Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

To my husband Kenneth—I am truly grateful for your endless love, support of our family life, and pride in my career, for without those things, this book and all of my work would not exist.

To my sons Noah and Andrew—I am continually amazed by your gifts of love, patience, and wisdom beyond your years. You have made every minute of my life worthwhile.

To my parents—you gave me the right start and never stopped encouraging me to be what I wanted to be.

To an extraordinary mentor, James S. Seidel, MD, PhD, who opened many doors in the world of pediatric emergency medicine and encouraged me to go through them.

To my co-editors John, Lance, and Steve—thank you for your friendship, creativity, humor, persistence, high standards, and the countless hours you spent making this a reality.

Jill Baren

I dedicate this work to the two loves of my life—my wife Angela, and my daughter Ava. It is my hope that this text serves to help protect, repair and sustain the health and lives of children and parents everywhere.

Steve Rothrock

To my wife, Mary Beth, and our children, Kelly, Matthew and Colleen for all their help, love and patience. To my friends and colleagues for all the support and mentoring they have given me over the past 25 years. Especially to all the children and parents who, in a time of crisis, put their faith and confidence in our care.

John A. Brennan

To acutely ill and injured children and the professionals who care for them.

Lance Brown

Contributors

Fredrick M. Abrahamian, DO, FACEP

Assistant Professor of Medicine, UCLA School of Medicine, Los Angeles; Director of Education, Department of Emergency Medicine, Olive View-UCLA Medical Center, Sylmar, California

Tetanus Prophylaxis; Rabies Postexposure Prophylaxis

Thomas J. Abramo, MD, FAAP, FACEP

Professor of Emergency Medicine and Pediatrics, Director, Pediatric Emergency Department, Medical Director of Pediatric Transport, and Pediatric Emergency Physician-in-Chief, Department of Emergency Medicine, Vanderbilt University Medical Center, Monroe Carell Jr. Children's Hospital at Vanderbilt, Nashville, Tennessee

Monitoring in Critically Ill Children

Robert Acosta, MD

Assistant Professor, Department of Pediatrics, Albert Einstein College of Medicine; Attending Physician, Department of Pediatric Emergency Medicine, Jacobi Medical Center, Bronx, New York

Rhinosinusitis

Paula Agosto, RN, MHA

Director of Nursing, Emergency, Critical Care, and Transport, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Burns

Coburn Allen, MD

Assistant Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Texas Children's Hospital, Houston, Texas

Bone, Joint, and Spine Infections

Elizabeth R. Alpern, MD, MSCE

Assistant Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Division of Emergency Medicine, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Bacteremia

Jesus M. Arroyo, MD

Assistant Professor of Emergency Medicine, Department of Emergency Medicine, University of Texas Medical School at Houston, Houston, Texas

Sepsis

Miriam Aschkenasy, MD, MPH

Assistant Professor, Boston University School of Medicine; Attending Physician, Boston Medical Center, Boston, Massachusetts

Ear Diseases

Peter S. Auerbach, MD, FAAEM, FAAP

Attending Physician, Department of Emergency Medicine, Inova Fairfax Hospital and Inova Fairfax Hospital for Children, Falls Church, Virginia

Pelvic and Genitourinary Trauma

Franz E. Babl, MD, MPH

Clinical Associate Professor, University of Melbourne; Pediatric Emergency Physician, Royal Children's Hospital, Melbourne, Victoria, Australia

Central Nervous System Vascular Disorders; Vaccination-Related Complaints and Side Effects

Michael C. Bachman, MD, MBA

Assistant Medical Director, Department of Pediatric Emergency Medicine, and Pediatric Emergency Medicine Fellowship Director, Newark Beth Israel Medical Center, Newark, New Jersey

Eye Disorders

Megan H. Bair-Merritt, MD, MSCE

Assistant Professor, Division of General Pediatrics and Adolescent Medicine, Johns Hopkins School of Medicine, Baltimore, Maryland

Interpersonal and Intimate Partner Violence

Roger A. Band, MD

Department of Emergency Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Penile and Testicular Disorders

Isabel Barata, MD

Assistant Professor of Pediatrics, New York University Medical School, New York; Director of Pediatric Emergency Medicine, North Shore University Hospital, Manhasset, New York

