremely sensitive to trauma, and blisters form after very slight pressure or friction. The newly healed areas may be hypersensitive or hyposensitive to cold, heat, or touch. Ward and colleague<sup>76</sup> studied loss of cutaneous sensibility after grafting in 60 patients and found that 97% demonstrated markedly diminished or absent responses to sharp/dull, hot/cold, and light touch stimuli over the grafted areas. Grafted areas are more likely to be hyposensitive until peripheral nerve regeneration occurs, although donor sites harvested several times will show all the same healing pathologic process as healed burn wounds.

**FIGURE 54-8** The custom-fitted anti-scar support garment modeled here effectively provides pressure therapy over wounds, which helps to minimize the development of hypertrophic scarring. (From Black JM, Hawks JH, editors: *Medical-surgical nursing: clinical management for positive outcomes*, ed 7, Philadelphia, 2005, Saunders. Courtesy Medical Z, San Antonio, TX.)

Scarring is a genetically inherited trait. Some people will have minimal scarring, whereas others, especially African Americans and Caucasians with red hair, tend to have significant scarring and keloid formation in which the scar tissue actually outgrows the boundary of the original wound. Healed burn wounds must be protected from direct sunlight for 1 year to prevent hyperpigmentation.

The most common complications during the rehabilitation phase are related to the formation of skin and joint contractures. Because of pain associated with movement, the patient will want to assume the position of comfort, which is with all extremities flexed, but this position predisposes to contracture formation. To minimize contracture formation, positioning in extension, splinting in the position of function, and performing active range-of-motion exercises are initiated on admission and continue throughout the course of treatment. The areas most subject to contracture formation include the anterior and lateral neck areas, axillae, antecubital fossae, fingers, groin areas, popliteal fossae, and ankles. Not only do contractures develop in the skin, but also the underlying tissues such as ligaments and tendons have a tendency to shorten during the healing process. Therapy is aimed at extension of body parts to ensure that the flexors are longer than the extensors.<sup>10</sup>

#### KEY POINTS

- The emergent phase is the time between the end of burn shock and closure of the wound to less than 20% of the TBSA. Wound management, nutritional support, and surgical grafting of full-thickness wounds are the priorities of treatment during the emergent phase.
- Wound management is necessary to prevent bacterial colonization of the wound and subsequent septicemia. Early surgical wound management is

essential. Topical antibiotics are used because systemic antibiotics cannot reach the wound because of a lack of blood supply.

- Nutritional requirements after burn injury are high. A high-calorie, high-protein diet is needed. Persons with major burns usually cannot ingest sufficient nutrients and require parenteral and enteral supplementation. A positive nitrogen balance is essential for healing.
- Early surgical excision and skin grafting are the treatments of choice for deep burns. Excision procedures result in significant blood loss requiring blood transfusions. Skin grafts are taken from a healthy portion of the patient's skin. Temporary grafts (e.g., cadaver skin, synthetics, porcine skin) may be used to cover the wound until an autograft can be obtained.
- The rehabilitation phase begins when the burn is reduced to less than 20% of the TBSA. Problems during this phase include skin contracture and excessive scarring. Healing is complete at 6 to 12 months. Positioning in extension and performing range-of-motion exercises are important to prevent contracture.

## ELECTRICAL INJURY

### Incidence and Mortality

Electrical injury accounts for fewer than 2% of admissions to burn facilities; however, their incidence has been increasing in the United States.<sup>77</sup> Based on data from the National Institute for Occupational Safety and Health (NIOSH) National Traumatic Occupational Fatalities (NTOF) surveillance system, electrocutions were the fifth-leading cause of death from 1980 through 1992.<sup>78</sup>

Electrical injuries are classified as high-voltage (1000 volts or greater) or low-voltage. Household currents of 120 and 220 volts typically cause low-voltage electrical injury. High-voltage injuries are frequently due to high-tension sources, which commonly carry from 7200 to 19,000 volts (Figure 54-9) but may involve 100,000 to 1 million volts.<sup>79</sup>

According to the National Weather Service Storm Data, between the 1981-2010 the United States has averaged 55 reported lightning fatalities per year. Of all lightning strikes, only 10% are fatal, leaving

**FIGURE 54-9** High-voltage electrical injuries produce devastating consequences, such as the damage to the right hand of this electrician who inadvertently contacted a 17,000-V line. The underlying muscle damage is often greater than that found in a thermal skin burn. Myoglobinuria, if inadequately managed, can lead to acute tubular necrosis. Early fasciotomies are mandatory, and amputation may be necessary to control rhabdomyolysis. (Courtesy Michael Peck, MD, University of North Carolina Burn Center, Chapel Hill.)

90% with various degrees of disability.<sup>80</sup> Lightning injuries kill between 150 and 300 people per year in the United States.<sup>81</sup> Lightning carries a direct current of 100 million or more volts and up to 200,000 amperes, and it can injure either by a direct strike or by a side flash as a result of the flow of current between the victim's body and a nearby object struck by lightning.<sup>81</sup>

Arnoldo and colleagues reviewed electrical injuries at a single institution over a 20-year period and reported that the highest mortality resulted from lightning strikes (17.6%) followed by high-voltage (5.3%) and low-voltage (2.8%) injuries, with the lowest electrical injury mortality resulting from electric arc injuries without passage of current through the patient (1.1%). Complication rates, mean length of hospital stay ( $18.9 \pm 1.4$  days), and number of operative procedures ( $3.0 \pm 0.2$ ) were increased in the high-voltage group. Work-related activity was responsible for the majority of these high-voltage injuries, with the most common occupations being linemen and electricians.<sup>82</sup>

### Pathophysiology

The pathophysiologic mechanism of electrical injury is related to the subsequent tissue damage as electrical energy is converted to heat. Workplace electrocutions account for 5% of all worker deaths.<sup>83</sup> In children, electrical burns account for 2% to 3% of all burns, and 60% to 70% of these result from biting extension cords.<sup>84,85</sup>

Arcing electricity produces surface heat, which may ignite clothing and destroy superficial tissue, but internal damage is absent; this injury is actually a flame or thermal injury and not electrical. These injuries are properly classified as heat injuries, for which the treatment plan is identical to that for other heat injuries.<sup>77</sup> True electrical injury occurs as electrical current enters the body, traverses a portion of the body, and exits at another body site. Electrical injuries are usually deeper than full-thickness skin injury and are often classified as fourth-degree injury.

Voltage, type of current (direct or alternating), and length of contact all influence the extent of damage. Alternating current (AC) produces prolonged tetanic muscle contraction. At low voltages it can cause ventricular fibrillation, tetanic contraction of the respiratory muscles, superficial burns, and rhabdomyolysis. At lower voltage, AC is associated with low mortality. High-voltage AC or direct current (DC) causes ventricular fibrillation, a single sustained contraction, rhabdomyolysis, and higher overall mortality.<sup>86</sup>

Each true electrical injury produces an entrance wound and at least one exit wound, with the most extensive damage commonly occurring at the exit point. Electrical current follows the path of least resistance: in humans, this path is through blood vessels, nerves, tendons, and bone. Skin has high resistance; thus the current enters through the skin but goes deeper to travel the path of least resistance until it exits the body. The current rarely produces direct visceral damage, but severe injuries to the extremities are common. The amputation rate after severe electrical injury exceeds 90%. The pathophysiologic process, in addition to direct tissue destruction, involves heat coagulation of blood vessels, which leaves distal areas without blood supply. Electrical injuries produce both systemic and local alterations. The systemic changes produce three common complications during the acute period: dysrhythmias or cardiac arrest, metabolic acidosis, and myoglobinuria. Electrical injury may also cause direct myocardial necrosis. Dysrhythmias are exacerbated by any given voltage of AC. Higher voltage may also cause asystole. Locally, electrical injury produces direct cellular denaturation; areas of healthy tissue are devascularized as a result of heat coagulation of arteries and veins. These events are followed 48 to 72 hours after injury by gross tissue necrosis and subsequent gangrene resulting from lack of blood flow. Amputation is required early in electrical injury to prevent the development of deep soft-tissue infections and sepsis, leading to death.

## Management and Complications

Once the patient is admitted, airway management is the primary focus; patients with major electrical injury often require endotracheal intubation to ensure a patent airway. A condition similar to burn shock develops within a few minutes of major electrical injury and requires similar fluid resuscitation measures; however, there is no standardized formula to predict fluid requirements because often the only apparent damage is the entrance and exit wounds and no assessment of internal damage is possible. An adult patient is given a 1-L bolus of Ringer lactate solution intravenously within the first 15 minutes after intravenous line placement; children are given a smaller, size-appropriate amount. Thereafter, fluid is infused at a rate to produce a urine volume of 100 ml/hr in adults and 1 to 2 ml/kg/hr in children. Adult patients frequently require 1 to 2 L of fluid per hour to support the cardiovascular system.

Cardiovascular complications associated with lightning injury range from benign electrocardiogram (ECG) changes to sudden cardiac death. Atrial or ventricular fibrillation and T-wave inversions and prolonged QT intervals are the more common dysrhythmias and ECG findings. Traditionally, cardiac monitoring has been performed on these patients for the first 24 hours after injury. Bailey and colleagues determined that this is unnecessary, however, if the initial ECG is normal, there is no loss of consciousness at the scene, and the patient is an adult; 24-hour monitoring is indicated in adult patients with an abnormal initial ECG, a history of cardiac disease, positive loss of consciousness at the scene, and/or exposure to a voltage greater than 240 volts.<sup>86</sup> Measurement of the levels of cardiac enzymes initially reveals elevated values, also suggesting acute myocardial damage, but in such patients these findings are not indicative of a cardiac pathologic process.

Electrical injury also produces a profound, potentially lethal metabolic acidosis. These patients often have initial serum pH values of 6.8 to 7.2 on admission. Treatment consists of intravenous administration of sodium bicarbonate in amounts to correct the values toward normal. Metabolic acidosis is a recurring problem requiring ongoing treatment until it has been resolved for 24 to 48 hours after injury. The pathophysiologic mechanism is related both to the release of intracellular contents into the general circulation from areas of tissue damage and to the development of lactic acidosis that accompanies hypotensive shock states.

Myoglobinuria follows electrical injury as myoglobin, a component of muscle tissue, is released from muscles damaged by electrical current and enters the systemic circulation.<sup>87</sup> Myoglobin is a large protein that precipitates in the renal tubules and leads to cast formation. Subsequently, the tubules become obstructed and renal tubular acidosis develops. This accumulation is prevented by maintaining urine output at 100 to 200 ml/hr in adults and 2 ml/kg/hr in children until the urine clears. Mannitol, an osmotic diuretic, is administered along with large volumes of intravenous fluids to prevent the development of acute tubular necrosis, a totally preventable sequela of electrical injury with proper management. Sodium bicarbonate is often administered to alkalinize the urine, thereby increasing the solubility of myoglobin.

Local effects of electrical injury are related to alterations in tissue perfusion. Surgical decompression of areas of electrical burn by fasciotomy is performed for the purpose of releasing any increased compartment pressures that may be compromising blood flow. Amputation may be required during the initial surgery for devascularized areas. Because of the continued presence of necrotic tissue, areas of surgical decompression or initial amputation are not closed surgically.<sup>88</sup>

Central nervous system alterations can be noted in patients with major electrical injury. Memory deficits can occur for several weeks. This condition improves gradually and usually resolves within 4 to 6 weeks after injury. Other central nervous system deficits after electrical injury include ataxia and gait alterations accompanied

by sensory deficits. These alterations may or may not improve over time. Electrically injured patients experience all the challenges of rehabilitation plus possible adjustments to amputation and gait instability related to central nervous system impairment. Skin grafting in areas adjacent to amputation presents challenging prosthetic problems that may delay independent ambulation and restoration of self-care abilities.<sup>89</sup> In general, patients with major electrical injury experience longer rehabilitation periods than do thermally injured patients.

A unique complication of electrical injury is the formation of corneal cataracts,<sup>90</sup> which can be detected as early as 1 month post injury. Ophthalmic examinations should be performed monthly for the first year and every 3 months for 1 year thereafter to enable early identification. Patients will usually complain of blurring vision, but young children may not report this visual change because they do not recognize the concept. Treatment consists of corneal transplantation.<sup>90</sup>

### KEY POINTS

- Broadly speaking, persons wounded by major electrical burns have longer periods of rehabilitation than thermally injured patients. Systemic involvement is complex. Each true electrical injury produces an entrance wound and at least one exit wound, with the most extensive damage commonly occurring at the exit point.
- Management for electrical injury includes core practices of maintenance of airway, breathing, and circulation. Once the patient is admitted to the hospital for a serious electrical burn, airway management is the primary focus.
- A condition similar to burn shock develops within a few minutes of major electrical injury and requires similar fluid resuscitation measures; however, there is no standardized formula to predict fluid requirements because often the only apparent damage is the entrance and exit wounds and no assessment of internal damage is possible.
- Cardiovascular complications associated with electrical (lightning) injury range from benign electrocardiogram (ECG) changes to sudden cardiac death. Twenty-four-hour monitoring is indicated in adult patients with an abnormal initial ECG, a history of cardiac disease, positive loss of consciousness at the scene, and/or exposure to a voltage greater than 240 volts.
- Electrical injury also produces a profound, potentially lethal metabolic acidosis. These patients often have initial serum pH values of 6.8 to 7.2 on admission.
- Treatment for metabolic acidosis consists of IV administration of sodium bicarbonate. Metabolic acidosis is a recurring problem requiring ongoing treatment until resolved for 24-48 hours after injury. The pathophysiologic mechanisms are related both to the release of intracellular contents into the general circulation from areas of tissue damage and to the development of lactic acidosis that accompanies hypotensive shock states.
- Myoglobinuria follows electrical injury as myoglobin, a component of muscle tissue, is released from muscles damaged by electrical current and enters the systemic circulation. Myoglobin is a large protein that precipitates in the renal tubules and leads to cast formation. Subsequently, the tubules become obstructed and renal tubular acidosis develops.
- Accumulation of myoglobin is prevented by maintaining urine output at 100-200 ml/hr in adults and 2 ml/kg/hr in children until the urine clears. Mannitol, an osmotic diuretic, is administered along with large volumes of IV fluids to prevent the development of acute tubular necrosis. With proper treatment, acute tubular necrosis is totally preventable. Sodium bicarbonate is often administered to alkalinize the urine, thereby increasing the solubility of myoglobin.

- Local effects of electrical injury are related to alterations in tissue perfusion. Because of the continued presence of necrotic tissue, areas of surgical decompression or initial amputation are not closed surgically.
- Electrically injured patients experience all the challenges of rehabilitation plus possible adjustments to amputation and gait instability related to central nervous system impairment.
- A unique complication of electrical injury is the formation of corneal cataracts, which can be detected as early as 1 month post injury. Treatment consists of corneal transplantation.

## CHEMICAL INJURY

### Management and Complications

Chemicals are a mainstay in our everyday lives and encompass a diverse spectrum, ranging from occupational to household exposures. Chemical burns accounted for 3% of admissions to burn centers in the United States between 2000 and 2009.<sup>91</sup> Management protocols for these injuries share some basic core principles, yet have unique aspects depending upon chemical composition, making accurate knowledge of involved chemical(s) imperative.

Acids predominantly produce a coagulation necrosis by denaturing proteins and forming a coagulum (eschar) that limits the penetration of the acid. In contrast, alkalis produce a liquefaction necrosis that, in addition to involving denaturing proteins, also results in fat saponification, which does not limit tissue penetration and results in more severe injuries. The severity of a chemical burn is related to a number of factors including the agent's pH, concentration, volume, and physical form as well as the length of contact time. To minimize local and systemic toxic effects, it is critical that treatment be initiated immediately.

Initial management strategies include removing any contaminated clothing, brushing off dry agents, and irrigating with copious amounts of water. Care providers must ensure that they have taken the appropriate protection measures to avoid self-exposure as established by the Occupational Safety and Health Administration (OSHA). Water irrigation is contraindicated for certain chemicals and metals such as lime, phenol, muriatic acid, concentrated sulfuric acid (52% to 100%), elemental potassium, and sodium,<sup>92</sup> because it may result in an exothermic reaction or release of hazardous by-products. Antidotes have a minor role in the management of most chemical burns except for those secondary to hydrofluoric acid.

The true extent of chemical burns is often difficult to appreciate in the acute setting given the nature of these injuries to continue to evolve over time following exposure. As a result, a lack of appreciation for unrecognized deep tissue involvement may result in inadequate initial management. Systemic toxicity associated with these injuries occurs primarily as a result of absorption through the skin and inhalation.

Comprehensive management guidelines for clinicians for specific chemical exposures are readily accessible online at [www.osha.gov/dts/bestpractices/htm/hospital](http://www.osha.gov/dts/bestpractices/htm/hospital) or by calling regional poison control centers. The World Health Organization provides a listing of international poison centers online at [www.who.int/gho/phe/chemical\\_safety/poisons\\_centers/en/index.html](http://www.who.int/gho/phe/chemical_safety/poisons_centers/en/index.html).

### Common Agents and Treatment

#### Hydrofluoric Acid

Hydrofluoric acid is a highly corrosive inorganic acid used in glass etching, electronic industries, and cleaning solutions. Symptomatic

manifestation following exposure is dependent upon solution concentration, with concentrations greater than 15% manifesting more acutely. Because of the ability of hydrofluoric acid to penetrate tissue, poisoning can occur readily through exposure of skin or eyes, or when inhaled or swallowed. Symptoms of exposure to hydrofluoric acid may not be immediately evident. Hydrofluoric acid interferes with nerve function, meaning that burns may not initially be painful. Accidental exposures can go unnoticed, delaying treatment and increasing the extent and seriousness of the injury.

Hydrofluoric acid penetrates quickly into the dermis and deeper structures, where the fluoride ion forms complexes with calcium and magnesium. This complex formation in conjunction with the direct cardiotoxic effects of fluoride ions may contribute to the development of cardiac dysrhythmias, which are the primary cause of death in these patients.

Management of burn injuries consists of copious water irrigation and calcium administration. Calcium ions form complexes with free fluoride ions, thereby minimizing toxicity while also helping to correct any associated hypocalcemia. Calcium gluconate (2.5%) gel is massaged into affected areas for 30 to 60 minutes.<sup>93,94</sup> If discomfort persists, 5% calcium gluconate (0.5 ml/cm<sup>2</sup> wound area) may be injected intradermally directly into and around the affected areas. Injection directly into digits is not recommended. Burns refractory to these initial measures may necessitate intraarterial administration of calcium gluconate. This should only be undertaken in conjunction with the appropriate toxicology expert.<sup>95</sup> In cases where systemic toxicity is suspected (prolongation of QT interval, dysrhythmias) intravenous calcium and magnesium replacement should be considered.

#### Anhydrous Ammonia

Anhydrous ammonia is a colorless, pungent gas usually stored as a pressurized liquid at  $-33^{\circ}\text{C}$  ( $-28^{\circ}\text{F}$ ) and used extensively as a fertilizer and in the manufacture of synthetic fibers and methamphetamine. Exposure generally results in a combination of alkali burns and cold injury.<sup>96</sup> It is extremely water soluble and immediate treatment consists of copious water irrigation after all clothing has been removed. Repeat irrigation should be performed every 4 to 6 hours for the first 24 hours. Inhalation injury is concentration-dependent and may range from minor airway irritation to laryngospasm, glottic edema, and pulmonary edema. Early intubation in patients with suspected or clinical evidence of significant inhalation exposure is critical. There is unfortunately no specific therapy for these inhalation injuries except supportive care.

#### Cement Burns

Wet cement is highly alkalotic, with the pH increasing as the cement sets. Burn symptoms are generally delayed, with partial- or full-thickness burns not becoming evident for up to 48 hours.<sup>97</sup> Immediate treatment with copious water irrigation is highly effective in preventing injury progression. Management of burns is similar to that used for secondary thermal injuries. Prevention education that promotes appropriate use of protective gear can be highly successful in minimizing these injuries.

#### Chemicals Associated With Automobile Airbag Burns

Airbag perforations during deployment have been reported to cause both thermal and alkaline burns (sodium azide or sodium hydroxide).<sup>98</sup> Lack of recognition of associated airbag rupture often results in failure to treat the potential alkali component of the burn and therefore concomitant injury progression. Management is simply irrigation with copious amounts of water.

## Tar and Asphalt

In construction, both tar and asphalt are heated to high temperatures (approximately 140° C for paving; approximately 245° C for roofing); however, they cool rapidly. Initial treatment of injuries sustained by these substances consists of accelerating cooling by application of cold water. Subsequent removal of the substances, which may require multiple applications, can be facilitated by the application of several organic solvents (polymyxin-neomycin-bacitracin, petrolatum, sunflower oil, olive oil, butter, and baby oil).<sup>99</sup> Associated burns are treated in a fashion similar to that used in thermal burn treatment.

### KEY POINTS

- Burn injuries can be caused by thermal, electrical, or chemical agents. Depending on the cause, burn injuries influence a variety of complex systemic, circulatory, and metabolic changes.
- Management protocols for chemical burns share some basic core principles with electrical and thermal wounds, yet chemical injuries have unique treatment aspects depending on the composition of the etiologic agent, making accurate knowledge of involved chemical(s) imperative.
- To assist the clinician in the treatment of burns, comprehensive current management guidelines for specific exposures are also accessible online.
- The true extent of chemical burns is often difficult to appreciate, given that the nature of these injuries continues to evolve over the time following exposure.
- Systemic toxicity associated with chemical injuries occurs primarily as a result of absorption through the skin and by inhalation.

## SUMMARY

In recent decades, burn mortality rates have decreased significantly, with most patients achieving excellent functional and cosmetic outcomes. Improved outcomes have clearly been related to an improved understanding of the pathophysiologic mechanism of burns, advances in burn care management, and the development of a comprehensive, patient-centered, treatment-oriented approach.

Priorities for assessment and treatment of burn victims are no different than those of other trauma patients. However, accurate wound

management depends upon precise identification of the cause of the burn injury.

As a result, patient care is extremely complex. In order to make appropriate treatment decisions and recognize potential complications, a clear understanding of the etiologic agent of the burn injury, the associated pathophysiologic processes, and the importance of supportive care, treatment, and rehabilitation for the involved person are essential.

## Clinical and Laboratory Values

TABLE A-1 BLOOD, PLASMA, AND SERUM VALUES

TEST	NORMAL VALUES	SIGNIFICANCE OF CHANGE
Acid phosphatase	<i>Women:</i> 0.01-0.56 sigma U/ml <i>Men:</i> 0.13-0.63 sigma U/ml	↑ in kidney disease ↑ in prostate cancer ↑ after trauma and in fever
Alanine aminotransferase (ALT, SGPT)	7-56 U/L	↑ in liver damage
Albumin	3.5-5.0 g/dl	↓ in liver disease ↓ in malnutrition
Alkaline phosphatase	<i>Adult:</i> 38-110 IU/L <i>Child:</i> up to 104 IU/L	↑ in bone disorders ↑ in liver disease ↑ during pregnancy ↑ in hypothyroidism
Amylase	20-110 U/L	↑ in pancreatitis
α <sub>1</sub> -Antitrypsin	110-270 mg/dl	↓ in genetic emphysema
Aspartate aminotransferase (AST, SGOT)	0-35 U/L	↑ in liver damage
Bicarbonate (arterial)	22-26 mEq/L	↑ in metabolic alkalosis ↓ in respiratory alkalosis ↓ in metabolic acidosis ↑ in respiratory acidosis
Blood urea nitrogen (BUN)	5-25 mg/dl	↑ with increased protein intake ↑ in kidney failure
Blood volume	<i>Women:</i> 65 ml/kg body weight <i>Men:</i> 69 ml/kg body weight	↓ during hemorrhage
Calcium		
Total	8.4-10.5 mg/dl (2.1-2.6 mmol/L)	↑ in hypervitaminosis D
Ionized	4.6-5.3 mg/dl	↑ in hyperparathyroidism ↑ in bone cancer and other bone diseases ↓ in hypoparathyroidism ↓ in avitaminosis D (rickets and osteomalacia)
Carbon dioxide content (venous bicarbonate)	24-32 mEq/L	↑ in severe vomiting ↑ in hypoventilation disorders ↑ in obstruction of intestines ↓ in metabolic acidosis ↓ in severe diarrhea ↓ in kidney disease

TABLE A-1 BLOOD, PLASMA, AND SERUM VALUES—cont'd

TEST	NORMAL VALUES	SIGNIFICANCE OF CHANGE
Chloride	98-110 mEq/L	↑ in hyperventilation ↑ in kidney disease ↑ in Cushing syndrome ↓ in severe diarrhea ↓ in severe burns ↓ in Addison disease
Cholesterol Total	<200 mg/dl	↑ in chronic hepatitis ↑ in hyperthyroidism ↑ in atherosclerosis ↓ in acute hepatitis ↓ in hypothyroidism
High-density lipoprotein (HDL)	>40 mg/dl	↑ with regular exercise
Low-density lipoprotein (LDL)	<130 mg/dl	↑ with high-fat diet ↑ in diabetes mellitus ↓ in chronic obstructive pulmonary disease
Triglycerides	<165 mg/dl	↑ in cardiovascular disease ↑ in diabetes mellitus ↓ in hyperthyroidism ↓ with exercise
Clotting time (bleeding time)	5-10 min	↓ in hemophilia ↓ in platelet deficiency or defects
Copper	100-200 µg/dl	↑ in some liver disorders
Cortisol (at 8 AM)	5-20 µg/dl	↑ in Cushing disease ↓ in Addison disease
Creatine phosphokinase (CPK)	32-260 U/L	↑ in Duchenne muscular dystrophy ↑ during myocardial infarction ↑ in muscle trauma
Creatinine	0.6-1.5 mg/dl	↑ in some kidney disorders
Ferritin	<i>Women:</i> 4-161 ng/ml <i>Men:</i> 16-300 ng/ml	↑ in hemochromatosis ↑ in iron deficiency
α-Fetoprotein	0-15 ng/ml	↓ in neural tube defects
Fibrinogen	175-433 mg/dl	↑ may increase risk of thrombus ↓ in disseminated intravascular coagulation
Folic acid (RBC)	165-760 ng/dl	↓ in macrocytic anemia
Glucose	60-100 mg/dl (fasting)	↑ in diabetes mellitus ↑ in liver disease ↑ during pregnancy ↑ in hyperthyroidism ↓ in hypothyroidism ↓ in Addison disease ↓ in hyperinsulinism
Glycosylated hemoglobin (HbA <sub>1c</sub> )	3.9-6.9%	↑ in hyperglycemia
Hematocrit (packed cell volume)	<i>Women:</i> 38-47% <i>Men:</i> 40-54%	↑ in polycythemia ↑ in severe dehydration ↓ in anemia ↓ in leukemia ↓ in hyperthyroidism ↓ in cirrhosis of liver

TABLE A-1 BLOOD, PLASMA, AND SERUM VALUES—cont'd

TEST	NORMAL VALUES	SIGNIFICANCE OF CHANGE
Hemoglobin	<i>Women:</i> 12-16 g/dl <i>Men:</i> 13-18 g/dl <i>Newborn:</i> 14-20 g/dl	↑ in polycythemia ↑ in chronic obstructive pulmonary disease ↑ in congestive heart failure ↓ in anemia ↓ in hyperthyroidism ↓ in cirrhosis of liver
Iron	50-150 µg/dl (can be higher in men)	↑ in liver disease ↓ in iron-deficiency anemia
Total iron-binding capacity (TIBC)	250-460 µg/dl	↑ in iron deficiency
Lactate dehydrogenase (LDH)	88-230 U/L	↑ during myocardial infarction ↑ in anemia (several forms) ↑ in liver disease ↑ in acute leukemia and other cancers
Lipase	0-160 U/L	↑ in pancreatitis
Magnesium	1.8-3.0 mg/dl	↑ in excessive intake ↓ in alcoholism, renal disease
Mean corpuscular hemoglobin concentration	31-36%	↓ in iron-deficiency anemia
Mean corpuscular volume (RBC)	82-98 fl	↑ or ↓ in various forms of anemia
Osmolality	285-295 mOsm/L	↑ or ↓ in fluid and electrolyte imbalances
Paco <sub>2</sub>	35-43 mm Hg	↑ in severe vomiting ↑ in hypoventilation disorders ↑ in obstruction of intestines ↓ in metabolic acidosis ↓ in severe diarrhea ↓ in kidney disease
Pao <sub>2</sub>	75-100 mm Hg (breathing standard air)	↓ in cyanotic heart defects ↓ in chronic obstructive pulmonary disease
Partial thromboplastin time (activated PTT)	25-35 sec	↓ in intrinsic pathway defects
pH	7.35-7.45	↑ during hyperventilation ↑ in Cushing syndrome ↓ during hypoventilation ↓ in acidosis ↓ in Addison disease
Phosphorus	2.5-4.5 mg/dl	↑ in hypervitaminosis D ↑ in kidney disease ↑ in hypoparathyroidism ↑ in acromegaly ↓ hyperparathyroidism ↓ in hypovitaminosis D (rickets and osteomalacia)
Plasma volume	<i>Women:</i> 40 ml/kg body weight <i>Men:</i> 39 ml/kg body weight	↑ or ↓ in fluid and electrolyte imbalances ↓ during hemorrhage
Platelet count	150,000-400,000/µl	↑ in heart disease ↑ in some forms of cancer ↑ in cirrhosis of liver ↑ after trauma ↓ in anemia (some forms) ↓ during chemotherapy ↓ in some allergies

Continued

TABLE A-1 BLOOD, PLASMA, AND SERUM VALUES—cont'd

TEST	NORMAL VALUES	SIGNIFICANCE OF CHANGE
Potassium	3.5-5.1 mEq/L	↑ in hypoaldosteronism ↑ in acute kidney failure ↓ in vomiting or diarrhea ↓ in starvation
Prostate-specific antigen	0-4 ng/ml	↑ in prostate cancer
Protein		
Total	6-8.4 g/dl	↑ (total) in severe dehydration
Albumin	3.5-5 g/dl	↓ (total) during hemorrhage
Globulin	2.3-3.5 g/dl	↓ (total) in starvation
Prothrombin time (PT)	11-15 sec	↑ in extrinsic pathway defects
Red blood cell count	<i>Women:</i> 4.2-5.4 million/ $\mu$ l <i>Men:</i> 4.5-6.2 million/ $\mu$ l	↑ in polycythemia ↑ in dehydration ↓ in anemia (several forms) ↓ in systemic lupus erythematosus
Reticulocyte count	33,000-135,000/ $\mu$ l (0.5-1.5% of RBC count)	↑ in hemolytic anemia ↑ in leukemia and metastatic carcinoma ↓ in pernicious anemia ↓ in iron-deficiency anemia ↓ during radiation therapy
Sodium	135-145 mEq/L	↑ in dehydration ↑ in trauma or disease of the central nervous system ↑ or ↓ in kidney disorders ↓ in excessive sweating, vomiting, diarrhea ↓ in burns (sodium shift into cells)
Specific gravity	1.058	↑ or ↓ in fluid imbalances
Thyroid-stimulating hormone (TSH)	0.4-6 $\mu$ U/ml	↑ in hypothyroidism (primary) ↓ in hyperthyroidism (primary)
Thyroxin (T <sub>4</sub> )—total	5-11 $\mu$ g/dl	↑ in hyperthyroidism ↓ in hypothyroidism
Transferrin	190-375 mg/dl	↓ in certain anemias
Troponin I	<0.05 ng/ml	↑ in myocardial infarction
Uric acid	<i>Women:</i> 1.5-6.0 mg/dl <i>Men:</i> 3-9 mg/dl	↑ in gout ↑ in toxemia of pregnancy ↑ during trauma
Viscosity	1.4-1.8 times the viscosity of water	↑ in polycythemia ↑ in dehydration
Vitamin B <sub>12</sub>	140-820 pg/ml	↓ in pernicious anemia
White blood cell count		
Total	4500-11,000/ $\mu$ l	↑ in acute infections ↑ in trauma ↑ in some cancers ↓ in anemia (some forms) ↓ during chemotherapy
Basophils	0.5-1% of total	↓ in severe allergies
Eosinophils	2-4% of total	↑ in allergies
Lymphocytes	20-25% of total	↑ during antibody reactions
Monocytes	3-8% of total	↑ in chronic infections
Neutrophils	60-70% of total	↑ in acute infection

From Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 5, St Louis, 2003, Mosby, pp 1023-1026.

\*Values vary with the analysis method used.

TABLE A-2 CHARACTERISTICS OF URINE

TEST	NORMAL VALUES*	SIGNIFICANCE OF CHANGE
<b>Routine Urinalysis</b>		
Acetone and acetoacetate	0	↑ during fasting ↑ in diabetic acidosis
Albumin	0-trace	↑ in hypertension ↑ in kidney disease ↑ after strenuous exercise (temporary)
Ammonia	20-70 mEq/L	↑ in liver disease ↑ in diabetes mellitus
Bile and bilirubin	—	↑ during obstruction of the bile ducts
Calcium	<150 mg/day	↑ in hyperparathyroidism ↓ in hypoparathyroidism
Color	Transparent yellow, straw-colored, or amber	Abnormal color or cloudiness may indicate blood in urine, bile, bacteria, drugs, food pigments, or high solute concentration
Odor	Characteristic slight odor	Acetone odor in diabetes mellitus (diabetic ketosis)
Osmolality	500-800 mOsm/L	↑ in dehydration ↑ in heart failure ↓ in diabetes insipidus ↓ in aldosteronism
pH	4.6-8.0	↑ in alkalosis ↑ during urinary infections ↓ in acidosis ↓ in dehydration ↓ in emphysema
Potassium	25-100 mEq/L	↑ in dehydration ↑ in chronic kidney failure ↓ in diarrhea or vomiting ↓ in adrenal insufficiency
Sodium	75-200 mg/day	↑ in starvation ↑ in dehydration ↓ in acute kidney failure ↓ in Cushing syndrome
Creatinine	1-2 g/day	↑ in infections ↓ in some kidney diseases ↓ in anemia (some forms)
Creatinine clearance	100-140 ml/min	↑ in kidney disease
Glucose	0	↑ in diabetes mellitus ↑ in hyperthyroidism ↑ in hypersecretion of adrenal cortex
Urea	25-35 g/day	↑ in some liver diseases ↑ in hemolytic anemia ↓ during obstruction of bile ducts ↓ in severe diarrhea
Urea clearance	>40 ml blood cleared per min	↑ in some kidney diseases
Uric acid	0.6-1.0 g/day	↑ in gout ↓ in some kidney diseases

Continued

TABLE A-2 CHARACTERISTICS OF URINE—cont'd

TEST	NORMAL VALUES*	SIGNIFICANCE OF CHANGE
<b>Microscopic Examination</b>		
Bacteria	<10,000/ml	↑ during urinary infections
Blood cells (RBC)	0-trace	↑ in pyelonephritis ↑ from damage by calculi ↑ in infection ↑ in cancer
Blood cells (WBC)	0-trace	↑ in infection
Blood cell casts (RBC)	0	↑ in pyelonephritis
Blood cell casts (WBC)	0	↑ in infection
Crystals	0-trace	↑ in urinary retention Very large crystalline masses are calculi
Epithelial casts	0-trace	↑ in some kidney disorders ↑ in heavy metal toxicity
Granular casts	0-trace	↑ in some kidney disorders
Hyaline casts	0-trace	↑ in some kidney disorders ↑ in fever

From Thibodeau GA, Patton KT: *Anatomy & physiology*, ed 5, St Louis, 2003, Mosby, pp 1027-1028.

\*Values vary with the analysis method used.

## A

**A band** A dark band corresponding to an area where actin and myosin filaments overlap in skeletal or cardiac muscle.

**Abruptio placentae** Premature separation of the placenta before delivery; the separation may be partial or complete and may result in overt or concealed hemorrhage.

**Absolute anemia** Anemia involving a decrease in the number of red blood cells (as opposed to a decrease in the percent of red blood cells).