Neurovascular Injuries

Besh Barcega, MD, MBA

Assistant Professor, Emergency Medicine and Pediatrics, Loma Linda University School of Medicine; Medical Director, Pediatric Emergency Department, Loma Linda University Children's Hospital and Medical Center, Loma Linda, California

Lower Extremity Trauma

Jill M. Baren, MD, MBE, FACEP, FAAP

Associate Professor of Emergency Medicine and Pediatrics, University of Pennsylvania School of Medicine; Department of Emergency Medicine, Hospital of the University of Pennsylvania; Division of Emergency Medicine, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
End-of-Life Issues

Beverly H. Bauman, MD

Department of Emergency Medicine, Oregon Health and Sciences University, Portland, Oregon
Ovarian Disorders; Vaginal and Urethral Disorders

Lee S. Benjamin, MD

Assistant Professor, Division of Emergency Medicine, Department of Surgery, and Division of Pediatric Emergency Medicine, Department of Pediatrics, Duke University School of Medicine; Interim Associate Medical Director of Pediatric Emergency Medicine, Duke University Medical Center, Durham, North Carolina
Serum Sickness

Suzanne M. Beno, MD

Assistant Professor, Faculty of Medicine and Dentistry, University of Alberta; Faculty, Division of Pediatric Emergency Medicine, The Stollery Children's Hospital, Edmonton, Alberta, Canada; Formerly Clinical Instructor, University of Pennsylvania School of Medicine; Fellow, Pediatric Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Anaphylaxis; Renal Disorders

Deena Berkowitz, MD, MPH

Adjunct Professor, Department of Pediatrics, George Washington University of Medicine; Attending, Emergency Department, Children's National Medical Center, Washington, DC
Lumbar Puncture

Jason E. Bernad, MD

Attending Physician—Emergency Medicine, Saratoga Hospital, Saratoga Springs, New York
Wound Management

Daan Biesbroeck, MD

Attending Emergency Department Staff, OLVG Hospital, Amsterdam, The Netherlands
Urinary Tract Infections in Children and Adolescents

Jeffrey S. Blake, MD

Pediatric Emergency Medicine Fellow, Division of Emergency Medicine, Children's National Medical Center, Washington, DC
Gastrointestinal Bleeding

Frederick C. Blum, MD, FACEP

Associate Professor of Emergency Medicine and Pediatrics, West Virginia University School of Medicine, Department of Emergency Medicine, Ruby Memorial Hospital, Morgantown, West Virginia
Abdominal Trauma

Boura'a Bou Aram, MD

Department of Pediatrics, State University of New York Upstate Medical University, Syracuse, New York
Hemolytic-Uremic Syndrome; Utilizing Blood Bank Resources/Transfusion Reactions and Complications

John C. Brancato, MD

Assistant Professor of Pediatrics and Emergency Medicine, University of Connecticut School of Medicine, Farmington; Attending Physician, Division of Emergency Medicine, Connecticut Children's Medical Center, Hartford, Connecticut
Abdominal Hernias; Metabolic Acidosis; Metabolic Alkalosis

Daniel F. Brennan, MD

Clinical Associate Professor, Department of Emergency Medicine, University of Florida College of Medicine, Gainesville; Clinical Associate Professor, Department of Clinical Sciences, Florida State University College of Medicine, Orlando Campus, Tallahassee; Attending Physician, Department of Emergency Medicine, Emergency Medicine Residency Program, Orlando Regional Medical Center, Orlando, Florida
Ectopic Pregnancy

John A. Brennan, MD, FACEP, FAAP

Executive Director, Newark Beth Israel Medical Center and the Children's Hospital of New Jersey, Newark, New Jersey; Senior Vice President for Clinical and Emergency Services, and Director, Pediatric Emergency Medicine, Saint Barnabas Health Care System, West Orange, New Jersey
The Sick or Injured Child in a Community Hospital Emergency Department; Patient Safety, Medical Errors, and Quality of Care; Hernia Reduction

Allison V. Brewer, MD

Attending Physician, Mercy Hospital, Portland, Maine
Musculoskeletal Disorders in Systemic Disease

Kenneth B. Briskin, MD, FACS

Associate Clinical Professor, Temple University, Philadelphia; Assistant Clinical Professor, University of Pennsylvania, Philadelphia, Pennsylvania; Chief, Division of Otolaryngology, Crozer-Chester Medical Center, Upland, Pennsylvania
Epistaxis; Epistaxis Control

Kathleen Brown, MD

Assistant Professor of Pediatrics and Emergency Medicine, George Washington University School of Medicine; Medical Unit Director, Pediatric Emergency Medicine, Children's National Medical Center, Washington, DC
Lumbar Puncture

Lance Brown, MD, MPH, FACEP, FAAP

Chief, Division of Pediatric Emergency Medicine, and Associate Professor of Emergency Medicine and Pediatrics, Loma Linda University Medical Center and Children's Hospital, Loma Linda, California
Approach to Multisystem Trauma; Excessive Crying

Linda L. Brown, MD, MSCE

Assistant Professor of Pediatrics, Yale University School of Medicine; Attending, Pediatric Emergency Medicine, Yale-New Haven Children's Hospital, New Haven, Connecticut

Dental Disorders

Michael D. Burg, MD, FACEP

Assistant Clinical Professor of Emergency Medicine, Department of Emergency Medicine, University of California, San Francisco-Fresno, University Medical Center, Fresno, California

Upper Extremity Trauma

Sean P. Bush, MD, FACEP

Professor of Emergency Medicine, Department of Emergency Medicine, Loma Linda University School of Medicine; Director, Fellowship of Envenomation Medicine, Department of Emergency Medicine, Loma Linda University Medical Center, Loma Linda, California

Snake and Spider Envenomations

James M. Callahan, MD

Associate Professor of Clinical Pediatrics, Department of Pediatrics, Division of Emergency Medicine, University of Pennsylvania School of Medicine; Director, Medical Education, Emergency Department, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Wound Management

Richard M. Cantor, MD

Associate Professor of Emergency Medicine and Pediatrics, Upstate Medical University; Director, Pediatric Emergency Services, University Hospital, Syracuse, New York

Neonatal Resuscitation; Common Pediatric Overdoses

Nicole P. Carbonell, MD

Resident, School of Medicine, University of Alabama at Birmingham; Resident, Department of Emergency Medicine, University Hospital, University of Alabama at Birmingham, Birmingham, Alabama

Thoracostomy

Eric T. Carter, MD

Assistant Medical Director, Emergency Department, South Lake Hospital, Clermont, Florida

Hypokalemia; Hyperkalemia; Hypocalcemia

David D. Cassidy, MD

Clinical Assistant Professor, Department of Emergency Medicine, University of Florida College of Medicine, Gainesville; Clinical Assistant Professor, Department of Clinical Sciences, Florida State University College of Medicine, Tallahassee; Assistant Director, Department of Emergency Medicine, and Attending and Ultrasound Director, Emergency Medicine Residency Program, Orlando Regional Medical Center, Orlando, Florida

Pyloric Stenosis; Constipation

Marina Catalozzi, MD

Assistant Professor of Clinical Pediatrics and Population and Family Health, Columbia University—College of Physicians and Surgeons, Mailman School of Public Health, New York, New York

Human Immunodeficiency Virus Infection and Other Immunosuppressive Conditions

Esther H. Chen, MD

Assistant Professor, University of Pennsylvania; Attending Physician, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Postexposure Prophylaxis

Richard E. Chinnock, MD

Professor and Chair of Pediatrics, Loma Linda University School of Medicine; Physician-in-Chief, and Director, Pediatric Heart Transplant Program, Loma Linda University Children's Hospital, Loma Linda, California

Postsurgical Cardiac Conditions and Transplantation

Christine S. Cho, MD, MPH

Assistant Clinical Professor, Department of Pediatrics, University of California San Francisco, San Francisco; Attending Physician, Children's Hospital and Research Center, Oakland, California

Circulatory Emergencies: Shock

Thomas H. Chun, MD

Assistant Professor, Departments of Emergency Medicine and Pediatrics, Brown University; Attending Physician, Emergency Department, Hasbro Children's Hospital, Providence, Rhode Island