**Acalculous cholecystitis** An important subgroup of acute cholecystitis. It tends to occur in the setting of major surgery, critical illness, trauma, or burn-related injury and does not occur in association with gallstones.

**Accelerated (malignant) high blood pressure** Rapidly progressing, potentially fatal form of hypertension in which the diastolic blood pressure exceeds 120 mm Hg.

**Acclimatization** A normal adaptive response to environmental changes, such as changes in altitude. For example, the red blood cell count increases when a person moves to a high altitude.

**Accommodative capacity** Ability of the eye to adjust to see objects at changing distances. This is a function of the ciliary muscle's ability to flatten or thicken the lens, thereby focusing the image on the retina.

**Achalasia** A disorder of esophageal smooth muscle function resulting in difficulty in swallowing **both** liquids and solids.

**Acid** A substance that releases hydrogen ions in solution and from which hydrogen may be displaced by a metal to form a salt. An increase in acid concentration produces a decrease in pH.

**Acidemia** The state in which the blood is overly acidic; usually defined as a pH <7.35.

**Acidosis** Presence of a condition that tends to make body fluids overly acidic.

**Acne vulgaris** A common disease of the skin in which sebaceous glands are numerous (face, upper back, and chest). Characteristic lesions include open (blackhead) and closed (whitehead) comedones, inflammatory papules, pustules, nodules, and cysts.

**Acquired immunodeficiency syndrome (AIDS)** A syndrome caused by the human immunodeficiency virus (HIV) in which the CD4 lymphocyte count is <200 cells/ $\mu$ L or an AIDS-indicator condition is present.

**Acquired or secondary immunodeficiency** An immunodeficiency that develops after birth and is the result of an illness rather than a genetic defect. Examples include impaired immune function secondary to poor nutrition or medication. This type of immunodeficiency may be reversible.

**Acromegaly** A chronic metabolic condition characterized by excessive growth of bone, soft tissues, and organs in adults due to abnormally high levels of growth hormone.

**Acrosome** Covering on the head of the sperm that contains large quantities of hydrolytic (water-splitting) enzymes that are released during capacitation.

**Actin** A cytoskeletal protein that comprises the thin filament of the muscle sarcomere in skeletal and cardiac muscle. It is also present in non-muscle cells and is an important component of cell movement.

**Actinic keratosis** A horny premalignancy of skin epithelium caused by excessive exposure to sunlight.

**Action potential** An electrical impulse consisting of a self-propagating series of depolarizations and repolarizations, transmitted across the plasma membranes of excitable cells that have voltage-gated ion channels, such as nerve and muscle.

**Active immunity** A form of long-term, acquired immunity that protects the body against a new infection as the result of antibodies that develop naturally after an initial infection or artificially after a vaccination.

**Active transport pumps** The membrane proteins that move polar substances across lipid membranes against a concentration gradient.

**Acute** Relatively severe but running a short course.

**Acute coronary syndrome (ACS)** Sudden onset of cardiac ischemia from occlusion of coronary vessels resulting in unstable angina or myocardial infarction.

**Acute HAV infection** A viral hepatitis infection caused by the hepatitis A virus (HAV) characterized by jaundice and fatigue.

**Acute renal failure** An abrupt reduction of renal function that is potentially reversible.

**Acute rheumatic fever** An inflammatory disease following a group A  $\beta$ -hemolytic streptococcal pharyngeal infection.

**Acute tubular necrosis** Sudden onset of renal dysfunction from death of nephron tubule cells (tubular epithelium), usually resulting from nephrotoxicity, ischemia after major surgery, trauma, severe hypovolemia, sepsis, or burns.

**Acute viral hepatitis** Inflammatory liver disease usually caused by hepatitis A virus, hepatitis B virus, and hepatitis C virus.

**Adaptation** An alteration in structure or function in response to a changed environment, which enhances or promotes survival.

**Adapting** Making an adjustment to a change in internal or external conditions or circumstances.

**Addison disease** Primary adrenocortical insufficiency thought to be autoimmune in etiology.

**Adenosine triphosphate (ATP)** A nucleoside with three phosphate groups and an adenine base; it functions as the principal source of energy in cells.

**Adherence** The quality of clinging or being closely attached. The degree to which a patient complies with therapeutic interventions such as taking medications.

**Adhesive capsulitis** A shoulder condition characterized by stiffness, pain, and limited range of motion.

**Adrenocortical insufficiency** Abnormally diminished secretion of corticosteroids by the adrenal cortex, as in Addison disease.

**Adrenocorticotropic hormone (ACTH)** A hormone that stimulates growth of the adrenal cortex and the synthesis and secretion of corticosteroids.

**Affect** The outward expression of emotion associated with a mental state or in response to a stimulus.

**Affective disorders** Mood disorders consisting of a variety of conditions characterized by a disturbance in mood.

**Afferent neuron** A neuron that transmits impulses from the periphery (sensory receptors) to the central nervous system.

**Affinity** The "tightness" of a ligand-receptor bond; the tendency of ligand and receptor to remain bound at low ligand concentration.

**Afterload** The impedance or resistance that must be overcome in order to eject blood from a cardiac chamber. Systemic vascular resistance is the primary determinant of left ventricular afterload.

**Age-related macular degeneration** A progressive deterioration of the retina associated with abnormal retinal pigment epithelium that can progress to blindness.

**Aggregates** A total considered with reference to its constituent parts.

**Agnosia** Total or partial loss of the ability to recognize familiar objects or persons through sensory stimuli.

**Agonist** A substance with affinity for binding to receptors and mimicking the effect of the normal receptor-ligand interaction.

**Agoraphobia** Irrational fear of open spaces. In panic disorder, agoraphobia is a fear of any place or situation in which assistance would be unavailable in case of an unexpected panic attack. Agoraphobia is also known as *phobic avoidance*.

**Airway resistance** Relationship between pressure and flow of gas, as determined by the radius of the airway.

**Alagille syndrome** Also called *arteriohepatic dysplasia*; this autosomal dominant condition is associated with typical bony and vascular malformations and paucity of intrahepatic bile ducts.

**Alarm** The initial response to stress. The major features of the alarm reaction are attributable to activation of the sympathetic nervous system.

**Albinism** Partial or total absence of pigment in skin, hair, and eyes.

**Alcohol abuse** Overingestion of alcohol to the point of a person's being dependent on the substance.

**Colored terms** have audio pronunciation available on the Evolve site for this book. Visit <http://evolve.elsevier.com/Copstead/>.

- Alcoholic fatty liver** An accumulation of fat in the liver cells resulting from chronic alcohol consumption; also called *steatosis*.
- Alcoholic hepatitis** An active inflammation, especially of the centrilobular region of the liver, resulting from acute or chronic alcohol consumption.
- Alcoholic liver disease** Manifested by fatty liver, hepatitis, and cirrhosis. One or more of these manifestations may be found in alcoholic patients.
- Aldosterone** A mineralocorticoid synthesized by the adrenal cortex in response to angiotensin II that conserves sodium, producing increased water retention and consequently increased blood volume.
- Alkalemia** The state in which the blood is overly alkaline; usually defined as a pH >7.45.
- Alkalosis** Presence of a condition in which body fluids are overly alkaline.
- Allele** One of two or more alternative forms of a gene located at the same site on homologous chromosomes.
- Allergic contact dermatitis** Indicates delayed acquired hypersensitivity to a specific allergen on the skin. Chromates, nickel, ethylenediamine, *para*-phenylenediamine, neomycin, formaldehyde, and lanolin components may cause allergic contact dermatitis.
- Allergic purpura** A chronic disorder of the skin associated with urticaria, erythema, asthma, and rheumatic joint swellings. Platelet counts, bleeding times, and blood clotting are normal.
- Allergy** Type I hypersensitivity of the immune system to environmental agents. Antigens that trigger an allergic response are often called *allergens*.
- Allodynia** Perception of pain in response to normally nonpainful sensory stimuli.
- Allogeneic** Referring to transplanted tissue that was obtained from a closely matched donor, usually a sibling, parent, or child.
- All-or-none response** In a skeletal muscle, all of the muscle fibers innervated by a motor unit will respond as a single entity to its maximum or they will not contract at all. In a nerve, depolarization will result in either a full amplitude action potential or none at all.
- Alopecia** Loss of hair, usually referring to the scalp.
- Allotaxis** The process of achieving stability, or homeostasis, through physiologic or behavioral change.
- Allostatic load** A term coined as a more precise alternative to the term *stress*; used to refer to environmental challenges that cause an organism to begin efforts to maintain stability.
- $\alpha_1$ -Antitrypsin** A plasma protein produced primarily in the liver; it is an acute-phase reactant that inhibits the activity of elastase, cathepsin G, trypsin, and other proteolytic enzymes.
- Alveolar period** The last stage in fetal lung development when alveolar ducts form from terminal sacs and alveoli mature by increasing both in size and in number.
- Amblyopia** Reduced vision in an eye not correctable by a fraction adjustment.
- Amenorrhea** Absence or suppression of menstrual bleeding, usually attributable to an altered pattern of hormonal functioning that interrupts the normal sequence of endometrial proliferation and sloughing.
- Amniocentesis** A procedure in which fluid is obtained from the amniotic cavity by an ultrasound-guided needle. The fluid contains fetal cells that can be used to screen for chromosomal and other defects.
- Amniotic cavity** The space between the amniotic sac and the developing embryo. It is filled with a clear amniotic fluid that keeps the embryo moist and provides a measure of protection against mechanical injury.
- Amphipathic** Having different characteristics. For example, membrane lipids are partly hydrophobic and partly hydrophilic, and hence are amphipathic.
- Ampulla** A flasklike cavity or dilatation of a tubular structure.
- Amyloid plaque** A microscopic lesion in the cerebral cortex composed of fragmented axon terminals and dendrites surrounding a core of  $\beta$ -amyloid, as found in Alzheimer disease.
- Amyloid precursor protein** A member of a large family of proteins that is associated with cell membranes and a precursor to  $\beta$ -amyloid, a component of brain plaques in Alzheimer disease.
- Amyotrophic lateral sclerosis** A progressive degenerative disease affecting both the upper and lower motor neurons characterized by muscle wasting and atrophy of the hands, arms, and legs; also called *Lou Gehrig disease*.
- Anabolism** The energy-requiring phase of metabolism through which molecules, cells, and tissues are created.
- Anagen** The growing phase of the hair cycle.
- Anaphylactic shock** A severe and sometimes fatal systemic allergic reaction to an allergen.
- Anaplasia** A lack of differentiated features in a tumor cell as evidenced by variations in cell size and shape and presence of abnormal nuclei.
- Androgenic** Producing masculine characteristics such as the androgenic hormone testosterone.
- Anemia** A decrease in the quantity of hemoglobin, hematocrit, and/or red blood cells.
- Anergy** Diminished immune responsiveness to antigens.
- Aneuploidy** An abnormal number of chromosomes—either too few (hypoploidy) or too many (hyperploidy, polyploidy).
- Aneurysm** Local dilation of an arterial wall or muscular chamber (e.g., cardiac ventricle).
- Angina pectoris** A paroxysmal chest pain most often due to cardiac ischemia associated with atherosclerotic coronary artery disease.
- Angiogenesis** The physiologic process involving the growth of new blood vessels from pre-existing vessels.
- Angiomyolipoma** The most common benign tumor of the kidney; composed of blood vessels, smooth muscle cells, and fat cells.
- Angiotensinogen** A serum glycoprotein produced in the liver that is the precursor of angiotensin I.
- Anhedonia** Loss of interest in and withdrawal from all regular and pleasurable activities, often associated with depression.
- Ankylosis** The fusion of a joint, often in an abnormal position, usually resulting from destruction of articular cartilage and subchondral bone, as occurs in rheumatoid arthritis.
- Ankylosing spondylitis** An arthritis of the axial skeleton including the sacroiliac joints, spine, hips, and shoulders. Marked limitation of motion develops, and a flexed spinal posture with flexed hips and knees may predominate.
- Anorexia** Loss of appetite.
- Anorexia nervosa** A refusal to eat or an aberration in eating patterns to the point of danger. The clinical syndrome may be due to an intense fear of becoming obese or to emotional states such as anxiety, irritation, or anger. Affected individuals become obsessed with the desire to become thin, and food intake is restricted even as weight falls well below minimal normal value for age and height. Periods of fasting may alternate with periods of bingeing.
- Anosognosia** Lack of insight or denial of a neurologic defect, or illness in general (especially paralysis), on one side of the body.
- Antagonist or blocking agent** A substance that has affinity to bind to a cellular receptor and blocks the activity of the normal receptor-ligand interaction.
- Anthropometric** Pertaining to measurements of the body or body parts such as height and weight for the purposes of understanding human physical variation.
- Antibody** Protein produced by B cells that destroys or inactivates a specific antigen.
- Anticipatory anxiety** Anxious anticipation of an anxiety-provoking event.
- Anticodon** Sequence of three nucleotides in a transfer RNA molecule that is complementary to the messenger RNA codon.
- Antidiuretic hormone (ADH)** A posterior pituitary hormone that induces renal collecting duct cells to become permeable to water, thus decreasing the production of urine and reducing the osmolality of the blood.
- Antigen** Macromolecule that provokes an immune system response.
- Antimicrobial** A chemical or agent that inhibits microbial activity.
- Antisocial personality disorder** A mental disorder characterized by failure to acquire the conditioned responses that are necessary for the learning of avoidance behaviors, conventional morality, and socialized positive responses to others. Also known as *antisocial reaction*.
- Anuria** Severe decrease or lack of urine output of less than 100 ml per day.
- Anxiety disorders** General group that comprises three major diagnoses: panic disorder, generalized anxiety disorder, and obsessive-compulsive disorder. Anxiety disorders are characterized by irrational fears and have great potential to cause disability in affected persons.
- Aortic valve** The cardiac valve that lies between the left ventricle and the aorta. It is open during ventricular systole and closed during ventricular diastole. Aortic valve closure contributes to heart sound S<sub>2</sub>.
- Aphasia** A global disorder of language involving impaired speech (expressive aphasia) and

impaired ability to understand the spoken word (receptive aphasia).

**Aplastic anemia** A deficiency of the formed elements of blood (specifically erythrocytes, leukocytes, and platelets) because of failure of the bone marrow to produce them.

**Apocrine sweat gland** A sweat gland that becomes functional only after puberty and discharges its products onto the skin through the hair follicle (hair pore).

**Apoprotein** A polypeptide chain not yet bound to its specific prosthetic group.

**Apoptosis** Programmed cell death; characterized by DNA degradation and cell dissolution, but without necrosis.

**Appendicitis** Inflammation of the vermiform appendix due to an obstruction. This inflammation may lead to necrosis of the appendix, with subsequent abscess formation and peritonitis.

**Apraxia** An inability to execute previously learned skills, usually following a stroke.

**Arachnoid villi** Fingerlike projections in the delicate membrane between the dura mater and the pia mater of the brain.

**Archaea** A group of single-celled microorganisms, distinct from bacteria.

**ARDS** Acute respiratory distress syndrome; severe pulmonary dysfunction characterized by diffuse inflammatory injury to alveolar-capillary membranes.

**Arnold-Chiari II malformation** A congenital anomaly associated with meningocele and hydrocephalus in which the cerebellum and medulla oblongata protrude into the cervical spinal canal through the foramen magnum.

**Arterial pulse pressure** The difference between systolic and diastolic blood pressures.

**Arteriosclerosis** Generalized term for pathologic conditions resulting in decreased distensibility of arteries; also known as *hardening of the arteries*.

**Arteriovenous fistula** Abnormal communication between an artery and a vein.

**Arteriovenous malformation (AVM)** A congenital disorder of the connections between veins and arteries in the vascular system.

**Arteritis** Inflammation of an artery. May be associated with an autoimmune reaction.

**Arthralgia** Joint pain.

**Arthritis** Any inflammatory condition of the joints; characterized by pain, swelling, heat, redness, and limitation of movement.

**Articular (hyaline) cartilage** Connective tissue that forms a smooth, resilient, low-friction surface for articulation of two bones. It is without nerves, is avascular in adults, and derives nourishment from synovial fluid. It tolerates extreme compression stress.

**Articulation** A point of contact between bones. Also called *joint*.

**Ascites** Abnormal accumulation of fluid in the peritoneal cavity. Causes include liver disease, heart failure, constrictive pericarditis, infection, malnutrition, pancreatitis, lymphatic obstruction or leakage, renal disease, hypothyroidism, collagen vascular diseases, and malignancy.

**Aspiration** Inadvertent entry of food substances, liquids, or gastric contents into the respiratory system. This potentially life-threatening occurrence is normally prevented by the coordinated set of actions performed by the muscles in the pharynx during swallowing.

**Asthenia** The lack or loss of strength or energy; weakness.

**Asthma** A respiratory condition characterized by increased responsiveness of the trachea and bronchi to various stimuli and manifested by widespread narrowing of the airways and inflammation.

**Astigmatism** An abnormal condition of the eye in which the light rays cannot be focused clearly in a point on the retina because the spherical curve of the cornea or lens is not equal in all meridians. Vision is typically blurred.

**Ataxia** Failure of muscular coordination, resulting in incoordination and disturbances in posture and gait.

**Atelectasis** Full or partial collapse of the lung alveoli.

**Atherosclerosis** A type of arteriosclerosis characterized by proliferation of smooth muscle cells and lipid collection within the walls of arteries, resulting in narrowed lumina and impaired ability to dilate.

**Atopic** Pertaining to a hereditary tendency to experience immediate allergic reactions because of the presence of an antibody.

**Atopic dermatitis** An intensely pruritic, often excoriated inflammation of skin in allergy-prone individuals.

**Atopy** A genetic predisposition to allergies.

**Atresia** Congenital failure to develop (absence) or abnormal closure of a normally open passage.

**Atrial fibrillation** A completely disorganized and irregular atrial rhythm accompanied by an irregular ventricular rhythm of variable rate.

**Atrophy** A reduction in size and function of a cell or tissue; wasting.

**Attention-deficit/hyperactivity disorder (ADHD)** A mental disorder involving impaired or diminished attention, and impulsivity, and hyperactivity.

**Aura** A peculiar sensation preceding the appearance of more definite symptoms, as in migraines and seizures.

**Auscultatory gap** The time during cuff deflation after systolic blood pressure when the Korotkoff sounds disappear.

**Autism** A mental disorder primarily characterized by abnormal development of social interaction and communicative skills. Affected individuals may manifest an inability to perceive or understand others' feelings or to express their own feelings, and may adhere to rigid, nonfunctional behaviors or rituals.

**Autocrine** Relating to hormone-like chemicals in which the target cell is the same cell that secretes the chemical.

**Autocrine signaling** The secretion of factors that feed back onto the cell that secreted them. Usually used in reference to growth factors.

**Autografting** Surgical procedure to move skin from one area of the body to an area of injury.

The purpose is to provide permanent skin coverage to the injured area.

**Autoimmune liver disease** Hepatic injury from self-reactive antibodies produced by errant B lymphocytes.

**Autoimmunity** An inappropriate and excessive response of the immune system to self antigens causing disease. Disorders that result from an autoimmune response are called *autoimmune diseases*.

**Autologous** Pertaining to a tissue or structure occurring naturally and derived from the same individual such as blood donated by a patient before surgery to be returned to the patient.

**Automaticity** A property of specialized excitable tissue that allows self-activation through spontaneous development of an action potential, as in the pacemaker cells of the heart.

**Autonomic dysreflexia** Hyperreflexia; an uninhibited and exaggerated reflex of the autonomic nervous system in response to stimulation in patients with spinal cord injuries.

**Autoregulation** The intrinsic tendency of an organ or tissue to maintain adequate blood flow despite changes in metabolism or blood pressure.

**Autosomal dominant polycystic kidney disease** Hereditary disorder associated with defects on chromosome 16 (95% of cases) or chromosome 4 (5% of cases), resulting in dilation of all collecting ducts and impaired renal function.

**Autosomal recessive polycystic kidney disease** Congenital disorder linked to a defect on chromosome 6 that results in dilations of the renal collecting ducts and hepatic fibrosis.

**Autosome** Any ordinary paired chromosome, as distinguished from a sex chromosome.

**Avoidance** Refers to conscious or subconscious defensive reactions used to increase feelings of control and decrease the risk of anxiety.

**Avulsion fracture** A separation of a small fragment of bone at the site of attachment of a ligament or tendon.

**Axoneme** 1. Central core of a cilium or flagellum, consisting of two central fibrils surrounded by nine peripheral fibrils. 2. Motor apparatus of the sperm's tail.

**Azotemia** Increased levels of nitrogenous waste products, especially urea nitrogen, in the blood indicative of impaired renal clearance.

## B

**B cell** A type of lymphocyte that either produces antibodies to attack pathogens or directs other cells to attack pathogens. B cells that are actively producing antibodies are called *plasma cells*.

**Bacillus** A genus of aerobic or facultatively anaerobic, gram-positive, spore-bearing, rod-shaped bacteria that may or may not be motile.

**Bacteria** A domain of life existing as small unicellular microorganisms.

**Bacterial enzyme** An enzyme that aids in the microorganism's ability to spread or invade tissues; examples include fibrinolysin, coagulase, and hyaluronidase.

**Ball-and-socket joint** Formed by a ball-like surface fitting into a concave socket. Ball-and-socket joints permit flexion-extension,

- adduction-abduction, and rotational movements, such as those of the hip and shoulder.
- Baroreceptors** One of the pressure-sensitive nerve endings in the walls of the atria of the heart, the aortic arch, and the carotid sinuses.
- Barrett esophagus** A complication of chronic gastroesophageal reflux disease that represents replacement of the normal squamous epithelium of the distal esophagus by columnar tissue. Considered to be a preneoplastic condition.
- Bartholinitis** An inflammatory condition of one or both Bartholin glands; caused by bacterial infection.
- Basal energy expenditure** A term used to describe the calculated basal metabolic rate—the metabolic rate at rest.
- Basal ganglia** Groups of cell bodies (nuclei) located deep within the cerebral hemispheres that help plan and execute motor activities, including the caudate, putamen, globus pallidus, substantia nigra, and subthalamus.
- Basal metabolic rate** The amount of energy required for an individual to maintain vital processes such as respiration, digestion, and circulation at rest.
- Base** 1. The nonacid part of a salt. 2. A substance that accepts hydrogen ions in solution to form salts and increases pH.
- Basophil/basophilic granulocyte** A leukocyte that is functionally and chemically related to the mast cell; it has a kidney-shaped nucleus and large, deep basophilic granules, which contain vasoactive amine and heparin and are important in IgE binding.
- Beau line** Transverse furrow in the nail that indicates a disturbance in nail growth.
- Becker dystrophy** A milder form of inherited muscle degeneration than the Duchenne type and somewhat less common, with an annual incidence of 5 per 100,000. The genetic mutation leads to production of a reduced amount of an abnormal dystrophin protein and slower muscular degeneration.
- Bell palsy** An acute idiopathic unilateral paresis or paralysis of the facial nerve (cranial nerve VII) involving an inflammatory reaction at or near the stylomastoid foramen or in the bony facial canal.
- Bence Jones proteins** Proteins found in the urine of patients with plasma cell (multiple) myeloma. They are derived from overproduction of light chain fragments of antibodies by malignant plasma cells. Bence Jones proteins are nephrotoxic and may contribute to development of kidney disease.
- Benign breast disorders** A group of lesions affecting the breast, which are usually divided into two categories: fibrocystic breast disease and benign neoplasms of the breast.
- Benign prostatic hyperplasia or hypertrophy (BPH)** A noncancerous enlargement of the prostate gland.
- Benign tumor** A type of tumor that is strictly local, is usually well differentiated, and does not metastasize.
- β-Amyloid** Protein fragment snipped from a larger molecule—called *amyloid precursor protein*—during metabolism. Abnormal β-amyloid is a component of neuritic plaques found in Alzheimer disease.
- Biaxial joint** A joint that has two axes of movement and permits movement in two planes.
- Bile** A substance produced by hepatocytes in the liver and stored in the gallbladder. It is composed primarily of water, electrolytes, bile salts, cholesterol, and phospholipids. The major functions of bile are to aid in the digestion of dietary lipids through emulsification and to transport waste products, particularly bilirubin, into the intestine for disposal or reabsorption.
- Biliary atresia** Also called *extrahepatic ductopenia* or *progressive obliterative cholangiopathy*; biliary atresia can be either congenital or acquired. The latter occurs in the setting of certain autoimmune illnesses and is one of the principal forms of chronic rejection of a transplanted liver allograft. Biliary atresia is a rather common birth defect, occurring in 1 of 10,000 to 15,000 live births.
- Biliary cirrhosis** A disease initiated by damage to the bile ducts, which may be due to macroscopic or microscopic biliary obstruction. Persistent biliary obstruction results in inflammation and scarring of the liver, with obliteration of the bile ductules.
- Biliary colic** Persistent epigastric pain related to intermittent obstruction of the cystic duct, usually by a gallstone. A typical episode lasts several hours.
- Bilirubin** A substance formed from the degradation of erythrocytic hemoglobin by reticuloendothelial cells.
- Biliverdin** A greenish bile pigment formed in the breakdown of hemoglobin and converted to bilirubin.
- Bipennate** Pertaining to a muscle with a central tendon toward which the fibers converge on either side like the barbs of a feather.
- Bipolar disorder** A mood disorder characterized by alternating periods of mania and depression.
- Bladder calculus** A solid mass (stone) formed from debris within the bladder.
- Blast** An immature precursor form of a lymphoid or myeloid white blood cell. Blasts are not normally found in the peripheral blood because they are retained in the marrow until mature. The presence of blasts in the peripheral blood indicates leukemia.
- Blood pressure** The pressure exerted by the circulating volume of blood on the walls of the arteries.
- Blood urea nitrogen (BUN)** Urea is an end product of amino acid metabolism, measured in the blood as BUN and excreted primarily by the kidney.
- Blunted affect** A severe reduction in the intensity of externalized feelings.
- Body fluid** The water contained in the body plus the substances dissolved in it.
- Body mass index (BMI)** A weight reference standard. The formula for BMI is weight (kg) divided by height squared (m<sup>2</sup>).
- Body water** All of the water contained in the body.
- Bolus** 1. A round mass of food that has been softened and formed into an appropriate size for swallowing by the action of chewing. 2. A concentrated mass of pharmaceutical preparation.
- Bone and joint tuberculosis** An extrapulmonary form of tuberculosis that occurs after lymphohematogenous spread from a primary lung lesion.
- Bone marrow suppression** Suppression of bone marrow activity, resulting in reduction in the number of platelets, red blood cells, and white blood cells, such as in aplastic anemia. Also called *myelosuppression*.
- Borderline personality disorder** Personality disorder that represents a pervasive and persistent disturbance in ways of handling events and situations. Personalities influenced by this disorder are unstable, unpredictable, impulsive, and often moody and self-deprecating. Some overlap with depression is suggested.
- Brainstem** Portion of the brain consisting of the midbrain, pons, and medulla oblongata and mesencephalon.
- Branched-chain amino acids** A group of amino acids that includes valine, leucine, and isoleucine; they are mainly metabolized in the muscle for energy.
- Bronchiectasis** A disorder characterized by destruction of the elastic and muscular structures; results in dilation of the bronchi.
- Bronchiolitis** Inflammation of small bronchi.
- Bronchitis** Widespread inflammation of bronchi and bronchioles attributable to infectious agents or allergic reactions.
- Bronchospasm** Narrowing of the bronchi and bronchioles because of abnormal contraction of the smooth muscles of the bronchial walls.
- Bruit** Sound generated by turbulent blood flow auscultated over a blood vessel.
- Brush border** Covering of the microvilli projecting from some types of epithelial cells, such as proximal renal tubule cells and the intestinal villi. This fuzzy coating contains many enzymes and transporters.
- Buck fascia or fascia of Buck** Thick fibrous envelope surrounding the tunica albuginea, which encloses each of the erectile bodies of the penis.
- Buckle fracture** A fracture in children whereby the bone buckles and eventually cracks as a result of a compression injury to cancellous bone of the metaphysis of a long bone.
- Buffer** A chemical that releases hydrogen ions when a fluid is too alkaline and takes up hydrogen ions when a fluid is too acidic.
- Bulbourethral glands** Also called *Cowper glands*, these two glands produce viscous fluid that is secreted into the urethra near the base of the penis.
- Bulbous urethra** The proximal portion of the penile urethra. The bulbous urethra is surrounded by the bulb of the urethra and the bulbospongiosus muscle.
- Bulimia nervosa** Recurrent episodes of binge eating followed by self-induced vomiting or diarrhea, excessive exercise, strict dieting, or fasting; person has an exaggerated concern about body shape and weight.

**Bulla** Large, thin-walled cyst. Commonly used in reference to lung or skin.

**Bursa** Pocket of connective tissue lined with liquid-containing synovium; located between muscles or between muscle or tendon and bone.

**Byler syndrome** A rare autosomal recessive disorder involving severe jaundice, pruritus, and malabsorption caused by an error in bile salt metabolism. Also called *progressive intrahepatic cholestasis* and *progressive familial intrahepatic cholestasis*.

## C

**Cachexia** A combination of symptoms, including anorexia, weight loss, muscle wasting, and weakness, that is associated with the severe malnutrition of chronic diseases such as cancer.

**Calcitonin** A hormone produced by thyroid parafollicular cells, it influences the processing of calcium by bone cells.

**Calculus** A mass of solid mineral or metabolic substance. A stone.

**Callus (bone)** The bony deposit formed between and around the broken ends of a fractured bone during healing. Also called *keratoma*.

**Calluses (skin)** Common, usually painless thickenings of the stratum corneum at locations of external pressure or friction.

**Cancellous bone** Bone with a spongy or lattice-like appearance; found in the interior of bones. Cancellous bone does not tolerate compression stress.

**Cancer cachexia** The severe nutritional effects of cancer. See *cachexia*.

**Capacitation** The multiple changes that activate sperm and enhance their ability to participate in the final process of fertilization.

**Capillary hydrostatic pressure** The outward push of the vascular fluid against the capillary walls that is caused by blood pressure.

**Capillary osmotic pressure** The inward pull of particles in the vascular fluid from dissolved proteins in the blood; also called *oncotic pressure*.

**Carbohydrates** The main energy source for the body; consists of simple or complex sugars. They must be supplied in a fairly constant manner to meet the energy requirements for normal body functioning. Provides 4 kcal/gm of energy when metabolized.

**Carbonic anhydrase** The enzyme that catalyzes the reversible conversion of carbon dioxide and water to carbonic acid.

**Carcinogen** A substance that initiates or promotes the development of cancers. Most carcinogens cause cancer by damaging DNA to produce mutations.

**Carcinoma in situ** A premalignant neoplasm that has not invaded the basement membrane but shows cytologic characteristics of cancer.

**Cardiac asthma** Results from bronchospasm precipitated by congestive heart failure.

**Cardiac catheterization** A diagnostic procedure in which a catheter is introduced through an incision into a large vein or artery (cardiac angiography) and threaded through the circulatory system to the heart.

**Cardiac cycle** A cardiac cycle includes one diastolic and one systolic phase.

**Cardiac index** A measure of the heart's pumping ability taking into account body surface area. The cardiac index is calculated by dividing cardiac output by body surface area. A cardiac index less than 2.0 L/min/m<sup>2</sup> is considered to be insufficient for adequate peripheral perfusion.

**Cardiac output** A measure of the amount of blood pumped by the heart in 1 minute; usually expressed in liters per minute.

**Cardiac tamponade** Abnormal external pressure on the heart that results in poor cardiac filling and decreased cardiac output.

**Cardiogenic shock** A condition of low cardiac output and inadequate perfusion of tissues associated with acute myocardial infarction and congestive heart failure.

**Cardiomyopathy** Diseases that primarily affect myocardial cells, often of unknown cause. Three common types of cardiomyopathy are dilated, hypertrophic, and restrictive.

**Carina** A ridgelike structure at the base of the trachea that projects from the area that separates the left and right bronchi.

**Carpal joint** A synovial joint between the carpal bones.

**Carrier** A person who harbors a recessive gene for a particular trait. A recessive heterozygote.

**Carrier proteins** Proteins located in lipid bilayers that transport ions and small molecules through the membrane by first binding on one side and then moving to the other side by changing conformation.

**Cartilaginous joint** A joint that connects bony segments by fibrocartilage or hyaline growth cartilage.

**Casts** White or red blood cells that collect in a nephron tubule and conform to the shape of the tubule; their presence indicates infection or inflammation of the kidney.

**Catabolism** The process of converting large molecules of carbohydrate, protein, and fat to smaller molecules to be utilized for energy.

**Cataracts** An abnormal progressive condition of the lens of the eye that is characterized by loss of transparency.

**Catecholamine** A hormone (e.g., epinephrine and norepinephrine) that stimulates glycogenolysis and gluconeogenesis. An amine neurotransmitter (e.g., norepinephrine, dopamine).

**Catecholamine hypothesis** A hypothesis that abnormally low catecholaminergic neurotransmission leads to depression and abnormally high catecholaminergic neurotransmission leads to mania.

**Caudal** Signifying a position toward the distal end of the body, or an inferior position.

**Caudate nuclei** Portion of each cerebral hemisphere that, together with the lentiform nuclei, forms the corpus striatum of the basal ganglia.

**Celiac disease** Also called *celiac sprue*, this disease is characterized by intolerance of gluten, a protein in wheat and wheat products; ingestion of gluten causes abdominal distention and malabsorption.

**Cell cycle** The phases through which a cell progresses during cellular reproduction, including gap 1, synthesis, gap 2, and mitosis.

**Central venous pressure** The blood pressure in the large veins of the body measured in the right atrium of the heart.

**Centromere** Constricted region that holds two sister chromatids together. The centromere is the site of attachment to the microtubules, which pull the chromatids apart during mitosis.

**Centrosome** A centrally located organelle that organizes microtubules in the cell. It acts as the spindle pole during mitosis.

**Cerebellum** Portion of the brain attached to the brainstem; it has an essential role in maintaining muscle tone and posture and coordinating normal movements.

**Cerebral dysrhythmia** An abnormality in an otherwise normal rhythmic pattern, as seen on electroencephalography.

**Cerebral edema** An accumulation of fluid in the brain tissues. Causes include infection, tumor, trauma, or exposure to certain toxins. Because the skull cannot expand to accommodate the fluid pressure, brain tissues are compressed.

**Cerebral palsy** Refers to a diverse group of crippling syndromes that appears during childhood and involves permanent, nonprogressive encephalopathic damage to the developing brain.

**Cerebrospinal fluid** Fluid found in the cavities and canals of the brain and spinal cord.

**Cerebrotendinous xanthomatosis** A steroid hydroxylase deficiency that leads to premature atherosclerosis and encephalopathy. Also known as *van Bogaert disease*.

**Cerebrovascular accident (CVA)** An abnormal condition of the brain characterized by occlusion by an embolus, thrombus, hemorrhage, or vasospasm, resulting in ischemia of the brain tissues. Also called *stroke*, or *brain attack*.

**Cerebrum** Portion of the brain that controls consciousness, memory, sensations, emotions, and voluntary movements. The largest part of the brain, it consists of two hemispheres.

**Ceruminous gland** A special variety or modification of an apocrine sweat gland. The mixed secretions of sebaceous and ceruminous glands form a brown waxy substance called *cerumen*, which protects the ear canal from dehydration.

**Chagas disease** Caused by *Trypanosoma cruzi* and transmitted to humans by bloodsucking insects. It is a common cause of acquired myocarditis and megacolon in Central and South America but is rarely seen in the United States.

**Chancere** Painless, ulcerative lesion arising at the original port of entry of the spirochete that causes syphilis.

**Chancroid** An ulcerative, infectious disease of the genital tract caused by the sexually transmitted bacillus *Haemophilus ducreyi*. Unlike the chancre in syphilis, the lesion in chancroid is painful, tender, and often multiple.

**Channel proteins** Proteins located in lipid bilayers; they form porelike structures that allow ions to pass through by diffusion when appropriately stimulated.

- Chemodissolution** Use of chemical substances, such as bile acids or organic solvents, to dissolve gallstones. Used as a nonoperative method to treat gallstones.
- Chemokines** Any of a group of low-molecular-weight cytokines. They function as regulators of the immune system that help immune cells localize to areas of injury.
- Chemotaxis** The movement of cells according to chemical gradients (chemotaxins) that attract them.
- Chemotherapy** The treatment of cancer, infections, and other diseases with chemical agents. Chemotherapeutic agents are often cytotoxic.
- Chest physiotherapy** Use of percussion and postural drainage to mobilize secretions from specific segments of the lungs.
- Chickenpox** Also called *varicella*. Chickenpox is a common communicable childhood disease. It is caused by the varicella-zoster virus, which is also the causative agent in shingles. The characteristic skin lesion occurs in three stages: macule, vesicle, and granular scab.
- Chlamydia** Genus of a microorganism that lives as an intracellular bacterium. *Chlamydia trachomatis* inhabits the epithelium of the urethra and cervix and is responsible for the highly contagious systemic infection *lymphogranuloma venereum*.
- Chloride shift** An exchange of chloride ions for bicarbonate ions ( $\text{HCO}_3^-$ ) in red blood cells in peripheral tissues as a response to changes in the  $\text{PCO}_2$  of blood.
- Cholecalciferol** Precursor substance of active vitamin D.
- Cholecystectomy** Surgical removal of the gallbladder.
- Cholecystitis** Inflammation of the gallbladder wall; may be acute or chronic and usually is associated with cholelithiasis.
- Cholecystokinin** Hormone secreted from the small intestinal mucosa; two of its chief functions are stimulation of the release of pancreatic enzymes during a meal and contraction of the gallbladder.
- Cholelithiasis** Formation of stones in the gallbladder.
- Cholesterol** A lipid-soluble compound that facilitates the absorption and transport of fatty acids in bile and provides the building blocks for steroid hormone production.
- Cholinergic-noradrenergic imbalance hypothesis** A hypothesis that suggests that a relative increase in the ratio of acetylcholine activity to norepinephrine activity produces depression and that mania is the result of a relative increase in the ratio of norepinephrine activity to acetylcholine activity.
- Chondroblasts** Any one of the cells that develop from the mesenchyme and form cartilage. They play an important role in endochondral ossification and especially in longitudinal bone growth.
- Chondroma** Also called *enchondroma*; a cartilage-forming tumor located within bone that accounts for about 15% of benign bone tumors.
- Chondrosarcoma** A malignant cartilage-forming tumor; chondrosarcomas tend to develop in the pelvic and shoulder girdles and the proximal ends of long bones.
- Chordae tendineae** Bands of fibrous connective tissue that anchor the atrioventricular valves to the papillary muscles of the ventricular chambers.
- Chorionic villus sampling** A procedure in which tissue is obtained from the placenta by ultrasound-guided biopsy. Chorionic villus sampling can be performed earlier in pregnancy (10 to 12 weeks) than amniocentesis (16 weeks).
- Chromatid** One copy of a chromosome formed by DNA replication that may be joined to the other copy (sister chromatid) at the centromere.
- Chromosome** A linear thread of nuclear DNA that becomes visible under the microscope during cell mitosis.
- Chronic** Refers to a condition that lasts for a long time, generally from 6 months to years.
- Chronic active hepatitis** A progressive, destructive inflammatory disease that extends beyond the portal triad to the hepatic lobule (piecemeal necrosis).
- Chronic bronchitis** A condition characterized by excessive secretion of bronchial mucus and manifested by productive cough for 3 or more months in at least 2 consecutive years in the absence of any other disease process that may cause this symptom.
- Chronic hepatitis** Ongoing inflammation of the liver, usually of more than 6 months' duration, following viral hepatitis or attributable to autoimmune disease.
- Chronic persistent hepatitis** Also called *triditis* or *transaminitis*. A benign disease in which the inflammation is confined to the portal triads without destruction of normal liver functions despite elevated serum transaminase levels.
- Chronic renal failure** Gradual loss of renal function that is progressive and irreversible.
- Chronic venous insufficiency** Varicosity of the deep veins that prevents effective return of blood from the periphery. Usually manifests as edema.
- Chylothorax** An accumulation of chylous fluid attributable to leakage of chyle (lymph fluid) from the thoracic duct or to rheumatoid pleural effusion or tuberculous pleuritis. Also called *chylous pleural effusion*.
- Chyme** Viscous, semifluid contents of the stomach following the mixture of ingested nutrients with gastric secretions. Chyme then passes through the pylorus into the duodenum, where further digestion occurs.
- Cilia** Motile hairlike processes on the surface of some cells.
- Circadian rhythm** The regular recurrence of certain biological phenomena in approximately 24-hour cycles, regardless of constant darkness or other conditions of illumination.
- Circumferential burn** A burn injury that wraps completely around an extremity or the trunk. Loss of elasticity of skin results in a tourniquet effect, compromising circulation to distal tissues or respiratory expansion of the chest. Escharotomy or fasciotomy is necessary.
- Cirrhosis** A diffuse, irreversible scarring of the liver resulting in abnormal nodules of liver cells surrounded by fibrosis.
- Citric acid cycle** A sequence of enzymatic reactions in the mitochondrial matrix that produces carbon dioxide and high-energy electrons from acetyl coenzyme A.
- Clang association** Association of words similar in sound but not in meaning, or words having no logical connection; may include rhyming and punning.
- Clinical dehydration** The combination of extracellular fluid volume deficit and hypernatremia.
- Clinical manifestations** The functional consequences of the structural and associated alterations in cells or tissues that are either characteristic of the disease or diagnostic of the process.
- Clonic** Characterized by alternating periods of involuntary muscular contraction and relaxation in rapid succession.
- Closed fracture** A type of fracture that occurs when fragments of a fracture do not extend through mucous membranes or skin and skin is not broken.
- Closing volume** Lung volume at which airways in the lower lung zones collapse and ventilation ceases.
- Clotting factors** Proteins that circulate in inactive forms and can be triggered to initiate a clotting cascade to produce insoluble fibrin clots.
- Clubbing** A process characterized by flattening of the angle of the base of the nail. It may occur in association with cardiovascular disease, subacute bacterial endocarditis, and pulmonary disease.
- CO<sub>2</sub>** Carbon dioxide; this gas is produced by cells during metabolism, is carried in the blood as carbonic acid, and is excreted by the lungs.
- Coagulation** The process of blood clot formation.
- Coagulopathy** An abnormality in blood clot formation.
- Cocci** Round nonmotile bacteria.
- Codon** Sequence of three nucleotides in DNA or messenger RNA that represents the instruction for a particular amino acid in a polypeptide chain.
- Collagen** Most abundant protein in the body. The major protein of the white fibers of connective tissue. Has tensile strength similar to that of steel and is responsible for functional integrity of connective tissue.
- Colloid osmotic pressure** Pressure produced by passage of fluid from an area of less concentration to an area of higher concentration of colloids (large charged molecules such as proteins).
- Colonic or anal agenesis** Imperforate anus.
- Colonization** Harmless inhabitation of the skin or mucous membranes by microorganisms.
- Colostomy** Establishment of an artificial opening of the colon on the abdominal wall; usually performed following removal of a diseased or injured bowel segment.
- Comminuted fracture** A fracture consisting of more than one fracture line and more than two bone fragments.

- Compact bone** Hard, dense bone that is usually found at the periphery of skeletal structures.
- Compartment syndrome** A syndrome resulting from trauma to soft tissue caused by swelling within the unyielding structure of a nonelastic tissue or device (e.g., a cast).
- Compensation** The counterbalancing of any defect of structure or function. For example, a process that tends to restore pH to normal by making other blood chemistry values abnormal.
- Complement** A protein that participates in a cascade of reactions resulting in inflammation and cell lysis. Complement activation can occur by the classical or the alternative pathways.
- Complete fracture** A fracture whose line disrupts bone continuity through the whole thickness of the bone, including the cortex.
- Compliance** A measure of the ease of elastic distensibility of a hollow organ.
- Complication** A new or separate process that may arise secondarily because of some change produced by the original entity. For example, bacterial pneumonia may be a complication of viral infection of the respiratory tract.
- Compression fracture** Consistent with cancellous bone trauma. Also called a *crush fracture*.
- Compulsion** Repetitive ritualistic behavior that has a driven quality.
- Concentric contraction** The shortening contraction of a muscle when the muscle force generates sufficient tension to overcome the resistance of the limb. One example is lifting a cup of water to one's mouth.
- Condyloid joint** A joint that permits flexion and extension at one axis and adduction and abduction around another axis, such as the metacarpophalangeal joint of the hand.
- Condyloma acuminatum; condylomata acuminata** Genital wart(s) caused by papillomavirus forms.
- Conformational change** A movement or alteration in the three-dimensional formation of a protein without any change in amino acid structure.
- Congenital adrenal hyperplasia** Overproduction of adrenal androgens attributable to a lack of an enzyme needed for cortisol production. Symptoms include virilization of the female infant's genitalia.
- Congenital ichthyosis** An inherited disease characterized by an excessive growth of keratinocytes and keratin, which gives the skin a fish-scale appearance.
- Congenital immunodeficiency** Rare condition that results from improper development of immune system components before birth.
- Congenital malformation** A general term meaning a defect in form or function that is present at birth.
- Congestive heart failure** Dysfunctional cardiac pumping that results in congestion of blood behind the dysfunctional cardiac pump. Right-sided heart failure is associated with systemic venous congestion. Left-sided heart failure is associated with pulmonary congestion.
- Consanguinity** Mating of blood-related individuals.
- Consolidation** The process of tissues becoming firm and solid, such as when the lung alveoli become firm while air spaces are filled with exudate in pneumonia.
- Constipation** A condition of having small, infrequent, and difficult bowel movements. Authorities have established a norm of fewer than three stools per week as a guideline for defining constipation.
- Contact dermatitis** A cutaneous reaction to topical irritation or allergy. Irritant contact dermatitis can develop in any person exposed to a sufficiently high concentration of the irritating agent. Some of the more active irritants are acids, alkalis, and hydrocarbons.
- Contact hypersensitivity** Allergy to a substance that produced a reaction in a previous contact. Usually occurs on the skin and may take several hours to develop (type IV hypersensitivity).
- Continent** The ability to control bladder or bowel function.
- Contractile tissue** Tissues involved in the contraction of muscle, including not only the muscle belly but also the tendon and bony insertion.
- Contractility** The force and velocity of cardiac muscle shortening in response to stimuli that increase cytoplasmic free calcium ion levels.
- Contraction time** The time from initial tension development to peak tension.
- Contralateral** Referring to the opposite side of the body.
- Convalescence** The stage of recovery after a disease, injury, or surgical operation.
- Coombs antiglobulin test** The direct test is an assay for antibody that is attached to red blood cells; the indirect test is an assay for antibody circulating in serum.
- Coping** A measure of the individual's resourcefulness and ability to deal with stress and stressors.
- Corns** Horny masses of condensed epithelial cells overlying bony prominences. Corns result from chronic friction and pressure.
- Coronary angiography** Radiographic visualization of the internal anatomy of the heart and blood vessels with the use of intravascular introduction of radiopaque contrast medium.
- Cor pulmonale** Right ventricular hypertrophy secondary to pulmonary diseases that increase right ventricular afterload.
- Corpora cavernosa** Two paired erectile bodies that lie dorsally in the penis.
- Corpus luteum** Anatomic structure on the surface of the ovary that grows in the ruptured ovarian follicle following ovulation and acts as a temporary endocrine organ that secretes progesterone.
- Corpus spongiosum** Erectile body in the penis containing the urethra.
- Correction** A process whereby normal values are restored when the underlying cause is addressed. An example would be restoring pH to normal by addressing the underlying cause of an acid-base imbalance.
- Cortical bone** The dense cortex or outer shell of bone; designed to tolerate compression and shearing forces.
- Corticosteroid** A hormone produced by the adrenal gland that stimulates gluconeogenesis and contributes to insulin resistance (e.g., cortisol); or a drug that has similar effects.
- Cortisol** A glucocorticoid (steroid hormone) released by the adrenal gland that causes an increase in blood glucose level by promoting liver gluconeogenesis.
- Coryza** A head cold with profuse nasal drainage.
- Costovertebral angle** Area lateral to the sacrospinalis muscle and beneath the twelfth rib used as an external landmark for the kidneys.
- Cowper glands** Also called *bulbourethral glands*, these two glands produce viscous fluid that is secreted into the urethra near the base of the penis.
- Crackles** (pronounced "rahls"); discontinuous fine crackling sounds, usually heard on inspiration, that are indicative of air moving through fluid.
- Cradle cap** A seborrheic condition in infants characterized by scaling of the scalp. Occurs as a result of infrequent or inadequate washing of the scalp.
- Cranial nerve reflexes** The 12 pairs of nerves emerging from the cranial cavity that carry impulses for such functions as the senses.
- Creatine kinase** An enzyme that catalyzes the transfer of a phosphate group between adenosine triphosphate and creatine. The isoenzyme found in cardiac muscle is called *CK-MB* (the MB fraction of creatine kinase).
- Creatinine** End product of muscle metabolism that is filtered freely through the glomeruli and excreted by the kidney only. Creatinine clearance is used as a measure of glomerular filtration rate.
- Cretinism** Extreme hypothyroidism during infancy and childhood that causes mental and physical abnormalities.
- Cricothyroidotomy** Incision through the site below the thyroid cartilage for emergency opening of the tracheal passageway.
- Crigler-Najjar syndrome** A rare autosomal recessive disorder marked by severe unconjugated hyperbilirubinemia seen shortly after birth.
- Crohn disease** An inflammation of the gastrointestinal tract that extends through all layers of the intestinal wall, most commonly affecting the terminal ileum. It may affect multiple portions of the intestine, leaving intervening normal areas in between the affected regions. The manifestations of Crohn disease differ in some respects from those of *ulcerative colitis*, although some overlap may occur. In Crohn disease, abdominal pain is the predominant symptom.
- Cross-bridge** The interaction between thick and thin filaments of the contractile apparatus when myosin heads bind to actin.
- Cross-bridge theory** This theory of muscle contraction is suggested by the anatomic configuration of the sarcomere. Muscle shortening is accomplished by increasing the amount of overlap of actin and myosin filaments. Also called the *sliding filament theory*.
- Croup** An acute infection of the upper and lower respiratory tracts that occurs primarily in

- infants and young children; it is characterized by hoarseness and a distinctive harsh cough.
- Crush fracture** A fracture that is consistent with cancellous bone trauma. Also called *compression fracture*.
- Cryptogenic cirrhosis** Advanced liver disease in a small number of patients with neither a suggestive history nor any detectable markers that would place them in any of the four main groups of cirrhosis.
- Cryptorchidism** Undescended testes.
- Culture** An integrated pattern of customs, attitudes, values, and shared beliefs that bind people together to form a society.
- Cushing disease** Hyperfunctioning of the adrenal cortex with increased glucocorticoid (cortisol) secretion because of excessive secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary.
- Cushing syndrome** The clinical features of hypercortisolism, regardless of cause.
- Cutaneous membrane** Thin, flat organ, also known as *skin*. It is composed of two main layers: an outer, thinner layer, termed the *epidermis*; and an inner, thicker layer, termed the *dermis*.
- CVA tenderness** The costovertebral angle is one of two angles that outlines a space over the kidneys. Pain in this area is a common finding in pyelonephritis and other infections of the kidneys.
- Cyanosis** A blue coloration of the skin as a result of poor saturation of hemoglobin with oxygen. Cyanosis is usually not evident until saturation falls below 75%.
- Cystectomy** Surgical removal of all or part of the urinary bladder.
- Cystic fibrosis** An autosomal recessive condition with abnormal chloride channel function, producing lung and pancreatic disease in children.
- Cystic kidney disease** Acquired cystic kidney disease and polycystic kidney disease, where cysts form in the kidneys.
- Cystitis** Inflammation of the urothelium (lining of the bladder) resulting from infection, irritation, presence of foreign body, or trauma.
- Cystocele** Protrusion of a portion of the urinary bladder into the anterior vagina at a weakened part of the vaginal musculature. Predisposing factors include obesity, aging, inherent weakness, history of heavy-object lifting, or injury during childbirth or surgery.
- Cytokine** A peptide factor released by cells to influence the behavior of target cells. Cytokines have signaling, inflammatory, growth, and inhibitory functions.
- Cytopathic** Pertaining to significant cellular injury or death.
- Cytoskeleton** System of protein filaments in the cytoplasm of a cell that give the cell its shape and the capacity for purposeful movement.
- D**
- Decubitus ulcer** Localized area of cellular necrosis resulting from prolonged pressure between a bony prominence and an external object such as a bed or wheelchair. The tissues are deprived of blood supply and eventually die. Also called *pressure sore*.
- Deep partial-thickness burn** Second-degree burn characterized by destruction of entire dermis, leaving only epidermal skin appendages. All physiologic functions of skin are absent.
- Deep vein thrombosis (DVT)** A disorder involving a thrombus in one of the deep veins of the body, most commonly in the lower extremities.
- Degranulate** The release of granules by mast cells and basophils; the granules contain proinflammatory chemicals.
- Degranulation** Exocytosis of stored molecules contained in cytoplasmic vesicles.
- Dehydration** Excessive loss of water from body tissues, accompanied by an increase in serum osmolality and an increase in serum sodium level (hypernatremia).
- Dehydroepiandrosterone (DHEA)** An androgenic steroid hormone secreted largely by the adrenal cortex and found in human urine.
- Deletion** The loss of a piece of a chromosome.
- Delirium** An acute organic mental disorder characterized by confusion, disorientation, restlessness, and incoherence.
- Delusion** A fixed, false belief that is held despite considerable contradictory evidence.
- Delusional disorder** A behavioral constellation dominated by a system of fixed, false beliefs that are tenacious and typically refractory to contrary evidence.
- Dementia** Syndrome characterized by a general loss of intellectual abilities caused by either reversible or progressive disorders, most typically Alzheimer disease or multiinfarct dementia.
- Demyelination** Destruction, removal, or loss of the myelin sheath of a nerve or nerve fibers.
- Dendritic cells** A cell that captures antigens and migrates to the lymph nodes and spleen, where it presents the processed antigen to T cells.
- Deoxyribonucleic acid (DNA)** The biomolecule that carries genetic information in the cell. DNA is composed of covalently linked nucleotides that form long polymers.
- Depressed fracture** A fracture in which the fragment is displaced below the level of the surface of the bone, usually in the skull.
- Depressed mood** A hallmark symptom of major depression. This change in mood is relatively constant and is recognized both by the depressed person and by others.
- Depression** An abnormal mood disturbance characterized by exaggerated feelings of sadness and melancholy. Also known as *clinical depression*.
- Dermatitis** Inflammation of the skin.
- Dermatome** An area of skin that is innervated by a specific spinal cord segment.
- Dermatomyositis** A rare collagen disorder characterized by the acute or insidious onset of muscle pain, weakness, fever, arthralgia, and, in some cases, a puffy erythematous eruption that is usually confined to the face and the eyelids.
- Dermatophyte** A fungus that causes infection of the skin. The most common dermatophytes are *Microsporium*, *Trichophyton*, and *Epidermophyton*.
- Dermatosis** Any disorder of the skin, especially those not associated with inflammation.
- Dermis** Inner, thicker layer of the cutaneous membrane.
- Dermoepidermal junction** The specialized area where the cells of the epidermis meet the connective tissue cells of the dermis.
- Desensitization** The process of manipulating or “training” the hypothalamus to react less forcefully to a perceived threat or stressor. This technique works by changing the predominant brain waves of the individual from beta waves to alpha waves that are slower and more normal.
- Desquamation** The shedding of epithelial elements from the skin surface.
- Detrusor muscle** Smooth muscle of the bladder body.
- Diabetes insipidus** An endocrine deficiency of antidiuretic hormone manifesting as excretion of large quantities of very dilute urine and excessive thirst.
- Diabetes mellitus** An endocrine disorder characterized by impaired glucose entry into insulin-sensitive cells because of an absolute or relative deficiency of insulin.
- Diabetic retinopathy** A disorder of retinal blood vessels characterized by capillary microaneurysms. It occurs most frequently in patients with long-standing poorly controlled diabetes mellitus.
- Dialysate fluid** Prepared solution with varying concentrations of glucose and electrolytes used to aid dialysis.
- Dialysis** An artificial process that replaces the renal functions of diffusion and filtration necessary to maintain homeostasis.
- Diaper rash** A skin irritation resulting from feces or the ammonia and alkali by-products of urine breakdown.
- Diarrhea** An increase in the frequency and fluidity of bowel movements. It is usually a primary sign of gastrointestinal tract disorders.
- Diarthrosis** Also called *synovial joint*; a freely movable joint in which a contiguous bony surface is covered by articular cartilage and connected by a fibrous connective tissue capsule lined with a synovial membrane.
- Diastole** A phase of the cardiac cycle in which the ventricles are relaxing and filling with blood.
- Diastolic blood pressure** The lowest measured pressure in the arteries just prior to the next ventricular ejection.
- Dicrotic notch** A small, downward deflection observed on the downstroke of an arterial pressure waveform, representing closure of the aortic or pulmonic valves at the onset of ventricular diastole.
- Diencephalon** “Between” brain; part of the brain between the cerebral hemispheres and the midbrain.
- Diffusion** Passive movement of a gas or other substance from an area of high concentration to low concentration, or the process by which solutes move across a semipermeable membrane from an area of greater concentration to one of lesser concentration.
- Diffusion coefficient** A constant that depends on the properties of the tissue and the solute; the rate of movement of a solute is proportional to the diffusion coefficient.

**Diploid** Containing two sets of homologous chromosomes and, therefore, two copies of each gene—one from each parent.

**Disconjugate** An abnormal positioning of the eyes such that they deviate from one another in the direction of gaze.

**Disease** Sum of the deviations from normal structure or function of any part, organ, or system (or combination thereof) of the body manifested by a characteristic set of symptoms and/or signs and whose cause, pathogenesis, and prognosis may be known or unknown.

**Dislocation** Displacement of a bone from its normal position in a joint to the degree that the articulating surfaces lose contact.

**Displaced fracture** A fracture in which the ends of fragments are separated.

**Disseminated intravascular coagulation (DIC)** A grave coagulopathy resulting from the inappropriate stimulation of clotting and fibrinolytic processes within the vascular system; it is often precipitated by immune mechanisms.

**Distributive shock** State of insufficient perfusion of body tissues because of abnormal distribution of blood (for example, with anaphylaxis, sepsis, and spinal cord injury).

**Disuse atrophy** The tendency of cells and tissues to reduce size and function in response to lack of trophic stimuli.

**Disuse osteoporosis** Reduction in quantity of bone or atrophy of skeletal tissue in response to lack of weight-bearing activity. May occur with prolonged bed rest.

**Diuresis** Excretion of large amounts of urine as a result of the actions of a diuretic.

**Diurnal variation** The regular (24-hour) recurrence of certain biological phenomena under conditions of illumination; recurring during the daytime, or period of light.

**Divergence** A separation or movement of objects away from each other.

**Diverticulitis** Inflammation of one or more diverticula, or outpouchings, in the intestinal wall.

**Diverticulosis** The presence of diverticula, or outpouchings, in the wall of the colon.

**Diverticulum** Outpouching of one or more layers of the wall of a structure in the gastrointestinal tract, especially in the colon or esophagus.

**DNA polymerase** An enzyme complex that binds to DNA, using it as a template for synthesis of a complementary DNA strand.

**Dominant** Referring to the gene allele that is overtly expressed in the cell's phenotype. Opposite of recessive.

**Dopamine hypothesis** A hypothesis that postulates that schizophrenia is the result of neuronal overactivity dependent on dopamine.

**Down-regulation** A decrease in the number of cell receptors for a specific hormone resulting from the cell's prolonged exposure to high concentrations of the hormone. Down-regulation results in a decrease in the target cell response to a hormone.

**Drug-induced asthma** Asthma related to an ingested drug. An attack may occur within minutes of ingestion or may be delayed up to

12 hours. Nonsteroidal antiinflammatory drugs including indomethacin (Indocin) and ibuprofen (Motrin, Advil) are common causes.

**Duchenne muscular dystrophy** The most common and most severe form of muscular dystrophy; it is inherited as an X-linked trait and therefore afflicts only males.

**Ductus deferens** Thick, muscular tube that is continuous with the epididymis. The ductus deferens travels along the pelvic wall and joins with the seminal vesicle duct at the prostate to form the ejaculatory duct. Also called *vas deferens*.

**Dumping syndrome** The rapid emptying or “dumping” of stomach contents into the proximal small intestine attributable to loss of pyloric regulation of gastric emptying. This loss of function may occur following a gastrectomy.

**Dysconjugate** See *disconjugate*.

**Dysfunctional uterine bleeding** Abnormal endometrial bleeding not associated with tumor, inflammation, pregnancy, or trauma. It is most common around the time of menarche and menopause.

**Dyslipidemia** Abnormality in the concentrations of lipids and lipoproteins in the blood, especially an elevated low-density lipoprotein (LDL) level and a reduced high-density lipoprotein (HDL) level.

**Dysmenorrhea** Pain associated with menstruation; usually classified as primary (unrelated to an identifiable disease) or secondary (related to the presence of an underlying disease).

**Dyspareunia** Pain during sexual intercourse because of vaginal muscle spasms.

**Dysphagia** Difficulty in swallowing as perceived by the individual. It may include the inability to initiate swallowing and/or the sensation of ingested substances sticking to the esophagus.

**Dysphoria** The constant experience of unpleasant emotions.

**Dysplasia** An alteration in cellular growth in which cell morphologic characteristics are variable and disorderly. Dysplastic cells may become cancerous and therefore are often termed *preneoplastic*.

**Dyspnea** Breathlessness or difficulty breathing.

**Dysrhythmia** An abnormality of heart rhythm, including altered rates or sites of impulse initiation and abnormal conduction pathways.

**Dysthymia** A state of chronic depression.

**Dystrophic** Abnormal tissue growth that impairs function. May result from disordered growth (trophic) signals.

## E

**Eating disorder** A group of behaviors often fueled by unresolved emotional conflicts symptomized by altered food consumption. Disorders include anorexia nervosa, bulimia, and binge eating.

**Eccentric contraction** A lengthening contraction that occurs when the load is greater than the amount of tension that the muscle is able to generate, such as walking down stairs (eccentric contraction of the quadriceps muscles).

**Echymosis** Bluish discoloration of the skin (bruise) caused by escape of blood into the tissues.

**Eccrine sweat gland** A sweat gland that opens directly onto the skin surface.

**Echocardiogram** A graphic representation of heart structures and movement produced by ultrasonography.

**Ectasia** Dilation of a tubular structure, as in mammary duct ectasia (in which the collecting ducts beneath the nipple and areola become dilated, thinned, and filled with secretions).

**Ectopic** In an abnormal location.

**Ectopic ureter** A single ureter that implants during fetal growth in any position other than normal, or an additional ureter.

**Ectopy (cardiac)** A cardiac impulse initiated at a site other than the sinoatrial node.

**Edema** An excess of fluid in the interstitial compartment.

**Efferent neuron** A neuron that carries information away from the central nervous system to the muscle cells, glands, or postganglionic neurons.

**Effusion** Presence of fluid in a contained space, causing pressure on structures within the space.

**Ejaculation** Expulsion of the ejaculate from the posterior urethra through the urethral meatus.

**Ejection fraction** Stroke volume divided by end-diastolic volume; indicates pumping efficiency of the ventricle.

**Elastin** A protein found in tendons and ligaments that provides some elasticity or extensibility.

**Elastosis** Skin wrinkling due to changes in collagen, with fibers becoming cross-linked and rearranged in thicker bundles.

**Electrocardiogram** A graphic record produced by an electrocardiograph, which records electrical conduction through the heart.

**Electrochemical gradient** A difference in concentration of charged particles across a membrane. Driving force that moves charged particles across a membrane as a result of the combined influences of concentration gradient and electrical charge gradient.

**Electroconvulsive therapy (ECT)** The induction of a brief convulsion by passing an electric current through the brain for the treatment of affective disorders.

**Electroencephalogram** Graphic tracing of the brain's action potentials; used to evaluate nervous tissue function.

**Electrolyte** Substance that releases charged particles (ions) when dissolved.

**Electromyography** A technique for evaluating muscle contraction. Using electromyography, aspects of the contractile process such as time relationships between the beginning of electrical activity and the actual contraction of the muscle can be studied.

**Electron transport chain** A series of proteins on the inner mitochondrial membrane that move an electron from a higher to a lower energy level and create a proton gradient.

**ELISA** Abbreviation for Enzyme-Linked Immunosorbent Assay, a test used in screening for HIV antibodies and measuring the quantity of numerous substances in blood and urine.

**Embolectomy** A surgical incision into an artery for the removal of an embolus.

- Embolus** A collection of material (thrombus, air, fat, tumor cells, bacteria, amniotic fluid) propelled by blood flow to another site, where it lodges and causes obstruction of flow.
- Embryoscopy** A procedure in which a scope is passed through the mother's abdominal wall and into the uterus to visualize and sample embryonic tissues.
- Emission** One of the two phases of ejaculation. During emission, secretions from the periurethral glands, seminal vesicles, and prostate are deposited with sperm into the prostatic urethra.
- Emphysema** A chronic obstructive respiratory condition characterized by abnormal, permanent enlargement of air spaces distal to the terminal bronchiole with destruction of their walls and without obvious fibrosis.
- Empyema** Accumulation of pus in a body cavity, especially the pleural space.
- Encapsulation** Physiologic process of enclosure in a sheath composed of a substance not normal to the part. Prevents opsonization (recognition and binding) by antibodies and thus prevents the microorganism from being phagocytized.
- Encephalitis** An inflammatory condition of the brain.
- Encopresis** Fecal holding with constipation and fecal soiling.
- Endemic disease** A physical or mental disorder caused by health conditions constantly present within a community.
- Endocardium** A layer of endothelial cells that lines the chambers of the heart. The layer of heart muscle immediately under the endocardium is called the subendocardium.
- Endocrine organ** Any organ that manufactures and secretes hormones into the bloodstream.
- Endocrine system** The cells and organs that produce and secrete hormones into the bloodstream.
- Endocytosis** Cellular ingestion of extracellular molecules.
- Endogenous depression** Mental depression arising from characteristics within the person as opposed to depression resulting from external events.
- Endometrioma** A mass of endometrial tissue that grows outside the lining of the uterine cavity in the condition known as endometriosis.
- Endometriosis** Growth of endometrial tissue outside the lining of the uterine cavity; an abnormal condition with potentially destructive effects on the pelvic organs.
- Endometrium** The innermost lining of the uterus, consisting of two layers: a thin deep layer, called the basilar layer; and a thick superficial layer, referred to as the functional layer. During a woman's reproductive years, the endometrium displays a constant cyclic activity of alternate proliferation and sloughing of the functional layer in response to hormonal secretion.
- Endomysium** The connective tissue that surrounds the sarcolemma of an individual muscle fiber.
- End-organ damage** Target organs refer to major organs fed by the circulatory system, such as the heart, kidneys, brain, and eyes. Damage may be from uncontrolled hyperglycemia, hypertension, hypotension, or hypovolemia.
- Endorphin** One of a group of potent endogenous opioid peptides derived from cells in the hypothalamus; also found in the periaqueductal gray matter of the brain.  $\beta$ -Endorphin has been found to have analgesic properties.
- Endoscopic retrograde cholangiopancreatography (ERCP)** A procedure whereby an optical scope is passed through the mouth, esophagus, stomach, and duodenum, and then guided in a retrograde fashion into the pancreaticobiliary system. Using this technique, physicians can complete a number of therapeutic procedures without performing a laparotomy.
- Endoscopic sclerosis** A procedure for the treatment of esophageal varices that is accomplished by passing a flexible needle through the gastroscope and injecting various sclerosant solutions into and around the bleeding varix.
- Endospore** A dormant, tough, and temporarily nonreproductive structure produced by a bacterium. It is not a true spore.
- Endosteum** The thin membrane that covers the medullary cavity in longer bones.
- Endotoxin** A heat-stable lipopolysaccharide derived from the cell wall of gram-negative bacteria that induces the release of pyrogens and inflammatory mediators from immune cells.
- Energy** The capacity to operate or work, measured in kilocalories (kcal); 1 kcal represents the amount of energy required to raise the temperature of 1 kg of water 1° C.
- Enkephalins** One of two types of pain-suppressing pentapeptides; they are produced in the body and located in the pituitary gland, brain, and gastrointestinal (GI) tract.
- Enteropathic arthritis** Refers to joint manifestations of inflammatory bowel diseases such as ulcerative colitis and Crohn disease.
- Inuresis** Involuntary voiding; the term is generally used when referring to inappropriate bed-wetting in children.
- Eosinophil** A leukocyte that is the same size as a neutrophil but contains a two-lobed nucleus and large, coarse, eosinophilic granules that fill the cell; eosinophils participate in allergic and inflammatory responses.
- Epicardium** A layer of epithelial cells that covers the outer surface of the heart and forms the inner (visceral) layer of the pericardial sac.
- Epidemic** An outbreak of a disease that occurs suddenly and affects numbers of people clearly in excess of normal expectancy.
- Epidemiology** The study of patterns of disease among human populations for the purpose of establishing programs to prevent and control their spread.
- Epidermal proliferating unit** Group of active basal cells, together with vertical columns of migrating keratinocytes, that are undergoing mitosis.
- Epidermis** Outer, thinner layer of the cutaneous membrane.
- Epididymis** Tightly coiled tube in which sperm mature and develop the ability to swim; lies along the top of and behind the testes.
- Epididymitis** Inflammation of the epididymis.
- Epigenetics** The transfer of heritable traits from parent cells to offspring that are not coded in the DNA.
- Epiglottitis** An inflammation of the epiglottis, characterized by fever and stridor. Can be a life-threatening condition.
- Epileptogenic focus** Cellular focus in the brain with the capacity to induce epilepsy.
- Epimysium** The connective tissue surrounding a muscle.
- Epinephrine** A neurotransmitter that produces some of the same effects as norepinephrine but has a greater influence on cardiac action. Epinephrine enhances myocardial contractility, increases heart rate, and increases venous return to the heart, thus increasing cardiac output and blood pressure.
- Epiphyseal plate** A segment of a long bone between the metaphysis and epiphysis developed from a center of ossification and distinct from the shaft. An area of growth in a bone.
- Epispadias** A congenital anomaly in which the urethra opens on the dorsal aspect of the penis at a point proximal to the glans.
- Epistaxis** Hemorrhage from the nose; nose-bleed.
- Epitope** A site on the surface of an antigen that is specifically recognized by an immune cell, thus stimulating an immune response.
- Equilibrium** Sense of balance.
- Erectile dysfunction** Inability of the adult male to achieve or sustain a penile erection.
- Erection** A complicated interaction of vascular, neurologic, and hormonal factors that enables the penis to achieve penetration and deposit sperm.
- Erythema** Diffuse redness of skin.
- Erythroblastosis** Presence of erythroblasts in the blood due to premature release from the bone marrow.
- Erythrocyte** Mature biconcave red blood cell that has no internal organelles.
- Erythromelalgia** Painful erythema (redness of the skin) of the palms and soles due to congestion of the capillaries.
- Erythron** The blood as a single body system.
- Erythropoiesis** The process of red blood cell production.
- Erythropoietin** Hormone produced primarily by the kidneys that stimulates bone marrow to produce erythrocytes.
- Eschar** Burn tissue.
- Escharotomy** A surgical incision through eschar of a circumferential extremity burn for the purpose of restoring distal blood flow, or through eschar of the chest to restore respiratory expansion.
- Esophageal atresia** Congenital anomaly in which the esophagus is closed off in a blind pouch. It occurs in about 1 of every 4000 live births and requires immediate surgical correction.
- Esophageal varix** Abnormally dilated blood vessel lying immediately below the mucous membrane of the esophagus that connects the hypertensive portal system with the systemic circulation. Esophageal varices may rupture, causing massive hemorrhage.