Psychobehavioral Disorders

Mark C. Clark, MD, FACEP, FAAP

Clinical Associate Professor, Department of Emergency Medicine, University of Florida College of Medicine, Gainesville; Medical Director, Department of Emergency Medicine, Arnold Palmer Hospital for Children, Orlando; Clinical Associate Professor, Department of Clinical Sciences, Florida State University College of Medicine, Tallahassee, Florida

Hernia Reduction

Robert L. Cloutier, MD

Assistant Professor, Department of Emergency Medicine & Pediatrics, Oregon Health & Science University, Portland, Oregon

Ovarian Disorders; Vaginal and Urethral Disorders

Teresa J. Coco, MD

Assistant Professor of Pediatric Emergency Medicine, University of Alabama at Birmingham School of Medicine; Administrator, After Hours Clinic Children's South, Children's Hospital of Alabama, Birmingham, Alabama

General Approach to Poisoning

Arthur Cooper, MD, MS

Professor of Surgery, Columbia University College of Physicians & Surgeons; Director of Trauma & Pediatric Surgical Services, Harlem Hospital Center, New York, New York

Thoracic Trauma; Abdominal Trauma

James D'Agostino, MD

Assistant Professor of Emergency Medicine and Pediatrics,
Department of Emergency Medicine, Upstate Medical
University, Syracuse, New York
Malrotation and Midgut Volvulus

Elizabeth M. Datner, MD

Associate Professor, University of Pennsylvania School of
Medicine; Medical Director, Department of Emergency
Medicine, Hospital of the University of Pennsylvania,
Philadelphia, Pennsylvania
Pregnancy-Related Complications

Sergio V. Delgado, MD

Associate Professor, Child and Adolescent Psychiatry,
Department of Psychiatry, University of Cincinnati
School of Medicine; Medical Director, Outpatient
Services, Department of Psychiatry, Cincinnati
Children's Hospital Medical Center, Cincinnati, Ohio
Major Depression and Suicidality

T. Kent Denmark, MD

Associate Professor of Emergency Medicine and Pediatrics,
and Medical Director, Medical Simulation Center, Loma
Linda University School of Medicine; Program Director,
Pediatric Emergency Medicine, Attending Physician,
Pediatric Emergency Department, Loma Linda
University Medical Center and Children's Hospital,
Loma Linda, California
*Inborn Errors of Metabolism; Near Drowning and
Submersion Injuries*

Andrew DePiero, MD

Assistant Professor of Pediatrics, Jefferson Medical College,
Philadelphia, Pennsylvania; Attending Physician,
Division of Emergency Medicine, A.I. duPont Hospital
for Children, Wilmington, Delaware
Apparent Life-Threatening Events

Stephanie J. Doniger, MD, FAAP

Pediatric Emergency Medicine Fellow, Children's Hospital
and Health Center/University of California, San Diego,
San Diego, California
Dysrhythmias

Aaron J. Donoghue, MD, MSCE

Assistant Professor of Pediatrics and Anesthesia, University
of Pennsylvania School of Medicine; Attending
Physician, Division of Emergency Medicine and Critical
Care Medicine, The Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Intubation, Rescue Devices, and Airway Adjuncts

Gregory M. Enns, MB, ChB

Associate Professor of Pediatrics, and Director, Biomedical
Genetics Program, Division of Medical Genetics,
Stanford University, Stanford, California
Hypoglycemia

Mirna M. Farah, MD

Assistant Professor, Division of Emergency Medicine,
Department of Pediatrics, University of Pennsylvania
School of Medicine; Attending Physician, The Children's
Hospital of Philadelphia, Philadelphia, Pennsylvania
Family Presence

Joel A. Fein, MD, MPH

Associate Professor of Pediatrics and Emergency Medicine,
University of Pennsylvania School of Medicine;
Attending Physician, Emergency Department, The
Children's Hospital of Philadelphia, Philadelphia,
Pennsylvania
Interpersonal and Intimate Partner Violence

George L. Foltin, MD

Associate Professor of Pediatrics and Emergency Medicine,
New York University School of Medicine; Director,
Center for Pediatric Emergency Medicine, Bellevue
Hospital Center, New York, New York
*Thoracic Trauma; Abdominal Trauma; Emergency Medical
Services and Transport*