**Esophagitis** Inflammation or infection of the esophagus.

**Essential amino acids** Amino acids that must be supplied in the diet because the body cannot manufacture them.

**Estrogen** One of a group of ovarian hormones that promote the development of female secondary sex characteristics. During the menstrual cycle, estrogen renders the female reproductive tract suitable for fertilization of the ovum, implantation of the zygote, and provision of nutrition for the early embryo.

**Etiology** Study of the assignment of causes or reasons for phenomena.

**Euchromatin** Chromatin that is less densely packed and potentially open to transcription, as opposed to heterochromatin that is condensed and not open to transcription. “Normal” chromatin.

**Eukaryote** A cell that has a true nucleus bounded by a nuclear membrane.

**Euphoria** Also called *expanded mood*, is a hallmark symptom of both mania and hypomania. Extreme cheerfulness, enthusiasm, and optimism are present, but the joyful, buoyant mood is disproportionate to events and surroundings.

**Ewing sarcoma** A malignant round cell tumor (marrow tumor) that is relatively uncommon but rapidly growing.

**Exacerbation** A relatively sudden increase in the severity of a disease or any of its signs and symptoms.

**Exercise-induced asthma** Asthma that manifests 5 to 10 minutes after the exercise period begins. The increased rate and depth of respiration during exercise, especially in cold air, leads to cooling and dehydration of the lower airways.

**Exhaustion** A stage in the stress response that occurs when the stressor is too great or prolonged, resulting in depletion of energy reserves.

**Exocytosis** The process of cellular secretion through the plasma membrane accomplished by opening vesicles into the extracellular space.

**Exon** The portion of an RNA transcript that remains after unwanted sections (introns) have been removed from the primary transcript. A linear section of DNA that serves as a template for synthesis of a particular RNA sequence.

**Exophthalmos** Protrusion of the eyeball.

**Exotoxin** Toxins, such as enzymes or pore-forming proteins, produced by bacteria that cause physiologic dysfunction in the host.

**Extracellular fluid** Body fluid that is not inside the cells; includes vascular, interstitial, and transcellular fluids.

**Extraocular** Outside the globe of the eyeball.

**Extrapyramidal system** Part of the brain that includes the corpus striatum, subthalamic nucleus, substantia nigra, red nucleus, and the interconnections with the reticular formation, cerebellum, and cerebrum.

**Extrapyramidal tract** Outside the pyramidal tract of the brain. Comprised of the nuclei and fibers involved in motor activities, extrapyramidal tracts control and coordinate postural, static, support, and locomotor mechanisms. Do not crossover in the medullary pyramid.

**Extrinsic** Originating from sources outside of the individual.

**Extrinsic asthma** Also called *allergic asthma*, it commonly affects children and young adults. Attacks are related to specific antigens and are mediated by immunoglobulin E.

**Extrinsic pathway of clotting** The mechanism that produces fibrin following tissue injury, beginning with formation of an activated complex between tissue factor and activated factor VII and leading to activation of factor X, which induces the reactions of the common pathway of coagulation.

**Exudate** Fluid of high protein content that moves into tissues or cavities as part of a reaction to inflammation or injury.

## F

**Fascia** A sheath of connective tissue that envelops muscles or other parts of the body.

**Fascia of Buck** Layer of deep fascia covering the penis.

**Fasciculus** Bundle of muscle fibers that compose individual muscles.

**Facioscapulothoracic muscular dystrophy** A rare inherited autosomal dominant trait that affects the muscles of the shoulder girdle and the face and upper arms.

**Fast twitch (type II, white)** A muscle fiber that can develop high tension rapidly. It is usually innervated by a single  $\alpha$ -motor neuron and has low fatigue resistance, low capillary density, low levels of aerobic enzymes, and low oxygen availability.

**Fat** The most concentrated dietary source of energy; derived from either animals or vegetables. Provides 9 kcal/gm of energy when metabolized.

**Fat emboli syndrome** A circulatory condition characterized by a plug of fat blocking an artery; it enters the circulatory system after the fracture of a long bone.

**Fatigue** A lack of physical or emotional energy or power.

**Fatty acid** An organic acid with a long, straight hydrocarbon chain that is a fundamental component of lipids. Some fatty acids are manufactured by the body; others are essential and must be supplied in the diet.

**Fetotoxic** Referring to a substance that is damaging to a developing fetus.

**Fibrillation** Cardiac dysrhythmia characterized by rapid, random myocardial contractions and uncoordinated pumping action.

**Fibrinolysis** Dissolution or breakup of a fibrin clot.

**Fibroblast** Connective tissue cells that produce collagen fibers, which compose the bulk of the dermis.

**Fibrocystic breast disease** A condition in which the presence of palpable breast masses (cysts) corresponds to fluctuations in the menstrual cycle; the masses may be associated with pain and tenderness.

**Fibromyalgia syndrome** A painful, noninflammatory musculoskeletal disorder associated with fatigue and multiple somatic complaints.

**Fibrosis** Condition of decreased elasticity because of excessive deposition of fibrin and collagen in the tissue (e.g., restrictive process characterized by thickening of the alveolar interstitium).

**Fight-or-flight response** The reaction of the body to stressors that is mediated by the sympathetic nervous system and produces elevated heart rate and release of glucocorticoids from the adrenal cortex.

**Filaments or protein filaments** Fine threadlike fibers found in most tissues and cells of the body.

**Filtration** Movement of fluid across capillary walls as a net result of opposing forces of hydrostatic and colloid osmotic pressures.

**First-degree burn** Superficial tissue destruction in the outermost layers of the epidermis. All physiologic functions of the skin remain intact.

**Fistula** An abnormal tubelike passage between two organs or between an internal organ and the body surface.

**Flagellum** Motile (whiplike) appendage that allows a cell to move or swim.

**Flail chest** A thorax in which there are two fractures on at least two adjacent ribs that cause instability in part of the chest wall and paradoxical breathing.

**Flank pain** Discomfort to the posterior portion of the body between the ribs and the ileum. Often associated with the ureters.

**Flat affect** Lack of appropriate emotional expression.

**Focal segmental glomerulosclerosis** A condition where only some of the glomeruli are involved, resulting in scarring of the glomerulus. It is a cause of nephrotic syndrome and renal failure.

**Fomite** An inanimate object that transmits a pathogen to a new host.

**Foreskin** Also called *prepuce*; penile skin that overlies the glans and is removed in circumcision.

**Fossa navicularis** Area of widening near the end of the penile urethra.

**Fournier gangrene** A rare condition involving a gangrenous necrosis of the scrotum, penis, or perineum.

**Fourth-degree burn** A full-thickness burn that penetrates the dermis to reach muscle or bone.

**Fracture** A break or disruption in the continuity of a bone, an epiphyseal plate, or cartilage.

**Frank-Starling law of the heart** Describes the relationship between diastolic stretch and subsequent increased strength of contraction. Also called the *length-tension relationship*.

**Free-living bacteria** Bacteria that can live outside the host cell.

**Free radical** An extremely reactive compound that avidly makes molecular bonds with other compounds.

**Full-thickness burn** Also called a *third-degree burn*, this type of burn is marked by destruction of epidermis, dermis, and underlying tissue. All physiologic functions of the skin are absent. This burn will not heal and requires autografting.

**Full-thickness excision** Removal by surgical knife of complete eschar to fascia. Full-thickness excision often leaves an uneven contour, which presents difficulty with grafting, resulting in poor cosmesis.

**Functional disorder of the endocrine system** An endocrine disorder caused by a non-endocrine disease (e.g., chronic renal failure, liver disease, or heart failure).

**Functional incontinence** Loss of urine or feces as a result of factors external to the urinary or digestive tract, such as physical or cognitive impairment.

**Functional syncytium** A multinucleate mass of protoplasm that results from the merging of cells. It is characteristic of the gastrointestinal tract and heart, meaning that its separate cells have the ability to function in concert with one another in a unified manner.

**Fungal infection** Any inflammatory condition caused by a fungus.

**Fungus** A nonphotosynthetic, eukaryotic protist that is disseminated throughout the environment.

## G

**Gallbladder** A distensible sac of about 30- to 50-ml capacity that connects the common hepatic duct to the common bile duct via the cystic duct.

**Ganglion** A group of neuronal cell bodies located outside of the central nervous system.

**Gangrene** Cellular death involving a large area of tissue; may be characterized as wet, dry, or gaseous.

**Gap junction** A cell-to-cell communication pore that allows small biomolecules to flow from the cytoplasm of one cell to the cytoplasm of an adjacent cell.

**Gas exchange** Diffusion of oxygen and carbon dioxide across the alveolar-capillary membranes of the lungs.

**Gastrectomy** Surgical removal of all or, more commonly, part of the stomach. This procedure may be used to remove a chronic peptic ulcer, to stop hemorrhage in a perforating ulcer, or to remove a malignancy.

**Gastrin** A stomach hormone that is released in response to certain types of food. Gastrin increases acid secretion by stomach parietal cells.

**Gastritis** Inflammation of the stomach lining. It may occur following the ingestion of irritating substances or in the presence of viral, bacterial, or chemical toxins.

**Gastroenteritis** Inflammation of the stomach and intestines; may occur on an acute or chronic basis and is commonly caused by viruses.

**Gastroesophageal reflux disease (GERD)** Backflow of gastric contents into the esophagus through the lower esophageal sphincter. GERD may or may not produce symptoms. The most common manifestations of GERD are heartburn, regurgitation, chest pain, and dysphagia.

**Gastroesophageal varices** A complex of longitudinal tortuous veins at the lower end of the

esophagus, enlarged and swollen as the result of portal hypertension.

**Gene** A unit of heredity consisting of a segment of DNA nucleotides that encodes a messenger RNA capable of being translated into a protein.

**General adaptation syndrome (GAS)** The total organism's nonspecific response to stress. Term was coined by Hans Selye.

**Generalized anxiety disorder (GAD)** Characterized by the continual presence of a moderate degree of anxiety without discrete periods of acute attacks. GAD symptoms include chronic anxiety and tension accompanied by headaches, abdominal problems, or sleep disturbances. Agoraphobia is rarely seen in GAD.

**Generalized seizure** A seizure that involves the whole brain surface and impairs consciousness.

**Genital herpes** A chronic viral infection usually transmitted by sexual contact.

**Genital warts** A condyloma of the genitals; caused by sexual transmission of human papillomavirus.

**Genome** The entire complement of genes located on chromosomes in the nucleus of a cell.

**Genotype** The genetic constitution of an individual; often described by listing the allele types at a certain gene locus.

**Gerontology** The study of all aspects of the aging process.

**Gestational diabetes mellitus** A condition of glucose intolerance first diagnosed in the mother during pregnancy. Usually disappears after delivery of the infant.

**Ghon tubercle** A nodule or swelling containing *Mycobacterium tuberculosis*.

**Giant cell tumor** Also called *osteoclastoma*; a benign but aggressive tumor with richly vascularized tissue consisting of plump spindle-shaped cells and numerous giant cells.

**Gilbert syndrome** A common, benign autosomal dominant condition that results in mild unconjugated (indirect) hyperbilirubinemia.

**Ginglymus** A type of joint that permits flexion and extension; examples include the interphalangeal joint of the finger, the elbow joint, or the knee joint. Also called a *hinge joint*.

**Glasgow Coma Scale** Scale developed by G. Teasdale and B. Jennett for the purpose of objectively assessing coma and impaired consciousness.

**Glaucoma** An abnormal condition of elevated pressure within the eye.

**Glial** Supporting or nonneuronal cells within the central nervous system.

**Glomerulopathies** Diseases of the renal glomeruli.

**Glomerular filtration rate** The rate of fluid filtration through the glomeruli into Bowman capsule per minute; normally 125 ml/min.

**Glomerulonephritis** Inflammation of the glomerular capillary walls that causes impaired filtration and renal function.

**Glucagon** Hormone produced by the  $\alpha$  cells of the pancreas that stimulates glycogenolysis and gluconeogenesis in the liver.

**Glucocorticoid resistance model** This model proposes a specific link between stress, immunity, and disease. Rather than viewing disease as

a result of increased vulnerability due to stress, this model proposes that overwhelming stress reduces the sensitivity of the immune system to cortisol.

**Glucocorticoids** A class of steroid hormones secreted by the adrenal cortex; they are necessary for use of carbohydrates, fats, and proteins and for the body's normal response to stress.

**Gluconeogenesis** The production of glucose from amino acids and other substrates in the liver.

**Glucose-6-phosphate dehydrogenase deficiency (G6PD)** An inherited disorder characterized by red cells partially or completely deficient in G6PD, an enzyme critical in anaerobic glycolysis.

**Glycogen** A carbohydrate consisting of branched chains of glucose produced by muscles and the liver as a storage form of glucose.

**Glycogenesis** Production of glycogen from glucose in hepatic and muscle tissue.

**Glycogenolysis** Production of glucose from the breakdown of glycogen in hepatic and muscle tissue.

**Glycolysis** The anaerobic process of breaking down carbohydrates into simpler molecules, with the net production of two adenosine triphosphate and two pyruvate molecules per glucose molecule.

**Glycosaminoglycan** A protein polysaccharide contained in ground substances surrounded by collagen fibers in bone.

**Glycosylated hemoglobin** An index of glycemic control; the quantity of glucose attached to hemoglobin molecules (%), reflecting mean blood glucose values for a period of 120 days, usually reported as HbA<sub>1c</sub>.

**Goiter** Enlargement of the thyroid gland.

**Golgi apparatus** A membrane-bound organelle in which the proteins and lipids that are synthesized in the endoplasmic reticulum are modified and sorted in preparation for transport to the lysosomes or plasma membrane.

**Gomphosis joint** An articulation created by the insertion of a conical process into a socket, such as the insertion of a root of a tooth into an alveolus of the mandible or the maxilla. Gomphosis is not a connection between true bones but is considered a type of fibrous joint.

**Gonad** An organ that produces sex cells. Derived from the urogenital ridge, the undifferentiated and primitive gonads become the testes in males and the ovaries in females.

**Gonadotropins** Hormones that stimulate the function of the testes and the ovaries (FSH and LH).

**Gonorrhea** Common sexually transmitted infection involving the inflammation of epithelial tissue by the organism *Neisseria gonorrhoeae*. Characteristic symptoms include urethritis, dysuria, purulent urethral discharge, and redness and swelling at the site of the infection.

**Goodpasture syndrome** A chronic relapsing autoimmune disease usually associated with glomerulonephritis.

**Gout** A condition caused by lack of the enzyme uricase and by inability to oxidize uric acid into a soluble compound; characterized by recurrent

attacks of articular and periarticular inflammation, accumulation of tophi (crystalline deposits) in bony and connective tissue, renal impairment, and formation of uric acid calculi.

**Grading** Assignment of degree of differentiation of tumor cells by histologic examination. The degree of anaplasia usually correlates with the degree of malignancy, with higher grades conferring greater malignant potential.

**Gram stain** A process by which it is determined whether bacteria can retain a basic dye after iodine fixation. This ability is the basis for classifying bacteria into gram-negative and gram-positive organisms.

**Granulocyte** A leukocyte with polymorphic nuclei and cytoplasmic granules. Neutrophils, basophils, and eosinophils are types of granulocytes.

**Granulocytopenia** An abnormal decrease in the total number of granulocytes in the blood.

**Granuloma** Tissue that forms into a nodular mass as a result of inflammation, infection, or injury.

**Granuloma inguinale** An ulcerative disease of the genital tract caused by the bacterium *Calymmatobacterium granulomatis*. The communicability of the disease is relatively low, and it is generally believed that repeated exposure is necessary for infection.

**Granulomatous** Relating to granulomas; chronic inflammatory lesions characterized by an accumulation of macrophages; epithelioid macrophages, with or without lymphocytes; and giant cells into a discrete granule.

**Graves disease** Hyperthyroid state characterized by exophthalmos and goiter from autoimmune stimulation of the thyroid.

**Greenstick fracture** An incomplete break in the bone with the intact side of the cortex flexed; this is usually seen in children.

**Ground substance** A material composed of a hydrated network of proteins, mainly glycoproteins and proteoglycans, that serves as the “cement” between layers of collagen fibers. Also known as *matrix*.

**Growing pain** A common soft-tissue syndrome in children. The most common symptom is nocturnal pain that usually occurs in the calves, shins, and thighs. Also called *nonarticular rheumatism*.

**Growth hormone** A hormone secreted by the anterior pituitary gland with wide-ranging action, including effects on energy metabolism and increasing lean body mass.

**Guillain-Barré syndrome** Also called *acute idiopathic polyneuropathy* or *polyradiculoneuropathy*; Guillain-Barré syndrome is an inflammatory demyelinating disease of the peripheral nervous system.

**Gustatory** Pertaining to the sense of taste.

**Gyrus** A raised ridge or convolution on the surface of a structure (e.g., cerebral cortex).

## H

**H<sup>+</sup>** Hydrogen ion; released by acids; determines pH; also called a *proton*.

**HCO<sub>3</sub><sup>-</sup>** Bicarbonate ion; a base that binds and buffers H<sup>+</sup>.

**H<sub>2</sub>CO<sub>3</sub>** Carbonic acid; this acid is removed from the body in the form of carbon dioxide and water during exhalation.

**H zone** Corresponds to a region occupied solely by myosin filaments with no actin filament overlap in cardiac and skeletal muscle.

**Hair** Keratinized, threadlike outgrowth of the skin that covers most of the body.

**Hair follicle** Slender, cylindrical tube of epidermal cells in which hair grows.

**Hallucination** A perception for which there are no objective sensory data.

**Haploid** Containing only one set of chromosomes (as distinct from diploid), as in a sperm cell or egg cell.

**Hapten** Incomplete, lipid-soluble particle that is incapable of being an antigen by itself, but that becomes an antigen inside the body when it binds with a host protein called a carrier. When a hapten penetrates the epidermis and binds to a carrier, it can cause contact hypersensitivity.

**Haustral churning** The mixing movement of the haustra (the outpouchings in the colon wall) when material is in the proximal end of the colon.

**Haversian system** The basic unit of bone; also called *osteon*.

**HBV infection** Hepatitis B virus infection. Vertical transmission from an HBsAg-positive mother to the infant is a common mechanism of spread.

**HCV infection** Hepatitis C virus infection. A type of viral hepatitis that is usually chronic and transmitted most commonly by blood transfusion or percutaneous inoculation.

**HDV infection** Hepatitis D virus infection. A form of hepatitis that occurs only in patients co-infected with hepatitis B. HDV relies on HBV replication and cannot replicate independently. The disease usually progresses to a chronic state.

**Heimlich maneuver** An emergency procedure for dislodging an obstruction from the trachea. It consists of grasping the choking person from behind, placing the hands around the victim’s waist just below the sternum (in a fist with the thumb toward the body), and pulling inward and upward with force to dislodge the obstruction. Now called *abdominal thrusts*.

**Helicobacter pylori** An infectious gastrointestinal tract bacterium first identified in 1982. Since then, *H. pylori* has generated worldwide attention for its role in the promotion of chronic gastritis, peptic ulcer disease, and gastric carcinoma. The mode of transmission of *H. pylori* is still unclear, although person-to-person, fecal-oral spread is suspected because of the tendency of *H. pylori* infections to cluster in families.

**Hemangiomas** Benign tumors consisting of a mass of blood vessels.

**Hemarthrosis** Blood in a joint cavity.

**Hematemesis** Blood in vomitus.

**Hematochezia** Feces containing bright red blood.

**Hematoma** A mass caused by extravasation of blood into a tissue or cavity (bruise).

**Hematopoiesis** Production of cells in the bone marrow, including red blood cells, white blood cells, and platelets.

**Hematuria** Blood in the urine.

**Hemianopsia** Partial loss of the same field of vision in both eyes.

**Hemiparesis** Motor weakness affecting one side of the body, usually occurring with lateral cerebral injuries.

**Hemiplegia** Paralysis of one side of the body.

**Hemochromatosis** A disorder (usually genetic) of iron metabolism characterized by excess absorption of iron, elevation of ferritin levels, and deposition of iron in organs such as the liver.

**Hemodynamics** Physical laws governing blood flow.

**Hemoglobin** Oxygen-carrying protein in the red blood cells.

**Hemolysis** Separation of hemoglobin from red blood cells and its appearance in the fluid in which the corpuscles are suspended; red blood cell lysis.

**Hemophilia** A group of hereditary disorders characterized by a deficiency of one of the factors necessary for coagulation of the blood, usually factor VIII or IX.

**Hemoptysis** Expectoration of blood, the origin of which is the lungs or bronchial tubes.

**Hemostasis** Arrest of bleeding; prevention of blood loss.

**Hemothorax** Accumulation of blood and fluid in the pleural space.

**Hepatic encephalopathy** A neuropsychiatric manifestation of extensive liver damage. Also known as *hepatic coma*.

**Hepatitis** An inflammatory condition of the liver. Potential causes include viral, bacterial, fungal, and protozoal infections; drugs and toxins; autoimmune disorders; and metabolic disorders.

**Hepatocellular carcinoma** A common form of primary hepatic malignancy. Signs and symptoms include hepatomegaly, abdominal pain, weight loss, nausea, and, in advanced cases, jaundice and ascites. Also called *hepatoma*.

**Hepatocellular failure** Acute or chronic loss of essential liver function resulting in portal systemic encephalopathy and a variety of other problems, including coagulopathy, renal failure, bleeding, infection, hypoglycemia, respiratory failure, and death.

**Hepatorenal syndrome** A type of kidney failure characterized by gradual loss of function without signs of tissue damage.

**Hepatoma** A primary liver cancer arising from cells normally found in the liver, not to be confused with cancer metastatic to the liver from a distant site.

**Hereditary hemochromatosis** An autosomal recessive disorder caused by the activity of a mutant gene called *HFE*, which allows excessive and uncontrolled iron absorption by the GI tract.

**Herpes simplex virus** A virus causing infection of the skin and nervous system; often associated with painful fluid-filled vesicles.

**Herpesviruses** Important group of viral agents producing infections in humans. Two types of

- herpes simplex viruses, referred to as types 1 and 2, may be sexually transmitted.
- Herpes zoster (shingles)** An acute localized inflammatory disease of a dermatomal segment of the skin caused by the same herpesvirus that causes chickenpox.
- Heterochromatin** A type of chromatin (DNA) that is tightly compacted and genetically inactive.
- Heterozygous** Having two different alleles for a specific gene product.
- HEV infection** Hepatitis E virus infection. A self-limited type of hepatitis acquired by ingestion of fecally contaminated water or food.
- Hiatal hernia** A defect in the diaphragm that allows a portion of the stomach to protrude through the diaphragmatic opening into the thorax.
- High blood pressure** A persistent elevation of blood pressure >140 mm Hg systolic/90 mm Hg diastolic. High blood pressure is an elevated blood pressure reading. If it is consistently >120/80 mm Hg but <140/90 mm Hg, then it is called *pre-hypertension*.
- Hilum** Concave portion of the kidney that faces the vertebral column through which nerves, blood vessels, and ureters enter and exit the kidney.
- Hinge joint** A joint that permits flexion and extension, such as the interphalangeal joint of the finger, the elbow joint, or the knee joint. Also called a *ginglymus joint*.
- Hirschsprung disease** A congenital disorder of the large intestine in which the autonomic nervous system ganglia in the smooth muscle are absent or markedly reduced in number, which causes poor or absent peristalsis.
- Hirsutism** Excessive growth of hair or the presence of hair in unusual places.
- Histamine** A compound found in cells, especially mast cells; it is produced by the breakdown of histidine. It is released in allergic inflammatory reactions.
- Histiocyte** A type of cell normally present in small numbers around blood vessels, but in pathologic conditions it can migrate in the dermis as a tissue monocyte. It can also form abundant reticulum fibers. When it phagocytizes bacteria and particulate matter, it is referred to as a *macrophage*.
- Histone** A protein around which linear DNA is wrapped.
- Histrionic** Theatrical, dramatic.
- Hodgkin disease** A progressive malignancy of the lymph node characterized by the presence of Reed-Sternberg cells and slow, predictable dissemination through the lymphatic vessels.
- Homeostasis** A dynamic steady state, representing the net effect of all the turnover reactions.
- Homologous** Corresponding in structure. For example, the labia majora are *homologous* with the scrotum of the male.
- Homologous chromosomes** A pair of chromosomes in a diploid cell that contain similar gene loci, each being derived from a different parent.
- Homozygous** Having two identical alleles for a specific gene product.
- Hormone** A blood-borne chemical messenger that affects target cells anatomically distant from the secreting cells.
- Hormone agonist** A chemical that binds to a hormone receptor and initiates intracellular activities identical to those caused by hormones. Some medications exert their therapeutic effects through this process.
- Hormone antagonist** A chemical that competes with hormones for cell receptors. Antagonists bind to cell receptors and prevent the occurrence of intracellular activities associated with hormone-receptor binding. Some medications produce their therapeutic effects through this process.
- Hormone receptor** A protein on or within a target cell that binds to circulating hormones and allows the cellular response to a specific hormone. Hormone-receptor binding is the first step in the cellular response to a particular hormone.
- Host-parasite relationship** The interaction between the host and the microorganisms that reside on or in it.
- Human immunodeficiency virus (HIV)** A general term for several types of retroviruses that affect the immune system, causing a defect in cell-mediated immunity and failure of the immune system to function properly.
- Human leukocyte antigen (HLA) complex** The major histocompatibility complex (MHC) in human leukocytes.
- Human papillomavirus (HPV) infection** A virus that is the cause of common warts of the hands and feet, as well as lesions of the oral, anal, and genital cavities. More than 50 types of HPV have been identified.
- Humoral immunity** A form of immunity mediated by circulating antibodies that coat the antigens and target them for destruction.
- Hyaline membranes** Membranes in alveolar tissue that look like glass. The alveoli are filled with proteinaceous fluid and epithelial cells.
- Hydrocele** Accumulation of fluid in the tunica vaginalis testis; one of the most common causes of scrotal swelling.
- Hydrocephalus** Increase in the amount of cerebrospinal fluid attributable to blocked circulation or absorption and the consequent enlargement of the ventricles.
- Hydronephrosis** Distention of the pelvis and calyces of the kidney by urine that cannot flow past an obstruction in the ureter.
- Hydrophilic** Soluble in water but not in lipid.
- Hydrophobic** Insoluble in water but soluble in lipid.
- Hydropic swelling** An increase in intracellular fluid volume and changes in intracellular organelles in association with cell injury. Also termed *oncosis*.
- Hydrostatic pressure** Pressure exerted by a liquid.
- Hydroneurter** Distention of a ureter with urine, usually resulting from an obstruction process.
- Hyperacusis** Exceptionally acute hearing, the hearing threshold being unusually low. It may or may not be accompanied by pain.
- Hyperaldosteronism** A condition characterized by hypersecretion of aldosterone, occurring as a disease of the adrenal cortex or as a response to adrenal disease.
- Hyperalgesia** An increased sensitivity to painful stimuli characterized by a lower than normal pain threshold.
- Hypercalcemia** Serum calcium concentration greater than normal.
- Hypercapnia** An abnormally high amount of carbon dioxide in the blood.
- Hypercortisolism** Elevated serum level of cortisol.
- Hyperemesis gravidarum** A Latin term meaning “excess vomiting in pregnant women.” Unlike the transient nausea and vomiting that occurs in about half of women in the first trimester of pregnancy, hyperemesis gravidarum continues throughout the entire pregnancy.
- Hyperemia** Localized redness produced by increased blood flow.
- Hyperkalemia** Serum potassium concentration higher than normal levels.
- Hyperkeratosis** Horny overgrowth of epidermis, such as callous formation.
- Hypermagnesemia** Serum magnesium concentration greater than normal levels.
- Hypermetabolic state** A condition of abnormally high basal metabolic rate. May be indicated by an increase in skin temperature, such as that occurring in hyperthyroidism and after sun exposure or sunburn.
- Hypnatremia** Serum sodium concentration greater than normal levels; results from a gain of salt relative to water or a loss of water relative to salt; water deficit.
- Hyperopia** Farsightedness or the inability of the eye to focus on nearby objects.
- Hyperparathyroidism** An abnormal endocrine condition characterized by hyperactivity of the parathyroid glands.
- Hyperphosphatemia** Serum phosphate concentration greater than normal levels.
- Hyperplasia** Abnormal multiplication or increase in the number of normal cells in normal arrangement in a tissue.
- Hypersensitivity** An abnormal excessive response to a sensitizing antigen.
- Hypertension (see High blood pressure)** A persistent elevation of blood pressure >140 mm Hg systolic/90 mm Hg diastolic.
- Hypertensive crisis** A sudden, severe increase in blood pressure that could be life threatening.
- Hyperthyroidism** Overactivity of the thyroid gland.
- Hypertonic fluid** Fluid that has a higher particle concentration (osmolality) than normal body fluid; causes a net flow of water across cell membranes out of cells.
- Hypertrichosis lanuginosa** Excessive hair growth over the entire body.
- Hypertrophy** An increase in cell or tissue size and function.
- Hypocalcemia** Serum calcium concentration below normal values.
- Hypochromia** An abnormal decrease in the hemoglobin content of the erythrocytes.
- Hypodermis** Loose subcutaneous layer rich in fat and areolar tissue lying beneath the dermis. Also known as *superficial fascia*.

**Hypogonadism** A deficiency in the size or function of the ovary or testis.

**Hypoglycemic sweating** Sweating caused by low blood glucose concentration. Usually distinguishable from other causes of sweating attributable to the additional symptoms of weakness, tachycardia, hunger, headache, and “inward nervousness” manifested as mental irritability and confusion.

**Hypokalemia** Serum potassium concentration less than normal levels.

**Hypomagnesemia** Serum magnesium concentration less than normal levels.

**Hypomania** Also called *partial mania*, can include any symptoms of mania but without the loss of reality testing, without psychosis (e.g., hallucinations, delusions), and without impaired functioning.

**Hypomenorrhea** A deficient amount of menstrual flow, usually the result of an endocrine or systemic disorder that interferes with hormonal function. It may also result from partial obstruction of the menstrual flow by the hymen or a narrowing of the cervical os.

**Hyponatremia** Serum sodium concentration less than normal levels; results from gain of water relative to salt or loss of salt relative to water; water intoxication.

**Hypophosphatemia** Serum phosphate concentration less than normal levels.

**Hypophysis** The pituitary gland, which consists of anterior and posterior lobes.

**Hyposensitization** Reduction in sensitivity to an allergen, accomplished by administering low doses of the allergen, which binds with immunoglobulin G.

**Hypospadias** A congenital anomaly in which the urethral meatus is located on the undersurface of the penis or on the perineum.

**Hypothalamic-pituitary-adrenal (HPA) axis** Refers to a hierarchy of control mechanisms whereby the hypothalamus regulates the anterior pituitary and the pituitary regulates the secretion of hormones from the adrenal cortex.

**Hypothalamus** A group of nuclei at the base of the brain concerned with regulation of body processes: temperature, thirst, hunger, satiety, and adaptive sexual behaviors.

**Hypothyroidism** Underactivity of the thyroid gland.

**Hypotonic fluid** Fluid that has a lower particle concentration (osmolality) than normal body fluid; causes a net flow of water across cell membranes into cells.

**Hypoventilation** Decreased exchange of air in the alveoli in relation to oxygen consumption; influenced by a decreased rate and depth of respiration, and evidenced by elevated  $P_{aCO_2}$  values.

**Hypovolemic shock** A state of physical collapse and prostration usually caused by massive blood loss.

**Hypoxemia** An abnormally low amount of oxygen in the blood.

**Hypoxia** A reduction in oxygen at the tissue level that may lead to failure of aerobic production of adenosine triphosphate.

**I bands** “I” indicates “isotropic”; these bands are light in color and correspond to the position of thin actin filaments extending in both directions from the Z line in striated muscle.

**Iatrogenic** Resulting from the activity of a health care provider.

**Icterus** Also called *jaundice*. A yellow discoloration of the skin, mucous membranes, and sclerae of the eyes that is caused by greater than normal amounts of bilirubin in the blood.

**Idiopathic** Without known cause.

**Idiopathic hypertension** High blood pressure of unknown cause; also called *primary hypertension*.

**Ileocecal valve** Sphincter between the small and large intestines that is normally closed, so that the contents of the large intestine cannot move in a retrograde fashion back into the small intestine. It opens in response to peristaltic contractions in the small intestine, bringing intestinal contents toward it.

**Illusion** The misperception of a real sensory stimulus.

**Immobilization** A mechanical action of limiting or preventing movement of the body or a body part. Prolonged immobilization may cause a shortening of connective tissue, a breakdown of cartilage, a weakening of ligaments, and a decrease in the muscles’ ability to contract, as well as increased bone resorption.

**Immunity** A state of active resistance to a particular pathogen, which requires functional T- and B-cell memory cells.

**Immunization** Exposure of a susceptible host to an altered pathogen that does not cause disease but instigates the host to create antibodies to that pathogen.

**Immunodeficiency** Failure of immune system mechanisms to defend against pathogens. There are two broad categories of immunodeficiencies, based on the mechanism of lymphocyte dysfunction: primary and acquired.

**Immunogen** Foreign substance, cell, toxin, or protein that causes the components of the immune system to react and respond, inducing the formation of antibodies. Also known as an *antigen*.

**Immunogenicity** The ability to stimulate an immune response.

**Immunoglobulin** Any of five structurally distinct classes of proteins that function as antibodies in the serum and secretions of the body.

**Immunosuppression** The inability to produce an immune response to an antigen, resulting in reduced resistance to infection.

**Immunotherapy** The use of immune products such as monoclonal antibodies to treat specific diseases.

**Impacted fracture** A fracture caused by excessive force that telescopes or drives one fragment into another.

**Impaired fasting glucose** A disorder of glucose tolerance, not diagnostic of diabetes, that is characterized by a fasting blood glucose value between 100 and 125 mg/dl.

**Impaired glucose tolerance** A disorder of glucose tolerance, not diagnostic of diabetes, that

is characterized by a 2-hour postprandial blood glucose value of between 140 and 200 mg/dl.

**Impetigo** An acute, contagious skin disease characterized by the formation of vesicles, pustules, and yellowish crusts.

**Impotence** Failure to achieve and maintain an erection of the penis.

**Impulsivity** Spontaneous acting out of impulses accompanied by failure to plan ahead, predict consequences, or consider other possibilities.

**Incomplete fracture** A fracture in which the cortex of the bone buckles or cracks without disrupting bone continuity.

**Incontinence** The inability to control urination or defecation.

**Induction** The process of stimulating and determining morphogenetic differentiation in a developing embryo. Also the initial phase of cancer chemotherapy.

**Induration** Hardness, such as that resulting from multiple intramuscular or subcutaneous injections of medication.

**Inert tissue** Soft tissue that possesses no ability to contract or relax; this includes the joint capsule, ligament, bursa, fascia, dura mater, and nerve root.

**Infectious disease** A pathologic process caused by a microorganism that is transmissible from one host to another.

**Infiltrate** Fluid or material that has moved into tissues.

**Inflammation** The body’s protective response at the site of injury or tissue destruction. It is important to recognize that although infectious agents can produce inflammation, infection is not synonymous with inflammation.

**Inflammatory bowel disease** A general term for inflammatory diseases of the bowel, such as ulcerative colitis and Crohn disease.

**Inhalation injury** Cellular injury to lung tissue as a result of inhalation of a toxic substance such as smoke. Smoke inhalation significantly increases the morbidity and mortality from burn injury.

**Innate immune response** Part of the host defense system that is composed of mechanical and biochemical barriers, phagocytes, and chemical mediators.

**Inotropy** The force or rate of cardiac contraction; similar to contractility.

**Insulin** Hormone produced by the  $\beta$  cells of the pancreas; has wide-ranging effects on energy metabolism and protein synthesis.

**Insulin resistance** The condition of requiring an increased amount of insulin for the same level of tissue glucose utilization.

**Integrins** A large family of transmembrane proteins that mediate adhesion of cells to the extracellular matrix.

**Integument** Covering; refers to the skin.

**Integumentary system** The skin and its appendages, including the hair and nails.

**Intercurrent** Occurring during the course of an already existing disease.

**Interferons** Natural glycoproteins formed by cells exposed to a virus.

**Interleukins** One of a large group of proteins produced mainly by T cells. Most direct other cells to divide and differentiate.

**Intermembranous ossification** The process in which osteoblasts in the inner layer of the periosteum are responsible for the increase in width of bones.

**Interstitial cystitis** Inflammation of the bladder that is believed to be associated with an autoimmune or allergic response.

**Interstitial fluid** Fluid that lies between the cells; a component of extracellular fluid.

**Interstitial space** The space between cells.

**Intertrigo** An erythematous irritation of opposing skin surfaces caused by friction.

**Intestinal obstruction** Failure of the contents of the intestines to progress through the lumen of the bowel because of mechanical blockage.

**Intestinal villi** Fingerlike projections, numbering in the millions, that line the small intestine and serve to increase the surface area of the intestine for digestion and absorption of nutrients.

**Intraaortic** Within the aorta. For example, in intraaortic balloon counterpulsation, a catheter with a balloon at the distal segment is inserted through the femoral artery and positioned in the aorta just distal to the left subclavian artery.

**Intracellular fluid** Fluid that is inside the cells.

**Intracellular obligate parasites** Bacteria that must live inside a living cell.

**Intraocular** Inside the globe of the eyeball.

**Intrarenal** Occurring within the kidney.

**Intravenous pyelography** A diagnostic procedure in which an iodine-based contrast material is injected into the vascular system to allow visualization of the kidneys and urinary tract.

**Intrinsic** Originating from within the individual.

**Intrinsic asthma** Asthma caused by pathophysiological disturbances that do not involve IgE-mediated mechanisms. This type of asthma frequently develops in middle age. Psychological stress factors, pulmonary irritants, and exercise may precipitate an asthma attack.

**Intrinsic (enteric) nervous system** Neural structures belonging entirely to the gastrointestinal (GI) system that control most GI functions and are responsible for many reflexes occurring locally in the GI tract. Intrinsic nervous system is composed of two layers: the myenteric plexus and the submucosal plexus.

**Intrinsic pathway of coagulation** A sequence of reactions leading to fibrin formation, beginning with the contact activation of factor XII, followed by the sequential activation of factors XI and IX and resulting in the activation of factor X, which in activated form initiates the common pathway of coagulation.

**Intron** The portion of a primary RNA transcript that is removed prior to translation of the RNA message.

**Intussusception** A telescoping of a portion of the bowel into an adjacent distal portion. It is most common in infants and occurs three times more often in males than in females.

**Invasion** The process by which malignant cells move through the basement membrane and gain access to blood vessels and lymphatic channels.

**Inversion** An abnormal condition in which a section of chromosome is reversed and reinserted into DNA.

**Involucrum** A sheath or coating of new bone growth outside of existing bone seen in pyogenic osteomyelitis. It results from the stripping of the periosteum by the accumulation of pus within the bone, and new bone growing from the periosteum. It can be seen with x-rays, but is extremely rare in developed countries because osteomyelitis is rarely left untreated.

**Ipsilateral** Referring to the same side of the body.

**Iron deficiency anemia** A microcytic hypochromic anemia caused by inadequate supplies of iron needed to synthesize hemoglobin.

**Irritable bowel syndrome** The presence of alternating diarrhea and constipation accompanied by abdominal cramping in the absence of any identifiable pathologic process in the gastrointestinal tract.

**Ischemia** Inadequate blood flow through the arterial system, producing tissue hypoxia.

**Ischemic hepatitis** A lack of blood or oxygen supply to the liver that causes injury to liver cells.

**Isoforms** Isomeric forms of the same protein, with slightly different amino acid sequences but with the same function.

**Isoimmunity** The condition occurring when an individual's immune system reacts against antigens on tissues from other members of the same species, such as a blood transfusion reaction in which a person with type A blood reacts against a transfusion with type B blood.

**Isolated systolic hypertension** An elevation in systolic blood pressure greater than 140 mm Hg without an increase in diastolic blood pressure. Most commonly occurs in the elderly.

**Isolated urinary tract infection** A first infection or an infection that occurs more than 6 months after a previous infection.

**Isoelectric contraction** A contraction in which no movement takes place and the muscle maintains its specific length. For example, holding a weight in the hand with elbow flexed produces an isometric contraction.

**Isotonic fluid** Fluid that has the same particle concentration (osmolality) as normal body fluid.

**Isovolumic contraction** The early phase of systole, in which the myocardial muscle fibers have begun to shorten and all valves in the heart are closed.

## J

**Jaundice** Yellowness of skin associated with elevated serum bilirubin levels.

**Joint** A point of contact between bones. Also called *articulation*.

**Joint capsule** A dense layer of connective tissue surrounding a synovial joint. The capsule is solidly attached to the periosteum of the adjacent bony components. The joint capsule provides strength to the joint and, through its neural receptors, detects motion, compression, tension, vibration, and pain.

**Juxtaglomerular apparatus** The collection of macula densa cells in the distal convoluted tubule and the afferent and efferent arterioles and also the juxtaglomerular cells located around the arterioles; they work together to control glomerular filtration rate.

**Juxtamedullary nephron** A nephron with long loops of Henle that extend deep into the medulla and create a concentrated interstitium via the countercurrent mechanism.

## K

**Keratin** Tough, water-repellent protein produced by keratinocytes and found in hair, nails, and horny tissue.

**Keratinocyte** One of several types of epithelial cells. Keratinocytes are able to synthesize DNA and produce keratin.

**Keratosis** Any skin lesion in which there is overgrowth and thickening of the cornified epithelium.

**Kernicterus** An abnormal toxic accumulation of bilirubin in central nervous system tissues caused by hyperbilirubinemia.

**Ketoacidosis** Acidosis accompanied by an accumulation of ketones; it is usually associated with poorly controlled type 1 diabetes mellitus.

**Ketone bodies** The result of fatty acids in the liver that are transformed to acetyl coenzyme A, which is then processed into one of three compounds known as ketone bodies.

**Kilocalorie** The unit of measure for the energy value of foods.

**Kinin** A vasoactive peptide produced during inflammation and injury.

**Koilonychia** Dystrophy of the fingernails, in which the nails are concave; also known as *spoon nail*.

**Korotkoff sounds** Sounds heard during auscultation of arterial blood pressure. As the pressure in the blood pressure cuff is released, blood begins to flow turbulently through the artery, producing Korotkoff sounds.

**Kyphoscoliosis** An abnormal condition characterized by an anteroposterior and a lateral curvature of the spine.

## L

**Lactation** Formation and secretion of milk from the breasts for the nourishment of the infant.

**Lactic acidosis** An increase in the anaerobic production of lactate, which, when released into the bloodstream, creates a condition of metabolic acidosis.

**Laminar flow** Flow of air or fluid in which there is no turbulence and the direction of flow is linear and parabolic.

**Langerhans cell** One of several types of epithelial cells. Langerhans cells are thought to have a role in immunologic reactions that affect the skin and may serve as a defense mechanism for the body.

**Laparoscopic cholecystectomy** Surgical removal of the gallbladder using an optical scope and instruments inserted through four small abdominal incisions.

**Laparoscopy** Examination of the abdominal cavity via a small incision to permit the insertion of a variety of optical scopes for diagnosis or therapy.

**Latency period** A period of time when there is no apparent change in status even though a process has begun to occur.

**Leiomyoma** Benign neoplasm of the smooth muscle of the uterus that is characteristically firm, well circumscribed, and round. Uterine leiomyomas usually appear and exhibit growth activity during the reproductive years.

**Leprosy** A chronic infectious disease of the skin caused by the intracellular bacillus *Mycobacterium leprae*.

**Leptomeninges** The combined structures of the pia mater and arachnoid mater.

**Lesion** A general term for a demonstrable structural change produced in the course of a disease. Lesions may be evident at a gross or microscopic level.

**Leukemia** A malignant disease of bone marrow stem cells, with accumulation of immature blasts in the marrow and peripheral blood.

**Leukocyte** A cell that mediates immune function. Leukocytes protect the body by phagocytosis of microorganisms and production of antibodies and memory cells. Also called *white blood cell*.

**Leukoderma** Patch of depigmentation, also called *vitiligo*.

**Leukopenia** A deficiency of white blood cells in the peripheral circulation, which is usually indicative of bone marrow failure.

**Leukotrienes** A class of biologically active compounds produced by leukocytes that trigger allergic and inflammatory reactions similar to those of histamine.

**Leydig cell** An interstitial cell in the testes that produces and secretes testosterone.

**Libido** Sexual drive; feeling of sexual desire.

**Lichen planus** A relatively common, chronic, pruritic disease involving inflammation and papular eruption of the skin and mucous membranes.

**Ligament** A dense connective tissue with parallel-fibered collagenous tissues designed to connect bone to bone.

**Ligands** A general term for a molecule, such as a hormone, neurotransmitter, or drug, that attaches to a receptor protein; usually involved in cell-to-cell communication.

**Limbic system** A group of structures surrounding the corpus callosum that produce various emotional feelings.

**Lipid bilayer** A double layer of lipid molecules that forms cellular membranes, including the plasma membrane, organelle membranes, and vesicles.

**Lipodystrophy** A group of conditions caused by defective metabolism of fat, resulting in atrophy of subcutaneous fat.

**Lipolysis** Production of free fatty acids resulting from the breakdown of fat in adipose tissue.

**Lipoproteins** A group of biomolecules composed of differing amounts of cholesterol, triglyceride, and protein, such as high-density lipoprotein (HDL) and low-density lipoprotein (LDL).

**Lithotripsy** Mechanical or chemical fragmentation of a calculus (stone).

**Liver transplantation** Surgical transfer of an appropriately matched donor liver into a host who has inadequate liver function to sustain life.

**Longitudinal fracture** Fracture in which a bone is split along its length.

**Loose association** Flow of thought in which ideas shift from one subject to another in a completely unrelated or noncohesive way. When severe, speech may be unintelligible.

**Lower esophageal sphincter** The circular band of muscular tissue at the lower end of the esophagus. It serves to prevent the highly acidic gastric contents from moving in a retrograde motion back into the esophagus.

**Lumpectomy** Surgical removal of only the malignant tumor or “lump” from an affected breast.

**Lung compliance** A measure of the ease of expansion of the lungs and thorax, determined by pulmonary elasticity (volume divided by pressure).

**Lunula** “Little moon”; the crescent-shaped white area nearest the root of the nail body.

**Lupus erythematosus** A chronic inflammatory disease affecting many systems of the body. It is an example of a collagen disease.

**Lusitropy** Rate of relaxation of cardiac muscle and chambers.

**Lyme disease** An infectious, immune-mediated multisystem disease caused by a tick-borne spirochete. It is characterized by an erythema migrans rash in which the area of redness begins at the site of the tick bite.

**Lymphadenopathy** A pathologic lymph node enlargement, which is usually painless and may be associated with malignancy, especially lymphoma. Lymphadenopathy must be distinguished from normal reactive lymph node enlargement in response to infection. Reactive nodes are usually tender and are situated “downstream” from a site of infection.

**Lymphedema** Swelling produced by an obstruction of lymphatic flow.

**Lymphoblast** A large, immature cell that develops into a lymphocyte. When found in the circulation lymphoblasts are indicative of leukemia.

**Lymphocyte** A white blood cell derived from the lymphoid stem cell that is not affected by diseases of the myeloid stem cell. Lymphocytes are of three basic types: T, B, and natural killer cells.

**Lymphogranuloma venereum** Highly contagious systemic infection caused by a number of strains of *Chlamydia*. It has progressive stages of development in which an initial lesion forms, and systemic disease occurs following dissemination via the lymphatic system.

**Lymphoid group** Dermal cells consisting of lymphocytes commonly found in inflammatory lesions of the skin.

**Lymphopoiesis** Formation of lymphocytes in the bone marrow.

**Lysis** Destruction or breakage of a cell membrane or molecule.

**Lysosome** An organelle containing hydrolytic enzymes that function to digest intracellular materials.

**Lysozyme** An enzyme secreted by macrophages and neutrophils to control foreign particle activity.

## M

**M line** Marks the center of the A band and the midpoint of myosin filaments in striated muscle.

**Macrocyte** An abnormally large erythrocyte.

**Macromolecule** A molecule of colloidal size, such as a protein.

**Macrophage** A mature monocyte that migrates from the blood vessels to sites in the tissues. Macrophages are powerful phagocytes and secrete a number of cytokines that stimulate inflammation.

**Major depressive disorder** A mood disorder characterized by persistent dysphoria, anxiety, irritability, and fear.

**Major histocompatibility complex (MHC)** The regions on chromosome 6 that contain the genes for MHC proteins. Class I proteins are present on virtually all nucleated cells. Class II proteins are found mainly on antigen presenting cells: B cells, macrophages, and dendritic cells.

**Malabsorption** Failure of the gastrointestinal tract to absorb or normally digest one or more dietary constituents.

**Maladaptation** Ineffective, inadequate, or inappropriate change in response to new or altered circumstances.

**Malignant tumor** A type of tumor that has a tendency to invade local tissues and spread to distant sites (metastasis). Malignant tumors are generally poorly differentiated and are associated with a poor prognosis if not promptly managed.

**Mallory-Weiss syndrome** Mild to massive bleeding due to a tear in the mucosa or submucosa of the cardia or lower esophagus. The tear is usually longitudinal and is caused by forceful or prolonged vomiting during which the upper esophageal sphincter fails to relax.

**Malnutrition** A disorder of nutrition that may result from an unbalanced, insufficient, or excessive diet or from impaired absorption.

**Malunion** An imperfect union of previously fragmented bone or other tissue.

**Mania** Also called *full mania*, it is characterized by an overwhelming increase in energy and drive manifested as nonstop activity, grandiose thinking, impulsivity, euphoria, impaired judgment, acting-out behaviors, and hypersexuality.

**Mass lesion** Any lesion in the cranium that behaves like a space-occupying mass. Mass lesions tend to progress and cause signs and symptoms of increased intracranial pressure.

**Mast cell** Also called *histiocytic cell*. Mast cells have intracytoplasmic basophilic metachromatic granules containing heparin and histamine. The normal skin contains relatively few mast cells, but their number is increased in many different skin conditions, particularly the itching dermatoses.

**Mastectomy** Surgical removal of a breast. See *modified radical mastectomy* and *radical mastectomy*.

**McBurney point** Located in the lower right quadrant of the abdomen; situated in the normal area of the appendix midway between the umbilicus and the anterior iliac crest.

- Mean arterial pressure** The average pressure in the arterial system through the cardiac cycle. It is calculated by adding the systolic pressure to two times the diastolic reading and dividing the sum by 3.
- Measles** Known as *hard measles*, *7-day measles*, or *rubeola*. This is a communicable viral disease caused by paramyxovirus of the genus *Morbillivirus* with a characteristic macular and blotchy rash; sometimes the macules become confluent.
- Mediastinum** The area of the chest between the sternum and vertebral column and between the lungs. Mediastinal structures include the trachea, esophagus, aorta, heart, and lymph nodes.
- Medullary cavity** Central cavity in longer bones.
- Megacolon** Abnormal massive dilation of the colon that may be congenital, toxic, or acquired.
- Megakaryocyte** A large bone marrow cell that sheds platelets into the circulation from its cytoplasm.
- Megaloblastic dysplasia** Abnormal development of large red blood cells and nonlymphocytic bone marrow cells.
- Megaloblasts** Large abnormal hematopoietic bone marrow cells.
- Meiosis** A type of cell division that results in daughter cells with one half the normal number of chromosomes. Meiosis occurs in gonadal germ cells.
- Melanin** Dark pigment found in melanocytes that gives color to hair and skin.
- Melanocyte** One of several types of epithelial cells. Melanocytes contribute color to the skin and serve to filter ultraviolet light.
- Melena** Tarry, black feces due to the action of gastrointestinal secretions on blood in the intestine.
- Membranous urethra** The urethral segment that passes through the muscular layers of the urogenital diaphragm.
- Memory cells** T and B lymphocytes that mediate immunologic memory through development of clones of long lived cells.
- Menarche** The first menstrual period at the time of puberty, usually occurring around age 12 years in North America.
- Meniere disease** A chronic disease of the inner ear characterized by recurrent episodes of vertigo.
- Meninges** Membranes surrounding the brain and spinal cord, which include the dura mater, arachnoid, and pia mater.
- Meningitis** Any infection or inflammation of the membranes covering the brain and spinal cord.
- Meningocele** Hernial protrusion of meninges through a neural tube defect in the skull or vertebral column.
- Meniscus** Curved, fibrous cartilage located in the knee and other joints. Menisci facilitate rotation at the knee by allowing better contact of the tibial surfaces with the femoral condyles.
- Menopause** A process by which the supply of ovarian follicles and estrogen hormones declines, usually beginning between the ages of 45 and 55 years.
- Menorrhagia** An increase in the amount or duration of menstrual bleeding, usually resulting from a lesion of the female reproductive organs.
- Menstrual cycle** The rhythmic pattern of changes in hormonal secretions and in sexual organs occurring approximately every 28 days during a female's reproductive years. The cycle culminates in the production of an ovum and the preparation of the uterus for implantation of a fertilized ovum.
- Merkel cells** One of several types of epithelial cells. Merkel cells consist of free nerve endings attached to modified epidermal cells. It is generally agreed that Merkel cells function as touch receptors.
- Mesoblastic nephroma** Benign congenital renal tumor.
- Mesonephros** One of three distinct stages in the development of the renal system. Mesonephros, which is the middle stage, corresponds to the mature excretory organ of some amphibians. In humans, it begins developing at about the fourth to fifth week of gestation.
- Metabolic acidosis** Any of the types of acidosis resulting from accumulation in the blood of noncarbonic, nonvolatile acids; characterized by a low  $\text{HCO}_3^-$  concentration.
- Metabolic alkalosis** A disturbance in which the acid-base balance shifts to alkaline because of uncompensated loss of acids, ingestion or retention of excess base, or depletion of potassium.
- Metabolic syndrome** A disorder of metabolism including at least three of the following: abdominal obesity, hypertriglyceridemia, low level of high-density lipoproteins, hypertension, and high fasting plasma glucose level. It is associated with an increased risk for development of diabetes mellitus and cardiovascular disease.
- Metabolism** Synthesis and breakdown of molecules in a living organism. Metabolism involves both the use and the release of energy.
- Metanephros** The final stage of development of the renal system. The metanephros begins in the fourth week of gestation when the ureteral bud grows out of the mesonephric duct.
- Metaplasia** Transformation of one kind of tissue to another fully differentiated tissue.
- Metastasis** Dissemination of cancer cells from the location of origin to other distant areas in the body.
- Methemoglobin** A transformation product of oxyhemoglobin that is formed when the iron of the hemoglobin molecule is oxidized to the ferric state ( $\text{Fe}^{3+}$ ).
- Metrorrhagia** Bleeding between menstrual periods, usually the result of slight physiologic bleeding from the endometrium during ovulation. It may also result from other causes such as uterine malignancy, cervical erosions, endometrial polyps, or estrogen therapy.
- Microbial adherence** The ability of the microorganism to latch onto and gain entrance into the host.
- Microcytic** Referring to an abnormally small erythrocyte.
- Micropenis** A small, normally formed penis with an engorged length more than 2 standard deviations below the mean, or an engorged length less than 2.5 cm.
- Micturition** Urination.
- Mineralocorticoids** A class of steroid hormones secreted by the adrenal cortex that regulate the mineral salts (electrolytes) and water balance in the body.
- Minimal change disease** A kidney disorder characterized by subtle changes in glomerular structure.
- Mitochondrion** A membrane-bounded organelle that carries out oxidative phosphorylation to synthesize most of the adenosine triphosphate in a eukaryotic cell.
- Mitosis** A type of cell division that results in daughter cells with chromosomes that are identical to the parent cell. Mitosis occurs in somatic cells.
- Mitral valve** The cardiac valve that lies between the left atrium and left ventricle. The valve is normally closed during ventricular systole and open during ventricular diastole. Mitral valve closure contributes to heart sound  $S_1$ . Also called the *bicuspid atrioventricular valve*.
- Mixed acid-base imbalance** A combined disturbance of acid-base balance in which a primary respiratory disorder and a primary metabolic disorder coexist.
- Mixed incontinence** Loss of bladder control with symptoms of both stress and urge incontinence.
- Mobility** The ability to achieve purposeful movement.
- Modified radical mastectomy** Surgical removal of the breast accompanied by dissection of a portion of the axillary lymphatic system.
- Molluscum contagiosum** A viral skin disease with two forms. One form affects children and is spread through indirect contact; the other is sexually transmitted and occurs in young adults. It is characterized by pink and white lesions on the genitalia with an exudative core.
- Mongolian spots** Caused by selective pigmentation. They usually occur on the buttocks or sacral area and are commonly seen in Asian Americans and African Americans.
- Monoclonal antibodies** Identical antibodies produced in the body or in a laboratory from a single clone of B lymphocytes.
- Monocyte** An immature circulating macrophage.
- Monosaccharide** A simple sugar (e.g., glucose, fructose).
- Monosomy** Having only one member of a homologous chromosome pair, as in monosomy X, also called *Turner syndrome*.
- Monounsaturated fatty acid** A fatty acid with one double bond.
- Mood** Sustained expression of an emotion that affects one's outlook.
- Mood disorder** A disturbance of mood that may be caused by either organic damage to the brain or chemical alterations in neurotransmission. Mood disorders may also have no known biological basis.

**Mood swings** Oscillation between periods of euphoria (elevated mood) and depression or anxiety.

**Morphogen** A substance that triggers growth, proliferation, and differentiation of cells in a concentration-dependent manner.

**Morphogenesis** Arrangement of cells in a particular order during the development of complex organisms.

**Morphologic changes** Structural and associated functional alterations in cells or tissues that are either characteristic of the disease or diagnostic of the etiologic process.

**Motor end-plate** The points of contact between an  $\alpha$ -motor neuron and the skeletal muscle cells it innervates.

**Mucocutaneous candidiasis** Candidal infection of the mucous membrane and the skin.

**Mucosal edema** Swelling of the membranes of the respiratory, gastrointestinal, or urogenital systems; usually a consequence of inflammation.

**Müllerian ducts** Genital structures, also called *paramesonephric ducts* because they develop alongside the mesonephric ducts. A pair of embryonic ducts that become the fallopian tubes, uterus, and vagina in females.

**Multifactorial** Pertaining to or characteristic of any condition or disease resulting from the interaction of many factors.

**Multipennate muscle** A muscle with several central tendons toward which the muscle fibers converge like the barbs of feathers.

**Multiple myeloma (plasma cell myeloma)** A malignant disorder of antibody-secreting plasma cells that produce large quantities of monoclonal antibodies and have a predilection to settle in the skeleton, where osteoclastic bone lesions are produced.

**Multiple sclerosis** A chronic demyelinating disease of the central nervous system that causes significant disability in young adults. It is thought to be an autoimmune disorder that results in inflammation and scarring (sclerosis) of the myelin sheaths covering nerves.

**Muscular dystrophy** Term referring to a group of genetically determined myopathies characterized by progressive degeneration of muscle fibers.

**Mutagen** A physical or chemical agent capable of causing alterations in an organism's DNA by inducing mutations.

**Mutation** A heritable change in the nucleotide sequence of a chromosome; it is passed on to daughter cells when the cell divides.

**Myasthenia gravis** A chronic autoimmune disease affecting the neuromuscular function of voluntary muscles and characterized by profound muscle weakness and fatigability.

**Mycosis** Infection caused by a fungus.

**Myeloid group** Cells of the dermis consisting of polymorphonuclear leukocytes and eosinophilic leukocytes. These cells occur commonly with allergic dermatoses.

**Myelomeningocele or meningocele** Hernial protrusion of meninges, spinal fluid, and a portion of the spinal cord with its nerves through a defect in the skull and vertebral column.

**Myocardial infarction** Localized area of cardiac necrosis most often associated with coronary heart disease and sudden acute occlusion of a coronary artery by a thrombus.

**Myocardium** The middle layer of the heart, composed of cardiac muscle tissue.

**Myopia** A condition of nearsightedness caused by elongation of the eyeball or by an error in refraction so that parallel rays are focused in front of the retina.

**Myosin** A cytoskeletal protein that comprises the thick filament of the muscle sarcomere in skeletal and cardiac muscle. It is also present as a contractile filament in other types of cells. Myosin binds with actin during muscular contraction.

**Myositis ossificans** An abnormal calcification within a muscle.

**Myxedema** Nonpitting edema caused by advanced hypothyroidism in adulthood.

## N

**Narcissism** Self-absorption; excessive self-love.

**Natural killer cells** A lymphocyte that is capable of binding to and killing virus-infected cells and some tumor cells by releasing cytotoxins.

**Necrosis** Death and degradation of body cells or tissues in response to irreversible injurious events.

**Necrotizing enterocolitis** A disorder occurring most often in premature infants (less than 34 weeks' gestation) and infants with low birth weight (less than 5 lb or 2.25 kg). This disorder is characterized by diffuse or patchy intestinal necrosis accompanied by sepsis.

**Necrotizing inflammation** Also called *vasculitis*. This response can occur when antigen and antibody react in blood vessels in the skin. Necrotizing inflammation can be caused by drug allergies; disorders such as systemic lupus erythematosus, rheumatoid arthritis, and glomerulonephritis; and certain infectious diseases such as hepatitis B.

**Negative feedback** A term used to explain homeostatic mechanisms. Negative feedback causes the controller to respond in a manner that opposes or negates deviation from normal level (set point). Most body systems operate on the principle of negative feedback.

**Negative nitrogen balance** The condition of protein catabolism (breakdown) exceeding daily protein intake and synthesis.

**Negative symptoms (schizophrenia)** Symptoms of schizophrenia that are thought to be mediated by dopamine D<sub>1</sub> receptors in the brain. Drugs that block D<sub>1</sub> receptors may alleviate some of the negative symptoms, which include social withdrawal, flat affect, poverty of speech, ritualistic posturing, and autism.

**Neoantigen formation** A new specific antigen that develops in a tumor cell.

**Neologism** New word, often created by combining syllables of other words; or a word given special or private significance.

**Neoplasia** New growth. The term implies an abnormality of cellular growth and may be used interchangeably with the term tumor.

**Neoplasm** A new and abnormal proliferation of cells. If malignant, the growth infiltrates

tissue, metastasizes, and often recurs, even after attempts at surgical removal.

**Nephralgia** Renal pain.

**Nephrectomy** The surgical removal of a kidney.

**Nephritic syndrome** A group of signs and symptoms of a urinary tract disorder, including hematuria, hypertension, and renal failure.

**Nephroblastoma (Wilms tumor)** The most common childhood malignant kidney tumor, resulting from a defect on chromosome 13.

**Nephrogenic rests** Remnants of embryonic tissue found in or around the kidney, retained after the period of embryonic development. Nephrogenic rests are sometimes precursors (forerunners) of Wilms tumor.

**Nephrolithiasis** The presence of a stone or calculus anywhere in the urinary tract.

**Nephroma** Tumor of the kidney or area of the kidney.

**Nephron** Functional unit of the kidney composed of epithelial cells forming the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct.

**Nephropathy** A pathologic process in the kidney, including inflammatory, degenerative, and sclerotic conditions. Many disorders can lead to nephropathy, as in diabetic nephropathy, toxic nephropathy, ischemic nephropathy, and obstructive nephropathy.

**Nephrotic syndrome** A common set of symptoms caused by damage to the glomeruli, in which proteins cross the glomerulus and are lost in the urine at a rate of >3.5 g/day.

**Nephrotoxic** Poisonous to the kidney.

**Neural thread protein** Microscopic protein thread that binds and helps stabilize microtubules (the cell's internal support structure or skeleton). In Alzheimer disease, the threads become chemically altered and twist into paired helical filaments, known as neurofibrillary tangles. See *tau protein*.

**Neurocrine** Secretion of hormone signaling molecules into the bloodstream from neurons.

**Neurofibrillary tangle** Abnormal bundle of twisted threads inside a nerve cell that is the collapsed remains of the neuron's microtubules, which normally provide structural support.

**Neurogenic bladder** Bladder dysfunction caused by a lesion at any level in the nervous system.

**Neurogenic shock** Often called "fainting," neurogenic shock may be caused by severe pain, fear, an unpleasant sight, or other strong stimuli that overwhelm the usual regulatory capacity of the nervous system.

**Neuroglia, glia** A group of cell types, including astrocytes, microglia, ependymal cells, and oligodendrocytes, that support nerve cells and do not themselves conduct action potentials.

**Neurohormones** A hormone secreted by a specialized neuron into the bloodstream, the cerebrospinal fluid, or the intercellular spaces of the nervous system.

**Neuropathic osteoarthropathy** A neurologic disease that leads to bone abnormalities and joint involvement. The mechanics of disease development are probably a combination of neurovascular and neurotraumatic processes.

**Neurovascular injury** An injury that affects the nerves that control the caliber of blood vessels.

**Neutropenia** A type of leukopenia in which the absolute neutrophil count is below 500 cells/ $\mu$ l. Neutropenia is associated with a high risk of bacterial sepsis.

**Neutrophilia** A high blood neutrophil count.

**Neutrophil/neutrophilic granulocyte** A cell that contains small lysosomal granules and a segmented nucleus with two to five lobes. These cells compose 60% to 70% of leukocytes.

**Nevus** Congenital discoloration of a circumscribed area of the skin; commonly called mole or birthmark.

**Nociception** Activation of nociceptors by potentially tissue-damaging stimuli, resulting in the perception of pain by the central nervous system. Nociception includes the processes of receptor transduction, signal transmission, perception, and signal modulation.

**Nociceptor** Pain receptor.

**Nocturia** Excessive urination at night.

**Nonarticular rheumatism** A common soft-tissue syndrome in children. The most common symptom is nocturnal pain that usually occurs in the calves, shins, and thighs. Also called *growing pain*.

**Noncontractile tissue** Soft tissue that possesses no ability to contract or relax; this includes the joint capsule, ligament, bursa, fascia, dura mater, and nerve root. Also called *inert tissue*.

**Nondisjunction** The failure of homologous chromosomes to separate normally during meiosis or mitosis, resulting in unequal distribution of chromosomes to daughter cells.

**Nondisplaced fracture** A fracture in which the fragments remain in alignment and position.

**Non-Hodgkin lymphoma** A varied group of malignant disorders of lymph node cells involving B cells, T cells, and natural killer cells. In comparison with Hodgkin disease, these lymphomas tend to spread unpredictably and metastasize early, and thus carry an overall worse prognosis.

**Non-Q-wave infarct** A subendocardial infarct affecting only the inner third to half of the ventricular wall and generally associated with less severe symptoms.

**Nonspecific immune response** Referring to a series of mechanical, biochemical, and phagocytic barriers to infection; also called the *innate immune system*.

**Non-STEMI** A myocardial infarction that does not have ST-segment elevation.

**Nonunion** Pertaining to a fractured bone that fails to heal properly.

**Norepinephrine** A major monoamine neurotransmitter of the sympathetic nervous system that is involved in the etiologic development of mood disorders.

**Normochromic** Pertaining to a blood cell having normal color resulting from the presence of an adequate amount of hemoglobin, measured by the mean corpuscular hemoglobin concentration (MCHC).

**Normocytic** Description of a typical adult red blood cell of average size, measured by the mean corpuscular volume (MCV).

**Nuclei** A cluster of neuronal cell bodies located in the central nervous system.

**Nucleocapsid** The core of the human immunodeficiency virus (HIV), which contains two strands or chains of RNA, protein, and enzymes.

**Nucleotide** A biomolecule composed of a purine or pyrimidine base linked to a ribose or deoxyribose sugar, with one or more phosphate groups attached to the sugar. DNA and RNA are polymers of nucleotides.

**Nucleus** A cellular organelle that contains chromosomal DNA.

**Nutritional screening** A method for quickly determining the nutritional status of an individual from a selected group of anthropometric and biochemical tests.

**Nutritional status** The state of an individual's nutrition, resulting from the consumption and utilization of nutrients to meet metabolic needs.

**Nystagmus** Involuntary, rapid, rhythmic movements of the eyeball; these occur commonly in a horizontal direction, but can also occur in a vertical or a rotational direction.

## O

**Oblique fracture** Fracture resulting from a rotational force; however, unlike a spiral fracture, the break is along an oblique course (45-degree angle) and does not rotate around the entire bone.

**Obsession** A powerful, persistent, intrusive thought, impulse, or image that dominates the mental life of the individual to the extent of seriously interfering with normal living.

**Obsessive-compulsive disorder (OCD)** An anxiety disorder characterized by recurrent and persistent thoughts, ideas, and feelings or repetitive acts.

**Obstruction** Refers to an anomaly that compromises or prevents flow because of abnormal narrowings. Stenosis or atresia (failure to develop) of valves and coarctation of the aorta are examples of the most common cardiac obstructive defects.

**Obstructive sleep apnea** A form of sleep apnea involving a physical obstruction in the upper airways.

**Occupational asthma** Resembles allergic asthma and may be accompanied by positive skin test reactions to protein allergens in the work environment.

**Odynophagia** A severe sensation of burning, squeezing pain with swallowing; may accompany dysphagia, or difficulty with swallowing.

**Ogilvie syndrome** The idiopathic syndrome of intestinal pseudoobstruction; may result in megacolon.

**Olfactory** Pertaining to the sense of smell.

**Oligomenorrhea** Infrequent menstruation, usually the result of failure to ovulate as a result of inappropriate hormonal function.

**Oligosaccharide** A compound consisting of 2 to 10 joined monosaccharide units.

**Oliguria** Urine output of less than 500 ml/day.

**Omphalocele** Congenital anomaly in which a herniation of viscera at the base of the umbilical cord is present; requires surgical correction.

**Oncocytoma** Benign renal tumor consisting of large eosinophilic cells that have granular cytoplasm and round, uniform nuclei.

**Oncogene** A gene associated with the initiation of cancerous behavior in a cell.

**Onycholysis** Separation of the nail from its nail bed.

**Oogonia** The cells present in the female ovaries during prenatal development that ultimately develop into ova. The entire lifetime supply of ova is established prenatally; no new oogonia arise after birth.

**Open fracture** Fracture occurring when bone is broken and an external wound leads to the fracture site.

**Ophthalmia neonatorum** Purulent gonococcal conjunctivitis and keratitis in the newborn resulting from exposure of the infant's eyes to infected maternal secretions during the passage through the vagina at birth.

**Ophthalmoscopic examination** Examination of the structures of the eye, both extraocular and intraocular, using an ophthalmoscope.

**Opioid** Any of a group of drugs with an affinity for opioid receptors in the central nervous system. Morphine is the standard opioid with which others are compared for characteristics and potency.

**Opportunistic infection** An infection caused by organisms that are usually nonpathogenic but that become pathogenic because of decreased function of the immune system.

**Opsonization** The process of proteins, usually antibodies or complement fragments, binding to an antigen in order to make the antigen easier for phagocytic cells to locate. Phagocytic cells have receptors for opsonins.

**Organelles** The membrane-bound structures in the cell cytoplasm, including nucleus, mitochondria, endoplasmic reticulum, and Golgi apparatus.

**Orthopnea** Difficulty with breathing that is instigated or exacerbated by lying supine.

**Orthostatic (postural) hypotension** A form of low blood pressure that occurs after positional change from supine to standing. Diagnosed by an increase in heart rate of more than 15% and a decrease in either systolic blood pressure by more than 15 mm Hg, or diastolic blood pressure, by more than 10 mm Hg.

**Osmolality** A measure of degree of concentration; number of particles per kilogram of solvent.

**Osmosis** Movement of water across a semipermeable membrane to equalize the particle concentration of the fluid on both sides of the membrane.

**Ossicle** One of several small bones in the middle ear responsible for transmitting sound waves to the inner ear.

**Osteoarthritis** A common degenerative joint disease characterized by progressive loss of articular cartilage and by formation of new bone from subchondral bone at joint margins.

**Osteoblast** A bone-forming cell that is derived from the embryonic mesenchyme and, during the early development of the skeleton, differentiates from a fibroblast to function in the formation of bone tissue.