Eron Y. Friedlaender, MD, MPH

Assistant Professor of Clinical Pediatrics, University of
Pennsylvania School of Medicine; Attending Physician,
Division of Emergency Medicine, Department of
Pediatrics, The Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Cystic Fibrosis

Susan Fuchs, MD

Professor of Pediatrics, Feinberg School of Medicine,
Northwestern University; Associate Director, Division of
Pediatric Emergency Medicine, Children's Memorial
Hospital, Chicago, Illinois
*The Child-Friendly Emergency Department: Practices,
Policies, and Procedures*

Gregory Garra, DO

Assistant Clinical Professor of Emergency Medicine, Stony
Brook University School of Medicine; Emergency
Medicine Residency Program Director, Stony Brook
University Hospital, Stony Brook, New York
*Removal of Ocular Foreign Bodies; Fracture Reduction and
Splinting Techniques*

Marianne Gausche-Hill, MD

Professor of Clinical Medicine, David Geffen School of
Medicine at UCLA, Los Angeles; Director, EMS and
Pediatric Emergency Medicine Fellowships, Harbor-
UCLA Medical Center, Torrance, California
Respiratory Distress and Respiratory Failure

Barry G. Gilmore, MD, MSW

Associate Professor of Pediatrics, Department of Pediatrics,
University of Tennessee Health Sciences Center College
of Medicine; Attending Physician, and Director of
Emergency Services, Division of Emergency Services,
LeBonheur Children's Medical Center, Memphis,
Tennessee
Disorders of Movement; Ultrasonography

Timothy G. Givens, MD

Associate Professor, Emergency Medicine and Pediatrics,
Vanderbilt University Medical Center; Associate Medical
Director, and Fellowship Director, Pediatric Emergency
Medicine, Monroe Carell Jr. Children's Hospital at
Vanderbilt, Nashville, Tennessee
Sickle Cell Disease

Nicole Glaser, MD

Associate Professor of Pediatrics, University of California, Davis, School of Medicine; Department of Pediatrics, University of California, Davis, Medical Center, Sacramento, California

Diabetic Ketoacidosis; Hypoglycemia

Theodore E. Glynn, MD

Department of Emergency Medicine, Ingham Regional Medical Center, Lansing; Assistant Clinical Professor, Michigan State University, East Lansing, Michigan

Syncope

Ran D. Goldman, MD

Division Head and Medical Director, Division of Pediatric Emergency Medicine, BC Children's Hospital; Associate Professor, Department of Pediatrics, University of British Columbia; Senior Associate Clinician Scientist, Child & Family Research Institute (CFRI), Vancouver, British Columbia, Canada

Oral, Ocular, and Maxillofacial Trauma

Marc H. Gorelick, MD, MSCE

Professor of Pediatrics and Population Health, Medical College of Wisconsin; Jon E. Vice Chair in Emergency Medicine, Children's Hospital of Wisconsin, Milwaukee, Wisconsin

Urinary Tract Infection in Infants

Vincent J. Grant, MD, FRCP(C), FAAP

Assistant Professor, Division of Pediatric Emergency Medicine, Department of Pediatrics, University of Ottawa; Medical Director, Trauma Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada

Head Trauma

Steven M. Green, MD

Professor of Emergency Medicine and Pediatrics, Loma Linda University, Loma Linda, California

Procedural Sedation and Analgesia

Victoria S. Gregg, MD

Assistant Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Emergency Department, Texas Children's Hospital, Houston, Texas

Overuse Syndromes and Inflammatory Conditions

Jacqueline Grupp-Phelan, MD, MPH

Associate Professor of Clinical Pediatrics, University of Cincinnati College of Medicine; Assistant Professor of Clinical Pediatrics, Division of Emergency Medicine, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio

Major Depression and Suicidality

Martin I. Herman, MD

Professor of Pediatrics, University of Tennessee Health Sciences Center College of Medicine; Attending Physician, Director of Urgent Care Services, and Assistant Director, Emergency Services, LeBonheur Children's Medical Center, Memphis, Tennessee

Disorders of Movement; Testicular Torsion

Marilyn P. Hicks, MD*

Director of Pediatric Emergency Medicine Education, Department of Emergency Medicine, WakeMed Health Systems, Raleigh; Adjunct Assistant Professor of Emergency Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina

Excessive Crying

Nancy E. Holecek, RN

Senior Vice President for Patient Care Services, Saint Barnabas Health Care System, West Orange New Jersey

Patient Safety, Medical Errors, and Quality of Care

Mark A. Hostetler, MD, MPH, FACEP, FAAP

Associate Professor, Department of Pediatrics, and Chief, Section of Pediatric Emergency Medicine, The University of Chicago, Pritzker School of Medicine; Medical Director, Pediatric Emergency Department, The University of Chicago Comer Children's Hospital, Chicago, Illinois

Inhalation Exposures

Vivian Hwang, MD

Assistant Clinical Professor of Emergency Medicine, The George Washington University School of Medicine and Health Sciences, Washington, DC; Attending Physician, Inova Fairfax Hospital, Falls Church, Virginia

Muscle and Connective Tissue Disorders

Alson S. Inaba, MD, PALS-NF

Associate Professor of Pediatrics, University of Hawaii John A. Burns School of Medicine; Pediatric Emergency Medicine Attending Physician and Course Director, Kapiolani Medical Center for Women and Children; Course Director, Pediatric Advanced Life Support, The Queen's Medical Center; Pediatric Advanced Life Support National Faculty and PROAD Subcommittee, American Heart Association National ECC Committee, Honolulu, Hawaii

Congenital Heart Disease

Sean F. Isaak, MD

Clinical Assistant Professor, Department of Clinical Sciences, Florida State University College of Medicine, Tallahassee; Attending Emergency Medicine, Department of Emergency Medicine, Orlando Regional Healthcare, Orlando, Florida

Incision and Drainage

Paul Ishimine, MD

Assistant Clinical Professor, Departments of Medicine and Pediatrics, University of California, San Diego, School of Medicine; Director, Pediatric Emergency Medicine, Department of Emergency Medicine, University of California, San Diego, Medical Center; Associate Fellowship Director, Division of Pediatric Emergency Medicine, Rady Children's Hospital—San Diego, San Diego, California

Hyperthermia; Hypothermia

*Deceased

Cynthia R. Jacobstein, MD, MSCE

Clinical Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Emergency Department, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Issues of Consent, Confidentiality and Minor Status

Gloria Cecelia C. Jacome, MD

Emergency Medical Associates, Long Branch, New Jersey

Digital Injuries and Infections

David M. Jaffe, MD

Dana Brown Professor of Pediatrics, and Director, Division of Emergency Medicine, Washington University, and St. Louis Children's Hospital, St. Louis, Missouri

Fever in the Well-Appearing Young Infant

David P. John, MD

Director of Quality and Risk Management, Department of Emergency Medicine, Middlesex Healthcare System, Middletown, Connecticut

Patient Safety, Medical Errors, and Quality of Care

Madeline Matar Joseph, MD

Associate Professor of Emergency Medicine and Pediatrics, Chief, Pediatric Emergency Medicine Department, and Medical Director, Pediatric Emergency Department, University of Florida Health Science Center, Jacksonville, Florida

Gastrointestinal Foreign Bodies; Hepatitis; Pancreatitis

Kelly A. Keogh, MD

Assistant Professor of Paediatrics, University of Toronto; Division of Pediatric Emergency Medicine, Hospital for Sick Children Toronto, Ontario, Canada

Enterostomy Tubes

Nazeema Khan, MD

Pediatric Emergency Medicine Attending, Joe DiMaggio Children's Hospital, Hollywood, Florida

Hypertensive Emergencies; Valvular Heart Disease

Grace J. Kim, MD

Assistant Professor of Emergency Medicine, Loma Linda University School of Medicine; Assistant Program Director, Pediatric Emergency Medicine Fellowship, Loma Linda University Medical Center, Loma Linda, California

Postsurgical Cardiac Conditions and Transplantation

Tommy Y. Kim, MD

Assistant Professor, Department of Pediatric Emergency Medicine, Loma Linda University Medical Center, Loma Linda, California

Headaches; Conditions Causing Increased Intracranial Pressure

Brent R. King, MD

Professor of Emergency Medicine and Pediatrics, and Chairman, Department of Emergency Medicine, The University of Texas