**Osteochondroma** A benign bone tumor consisting of bone and cartilage.

**Osteoclast** A cell responsible for bone resorption.

**Osteocyte** A mature bone cell.

**Osteonecrosis** The destruction and death of bone tissue, such as from ischemia, infection, malignant neoplastic disease, or trauma.

**Osteoid osteoma** A painful but benign bone-forming tumor that is often found in the cortex of the tibia and femur.

**Osteomalacia** An abnormal condition of lamellar bone, characterized by a loss of calcification of the matrix and consequent softening of the bone. The condition is the result of an inadequate amount of phosphorus and calcium available in the blood for mineralization of the bones.

**Osteomyelitis** A severe pyogenic infection of bone and local tissue that requires immediate management.

**Osteon** The basic unit of bone; also called the *Haversian system*.

**Osteoporosis** A common metabolic bone disease in which reduction in bone mass results from bone resorption proceeding at a rate faster than that of new bone formation.

**Osteoprogenitor** A type of bone stem cell that lines bone surfaces.

**Osteosarcoma** A malignant bone-forming tumor and the most common primary malignant bone tumor that develops in the metaphyseal region of long bones.

**Otosclerosis** A hereditary condition of unknown cause in which irregular ossification occurs in the ossicles of the middle ear, causing hearing loss.

**Ototoxic** Damaging to the structures of the inner ear.

**Ovarian cyst** A sac on an ovary that contains fluid or semisolid material. It may develop at any time between puberty and menopause; the cause is presently unknown.

**Overflow incontinence** Loss of bladder control associated with urinary retention and bladder distention due to obstruction, detrusor underactivity or inactivity, or sphincteric malfunction.

**Oviduct** Another term for *fallopian tube*. Each oviduct runs laterally from the uterus to the uterine end of the ovary. The free end of the oviduct adjacent to the ovary is called the *infundibulum*.

**Oxidative phosphorylation** An ATP-generating process in which oxygen serves as the final electron acceptor. The process occurs in mitochondria and is the major source of ATP generation in aerobic organisms.

**Oxygen consumption** The amount of oxygen used by the tissues in 1 minute, usually expressed as  $\dot{V}O_2$ .

**Oxygen delivery** The amount of oxygen delivered to the tissues each minute. Oxygen delivery ( $\dot{D}O_2$ ) is calculated by multiplying cardiac output and arterial oxygen content.

**Oxytocin** Hormone secreted by the posterior pituitary. It causes uterine contraction and is thought to have a major role in promoting

increased uterine contractility during parturition. After birth, it is secreted in response to suckling by the infant and stimulates the release of milk, called the milk ejection reflex.

## P

**Paco<sub>2</sub>** Partial pressure of carbon dioxide in arterial blood; an indicator of the effectiveness of respiratory excretion of carbonic acid.

**Paget disease** Also called *osteitis deformans*; a slowly progressive metabolic bone disease characterized by an initial phase of excessive bone resorption followed by a reactive phase of abnormal excessive bone formation.

**Pain** An unpleasant sensation caused by noxious stimulation of the sensory nerve endings, or perceived as such.

**Pallor** Paleness of skin, nail beds, lips, and conjunctivae. A possible symptom of anemia.

**Pancreas** Gland located in the abdomen; has both endocrine and exocrine functions. The endocrine pancreas produces insulin, glucagon, and somatostatin.

**Pancreatitis** Inflammation of the pancreas; may be acute or chronic.

**Pancytopenia** Decreased production of red blood cells, white blood cells, and platelets.

**Pandemic** An epidemic that affects large geographic regions, possibly spreading worldwide.

**Panhypopituitarism** A condition of deficiency in all pituitary hormones.

**Panic disorder** Psychiatric disorder characterized by recurrent, unexpected episodes of acute anxiety, fear, and panic; often accompanied by the subject's belief that he or she is having a heart attack, is unable to breathe, is losing control, or is dying.

**Panmyelosis** A pathologic condition characterized by excessive proliferation of bone marrow cells of all types.

**Papillary layer** One of two layers of the dermis. The papillary layer consists of bumps (papillae) that project into the epidermis.

**Papillary muscles** Muscles within the ventricles that connect the chordae tendineae to the ventricular wall. Papillary muscles contract during ventricular systole to place tension on the valves and prevent backflow through them.

**Paracrine** Referring to hormone-like chemicals, the target cell of which is located next to the cell secreting the chemical.

**Parametritis** An infection of the connective tissue between the broad ligaments underlying the female reproductive organs.

**Paraneoplastic syndrome** A cluster of systemic conditions associated with cancer, such as hypercalcemia, hyponatremia, or Cushing syndrome.

**Paraphimosis** Painful constriction of the glans penis by the foreskin, which has been retracted behind the corona.

**Parasite** One of a variety of protozoa (single-celled animals), nemathelminths (roundworms), plathelminths (flatworms), and arthropods (invertebrate animals with jointed appendages). Parasites depend on another organism for survival.

**Parkinsonism** Parkinson disease symptoms; a neurologic disorder characterized by tremor,

muscle rigidity, hypokinesia, a slow shuffling gait, and difficulty in chewing, swallowing, and speaking caused by various lesions in the extrapyramidal motor system.

**Paroxysm** A sudden outburst or change from the norm, as in a sudden burst of electrical activity seen on electroencephalography, as occurs with seizure activity.

**Paroxysmal nocturnal dyspnea** A sudden severe feeling of suffocation; usually occurs at night and awakens the person from sleep.

**Partial seizure** A seizure in which part of the brain surface is involved in the seizure.

**Parturition** The process by which an infant is born.

**Passive immunity** A form of acquired immunity resulting from antibodies that are transmitted naturally through the placenta to a fetus or through the colostrum to an infant, or artificially by injection.

**Pathogen** An agent that causes disease.

**Pathogenesis** Development or evolution of disease. A description of the pathogenesis includes the processes that occur in the body from the initial stimulus to the ultimate expression of manifestations of the disease.

**Pathologic** Pertaining to a condition that is caused by or involves a disease process.

**Pathology** Study of the causes, characteristics, and effects of disease.

**Pathophysiology** The study of the biological and physical manifestations of disease including etiology, pathogenesis, clinical manifestations, and treatment implications.

**Pauciarticular onset** Affecting four or fewer joints; used in association with juvenile rheumatoid arthritis.

**Pedigree** Genetic lineage or family history of traits; used to trace the pattern of inheritance.

**Pelvic inflammatory disease** Any acute or subacute recurrent or chronic infection of the oviducts and ovaries with involvement of the adjacent reproductive organs.

**Pemphigus** A group of disorders including vulgaris, vegetans, foliaceus, and erythematousus. The pemphigus group disorders are characterized by bullous eruptions (blisters) thought to be caused by autoimmune reactions.

**Pemphigus vulgaris** Included in the pemphigus group of disorders, pemphigus vulgaris has the worst prognosis. Bullae can erupt on the skin and mucous membranes (e.g., esophagus), and toxemia and infection can cause death if proper treatment (cortisone) is not administered.

**Penile urethra** The longest segment of the male urethra, extending about 15 cm in length from the membranous urethra to the external meatus.

**Penis** Male organ of copulation and urinary excretion.

**Penumbra** The margin or fringe surrounding a central part. In the case of stroke, a penumbra of viable tissue surrounds the necrotic core that can survive if optimal conditions exist and if it is not subject to further insults.

**Peptic ulcer disease** Disorder of the upper gastrointestinal tract caused by the action of acid

- and pepsin. This disorder may include injury to the mucosa of the esophagus, stomach, or duodenum, and may range from a slight mucosal injury to severe ulceration.
- Percutaneous** Referring to a procedural approach that traverses the skin and is less traumatic than open surgical methods.
- Perfusion** The delivery of blood flow to a specific organ or an area of the body.
- Pericardial effusion** The escape of blood or other fluid into the pericardial sac.
- Pericarditis** Inflammation of the pericardium associated with trauma, malignant neoplastic disease, or infection.
- Pericardium** A protective covering of the heart that is made of two layers separated by a fluid-filled space. The inner (visceral) layer is attached to the heart itself, whereas the outer (parietal) layer forms a sac around the heart.
- Perimysium** The connective tissue surrounding the fasciculi.
- Peripheral vascular disease (peripheral arterial disease)** Decreased localized blood flow, often to the feet, resulting in decreased arterial pressure and chronic ischemia.
- Peristalsis** The basic propulsive movement of the gastrointestinal (GI) tract. During normal functioning, this coordinated, rhythmic, serial contraction of smooth muscle propels the contents of the GI tract in a downward direction.
- Peritoneal dialysis** A procedure performed to correct an imbalance of fluid or electrolytes in the blood or to remove toxins by intermittent infusion and removal of dialysis fluid through a catheter in the peritoneal cavity.
- Permissive hypothermia** A hypothesis positing that poor dampening by serotonin of other neurotransmitter systems (e.g., norepinephrine and dopamine) allows wide variations in mood.
- Permissiveness** The process in which one hormone increases the number of cellular receptors for a second hormone, thus increasing the cellular response to the second hormone.
- Peroxisome (microbody)** Small membrane-bound organelle that uses molecular oxygen to degrade organic molecules.
- Perseveration** Persisting response to a previous stimulus after a new stimulus has been presented.
- Personality disorder** A disorder that represents immature, inflexible, and persistently maladaptive ways of dealing with the intrapersonal and interpersonal aspects of life.
- Pessary** A device inserted in the vagina to treat uterine prolapse.
- Petechiae** Nonblanching, pinpoint red or purple spots caused by capillary hemorrhages.
- Peyronie disease** Formation of palpable, fibrous plaques on the surface of the corpora cavernosa of the penis.
- pH** The negative logarithm of the hydrogen ion concentration; a measure of the acidity or alkalinity of a solution.
- Phagocytosis** Ingestion of pathogens by leukocytes using the process of receptor-mediated endocytosis.
- Phagosome** A cellular lysosome containing substances obtained by phagocytosis.
- Phenotype** The physical, biochemical, and biological composition of an individual; expressed as recognizable traits.
- Pheochromocytoma** Tumor of the adrenal gland that secretes catecholamines, resulting in elevated blood pressure. An example of a condition that causes secondary high blood pressure.
- Phimosis** A condition in which the penile foreskin fits so tightly over the glans that it cannot be retracted.
- Phlebitis** Inflammation of a vein.
- Photoreceptor** A receptor found in the eye that responds to light.
- Photosensitivity** An abnormal response to exposure to light. Certain medications are photosensitive and can cause a skin reaction if the person is exposed to excessive sunlight.
- Physiologic jaundice of the newborn** A harmless, short-term condition caused by immature bilirubin conjugation and transport mechanisms; characterized by yellowish staining of the skin and sclera.
- Physiology** The study of the specific characteristics and functions of a living organism and its parts.
- Pigmentary disturbance** Interruption of any organic coloring material produced in the body, such as melanin.
- Pinocytosis** A process of ingesting fluids and small particles that is common to most cell types. Also called “*cellular drinking*.”
- Pituitary gland** A gland located at the base of the hypothalamus. It consists of anterior and posterior lobes. Also called *hypophysis*.
- Pityriasis rosea** A rash of unknown origin that primarily affects young adults. The characteristic lesion of a macule or papule with surrounding erythema is thought to be viral in origin, but no virus has been isolated to date.
- Pivot joint** A synovial joint that allows rotation as its single axis movement. Examples include the superior radioulnar joint of the elbow and the union between the first and second vertebrae. Also called *trochoid joint*.
- Placenta** A highly vascularized organ through which the fetus receives nutrients and by which wastes are removed. It also is an endocrine organ, producing several hormones, most notably human chorionic gonadotropin.
- Placenta previa** Condition of pregnancy in which the placenta is implanted abnormally over the internal cervical os. It occurs in varying degrees of severity and may result in sudden massive hemorrhage following dilatation of the internal os.
- Plaque** A flat patch on the skin or a patch of atherosclerosis.
- Plasma** A complex, aqueous liquid in blood and lymph containing a number of organic and inorganic substances from which blood cells have been removed.
- Plasma cell** 1. An antibody-secreting B lymphocyte. 2. A dermal cell rarely seen in normal skin secretions, occurring in small numbers in most chronic inflammatory diseases of the skin and in larger numbers in granulomas.
- Plasmalemma** Plasma membrane.
- Plasma membrane** The lipid bilayer that surrounds a living cell.
- Plasmapheresis** Removal of plasma from withdrawn blood, with retransfusion of the formed elements into the donor.
- Platelet** A circulating cytoplasmic fragment of megakaryocytes that is essential in the formation of blood clots and in the control of bleeding.
- Pleural effusion** A collection of fluid in the pleural cavity resulting from a disease process.
- Pleurodesis** Instillation of a chemically irritating drug (e.g., tetracycline, sterile talc, bleomycin, doxycycline) into the pleural space to stimulate inflammation and adhesion.
- Pneumonia** An acute inflammation of lung tissue caused by an infectious agent or by aspiration of chemically irritating fluid.
- Pneumothorax** Accumulation of air in the pleural space.
- Polio myelitis** An infectious disease caused by one of three polioviruses.
- Polyarteritis nodosa** A form of systemic vasculitis that can cause inflamed arteries in visceral organs, brain, and skin.
- Polyarticular onset (oligoarticular)** Affecting five or more joints; used in association with juvenile rheumatoid arthritis.
- Polycystic kidney disease** A progressive genetic disease characterized by multiple dilations of the collecting ducts of the kidneys, which appear as if they are fluid-filled cysts, as a result of renal pathologic processes.
- Polycythemia** An excess of circulating red blood cells.
- Polydipsia** Excessive thirst.
- Polygenic** Referring to a trait determined by multiple genes at different loci, all having additive effects.
- Polymenorrhea** An increased frequency of menstruation, which may be associated with ovulation due to endocrine or systemic factors.
- Polymorphism** Inherited structural differences in proteins as a result of many alleles for a particular gene locus.
- Polymorphonuclear neutrophil (PMN)** A cell that contains small lysosomal granules and a segmented nucleus with two to five lobes. PMNs compose 60% to 70% of leukocytes.
- Polymyositis** Inflammation of many muscles, usually accompanied by deformity, edema, insomnia, pain, sweating, and tension.
- Polyp** A general descriptive term used for any mass of protruding tissue. Polyps may be either benign or malignant, although the term usually refers to the benign form.
- Polyploidy** Having more than two sets of homologous chromosomes.
- Polysaccharide** A saccharide containing 10 to 10,000 monosaccharide units.
- Polysomy** Having greater than the usual number of autosomal chromosomes.
- Polyunsaturated fatty acid** A fatty acid with several double bonds.
- Polyuria** Excretion of large amounts of urine.
- Portal hypertension** Abnormally high blood pressure in the blood vessels draining the intraabdominal alimentary tract, pancreas,

- gallbladder, and spleen. It may be due to increased resistance to blood flow, as in cirrhosis, or, rarely, to abnormally increased blood flow, as in arteriovenous communications.
- Portal systemic encephalopathy** A neuropsychiatric syndrome caused by liver dysfunction and resulting in mental status changes ranging from mild cerebral dysfunction to deep coma (hepatic coma) and death.
- Positive end-expiratory pressure** A method in which a ventilator is used to maintain positive airway pressure at the end of expiration, resulting in increased functional residual capacity and decreased shunt.
- Positive feedback** A term used to explain homeostatic mechanisms. Positive feedback increases deviation from the set point. Although most systems of the body operate on the principle of negative feedback, sneezing and childbirth are two examples of positive feedback.
- Positive nitrogen balance** The condition of dietary intake of proteins exceeding output.
- Positive symptoms (schizophrenia)** Symptoms of schizophrenia that are thought to be due to excessive dopamine D<sub>2</sub> receptor activation in the brain. Disorganized thinking (inability to connect thoughts logically), disorganized speech (rambling, tangentiality), delusions (fixed system of false beliefs), and hallucinations (sensory perception when no apparent stimulus exists) are typical positive symptoms.
- Positron emission tomography (PET)** A technique of brain imaging. PET studies measure changes in brain utilization of glucose.
- Postictal phase** The phase following a seizure during which the person is sleepy and confused.
- Postobstructive diuresis** Increased urinary output after resolution of partial or total obstruction of the urinary tract.
- Postrenal** A term referring to structures distal to the kidney, including the ureters and urethra, that may become obstructed and lead to kidney failure.
- Posttraumatic stress disorder (PTSD)** Psychiatric disorder characterized by an acute emotional response to a previous traumatic event.
- Potter syndrome** Congenital condition often associated with renal agenesis, but always manifesting with the following anomalies: wide-spaced eyes with epicanthal folds, low-set ears, broad and flat nose, hypoplastic lungs, and limb deformities.
- Poverty of speech** Speech that gives little information owing to vagueness, empty repetitions, or obscure phrases.
- Predictive value** A measure used by clinicians to interpret diagnostic test results, as in positive predictive value and negative predictive value
- Preeclampsia-eclampsia** Elevated blood pressure during pregnancy associated with edema and proteinuria. Blood pressure returns to normal after delivery. Eclampsia is present when preeclampsia progresses to seizures. Also known as *pregnancy-induced hypertension*.
- Pregnancy-induced hypertension** The rapid rise of arterial blood pressure associated with a loss of large amounts of protein in the urine occurring during pregnancy. Women at risk for pregnancy-induced hypertension include teenagers and women in their late 30s and early 40s (also known as *toxemia of pregnancy* and *preeclampsia-eclampsia*).
- Preload** The volume of blood in the cardiac chamber just prior to systole (end-diastolic volume).
- Prepuce** Also called *foreskin*; penile skin that overlies the glans and is removed with circumcision.
- Prerenal** Pertaining to the area proximal to the kidney, generally referring to blood flow to the kidney, which if disrupted can result in prerenal renal failure.
- Presbycusis** Hearing loss associated with aging.
- Presbyesophagus** Presence of slow or disorganized esophageal motility in the older adult.
- Presbyopia** A refractive condition in which the accommodative ability of the elderly eye cannot meet the accommodative demand for near vision.
- Pressure sores** Localized areas of cellular necrosis resulting from prolonged pressure between any bony prominence and an external object such as a bed or a wheelchair. The tissues are deprived of blood supply and eventually die. Also called *decubitus ulcers*.
- Priapism** Painful, persistent erection.
- Prickly heat** A rash caused by midepidermal obstruction and rupture of the sweat glands from prolonged exposure to a warm and humid environment.
- Primary biliary cirrhosis** A slowly progressive disease that destroys small to medium-sized bile ducts and results in cirrhosis and liver failure.
- Primary dysthymia** A long-term state of chronic depression not associated with any other disorder. It is neither a prelude to major depression nor a state existing between episodes of a cyclic form of mood disorder.
- Primary endocrine disorder** Direct malfunction of a hormone-producing gland not induced by the pituitary.
- Primary glomerulopathy** Disease states resulting from alterations in the structure and function of the glomerular capillary circulation, in which the kidney is the only or primary organ involved.
- Primary (essential, idiopathic) hypertension** High blood pressure of unidentified cause. Accounts for 90% of cases of high blood pressure.
- Primary lesion** Injury that originates in the skin and has not been altered by scratching or by treatment.
- Primary prevention** The first level of health promotion, designed to prevent disease.
- Primary sclerosing cholangitis** A progressive chronic fibrosing inflammation of the bile ducts of unknown cause, occurring most commonly in young men and frequently associated with chronic ulcerative colitis.
- Prodromal period** The period preceding the onset of a disorder. Symptoms indicate an impending seizure, migraine, or other problem.
- Progesterone** A hormone produced by the adrenal cortex and the corpus luteum during the luteal phase of the menstrual cycle; it promotes uterine changes essential for the implantation and growth of the fertilized ovum.
- Prognosis** A forecast about the probable outcome of a disease; the prospect of recovery from a disease indicated by the nature, signs, and/or symptoms of the case.
- Progression (cancer)** A phase of carcinogenesis when clones of cells that have undergone mutations begin to develop new properties that allow them to become increasingly malignant.
- Progressive familial intrahepatic cholestasis** A rare autosomal recessive disorder comprising severe jaundice, pruritus, and malabsorption attributable to a defect in bile salt excretion.
- Proinsulin** Precursor to insulin produced by the  $\beta$  cells of the pancreas.
- Prokaryote** A cell that does not have a membrane-bound nucleus or other membrane-bound organelles (e.g., bacteria).
- Prolactin** Hormone secreted by the anterior pituitary. Following birth of an infant, prolactin stimulates milk production.
- Proliferation** The reproduction or multiplication of similar forms. The term is usually applied to an increased number of cells as a result of mitosis.
- Pronephros** One of three distinct phases in the development of the renal system. The pronephros is the earliest state in humans, corresponding to the mature structure in primitive vertebrates.
- Prostate** Gland located below the bladder; its secretions help activate sperm and maintain their motility.
- Prostatic urethra** The widest and most distensible part of the male urethra.
- Prostatitis** Inflammation of the prostate.
- Prostatodynia** Pain in the prostate.
- Protein** A molecule composed of nitrogen, carbon, hydrogen, oxygen, and occasionally sulfur; when hydrolyzed, proteins yield amino acids.
- Proteoglycan** Any of a group of polysaccharide-protein conjugates occurring primarily in the matrix of connective tissue and cartilage; composed mainly of polysaccharide chains, particularly glycosaminoglycans, as well as minor protein components.
- Proto-oncogene** A normal cellular gene that is growth promoting and usually inhibited in nonproliferating cells. When erroneously activated, it becomes an oncogene and promotes cancer.
- Provirus** The viral DNA that is spliced into the host cell's DNA.
- Pruritus** Itching of the skin.
- Pseudocyst** A collection of fluid within or adjacent to the pancreas that often has a direct communication to the pancreatic duct. It is the most common localized complication of acute pancreatitis.
- Pseudoglandular period** The first stage in fetal lung development when the bronchial divisions are differentiated and the major elements of lung tissue are present except for those involved in gas exchange: the respiratory bronchioles and alveoli.

**Pseudomembranous enterocolitis** An acute inflammation and necrosis of the small and large intestines caused by *Clostridium difficile*, usually affecting the mucosa but sometimes extending to other layers.

**Psoriasis** A common chronic skin disease characterized by papules and plaques with an overlying silvery scale. Lesions can appear on any area of the body but especially the knees, elbows, lower part of the back, scalp, and nails.

**Psoriatic arthritis** An inflammatory arthritis associated with psoriasis occurring in approximately 0.1% of the population in the United States. Peak age of onset is 30 to 55 years of age, and the arthritis can occur in patients who have had psoriasis for many years.

**Psychogenic** Produced or caused by emotional or psychological factors rather than organic factors.

**Psychosis** The most serious and debilitating of mental disorders. The hallmarks of psychosis are delusions and hallucinations, thought disorders, and inappropriate emotional responses or social behavior.

**Psychosomatic medicine** The discipline involving the physiologic impact of psychic stress on the emergence of disease.

**Pulmonary embolism (PE)** The blockage of a pulmonary artery by fat, air, tumor tissue, or thrombus.

**Pulmonary function testing (PFT)** A procedure for determining the volumes and capacities of the lungs.

**Pulmonary hypertension** Abnormally high blood pressure within the pulmonary circulation.

**Pulmonary tuberculosis** Infection of the lungs by *Mycobacterium tuberculosis*.

**Pulmonic valve** The cardiac valve that lies between the right ventricle and the pulmonary artery. It is open during ventricular systole and closed during ventricular diastole. Pulmonic valve closure contributes to heart sound S<sub>2</sub>.

**Pulse pressure** The difference between the systolic and diastolic blood pressures.

**Purpura** Hemorrhagic lesions 2 to 4 mm in diameter; petechiae that occur in groups or patches, caused by a vascular or bleeding disorder.

**Putamen nuclei** The larger, darker, and more lateral part of the lentiform nucleus.

**Pyelonephritis** An infection of the kidney medulla or cortex.

**Pylorus** Muscular sphincter between the stomach and the duodenum that controls gastric emptying and limits the reflux of bile from the small intestine.

**Pyogenic** Creating the formation of pus; typically at the site of an inflammation caused by bacterial infection.

**Pyrogenic** Producing or produced by fever.

**Pyrosis** A substernal burning sensation that may radiate to the neck or throat. It is caused by the reflux of gastric contents into the esophagus (also called *heartburn*).

**Pyuria** The presence of an excessive number of white blood cells in the urine. It is generally a sign of urinary tract infection.

## R

**Radiation** Emissions of radioactive energy, rays, or waves. Can cause radiation sickness, but often used in the treatment of cancer.

**Radical mastectomy** Surgical removal of the entire breast, lymphatic drainage structures, and underlying pectoral muscles.

**Radiculopathy** A disease involving compression and dysfunction of a spinal nerve root.

**Radiolysis** Lysis or splitting of water molecules into H<sup>+</sup> and OH<sup>-</sup> ions by the action of radioactive particles.

**Rapidly progressing glomerulonephritis** A syndrome that combines abrupt hematuria and proteinuria followed by a swift decline in renal function.

**Rarefaction** Decrease in density and weight of bone, but not in volume.

**Raynaud phenomenon** Blanching or cyanosis of fingers or hands on exposure to cold or emotional stress. The phenomenon is attributed to vasospasm and structural disease of blood vessels. Puffiness and swelling of the hands and fingers are noted clinically.

**Reality testing** The act of evaluating and considering the differences between internal experiences and external events.

**Receptor activation** Binding of a ligand to a cellular receptor, resulting in a change in intracellular cell signaling or function.

**Receptor specificity** The principle of allowing intracellular processes to be activated only by certain hormones. If a cell does not have the specific receptors for a hormone, it will not respond to the hormone.

**Recessive** Referring to a gene allele that fails to be expressed in the phenotype when a dominant allele is present. The trait carried in a recessive allele is apparent only when two identical copies are present.

**Recruitment** The process of calling in additional motor units in response to an increase in stimulation of motor nerves.

**Rectocele** Protrusion of the anterior rectal wall into the posterior vagina at a weakened part of the vaginal musculature. It usually results from an injury during either childbirth or surgery, and it may also be the result of the aging process or an inherent weakness in the vaginal wall.

**Recurrent urinary tract infection** Repeated infections within a short period of time following verified resolution of an earlier infection.

**Red blood cell (erythrocyte)** Cell responsible for transporting oxygen to the tissues, removing carbon dioxide from the tissues, and buffering blood pH.

**Reed-Sternberg cell** A malignant cell type found in affected lymph nodes of patients with Hodgkin disease. The presence of Reed-Sternberg cells differentiates Hodgkin disease from all other forms of malignant lymphoma.

**Reentry** The proposed mechanism for many dysrhythmias, including premature complexes and fibrillation. Reentry occurs when an impulse is able to activate the cardiac muscle more than once because of abnormalities in conduction through a portion of the heart.

**Referred pain** Pain felt at a site different from that of an injured or diseased organ or body part.

**Reflex incontinence** Urine loss that occurs without sensory warning or awareness.

**Reflux (urinary)** Retrograde flow of urine from the bladder to the kidney.

**Refractory period** The time during which a nerve or muscle membrane is unable to respond to a stimulus by generating an action potential.

**Regurgitation (valvular)** Retrograde blood flow through a cardiac valve when the valve is supposed to be closed.

**Reiter syndrome** Seronegative arthritis that appears 2 to 6 weeks after onset of an infection; characterized clinically by diffuse swelling of fingers and toes, swelling in the Achilles tendon or plantar fascia, and low back pain.

**Relative anemia** Anemia characterized by normal total red blood cell mass with disturbances causing excessive plasma fluid volume resulting in low hematocrit value.

**Relative polycythemia** Polycythemia characterized by normal total red blood cell mass with reduced plasma volume resulting in elevated hematocrit value.

**Relaxation time** The period between peak tension and zero tension.

**Releasing hormone** A hormone secreted by the hypothalamus that stimulates the anterior pituitary gland to secrete other hormones.

**Reliability** The extent to which a test measurement produces the same results with different investigators or with repeated measures over time.

**Remission** Disappearance of clinical manifestations of disease. In leukemia, complete remission is determined by the absence of leukemic blasts in the bone marrow aspirate and peripheral blood. Malignant stem cells still may be present, and remission does not imply cure.

**Renal adenoma** A tumor smaller than 3 cm with a cellular makeup similar to that of renal cell carcinoma.

**Renal agenesis** Failure of one or both kidneys to develop.

**Renal angiomyolipoma (hamartoma)** Benign renal tumor composed of abdominal blood vessels, clusters of fat cells, and sheets of smooth muscle.

**Renal calculus** Concretion of crystals of material (e.g., uric acid, calcium phosphate, struvite) that initially form in the calices or pelvis of the kidney. Calculi may migrate down the urinary tract and cause pain, obstruction, and infection.

**Renal cell carcinoma** Most common malignant tumor of the kidney.

**Renal hypoplasia** An abnormally small kidney that is morphologically normal but has either a reduced number of nephrons or smaller nephrons.

**Renal or ureteral colic** Intermittent flank or abdominal pain caused by spasms in the kidneys and/or ureters.

**Renin** An enzyme stored and released by the juxtaglomerular cells; converts angiotensinogen to angiotensin I.

**Renin-angiotensin-aldosterone system (RAAS)** The regulation of sodium balance, fluid volume, and blood pressure by the cascade of reactions beginning with release of renin, an enzyme that cleaves angiotensinogen to angiotensin I, followed by conversion of angiotensin I to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II stimulates the release of aldosterone from the adrenal cortex.

**Reperfusion injury** Damage to tissues when blood flow is restored after a period of ischemia.

**Resident flora** Microorganisms that usually reside in a certain environment on the host without causing disease.

**Residual urine** Urine that remains in the bladder after urination.

**Resistance** In the stress response, resistance occurs when sympathetic activity declines while secretion of adrenocortical hormones is high.

**Respiratory acidosis** A pulmonary hypoventilation condition that tends to cause an excess of carbonic acid and results in acid-base imbalance.

**Respiratory alkalosis** A pulmonary hyperventilation condition that tends to cause a deficit of carbonic acid and results in acid-base imbalance.

**Respiratory quotient** The ratio of the volume of carbon dioxide produced to the volume of oxygen used in tissue metabolism.

**Respiratory syncytial virus** A member of a subgroup of myxoviruses that in tissue culture cause formation of giant cells or syncytia.

**Resting membrane potential** The transmembrane voltage that exists in nonexcitable cells and in neurons and muscle cells when not producing an action potential.

**Reticular formation** Fibers in the brainstem that arouse the cerebrum.

**Reticular layer** One of two layers of the dermis; consists of a more dense reticulum (network) of fibers than the papillary layer above it. The reticular layer is made of collagen and elastin and contains skeletal (voluntary) and smooth (involuntary) muscle fibers.

**Reticulocytosis** Increase in the number of circulating reticulocytes (immature red blood cells).

**Reticulohistiocytic group** Cells of the dermis consisting of fibroblasts, histiocytes, and mast cells. Immature cells of the reticulohistiocytic group are called reticulum cells.

**Retinal detachment** A separation of the retina in the back of the eye.

**Retinopathy** A group of noninflammatory eye disorders. Major contributing conditions include diabetes, hypertension, and atherosclerotic vascular disease.

**Retrodisplacement** Posterior displacement, such as an alteration in the position of the uterus in which the body of the uterus is displaced from its normal location overlying the bladder to a position in the posterior pelvis.

**Retroperitoneal** Referring to the anatomic space in the abdomen behind the peritoneal cavity, where the kidneys reside.

**Retrovirus** An RNA virus capable of transcribing its own RNA into DNA, which can be

integrated into the host genome through the actions of a viral polymerase, also called *reverse transcriptase*.

**Reverse transcriptase** An enzyme that allows certain viruses to convert RNA to DNA and incorporate their genome into the DNA of the host cell.

**Reye syndrome** Primarily a children's disease, it is characterized by fatty infiltration of the liver with severe hepatic dysfunction.

**Rheumatoid arthritis** A systemic, inflammatory, autoimmune connective tissue disease. Enzymes are released into the joint fluid, causing inflammation, proliferation of synovium, and tissue damage. The hands, wrists, knees, and feet are most commonly involved. Joint involvement is symmetric. Other systems affected include integumentary, ocular, otolaryngologic, pulmonary, cardiac, gastrointestinal, renal, neurologic, and hematologic.

**Rhinorrhea** Drainage of a watery fluid from the nasal mucosa.

**Rhonchus** Coarse, bubbling sound usually heard on expiration, but which also can be heard on inspiration; it is caused by secretions in the airways.

**Rhus dermatitis** An inflammatory reaction to poison ivy, poison oak, and poison sumac. Clinically, rhus dermatitis begins within 48 hours of contact. The first symptom is pruritus, followed by erythema and vesicle formation, sometimes in linear fashion.

**Rhythmicity** The ability to beat regularly without external stimuli. Also called *automaticity*.

**Ribonucleic acid (RNA)** A nucleic acid, found in both the nucleus and the cytoplasm of cells, that has several roles in the translation of the genetic code and the assembly of proteins.

**Ribosome** A cellular structure containing ribosomal RNA and proteins that bind to mRNA and perform the task of translating the RNA message into a protein.

**Rickets** A condition caused by the deficiency of vitamin D; seen primarily in infancy and childhood and characterized by abnormal bone formation.

**Rigor mortis** The stiffening of muscles throughout the body after death resulting from the formation of persistent actin-myosin cross-bridges.

**Risk factor** Characteristic related to the probability of a certain outcome; a risk factor may be shown to cause an outcome or may be correlated with an outcome.

**RNA polymerase** An enzyme complex that binds to a gene segment of DNA, using it as a template for the synthesis of an RNA strand.

**Rocky Mountain spotted fever** An infection caused by a tick that carries *Rickettsia rickettsii*. The characteristic rash is a macular or maculopapular one that spreads to the rest of the body. Other symptoms include generalized edema, conjunctivitis, petechial lesions, photophobia, lethargy, confusion, and cranial nerve deficits.

**Roseola infantum** A contagious viral disease that generally affects children younger than 4 years and usually those about 1 year of age. It produces a characteristic maculopapular

rash covering the trunk and spreading to the appendages.

**Rostral** A positional term referring to the head end.

**Rough endoplasmic reticulum** A portion of the endoplasmic reticulum that is studied by ribosomes. Ribosomes attached to the endoplasmic reticulum synthesize proteins that are destined for the plasma membrane or lysosomes.

**Rubella** Also known as *3-day measles* or *German measles*. Rubella is a childhood disease caused by the rubella virus. It is characterized by a diffuse punctate, macular rash that begins on the trunk and spreads to the arms and legs.

**Rugae** Folds in the lining of the body of the bladder (and stomach) that allow it to distend to accommodate volume at a low pressure.

## S

**Saddle joint** A joint in which the surfaces are convex in one plane and concave in the other, permitting both flexion-extension and adduction-abduction movements; the surfaces of a saddle joint fit together as a saddle fits a horse. The carpometacarpal joint of the thumb is a saddle joint. Also called a *sellar joint*.

**Saline deficit** Extracellular fluid volume deficit.

**Saline excess** Extracellular fluid volume excess.

**Saline imbalances** Imbalances of extracellular fluid volume.

**Salivary amylase** Digestive enzyme (also called *ptyalin*) contained in saliva; initiates carbohydrate digestion in the mouth.

**Sarcoidosis** A chronic disorder of unknown origin characterized by the formation of tubercles of non-necrotizing epithelioid tissue.

**Sarcolemma** The plasma membrane that encloses a muscle cell.

**Sarcomere** The unit of muscle contraction in striated muscle. A sarcomere extends from one Z disk to another and consists of overlapping actin and myosin filaments.

**Sarcoplasm** The cytoplasm of the muscle fiber.

**Sarcoplasmic reticulum** A calcium-storing structure in muscle cells analogous to the endoplasmic reticulum; it fills the space between myofibrils and forms sacs.

**Saturated fatty acid** Having the maximal number of hydrogen atoms present so that only single bonds exist in the carbon chain, as in saturated fatty acids.

**Saturation** The condition of being saturated. The degree of hydrogen saturation refers to the number of double bonds between the carbon atoms in the hydrocarbon chain. Hemoglobin saturation occurs when all four ions in the hemoglobin molecule are bound to oxygen.

**Scabies** Infestation with the mite *Sarcoptes scabiei* in humans. Scabies begins with eggs laid in the stratum corneum. These eggs hatch into larvae within 3 to 4 days and reach adulthood within 2 months.

**Scarlet fever** A systemic reaction to the toxins produced by group A  $\beta$ -hemolytic streptococci. It occurs when the person is sensitized to the toxin-producing variation of streptococci. Scarlet fever frequently occurs in association

- with streptococcal sore throat (strep throat), but it may also be associated with a wound, skin infection, or puerperal infection.
- Schizoaffective disorder** A psychiatric disorder in which either a major depressive or manic episode develops concurrently with symptoms of schizophrenia.
- Schizoid** Indifferent to social interaction and possessing a limited range of emotional experience and expression.
- Schizophrenia** A syndrome or combination of mental disorders characterized by paranoia, delusions, and hallucinations associated with impaired interpretation of reality.
- Scleroderma** A disorder characterized by massive collagen deposition with fibrosis accompanied by inflammatory reactions and vascular changes in the capillary network.
- Scoliosis** A lateral deviation of the spine resulting in an S- or C-shaped spinal column. The disorder, most common in adolescent girls, can be a consequence of congenital, connective tissue, or neuromuscular disorders.
- Scrotum** Pouchlike sac containing the testes, epididymis, and spermatic cord.
- Seasonal affective disorder** A condition in which lethargy results from seasonal changes of decreased periods of daylight and longer nights.
- Sebaceous gland** Oil- or sebum-producing gland that anoints hair and skin.
- Seborrheic dermatitis** A common chronic inflammatory skin disease characterized by greasy scales and yellowish crusts.
- Seborrheic keratosis** Benign skin tumor common in the elderly; composed of immature epithelial cells.
- Second messenger** An intracellular signal that is produced in response to an extracellular signal binding to receptors on the cell membrane.
- Secondary dysthymia** A long-term state of chronic depression that is associated with some other non-mood disorder, which may be a classic mental disorder (e.g., anorexia nervosa) or a physical illness.
- Secondary endocrine disorder** A malfunction of the hypothalamus/pituitary cells that control the hormone-producing gland.
- Secondary glomerulopathy** Alterations in the structure and function of the glomerular capillary circulation resulting from drug exposure, infections, or glomerular injury in the setting of multisystem or vascular abnormalities.
- Secondary hypertension** High blood pressure in which the cause can be identified.
- Secondary lesion** Injury modified by normal progress over time or by such external actions as scratching.
- Secondary prevention** The second level of health promotion, based on early detection and screening.
- Second-degree burn** A burn that affects the epidermis and the dermis; classified as superficial or deep according to the depth of injury.
- Secretin** A digestive hormone that is produced by the S cells lining the duodenum and jejunum when protein of partially digested food enters the intestine from the stomach; it stimulates the pancreas.
- Segmentation contractions** A set of movements that occur in the small intestine. The primary effect of these contractions is progressive mixing of solid chyme particles with secretions of the small intestine.
- Seizure** A transient neurologic event of paroxysmal abnormal or excessive cortical electrical discharges that is manifested by disturbances of skeletal motor function, sensation, autonomic visceral function, behavior, or consciousness.
- Self-identity disturbance** In schizophrenic patients, self-identity disturbances can be profound, both in terms of the ability to differentiate one's physical self from the physical environment and in terms of the psychological discernment of self as distinct from others.
- Semen** Male reproductive fluid that contains spermatozoa; released with ejaculation.
- Seminal vesicles** Two glands that contribute rich nutrients to the seminal fluid.
- Senile purpura** A skin condition affecting older people and characterized by fragile blood vessels that rupture with minimal trauma.
- Sensitivity** Susceptibility to a substance, such as a medication or antigen.
- Septic shock** A form of distributive shock that occurs in septicemia when endotoxins or exotoxins are released from certain bacteria in the bloodstream causing inappropriate vasodilation.
- Sequela, sequelae** A condition or conditions caused by and following a disease.
- Sequestra** Fragment of dead bone that is partially or entirely detached from the surrounding or adjacent healthy bone.
- Serotonin** A major monoamine neurotransmitter that is an etiologic factor in mood disorders. See *norepinephrine*.
- Sertoli cell** An elongated cell that supports and provides nutrition to attached spermatids until they mature into spermatozoa.
- Severe acute respiratory syndrome (SARS)** An infectious respiratory illness first reported in Asia.
- Sex chromosome** A chromosome that confers gender to the individual. In humans, females are designated as 46XX, whereas males are 46XY. The Y chromosome confers male gender.
- Sexually transmitted infection** One of many infections that can be transmitted by sexual contact, regardless of whether the disease has manifestations in the genital organs (previously referred to as venereal disease or sexually transmitted disease).
- Sharpey fibers** Fibers that attach tendons to bones; they are continuous with the perimysium.
- Shock** A condition of severe hemodynamic and metabolic disturbance resulting in an imbalance between oxygen supply and oxygen demand at the cellular level. The common types of shock are cardiogenic, hypovolemic, obstructive, and distributive.
- Short-bowel syndrome** Severe diarrhea and significant malabsorption that develop following the surgical removal of large portions of the small intestine. The severity of the manifestations depends on the amount and location of the bowel resected.
- Shunt (right-to-left)** An abnormal route of blood flow through the heart or lungs that allows movement of blood into the arterial system without passing through areas of the lung.
- Sickle cell** A red blood cell containing abnormal hemoglobin that causes the cell to assume a sickle shape under decreased oxygen tension.
- Sign** Objectively identifiable manifestation of the disease. Fever, reddening of the skin, and a palpable mass are signs of disease.
- Skeletal muscle** Striated muscle that is attached to bone. Constituting 40% of total body weight, skeletal muscle enables bones to move at the joint and provides strength and protection to the skeleton by distributing and absorbing shock.
- Skeletal system** Rigid system of bony structures designed to protect internal organs and provide bony attachments for muscles and ligaments; presents rigid levers to allow for functional movement of the body and its separate parts.
- Skin** A relatively flat membrane composed of an outer, thinner layer (epidermis) and an inner, thicker layer (dermis).
- Skin cancer** A cutaneous neoplasm caused by ionizing radiation, certain genetic defects, or chemical carcinogens, including arsenics, petroleum, tar products, and fumes from some molten metals, or by overexposure to the sun or other sources of ultraviolet light.
- Sleep study** Recording of electroencephalograph (EEG) motor activity and respirations during sleep to determine duration and type of sleep and number of awakenings.
- Sliding filament theory** This theory of muscle contraction is suggested by the anatomic configuration of the sarcomere. Muscle shortening is accomplished by increasing the amount of overlap between actin and myosin filaments. Also called *cross-bridge theory*.
- Slow twitch (type I, red)** A muscle fiber that develops tension more slowly than a fast-twitch fiber. This fiber is usually fatigue resistant and relies on oxidative phosphorylation for energy.
- Slow-wave electrical activity** One of the basic types of electrical activity in the gut. Slow waves represent an ongoing basic oscillation in membrane potential occurring in the smooth muscle of the gastrointestinal tract between 3 and 12 times per minute.
- Smooth endoplasmic reticulum** A portion of the endoplasmic reticulum that has no ribosomes. Smooth endoplasmic reticulum is a site of lipid synthesis.
- Soft-tissue injury** Any trauma to soft tissue with disruption of circulatory and lymphatic systems.
- Solar elastosis** Wrinkled, weather-beaten appearance of skin caused by overexposure to sunlight.
- Somatosensory receptors** Specialized nerve endings located in the dermis of all skin areas. Receptors permit the skin to serve as a sensory organ, transmitting sensations of pain, pressure, touch, and temperature.
- Somatotropic** Referring to the sequential arrangement of neurons related to sensory or motor function in specific anatomic regions.

- Specific immune response** Creation of specific antibodies by the host against a specific pathogen that leads to the destruction of the pathogen.
- Specificity** The quality of being distinctive and the probability that the test will be negative among patients who do not have the disease.
- Spermatid** An immature sperm cell.
- Spermatocele** A painless, cystic mass containing sperm.
- Spermatogenesis** Production of sperm cells.
- Spermatozoon** A mature sperm cell.
- Spherocyte** An abnormal spherical (round) erythrocyte that is less biconcave than a normal erythrocyte.
- Spherocytosis** The presence of spherocytes in the blood.
- Spike potential** Sudden increase in membrane potential in the smooth muscle of the gastrointestinal tract that appears on the peaks of slow waves in response to certain conditions, including stimulation by stretching or the effects of acetylcholine or parasympathetic excitation.
- Spina bifida** A developmental anomaly characterized by defective closure of the bony encasement of the spinal cord (neural tube) through which the spinal cord and meninges may or may not protrude.
- Spinal shock** A temporary physiologic suspension of spinal cord function and reflexes below the level of cord injury.
- Spiral (bacteria)** Referring to any bacterium of the genus *Spirochaeta* that is motile and spiral-shaped with flexible filaments. See *spirochete*.
- Spiral fracture** A fracture resulting from rotational forces and causing bone to separate in the form of an S around the bone.
- Spirochete** Spiral-shaped bacterium.
- Splinter hemorrhage** A linear hemorrhage, appearing as a red or brown streak, running parallel to the finger in the nail bed; may be linked to bacterial endocarditis and trichinosis.
- Spontaneous abortion** Expulsion of the products of conception from the uterus before the period of fetal viability. It is usually called “miscarriage” by laypersons, and is differentiated from an elective abortion.
- Squamous cell carcinoma** A type of cancer that often occurs in areas of skin excessively exposed to sunlight and arising from keratinocytes.
- Staging** The process of determining the extent and location of cancer in an individual.
- Standard deviations** A mathematical statement of the dispersion of a set of values or scores from the mean.
- Stasis** A “staying” of a substance in an anatomic location. A reduction in the normal rate of flow. A *stasis* of bile in the gallbladder promotes an increase in gallstone formation.
- Status asthmaticus** Severe, prolonged asthma attack that does not respond to routine therapy.
- Status epilepticus** Rapid succession of seizures without intervals of consciousness. Brain damage may result.
- Steatorrhea** Passage of high fat content in the feces; seen in malabsorption diseases where there is lack of pancreatic enzymes, such as cystic fibrosis.
- STEMI** ST-segment elevated myocardial infarction.
- Stenosis (valvular)** Obstruction to blood flow through cardiac valves that open incompletely.
- Steroid** A hormone produced from cholesterol and secreted by the adrenal cortex and other cells. Includes glucocorticoids, mineralocorticoids, and androgens.
- Still disease** Systemic-onset juvenile rheumatoid arthritis.
- Stomatitis** An inflammation of the oral mucosa that may extend to the buccal mucosa, lips, and palate.
- Strabismus** An abnormal ocular condition in which the visual axes of the eyes are not directed at the same point.
- Stratum** Layer.
- Stratum corneum** Outermost layer of the epidermis; composed of flat, compact cells that have lost their nuclei.
- Stratum germinativum** Also known as the *basal cell layer*, the final (fifth) layer of the epidermis is a line of cuboidal cells that marks the lowest boundary of the epidermis and divides it from the dermis.
- Stratum granulosum** Third layer of the epidermis, comprising flatter cells that contain protein granules, called *keratohyalin granules*.
- Stratum lucidum** Second layer of the epidermis, appearing as a translucent line of flat cells. This layer of the skin is present only on the palms and the soles.
- Stratum spinosum** Fourth layer of the epidermis, composed of upwardly migrating and maturing keratinocytes. This layer forms the bulk of the epidermis over most of the body.
- Strawberry hemangioma** A soft vascular nevus, usually present on the face or neck, occurring at birth or shortly afterward.
- Strawberry tongue** Bright red papillated tongue, characteristic of scarlet fever.
- Stress** The sum of biological reactions produced when an organism’s homeostasis is disrupted.
- Stress fracture** A fracture of one cortical surface of the bone; often caused by repetitive activity such as running.
- Stress incontinence** Loss of bladder control caused by increased intra-abdominal pressure combined with pelvic muscle laxity.
- Stressor** An agent or condition capable of producing stress. The term denotes both physical (gravity, mechanical force, pathogen, injury) and psychological (fear, anxiety, crisis, joy) forces that an individual may experience.
- Striation (muscle)** The typical pattern of banding apparent upon microscopic inspection of a skeletal or cardiac muscle cell.
- Stricture** A narrowing or constriction of the lumen of a tube, duct, or hollow organ, such as the intestine, ureter, or urethra.
- Stroke volume** The volume of blood ejected from the ventricle in one contraction (end-diastolic volume minus end-systolic volume).
- Structural scoliosis** The most severe form of scoliosis; can be progressive in which the mechanics of the curve are such that rotation of the vertebrae occurs in combination with lateral curvature. This usually produces a protruberance of one side of the rib cage, seen best when a person bends forward.
- Subarachnoid space** The space between the arachnoid and the pia mater.
- Subendocardium** The part of the myocardium lying in proximity to the endocardial surface.
- Subluxation** Displacement of a bone from its normal position (articulating surface) in a joint; less severe than dislocation.
- Substantia gelatinosa** Another term for areas in laminae II and III that are important in the transmission of pain signals in the spinal cord.
- Substantia nigra** The layer of gray matter separating the tegmentum of the midbrain from the crus cerebri; part of the basal ganglia.
- Sudden cardiac death (sudden cardiac arrest)** Death due to cardiac causes (or successful resuscitation) within 1 hour of symptom onset.
- Sulcus** A deep furrow or groove on the surface of a structure (e.g., cerebral cortex).
- Summation** The additive response to repetitive stimuli.
- Superficial fascia** Loose subcutaneous layer rich in fat and areolar tissue, which lies beneath the dermis. Also known as *hypodermis*.
- Superficial partial-thickness burn** Marked by destruction of the epidermis and dermis, a superficial partial-thickness burn is also a second-degree burn. The water vapor barrier is absent, but tactile and pain sensors are intact.
- Suppurative disease** A disease that produces purulent material (pus).
- Surface film** Thin film of emulsified material spread over the surface of skin.
- Surfactant** A surface tension-reducing agent produced by type II pneumocytes in the lung.
- Suture joints** A joint that unites bone with a thin but dense layer of fibrous tissue. Found only in the skull.
- Sweat gland** Most numerous of the skin glands. Sweat glands are of two types: apocrine and eccrine.
- Symphysis joint** A joint that connects bony segments by a fibrocartilaginous plate or disk.
- Symptom** Subjective feeling that an affected individual can report to an observer. Nausea, malaise, and pain are *symptoms* of disease.
- Symptomatically** Defined by symptoms.
- Synarthrosis** A fibrous or cartilaginous (non-synovial) joint.
- Synchondrosis** A joint connecting cartilage to a bony component; allows bone growth while providing stability.
- Syncytium** A complex of fused cells that act in concert.
- Syndesmosis** A fibrous joint in which opposing surfaces that are relatively far apart are connected by ligaments.
- Syndrome** A collection of signs and symptoms that occur together.
- Syndrome of inappropriate antidiuretic hormone (SIADH) secretion** Excessive antidiuretic hormone secretion either from the posterior pituitary gland or from other tissues. SIADH results in retention of water, hemodilution, and hyponatremia.

**Synostosis** The bony union that results from the fusion of a suture joint.

**Synovial fluid** A clear, pale yellow, viscous fluid similar to blood plasma but containing hyaluronic acid and a glycoprotein called lubricin. Synovial fluid reduces friction between the capsule and joint surfaces, lubricates the surface of the cartilage, resists shear forces, and provides nourishment for cartilage. The viscosity of the fluid is inversely related to joint velocity or rate of shear. High temperature decreases viscosity and low temperature increases viscosity.

**Synovial joint** Freely movable joint in which contiguous bony surfaces are covered by articular cartilage and connected by a fibrous connective tissue capsule lined with a synovial membrane.

**Synovial sheath** Also called *joint capsule*. A dense layer of connective tissue surrounding synovial joints. The capsule is solidly attached to the periosteum of the adjacent bony components. The synovial sheath provides strength to the joint and, through its neural receptors, detects motion, compression, tension, vibration, and pain.

**Synovitis** An inflammatory condition of the synovial membrane of a joint as the result of an aseptic wound or traumatic injury.

**Syphilis** Sexually transmitted disease caused by the spirochete *Treponema pallidum* and characterized by distinct stages of effects over a period of years.

**Systemic lupus erythematosus** A chronic inflammatory autoimmune disease resulting from a type III hypersensitivity reaction. It is a multisystem relapsing disease that can affect skin, mucosa, lung, heart, kidneys, central and peripheral nervous systems, and blood components. Arthralgias and synovitis are common features. Skin lesions are often present as a butterfly rash. Renal failure is the leading cause of death with this disease.

**Systemic vascular resistance** The impedance to blood flow exerted by the arterioles; determined primarily by vascular diameter.

**Systole** A phase of the cardiac cycle in which the ventricles are contracting to develop force and eject blood.

**Systolic blood pressure** The maximal pressure in the aorta and major arteries during ventricular ejection of blood.

## T

**T cell** Lymphocyte that provides cellular immunity, has regulatory functions, and attacks antigen in association with other cells. T cells have T-cell receptors (TCRs) and mature in the thymus.

**Tangential excision** Also called *full-thickness excision*. Done to remove eschar in thin layers until viable tissue is visible.

**Target cell or target organ** The cell or organ that is stimulated by the effects of a hormone.

**Tau protein** Neuronal protein that organizes microtubules. Also known as *neural thread protein*, tau protein becomes chemically altered in Alzheimer disease and twists into abnormal bundles, known as *neurofibrillary tangles*. See *neural thread protein*.

**Telangiectasia** A lesion created by dilated blood vessels.

**Telogen** The resting phase of hair growth.

**Telomerase** An enzyme that permits addition of nucleotides to the tips of the chromosomes to prevent progressive shortening of the telomeres during cell division. Telomerase is produced by cancer cells, enabling them to become immortal.

**Telomere** The end cap of the chromosome; this section shortens with each cell division.

**Tendinitis** Inflammation of the tendon within the sheath.

**Tension pneumothorax** Presence of air in the pleural space that develops a positive pressure and compresses mediastinal structures.

**Teratogen** An agent or factor that causes damage or physical defects in a developing embryo.

**Terminal hair** Long, coarse, thick, visible strands of tightly fused keratinized epidermal cells.

**Terminal sac period** The third stage in fetal lung development when terminal sacs become thinner, preparing the lung tissue for gas exchange. Proliferation of pulmonary capillaries is also prominent during this period.

**Tertiary prevention** The third phase of health promotion, based on supporting independent function and preventing further disease-related deterioration.

**Testis** The male gonad or reproductive gland that produces spermatozoa and houses the Leydig cells.

**Testosterone** Male sex hormone produced by interstitial cells in the testes.

**Thalamus** Portion of diencephalon; mass of gray matter involved in relay of sensory information, emotion, arousal, and complex reflexes.

**Thalassemia** An inherited form of anemia characterized by microcytic red blood cells that lack either  $\alpha$ - or  $\beta$ -hemoglobin chains.

**Thoracentesis** Surgical perforation of the chest wall and pleural space with a needle to aspirate fluid for diagnostic or therapeutic purposes or to remove a specimen for biopsy.

**Thoracotomy** Surgical opening of the chest wall.

**Threshold** The lowest level at which a stimulus can produce a response.

**Thrill** Vibration palpated over a blood vessel or heart chamber reflecting turbulent blood flow.

**Thromboangiitis obliterans (Buerger disease)** An occlusive vascular condition, usually associated with smoking and affecting a leg or a foot, in which the small- and medium-sized arteries become inflamed and thrombotic.

**Thrombocyte** Circulating cytoplasmic fragment of a megakaryocyte that is essential in the formation of blood clots and in the control of bleeding. Also called *platelet*.

**Thrombocytopenia** A deficiency of platelets (thrombocytes) in the peripheral blood. Any reduction in platelet count below normal is called *thrombocytopenia*, but significant risk of bleeding does not occur until the count drops below about 20,000/ $\mu$ l.

**Thrombocytosis** An abnormal increase in the number of platelets in the blood.

**Thromboembolus** An embolus that originated as a thrombus, most commonly in the venous system of the lower extremities.

**Thrombophlebitis** Inflammation of a vein accompanied by the formation of a clot.

**Thrombus** Stationary blood clot formed within a vessel.

**Thrush** Candidiasis of the tissues of the mouth. The condition is characterized by the appearance of creamy white patches of exudates on an inflamed tongue or buccal mucosa.

**Thyroid-stimulating hormone (TSH)** A peptide secreted by the anterior lobe of the pituitary gland that controls the release of thyroid hormone and is necessary for the growth and function of the thyroid gland.

**Thyroid storm** Extreme thyrotoxicosis. Massively elevated levels of thyroid hormones cause an increased basal metabolic rate, tachycardia, hypertension, and fever, eventually leading to cardiovascular collapse.

**Thyroxine (T<sub>4</sub>)** A hormone containing four iodine molecules secreted by the thyroid gland.

**Tight junction** Cell-to-cell junction that seals adjacent epithelial cells together and prevents the passage of most substances through the epithelial sheet.

**Tinea** The infection caused by fungal infections of the skin in any cutaneous area, including the hair and nails.

**Tinnitus** Ringing, buzzing, or roaring in the ears; commonly associated with exposure to loud noise or disorders such as Meniere disease.

**Tonic** Referring to continuous stimulation or muscular contraction.

**TORCH complex** An acronym used to describe the usual offending infectious agents that commonly cause congenital anomalies: *toxoplasmosis*, *others*, *rubella*, *cytomegalovirus*, *herpesvirus*.

**Torsion** Act of twisting or condition of being twisted. Applies to the state of the testes when abnormally rotated.

**Trabecular bone** Cancellous bone cells arranged in response to mechanical stress placed on the bone. Configuration of bone cells increases strength of bone.

**Tracheoesophageal fistula** Congenital anomaly in which an abnormal opening between the trachea and esophagus exists. It requires immediate diagnosis and surgical correction.

**Transcellular fluid** Body fluid contained in special compartments, such as the synovial or cerebrospinal compartments; a component of extracellular fluid.

**Transcription** The process by which a segment of DNA is used as a template to produce a complementary sequence of messenger RNA.

**Transient flora** Microorganisms that temporarily reside in a certain environment on the host.

**Transient ischemic attack** A temporary episode of cerebrovascular insufficiency that is usually associated with partial occlusion of a cerebral artery.

**Transitional flow** Airflow occurring in the larger airways, especially at bifurcations. Also known as *mixed pattern of airflow*.

**Translation** Formation of a polypeptide chain in a sequence dictated by messenger RNA.

**Translocation** Shifting of a segment of one chromosome into another chromosome.

**Transmission of infection** The process by which a pathogenic organism is transferred from one host to another.

**Transmural** Denoting the entire thickness of a wall (e.g., the myocardial wall). A transmural myocardial infarction extends throughout the entire cardiac muscle layer.

**Transportation** The movement or transference of biochemical substances from one site to another.

**Transudate** Fluid of low protein content that passes through membranes because of a difference in hydrostatic pressure.

**Transverse fracture** Fracture that occurs in a straight line at approximately a 90-degree angle to the longitudinal axis of the bone.

**Traumatic alopecia** Hair loss as a result of tight plaiting of hair or use of hot oil and tension on the scalp. Gradual damage to hair follicles occurs, leading to hair thinning and loss.

**Traumatic brain injury** Nondegenerative, noncongenital insult to the brain from an external mechanical force.

**Triad asthma** A subcategory of drug-induced asthma representing a combination of intrinsic asthma, aspirin sensitivity, and nasal polyposis.

**Triaxial joint** A joint that permits movement around three axes so that motion can occur in three planes. Permits gliding movement between two bones as exemplified by the carpal joints of the hand.

**Tricuspid valve** The cardiac valve that lies between the right atrium and right ventricle. The valve is normally closed during ventricular systole and open during ventricular diastole. Tricuspid valve closure contributes to heart sound  $S_1$ .

**Trigeminal neuralgia** A neurologic condition of the trigeminal cranial nerve, characterized by paroxysms of pain.

**Triglyceride** A simple fat compound consisting of three molecules of fatty acid and glycerol.

**Trigone** Triangular area, usually referring to the bladder muscle.

**Triiodothyronine ( $T_3$ )** A hormone containing three iodine molecules secreted by the thyroid gland and produced in tissues by the enzymatic deiodination of  $T_4$ .

**Trisomy** Having three homologous chromosomes instead of the usual pair, as in trisomy 21, also called *Down syndrome*.

**Tropic/trophic hormone** A hormone that stimulates the growth and maintenance of a tissue or gland.

**Tropical sprue** Inflammation of the mucosa of the small intestine secondary to infection.

**Tropomyosin** A structural protein involved in regulation of actin-myosin cross-bridge formation. Associated with the thin filament of the sarcomere in skeletal and cardiac muscle, where it blocks cross-bridge formation when intracellular calcium levels are low.

**Troponin** A regulatory protein involved in regulation of actin-myosin cross-bridge formation.

Associated with tropomyosin and actin in the thin filament of the sarcomere. Troponin binds calcium ion in the cell and regulates the position of tropomyosin, allowing muscle contraction when intracellular calcium levels rise.

**Tuberculosis** A chronic infection caused by the acid-fast bacillus *Mycobacterium tuberculosis*.

**Tumor marker** Biochemical substance, such as a specific enzyme, receptor, or surface protein, that helps identify the tumor cell.

**Tumor suppressor gene** A gene that regulates a group of growth-promoting genes and suppresses tumor formation. Mutation and underexpression of tumor suppressor genes are associated with the development of cancer.

**Tunica albuginea** Fascial layer covering the testes and erectile bodies of the penis.

**Turbulent flow** The friction and increased resistance caused by air movement from the nasal cavity through the large bronchi.

**Turnover and regeneration time** Time required for a population of cells to mature and reproduce. As the surface cells of the stratum corneum are lost, replacement of keratinocytes by mitosis must occur.

**Twitch** The mechanical response to a single stimulus of a motor unit.

**Type 1 diabetes mellitus** Insulin-dependent diabetes mellitus; characterized by an absolute deficiency of insulin.

**Type 2 diabetes mellitus** Non-insulin-dependent diabetes mellitus; characterized by tissue insulin resistance and impaired insulin production by the pancreas.

## U

**Ulcerative colitis** An inflammatory disease of the mucosa of the rectum and colon. Most commonly it affects the most distal portions of the colon, but eventually it may affect the entire colon. It is typically characterized by exacerbations and remissions. The clinical manifestations of ulcerative colitis are abdominal pain, diarrhea, and rectal bleeding.

**Ultrafiltration** Filtration through a filter capable of removing colloidal particles from a dispersion medium, as in the filtration of plasma at the capillary membrane.

**Ultrasound** An imaging modality that uses sound waves to assess the size, structure, and function of internal organs, tissue, or the fetus.

**Uniaxial joint** A joint that allows motion around a single axis.

**Unipennate** A muscle with a lateral tendon to which the fibers are attached obliquely, like one half of a feather.

**Unipolar depression** Depression without periods of mania.

**Unresolved urinary tract infection (UTI)** A urinary tract infection in which bacteriuria remains after initial antibiotic treatment.

**Unsaturated (fatty acid)** Referring to an organic compound in which one or more pairs of carbon atoms are united by double or triple bonds, as in unsaturated fatty acids.

**Up-regulation** An increase in the number of cell receptors for a specific hormone resulting from chronically low concentrations of the

hormone. Up-regulation helps maintain the target cell response to a hormone, even when circulating hormone levels are low.

**Urea** Substance produced in the liver from the breakdown of protein and excreted in the urine.

**Uremia** A clinical syndrome related to the severe loss of renal function and resulting in the accumulation of metabolic waste products in the blood.

**Ureter** One of a pair of fibromuscular, mucosa-lined narrow tubes that connect the kidneys to the bladder.

**Ureterocele** Congenital cystic dilatation of the distal ureter.

**Ureterolithiasis** The presence of calculi (stones) in the urinary system, particularly the ureters.

**Ureteropelvic junction obstruction** Disruption of urinary flow from the kidney(s) into one or both ureters.

**Urethral stricture** A fibrotic narrowing of the urethra, usually composed of scar tissue.

**Urethral valve** The most common cause of urinary obstruction in male newborns and infants. Posterior in location, occurring in the distal prostatic urethra, urethral valves are mucosal folds that resemble thin membranes and cause obstruction when the child attempts to void.

**Urethritis** Inflammation of the urethra.

**Urethrorectal fistula** A rare congenital anomaly almost always associated with an imperforate anus. The fistula results from failure of the urorectal septum to develop completely, leading to a persistent communication between the rectum posteriorly and the urogenital tract anteriorly.

**Urge incontinence** A strong and immediate urge to void instigated by involuntary detrusor overactivity.

**Urinary bladder** Muscular sac located in the anterior inferior pelvic cavity that holds urine until it is excreted through the urethra.

**Urodynamic testing** The study of the mechanics of urinary bladder filling, emptying, and voiding.

**Urolithiasis** The presence of calculi in the urinary system.

**Urothelial tumor** A malignant tumor of the lining of the renal pelvis, calyces, ureter, and bladder.

**Urothelium** Epithelial lining of the urinary tract from the renal pelvis to the bladder.

**Urticaria** A pruritic (itchy) skin eruption characterized by transient wheals of varying shapes and sizes with well-defined erythematous margins and pale centers.

**Uterine prolapse** A sinking of the uterus from its normal position. It usually occurs when supporting structures, such as the uterosacral ligaments and cardinal ligaments, relax, altering the relationship of the uterus to the vaginal axis.

## V

**Validity** The extent to which a test measures what it is intended to measure.

**Valvular incompetence** An acquired or congenital disorder of a cardiac valve resulting in regurgitation of blood through the valve

because it doesn't close properly, also called *valvular insufficiency*.

**Varicose veins** Incompetency of the superficial veins of the extremities, producing engorgement.

**Vas deferens** Thick, muscular tube that is continuous with the epididymis. It travels along the pelvic wall and joins with the seminal vesicle duct at the prostate to form the ejaculatory duct. Also called *ductus deferens*.

**Vascular fluid** Fluid that is in blood vessels; a component of extracellular fluid.

**Vasculitis** Inflammation of the lining (intima) of a blood vessel.

**Vasoconstriction** A decrease in the diameter of a blood vessel, usually referring to an arteriole, caused by relaxation of vascular smooth muscle.

**Vasodilation** An increase in the diameter of a blood vessel, usually referring to an arteriole, caused by a relaxation of the smooth muscles in the vessel wall.

**Vasospasm** Sudden inappropriate constriction of a blood vessel, producing obstruction of flow.

**Vellus** Tiny hair strands that are almost unnoticeable. Vellus covers the whole body of a child, except the palms and soles. In contrast, terminal hair strands cover the arms and legs of adults.

**Ventilation** The process of moving air into the lungs and distributing air within the lungs to gas exchange units (alveoli) for maintenance of oxygenation and removal of CO<sub>2</sub>.

**Ventricle** A fluid-filled compartment as in the brain or heart.

**Ventricular ejection** The forceful expulsion of blood from the ventricles into the aorta and the pulmonary arteries.

**Ventriculoperitoneal shunt** A shunt that extends all the way from the ventricular system of the brain to the peritoneal cavity of the body.

**Verrucae** Circumscribed elevations of the epidermis, commonly called *warts*.

**Vertigo** A sensation of loss of equilibrium, more than just dizziness.

**Verumontanum** A small elevation that is marked by a midline opening from the prostatic utricle, a remnant of the müllerian duct system.

**Vesicle** A portion of lipid bilayer membrane that forms a sphere and surrounds substances to be transported to a destination within the cell or plasma membrane.

**Vesicoureteral reflux** Retrograde movement of urine from the bladder to the kidney as a result of a disruption in the normal valvular mechanism at the ureter-bladder junction.

**Vibrissae** Large hairs of the nasal cavity.

**Virion** A virus particle.

**Virulence** The capacity of a microorganism to successfully evade host defenses and cause disease.

**Virulent** Referring to a microorganism's ability to evade host defenses and cause disease.

**Viruses** Tiny genetic parasites that are dependent on the host cell for replication. They take over the host cell "machinery" for energy and replication.

**Visual acuity** The ability of the eyes to focus clearly on an image at a known distance; it is assessed with a Snellen chart and often expressed as the ability of a person to accurately discern characters of various sizes at a distance of 20 feet.

**Vitamin** An organic substance that is essential in the diet and is required for the body's utilization of energy-containing nutrients.

**Vitiligo** Patch of depigmentation; also called *leukoderma*.

**Voiding dysfunction** A failure in the normal process of bladder emptying that results in urinary retention and/or incontinence.

**Volvulus** A twisting of the bowel on itself, which results in blood vessel compression.

**Vulvovaginitis** An inflammation of the vulva and vagina.

## W

**Wallerian degeneration** Complete disintegration of the distal portion of an axon that has been severed from the cell body. The axon, myelin sheath, and terminal arborization all disintegrate.

**Wart** Also called *verruca*; caused by a virus that provokes a benign proliferation of keratinocytes.

**Water imbalance** Imbalance of body fluid concentration; osmolality imbalance; hypernatremia and hyponatremia.

**Western blot** A laboratory test to detect the presence of antibodies to specific antigens. It is regarded as more precise than the ELISA and is sometimes used to check the validity of ELISA tests.

**White blood cell** A cell that mediates immune function. White blood cells include granulocytes, monocytes, and lymphocytes. Also called *leukocyte*.

**White-coat phenomenon** Elevated blood pressure readings when measured in a clinic setting by a nurse or physician.

**Wilson disease** A rare autosomal recessive disorder in which excessive amounts of copper accumulate in the liver or other organs; also called *hepatolenticular degeneration*.

**Wolffian ducts** Mesonephric ducts that develop as nephric ducts but mature to form male genital ducts.

**Wolff law** States that bone is established where needed and resorbed where not needed.

## X

**Xerostomia** Dryness of the mouth caused by cessation of normal salivary secretion.

## Z

**Z line** A dark band that defines a sarcomere; Z lines are perpendicular to actin and myosin filaments. A sarcomere extends from one Z line to the next.

**Zeitgeber** A cue given by the environment, such as a change in light or temperature, to reset the internal body clock.

**Zona pellucida** The thick covering of the ovum.

**Zone of calcifying cartilage** A very thin line of chondrocytes and the weakest segment of the epiphyseal plate.

**Zone of maturing cartilage** Contains the enlarged and mature cartilage cells as they migrate toward the metaphysis.

**Zone of resting cartilage** Maintains adherence of the plate to the epiphysis.

**Zone of young proliferating cartilage** Demonstrates the most active cartilage cell growth.

**Zygote** The developing ovum, from the time it is fertilized until it is implanted in the uterus.

## A

## B

**B-cell lymphoma**, 229–231, 230t

B lymphocytes (B cells), 159, 168, 168f  
activated, class switching in, 183–184, 187f  
antigen recognition by, 182–183, 183f–185f

B lymphocytes (*Continued*)

immunodeficiency disorders involving, 209–212  
signaling pathways in, 184f  
theories of autoimmunity involving, 197

B-type natriuretic peptide, secretion of, by cardiac myocytes, 372

Bacilli, 147–149, 149f

Bacteremia, 442  
definition of, 442t

Bacteria  
antiphagocytic factors in, 146  
cell injury from, 67  
endospores produced by, 146  
enzymes produced by, 146  
gram staining of, 149–150  
morphology of, 147–149, 148f–149f  
other microorganisms compared with, 152t  
pathogenic, 147–150, 147b–148b, 148f–149f  
classified by body part targeted, 150f  
toxins produced by, 146

Bacterial emboli, 321

**Bacterial infections**  
autoimmunity triggered by, 197  
cutaneous, 1063–1065, 1064f

**Bacterial meningitis**, 919, 919t

**Bacterial peritonitis**, spontaneous, 766–767, 766f

**Bacterial pneumonia**, 512–513, 513t, 514f

**Bacterial prostatitis**, 648, 650–651

Balance, 944

Ball-and-socket joint, 1009, 1009f

Balloon tamponade, of gastroesophageal varices, 762, 763f

Band cells, in infection, 162, 163f

Barbiturate-hypnotic combinations, for migraine, 967t

Baroreceptors  
altered sensitivity to, in orthostatic hypotension, 345–346  
in blood pressure regulation, 336  
in control of respiration, 462f  
in response to heart failure, 410, 411f  
in response to shock, 435, 436f

Barrett esophagus, 725

Bartholin cyst, 677

Bartholin glands, 657

**Bartholinitis**, 677

**Basal cell carcinoma**, 1076  
in HIV infection, 1063

Basal ganglia, 863, 867f  
injury to, in cerebral palsy, 929  
in obsessive-compulsive disorder, 993–994

Basal metabolic rate (BMR), 841  
factors affecting, 841t  
in physiologic stress, 848–849  
in starvation, 848

Base pairs, in DNA, 75–76, 76f

Basophils, 163  
characteristics of, 258t–259t  
functions of, 162t  
in type I hypersensitivity, 199

Beau lines, in nail in systemic diseases, 1081, 1081f

**Becker muscular dystrophy**, 1037

**Bedbug infestation**, 1071–1072

**Bell palsy**, 939–940, 939f

Bence Jones protein, in plasma cell myeloma, 224–225

- Benign prostatic hyperplasia (BPH)**, 649–653, 649f–650f
- Benign tumors  
characteristics of, 114, 114t

## C

### Cachexia

cancer, 131, 134f  
 cardiac, 850

Calcitonin, in calcium homeostasis, 812

### Calcium

in capacitation of sperm, 637  
 in clot formation, 296t  
 intracellular accumulations of, in cell injury, 59–60  
 in muscle contraction, 362, 363f, 1014, 1014f  
 plasma, imbalances in, 531–532, 531b–532b  
 removal of, in muscle relaxation, energy for, 362–363, 364f

Calcium homeostasis, 1003

### Calcium overload

in acute brain injury, 900, 900f  
 cellular injury from, 63–64, 64f

Calcium transporters, membrane, 40, 41f

### Calculi

bladder (vesical), 621–622  
 lower urinary tract, 621–622  
 renal, 583–586. *See also* Nephrolithiasis.  
 ureteral, 621

Callus formation, in fracture healing, 1005, 1005f, 1027, 1027f

Calluses, epidermal, 1075

Cancellous bone, 1002, 1024

healing in, 1028, 1028f

### Cancer

biliary, 747–748  
 biology of, cell cycle and, 53–55  
 bladder, 616–618, 617b  
 cervical, 679  
 colon, 737–738, 738f, 738t  
 deaths from  
   2011, 118f  
   1930–2007, 119f  
 effects of, on body, 131–135  
 endometrial, 679  
 epidemiology of, 116–118  
 esophageal, 736  
 genetic mechanisms of, 118–125. *See also* Carcinogenesis.  
 liver, 776  
 lung, 472–474  
 metastasis of, 129–131. *See also* Metastasis.  
 new cases of, 2011, 118f  
 nutritional requirements in, 854  
 ovarian, 679  
 pain related to, 969  
 pancreatic, 752  
 penile, 645–646  
 prostate, 646, 652f  
 risk factors for, 116–118  
   nutritional, 116–118  
   tobacco use as, 116, 119f–120f  
 screening guidelines for, 117t  
 small intestinal, 736–737  
 testicular, 648–649, 648f–649f  
 therapy of, 135–138  
   chemotherapy in, 136  
   gene therapy in, 136

### Cancer (Continued)

immunotherapy in, 136, 137f  
 molecular, 136  
 radiation in, 135  
 radiation-induced cell death and, 70  
 stem cell transplantation in, 135–138  
 surgery in, 135  
 tumor markers in, 129–130, 130t  
 tumors in  
   angiogenesis in, 131  
   grading and staging of, 131, 132t–133t, 134f  
   vaginal, 679  
   vulvar, 679–680  
   warning signs of, 134b

### Candidiasis, mucocutaneous, 1061–1063, 1064f

chronic, 211  
 in HIV infection, 247–248, 248f

Capacitation, of sperm, 637

### Capillary(ies)

anatomy of, 313, 314f  
 dynamics of, 317–318

Capillary fragility test, normal value and significance of, 300t

Capillary hydrostatic pressure, 317

Capillary leak syndrome, in burn injury, 1096, 1097f

Capillary permeability, 313

Capillary pressure gradient, 317, 317f

### Carbohydrates

absorption of, 715  
 digestion of, 712, 714t  
 metabolism of, 843–844, 843f, 844t

Carbon dioxide, partial pressure of (PCO<sub>2</sub>), 267  
 arterial (Paco<sub>2</sub>), in autoregulation, acute brain injury and, 902

Carbon dioxide transport, 267, 269f

Carbon monoxide poisoning, in burn injury, 1099

Carbonic acid, excretion of, by lungs, 541

### Carcinogen(s), 118–120

chemical, 128b  
 definition of, 126

### Carcinogenesis

initiation of, 126, 127f–128f  
 multistep nature of, 125–129  
 progression of, 127f, 128–129, 129f  
 promotion of, 127–128, 127f

Carcinoma in situ, 62

Cardiac cachexia, 850

Cardiac catheterization, 374–375, 375f–376f

### Cardiac cycle, 352–355, 353f

aortic and pulmonary artery events in, 353f, 355  
 atrial events in, 353f, 355  
 isovolumic contraction in, 353–354, 353f  
 isovolumic relaxation in, 353f, 355  
 pressure-volume loop in, 352–353, 353f  
 ventricular ejection in, 353f, 354–355

### Cardiac dysrhythmias, 420–429

abnormal sinus rhythms as, 422–423  
 abnormal site of impulse initiation in, 423–426  
 atrial dysrhythmias as, 424–425, 424f–425f  
 escape rhythms as, 423–424, 424f  
 junctional dysrhythmias as, 425, 425f  
 ventricular dysrhythmias as, 425–426, 425f–426f  
 analysis of, 421–422  
 normal sinus rhythm and, 421–422, 422f, 422t

### Cardiac dysrhythmias (Continued)

conduction pathway disturbances in, 426–429  
 atrioventricular, 426–427, 426f–427f  
 congenital, 427–428, 428f  
 intraventricular, 428–429, 428f–429f  
 in electrical injury, 1105–1106  
 mechanisms of, 420–421  
 automaticity as, 420  
 reentry as, 421, 421f  
 triggered activity as, 420–421, 420f  
 treatment of, 429, 430t

Cardiac function, 349–377. *See also* Heart;

contraction of.

alterations in, 378–407. *See also* Heart disease.

tests of

catheterization/angiography as, 374–375, 375f–376f  
 computed tomography as, 373  
 echocardiography as, 373, 374f  
 electrocardiography in, 368–369, 368f–369f, 372–373, 372f–374f  
 magnetic resonance imaging as, 373  
 nuclear cardiography as, 374

Cardiac muscle, 87–88, 88f. *See also* Myocardium.

### Cardiac myocyte(s), 358–362

action potential in, 364–365, 365f  
 contractile filaments of  
   characteristics of, 358–362, 361f  
   structure of, 358, 360f  
 contraction of  
   calcium in, 362, 363f  
   molecular basis of, 362–363  
   sliding filament/cross-bridge theory of, 362, 363f

energy metabolism in, 363–364

hypertrophy of, in heart failure, 411–413

oxygen utilization by, 363–364

relaxation of, energy of, 362–363, 364f

resting potential in, 364

rhythmicity of, 365–366, 366f

autonomic regulation of, 367–368

sarcomeres in, 358, 360f

sarcoplasmic reticulum of, 358, 359f

structure of, 358, 358f–359f

substrate utilization by, 364

### Cardiac output

determinants of, 369–372

heart rate and, 370

monitoring of, in shock, 445

stroke volume and, 370–371, 370f–371f

workload and, 371–372

### Cardiac tamponade, 398

Cardiac valve(s), 350, 351f

calcification and degeneration of, 390–391, 391f

### Cardiac valve disorders, 390–395

aortic, 393–394

regurgitation as, 393–394, 394f

stenosis as, 391f, 393, 394f

major etiologies of, 391t

mitral, 391–393

prolapse as, 393, 393f

regurgitation as, 392–393, 392f

stenosis as, 391–392, 392f

murmurs from, characteristics of, 391t

regurgitation as, 390

stenosis as, 390, 390f

Cardinal ligaments, in pelvic support, 673

- Cardiogenic shock**

 transplantation of, for chronic kidney disease, 606–607
- Kidney, ureter, and bladder (KUB)  
 roentgenography, 571
- Kidney stones**, 583. *See also* Nephrolithiasis.
- Kinins, 169–170, 170f
- Klinefelter syndrome**, 98–99, 99f
- Knee joint, structures of, 1021f
- Koilonychia, in systemic diseases, 1081
- Korotkoff sounds, in blood pressure measurement, 334–335, 335t
- Krause corpuscle, 889f
- Krebs cycle, 34–37, 36f
- Kupffer cells, 158, 159f
- Kyphoscoliosis**, respiratory effects of, 510–512, 511f
- L**
- L-selectins, 161–162
- Labia majora and minora, 657, 658f
- Lactation, 660–661
- Lactic acidosis, in ischemia-induced cell injury, 66
- Lamivudine (3TC, Epivir), 253t
- Language deficits, after stroke, 916
- Laparoscopic cholecystectomy, 747
- Laplace, law of, 316, 317f
- Large cell carcinoma, pulmonary, 472
- Large intestine. *See also* Colon; Colon *entries*;  
 Intestinal *entries*.  
 functional anatomy of, 697f, 701, 703f
- Larynx, 452–453
- Left bundle branch block, 428, 428f–429f
- Left-sided heart failure**, clinical manifestations of, 414–415, 416f
- Leiomyomas**  
 renal, 579t  
 uterine, 677, 677f
- Length-tension relationship, 370  
 in skeletal muscle contraction, 1015–1016
- Lens, of eye, 948, 949f
- Leprosy**, 1065
- Leptin, in metabolic syndrome, 847
- Leptomeninges, bacterial meningitis invading, 919
- Leukemia**  
 acute and chronic compared, 222t  
 acute lymphocytic and acute nonlymphocytic compared, 224t  
 hairy cell, 224, 224f  
 lymphoblastic, acute, 223–224, 224f, 224t  
 lymphoid, chronic, 222–223, 223f  
 myeloid  
   acute, 221–222, 222f  
   chronic, 220–221, 221f
- Leukocytes, 87, 87f, 161–168  
 basophils as, 163  
 characteristics of, 258t–259t  
 dendritic cells as, 165, 166f  
 emigration of, in inflammatory response, 173–174, 174f  
 eosinophils as, 162–163  
 lymphocytes as, 165–168  
 macrophages as, 164–165, 164f–165f  
 malignant disorders of, 214–231. *See also* Leukemia; Lymphoma; Plasma cell myeloma.  
 mast cells as, 163, 163f  
 monocytes as, 164–165  
 neutrophils as, 160f, 161–162  
 proportions and functions of, 162t
- Leukoderma**, 1076, 1077f
- Leukopenia  
 in cancer, 134  
 in hematologic neoplasms, 218
- Leukoplakia, oral hairy, in HIV infection, 248, 248f
- Leukotrienes, in inflammatory response, 172–173, 173f
- LeVeen shunt, for ascites, 766, 766f
- Leydig cells, 628, 629f  
 in spermatogenesis, 633–634, 636f
- Lice infestation**, 1071
- Lichen planus**, 1065–1066, 1067f
- Lichenification, 1059f–1060f
- Life stress, panic disorder and, 991
- Lifestyle alterations  
 in GI disorders, stress of, 738–739  
 in hypertension management, 341, 343t
- Lifestyle considerations  
 in epidemiology, 7–8, 8f  
 in hypertension risk, 340
- Ligament injuries**, 1020, 1021f
- Ligaments, structure and function of, 1011–1012, 1011f
- Ligand(s)  
 in intercellular communication, 45–47, 47f–48f  
 in intracellular communication, 50, 53f
- Ligand-gated ion channels, 41–42, 43f
- Limbic system, 863, 866f
- Lipid(s)  
 absorption of, 715  
 digestion of, 712–714, 714t  
 intracellular accumulations of, in cell injury, 58, 59f  
 metabolism of, 844–845, 845t  
 in elderly, 847  
 saturated and unsaturated, 844
- Lipid bilayer, in plasma membrane, 26–28, 27f–28f
- Lipidemia, HIV-associated, 250
- Lipodystrophy(ies)  
 complicating insulin therapy, 831–832  
 in systemic diseases, 1080
- Lipoid nephrosis, 590
- Lipoprotein(s)  
 atherosclerosis risk and, 325, 379–380, 380f
- Liquifactive necrosis, 63f, 64
- Lithium, for bipolar disorder, 985
- Lithium toxicity, 985
- Lithotripsy, shock-wave, for renal calculi, 585
- Liver, 753–782  
 bacteria targeting, 150f  
 fatty, alcoholic, 773  
 function of, normal, 756b  
 in lipid metabolism, 845  
 lobule of, 755f  
 structure and function of, 754–756, 754f–755f  
 transplantation of, 776–778, 776b–777b  
 in elderly, 781
- Liver abscess**, 775
- Liver cancer**, 776
- Liver disorders**, 767  
 advanced, complications of, 765–767, 765f–766f  
 age-related, 778  
 alcoholic, 773  
 in elderly, 780  
 cirrhosis as, 772–773  
 in elderly, 780–781  
 hemostatic disorders in, 307–308  
 hepatitis as, 767–772. *See also* Hepatitis.  
 in infants and children, 778  
 laboratory tests in, 759t  
 manifestations of, 756–767  
   ascites as, 765–766, 765f–766f  
   gastroesophageal varices as, 759–763  
   hepatic encephalopathy as, 763–764  
   hepatorenal syndrome as, 767  
   jaundice as, 756–759, 758f  
   pathophysiology underlying, 757t  
   spontaneous bacterial peritonitis as, 766–767, 766f  
   portal hypertension in, 759–763  
   portal systemic encephalopathy in, 763–765  
   structural, 775–776  
   toxic, 773–775
- Liver spots, 1087, 1087f–1088f
- Liver trauma**, 775–776
- Load-velocity relationship, in skeletal muscle contraction, 1016
- Long-term memory, 895
- Longitudinal bone fracture, 1024–1025, 1025f
- Loop diuretics, 567, 567t
- Loop of Henle, 552f–553f, 556–557, 558f  
 ascending limb of  
   epithelial cells of, 554f, 558f  
   functions of, 554t  
 countercurrent mechanism in, 557, 559f  
 descending limb of  
   epithelial cells of, 554f  
   functions of, 554t  
 filtrate composition in, 563f
- Lotions, in skin care, 1082–1083
- Low blood pressure**, 345–346
- Low-density lipoproteins (LDLs)  
 atherosclerosis risk and, 325, 379–380, 380f  
 target levels of, to reduce CHD risk, 383t
- Lower airway structures, 452–455
- Lower esophageal sphincter (LES), 699
- Lumbar plexus, 871–874, 873f–874f, 873t
- Lund and Browder chart, in burn assessment, 1094, 1095f
- Lung(s)  
 abscess of, pathogens associated with, 147b–148b  
 bacteria targeting, 150f  
 blood circulation in, 455–456, 457f  
 blood flow in, 463–464, 464f

- Lung(s) (*Continued*)  
 blood vessels of, 463  
 bronchopulmonary segments of, 453, 457f  
 compliance of, in ventilation, 460  
 disorders of, 475–496, 512. *See also* Pulmonary disorders.  
 fetal, development of, 450  
 HIV infection manifestations in, 247–248, 247f  
 infections of, pathogens associated with, 147b–148b  
 malnutrition and, 850–851  
 mechanics of breathing and, 459, 460f  
 ventilation in, 458–463. *See also* Ventilation.  
 ventilation-perfusion ratios in, 463–464, 464b
- Lung cancer**, 472–474
- Lung infection and inflammation**, 512–517, 513t, 514f, 516f–517f
- Lung parenchyma  
 disorders of, 498  
   diffuse interstitial lung disease as, 498–503, 500f  
   fibrotic interstitial lung diseases as, 498–503, 500f  
   hypersensitivity pneumonitis as, 500–501, 501t  
   occupational lung diseases as, 501–503, 502t  
   sarcoidosis as, 499–500  
 loss of, pulmonary obstruction from, 487–489
- Lung volumes and capacities, 458, 458f, 459t
- Lupus erythematosus**  
 discoid, 1065, 1066f  
   systemic compared with, 1065t  
 systemic, 206, 1046–1047  
   discoid compared with, 1065t
- Lusitropic effect, 367
- Luteal phase, of menstrual cycle, 659f, 660
- Luteinizing hormone (LH)  
 secretion of, 792–793  
 target organs and actions of, 660t
- Lyme disease**, 1049, 1072–1073
- Lymph, 318
- Lymph nodes, 162f  
   immune function of, 161
- Lymphatic drainage, blocked, edema from, 527–528, 527f
- Lymphatic flow, 318  
 control of, 319
- Lymphatic flow alterations**, 322, 329–331  
 in lymphedema, 329–331, 330f
- Lymphatic pumps, 318
- Lymphatic system(s)  
 organization of, 311, 311f–312f  
 renal, 550–551  
 structure of, 313–314, 314f
- Lymphatic vessels  
 dynamics of, 317–318  
 flow alterations in, 322  
 structure of, 313
- Lymphatics, immune function of, 161
- Lymphedema**, 318, 322, 329–331
- Lymphoblasts, 223, 224f
- Lymphocyte(s), 165–168  
 B, 168, 168f. *See also* B lymphocytes (B cells).  
 characteristics of, 258t–259t  
 functions of, 162t  
 natural killer cells as, 165–166  
 T, 166–168, 167f–168f. *See also* T lymphocytes (T cells).  
 in type IV hypersensitivity, 206
- Lymphocytic thyroiditis**, 803
- Lymphogranuloma venereum**, 691, 691f
- Lymphoid leukemia, chronic**, 222–223, 223f
- Lymphoid neoplasms**, 216f, 222–231, 223f  
 acute lymphoblastic leukemia/lymphoma as, 223–224, 224f, 224t  
 B-cell, T-cell, and NK-cell lymphoma as, 229–231, 230t  
 chronic lymphoid leukemia as, 222–223, 223f  
 classification of, WHO, 216b  
 complications of, prevention and management of, 218–220  
 diagnosis of, 217–218  
 etiology of, 215–217  
 hairy cell leukemia as, 224, 224f  
 Hodgkin disease as, 226–229, 227f–228f, 228b, 230t. *See also* Hodgkin disease.  
 management principles for, 217–220  
 manifestations of, 217b  
 plasma cell myeloma as, 224–226, 225f–226f  
 treatment principles for, 218
- Lymphoid system, 159–161, 160f–161f  
 primary organs of, 159  
 secondary organs of, 159–161
- Lymphokines, in contact hypersensitivity, 207–208, 207f
- Lymphoma**  
 B-cell, T-cell, and NK-cell (non-Hodgkin), 229–231, 230t  
 Hodgkin, 226–229. *See also* Hodgkin disease.  
 lymphoblastic, acute, 223–224
- Lymphopoiesis, definition of, 261
- Lysosomes  
 in cellular atrophy, 61  
 functions of, 56t

## M

- M line, in sarcomere, 1012–1013, 1013f
- Macrocytic erythrocytes, 274
- Macromolecules, membrane transport of, 38, 39f–40f
- Macrophages, 158–159, 159f  
 antigen presentation function of, 165  
 characteristics of, 258t–259t  
 cytokine secretion by, 170, 171t  
 destruction of, in hemolytic disease of newborn, 203  
 functions of, 162t  
 impaired, by HIV infection, 240  
 phagocytic function of, 164, 174–175  
 receptors on surface of, 164–165, 164f  
 secretory function of, 165, 165f  
 in wound healing, 175
- Macular degeneration**, age-related, 953–954, 954f
- Macule, 1059f–1060f
- Magnesium, plasma, imbalances in, 532–533, 533b, 533f
- Magnetic resonance imaging (MRI)  
 in cardiac function evaluation, 373  
 renal, 572
- Major depressive disorder (MDD)**, 980–984  
 clinical manifestations of, 982–983  
 etiology and neurobiology of, 981–982, 981t–982t, 982f–983f  
 risk factors for, 981t  
 treatment of  
   nonpharmacologic, 984  
   pharmacologic, 983–984, 983f
- Major histocompatibility complex (MHC), 177  
 antigen presentation by, 177–179  
   class I proteins in, 178, 178f–179f  
   class II proteins in, 178–179, 180f  
   genes for, autoimmunity and, 197, 197t
- Malabsorption**, 734, 735f
- Maladaptation, 20
- Malaria**, geographic distribution of, 8, 8f
- Male reproductive system, 624–638  
 aging and changes in, 635b  
 alterations in, 639–653. *See also* Male reproductive system disorders.  
 anatomy of, 625–630  
   external genitalia in, 627–630, 627f  
   genital glands in, 626–627, 627f  
   lower genitourinary tract in, 625–626, 625f–626f  
   upper genitourinary tract in, 625, 625f  
 embryology of, 630–633, 630f–632f, 663–664  
 physiology of, 633–638  
   hypothalamic-pituitary-testicular axis in, 633, 635f  
   spermatogenesis in, 633–635, 636f
- Male reproductive system disorders**, 639–653  
 of penis and urethra, 640. *See also* Penile disorders; Urethral disorders, male.  
 of prostate, 649–653, 649f–652f  
 of scrotum and testes, 646. *See also* Scrotal disorders; Testicular disorders.  
 sexually transmitted, 688–695. *See also* Sexually transmitted infections (STIs).
- Malignant cells, abnormal behaviors of, 115–116
- Malignant hypertension, 344
- Malignant melanoma**, 1076, 1077f
- Malignant tumors**  
 abnormal phenotype of, 115–116  
 characteristics of, 114, 114t  
 nomenclature for, 115t  
 pulmonary, 472–474
- Mallory-Weiss syndrome**, 725–726
- Malnutrition**  
 cell injury from, 67  
 complicating chronic kidney disease, 603  
 management of, 605  
 effects of, 850–851  
   cardiovascular, 850, 851f  
   immune system, 851, 852t  
   respiratory, 850–851, 852f  
 in HIV infection, 246  
 immune function in, 212  
 infection risk and, 143
- Malunion, in fracture healing, 1028
- Mammary duct ectasia**, 681, 681f
- Mammography, 683–684, 684f
- Mandibular nerve, 869t
- Mania, in bipolar disorder, 985
- Mantoux test, 208
- Maraviroc (Selzentry), 253t
- Marfan syndrome**, 100–101, 103f
- Margination, 173–174
- Mast cells, 163, 163f  
 autoimmunity and, 197  
 in type I hypersensitivity, 199, 200f
- Mastitis, periductal, 681
- Maternal age, Down syndrome frequency related to, 98, 99t
- Maxillary nerve, 869t
- Mean arterial pressure (MAP), 333–334

- Measles**, 1086

Oligoarticular onset, of juvenile idiopathic arthritis, 1052

Oligodendrocytes, 878, 879f–880f

**Oligomenorrhea**, 672

Oligosaccharides, dietary, 843

Oliguric phase, of acute tubular necrosis, 599–600

Oncocytoma, renal, 579t

Oncogenes, 120  
 activating proto-oncogenes to become, 122–123

**Onycholysis**, in systemic diseases, 1081

Oogonia, 655

**Open-angle glaucoma**, 954f, 955

**Open bone fractures**, 1025–1026, 1026f

**Ophthalmia neonatorum**, 690

Ophthalmic nerve, 869t

Opiates, for migraine, 967t

Opioids  
 endogenous  
 in pain modulation, 963–965, 965t  
 in presynaptic pain transmission, 962–963  
 receptor affinity of commonly used, 965t

**Opportunistic infections**  
 in HIV/AIDS, 244, 246–248, 246b, 1107

Optic nerve (CN II), 869–871, 869t, 872f, 943, 949–950, 949f

Oral cavity  
 in elderly, changes in, 699b  
 functional anatomy of, 698, 698f  
 infections of, 724  
 taste and, 957–958  
 disorders of, 957–958

Oral hairy leukoplakia, in HIV infection, 248, 248f

**Oral herpes simplex infections**, 692, 724, 1061, 1062f

OraQuick Rapid HIV-1, in HIV infection  
 diagnosis, 244

Organ of Corti, 943

Organelles  
 cytoskeleton and, 29  
 endoplasmic reticulum as, 30–31, 32f  
 Golgi apparatus as, 31–32, 32f  
 lysosomes in, 32  
 mitochondria in, 32–34  
 nucleus as, 30, 31f  
 peroxisomes in, 32

Organism(s)  
 death of, 72–73  
 disease-producing. *See* Pathogen(s).  
 infectious, classes of, 145t

Orthopnea, in left-sided heart failure, 414

**Orthostatic hypotension**, 345–346

Osmolality, 520–521  
 regulation of, kidneys in, 565–568

Osmoreceptors, 789–790

Osmotic diuretics, 567, 567t

Osmotic pressure, interstitial fluid, increased,  
 edema from, 527–528, 527f

Ossicles, 943, 944f

Ossification, in fracture healing, 1005, 1005f

**Osteoarthritis**, 1039–1042  
 clinical manifestations of, 1041, 1041f–1042f  
 etiology and pathogenesis of, 1040, 1040f  
 treatment of, 1041–1042

**Osteoarthropathy**, neuropathic, 1050

Osteoblasts, 1001–1002, 1001f

Osteochondroma, 1035

Osteoclastoma, 1035–1036

Osteoclasts, 1001, 1001f

Osteocyte, 1001, 1001f

Osteoid, 1001

Osteoid osteoma, 1035

Osteomalacia, 1034

**Osteomyelitis**, 1029–1030  
 clinical manifestations of, 1029–1030  
 etiology and pathogenesis of, 1029, 1030f  
 in fracture healing, 1028  
 healing complications in, 1030  
 pathogens associated with, 147b–148b  
 treatment of, 1030

Osteon, 1001, 1001f

Osteonecrosis, in fracture healing, 1028

Osteophyte spur formation, in osteoarthritis, 1040, 1040f

**Osteoporosis**, 1032–1033, 1032f, 1033b

**Osteosarcoma**, 1035f, 1036

**Otitis media**, 947–948, 947t

**Otosclerosis**, hearing loss in, 945

Ototoxic medications, 944–945  
 hearing loss from, 945

**Ovarian cancer**, 679

**Ovarian cysts**, 677–678

Ovarian follicles, 655, 656f

Ovary(ies), 655, 655f–656f  
 development of, 631, 632f, 633

**Overactive bladder syndrome**, 612

Overdrive suppression, in conduction system of heart, 366–367

Overflow incontinence, 612

Oviducts, 655f–656f, 656

Ovulation, 658–659

Oxidative phosphorylation, 37–38, 37f

Oxygen, partial pressure of, 265

Oxygen consumption (VO<sub>2</sub>), 267, 268t

Oxygen delivery (DO<sub>2</sub>), 267, 268t

Oxygen-hemoglobin dissociation curve, 265–267, 266f, 465, 466f

Oxygen radicals (free radicals)  
 in ischemic injury, 67  
 in shock, 433, 434f

Oxygen transport, 265–267, 266f, 465–466, 466f.  
*See also* Erythrocytes.  
 alterations in, 255–293. *See also* Anemia;  
 Polycythemia.

Oxygenation, alveolar, 459

**Oxygenation, tissue, impaired**, in shock, 433–435, 434f–435f, 435t

Oxytocin  
 in parturition, 665  
 physiologic actions of, 790  
 secretion of, 790  
 in stress and adaptation, 19

**P**

p24 antigen, in monitoring HIV disease status, 245

P53 gene, 125, 126f

Pacemakers, for heart failure, 418

Pacinian corpuscle, 889f

**Paget disease, of bone**, 1034, 1034f

Pain, 959–973  
 abdominal, 723  
 acute, 966–967  
 in cancer, 131  
 cancer-related, 969  
 chronic, 967–969  
 complicating chronic kidney disease, 603  
 management of, 606

- Pain (*Continued*)  
 in elderly, 971  
 esophageal, 721–723  
 from gastrointestinal disorders, 721–723  
 “growing”, 1052  
 in hematologic neoplasms, management of, 220  
 in infants, 971  
 ischemic, 970  
 neuropathic, 969–970  
 perception and integration of, altering, 972–973, 972t  
 physiologic responses to, 970–971  
 physiology of, 960–965  
 modulation of pain signals in, 960f, 962–965, 964f, 965t  
 perception of pain signals in, 960f, 962  
 transduction of stimuli in, 960, 960f  
 transmission of pain signals in, 960–962, 960f–963f, 960t  
 referred, 970, 971f  
 from myocardial ischemia, 384  
 in renal disease, 575  
 treatment modalities for, 971  
 types of, 965–966
- Pain threshold, 962
- Pain tolerance, 962
- Pallor, in systemic diseases, 1080
- Panacinar emphysema**, 487, 488f
- Pancreas**  
 embryonic development of, 743, 745f  
 functional anatomy of, 743–744

## PREFIXES AND SUFFIXES COMMONLY USED IN MEDICAL TERMINOLOGY

PREFIX	MEANING	SUFFIX	MEANING
a-	Without, not	-al, -ac	Pertaining to
a[d]-	Toward	-algia	Pain
all[o]-	[an]other, different		
an-	Without, not	-aps, -apt	Fit; fasten
ante-	Before	-arche	Beginning; origin
anti-	Against; resisting	-ase	Signifies an enzyme
auto-	Self	-blast	Sprout; make
bi-	Two; double	-centesis	A piercing
circum-	Around	-cide	To kill
co-, con-	With; together	-clast	Break; destroy
contra-	Against	-crine	Release; secrete
de-	Down from, undoing	-ectomy	A cutting out
dia-	Across; through	-emesis	Vomiting
dipl-	Twofold, double	-emia	Refers to blood condition
dys-	Bad; disordered; difficult	-flux	Flow
ectop-	Displaced	-gen	Creates; forms
ef-	Away from	-genesis	Creation, production
em-, en-	In, into	-gram	Something written
endo-	Within	-graph(y)	To write, draw
epi-	Upon	-hydrate	Containing H <sub>2</sub> O (water)
eu-	Good	-ia, -sia	Condition; process
ex-, exo-	Out of, out from	-iasis	Abnormal condition
extra-	Outside of	-ic, -ac	Pertaining to
hapl-	Single	-in	Signifies a protein
hem-, hemat-	Blood	-ism	Signifies "condition of"
hemi-	Half	-itis	Signifies "inflammation of"
hom(e)o-	Same; equal	-lemma	Rind; peel
hyper-	Over; above	-lepsy	Seizure
hypo-	Under; below	-lith	Stone; rock
infra-	Below, beneath	-logy	Study of
inter-	Between	-lunar	Moon; moonlike
intra-	Within	-malacia	Softening
iso-	Same, equal	-megaly	Enlargement
macro-	Large	-metric, -metry	Measurement, length
mega-	Large; million(th)	-oid	Like; in the shape of
mes-	Middle	-oma	Tumor
meta-	Beyond, after	-opia	Vision, vision condition
micro-	Small; millionth	-oscopy	Viewing
milli-	Thousandth	-ose	Signifies a carbohydrate (especially sugar)
mono-	One (single)	-osis	Condition, process
neo-	New	-ostomy	Formation of an opening
non-	Not	-otomy	Cut
oligo-	Few, scanty	-penia	Lack
ortho-	Straight; correct, normal	-philic	Loving
para-	By the side of; near	-phobic	Fearing
per-	Through	-phragm	Partition
peri-	Around; surrounding	-plasia	Growth, formation
poly-	Many	-plasm	Substance, matter
post-	After	-plasty	Shape; make
pre-	Before	-plegia	Paralysis
pro-	First; promoting	-pnea	Breath, breathing
quadr-	Four	-(r)rhage, -(r)rhagia	Breaking out, discharge
re-	Back again	-(r)rhaply	Sew, suture
retro-	Behind	-(r)rhea	Flow
semi-	Half	-some	Body
sub-	Under	-tensin, -tension	Pressure
super-, supra-	Over, above, excessive	-tonic	Pressure, tension
trans-	Across; through	-tripsy	Crushing
tri-	Three; triple	-ule	Small, little
		-uria	Refers to urine condition

From Patton KT, Thibodeau GA: Anatomy & physiology, ed 8, St Louis, 2013, Mosby.

## WORD ROOTS COMMONLY USED IN MEDICAL TERMINOLOGY

ROOT	MEANING	ROOT	MEANING
acro-	Extremity	men-, mens-, (menstru-)	Month (monthly)
aden-	Gland	metr-	Uterus
alveol-	Small hollow; cavity	muta-	Change
angi-	Vessel	my-, myo-	Muscle
arthr-	Joint	myc-	Fungus
asthen-	Weakness	myel-	Marrow
bar-	Pressure	myx-	Mucus
bili-	Bile	nat-	Birth
brachi-	Arm	natr-	Sodium
brady-	Slow	neph-	Nephron, kidney
bronch-	Air passage	neur-	Nerve
calc-	Calcium; limestone	noct-, nyct-	Night
capn-	Smoke; carbon dioxide	ocul-	Eye
carcin-	Cancer	odont-	Tooth
card-	Heart	onco-	Cancer
cephal-	Head, brain	ophthalm-	Eye
cerv-	Neck	orchid-	Testis
chem-	Chemical	osteo-	Bone
chol-	Bile	oto-	Ear
chondr-	Cartilage	ov-, oo-	Egg
chrom-	Color	oxy-	Oxygen
corp-	Body	path-	Disease
cortico-	Pertaining to cortex	ped-	Children
crani-	Skull	phag-	Eat
crypt-	Hidden	pharm-	Drug
cuspid-	Point	phleb-	Vein
cut(an)-	Skin	photo-	Light
cyan-	Blue	physio-	Nature (function) of
cyst-	Bladder	pino-	Drink
cyt-	Cell	plex	Twisted; woven
dactyl-	Fingers, toes (digits)	pneumo-	Air, breath
dendr-	Tree; branched	pneumon-	Lung
dent-	Tooth	pod-	Foot
derm-	Skin	poie-	Make; produce
diastol-	Relax; stand apart	pol-	Axis, having poles
dips-	Thirst	presby-	Old
ejacul-	To throw out	proct-	Rectum
electr-	Electrical	pseud-	False
enter-	Intestine	psych-	Mind
eryth(r)-	Red	pyel-	Pelvis
esthe-	Sensation	pyo-	Pus
febr-	Fever	pyro-	Heat; fever
gastr-	Stomach	ren-	Kidney
gest-	To bear, carry	rhino-	Nose
gingiv-	Gums	rigor-	Stiffness
glomer-	Wound into a ball	sarco-	Flesh; muscle
gloss-	Tongue	scler-	Hard
gluc-	Glucose, sugar	semen-, semin-	Seed; sperm
glutin-	Glue	sept-	Contamination; separation
glyc-	Sugar (carbohydrate), glucose	sigm-	Greek S or Roman S
hepat-	Liver	sin-	Cavity; recess
hist-	Tissue	son-	Sound
hydro-	Water	spiro-, -spire	Breathe
hyster-	Uterus	stat-, stas-	A standing, stopping
iatr-	Treatment	syn-	Together
kal-	Potassium	systol-	Contract; stand together
kary-	Nucleus	tachy-	Fast
kerat-	Cornea	therm-	Heat
kin-	To move; divide	thromb-	Clot
lact-	Milk; milk production	tom-	A cut; a slice
lapar-	Abdomen	tox-	Poison
leuk-	White	troph-	Grow; nourish
lig-	To tie, bind	tympan-	Drum
lip-	Lipid (fat)	varic-	Enlarged vessel
lys-	Break apart	vas-	Vessel, duct
mal-	Bad	vesic-	Bladder; blister
melan-	Black	vol-	Volume
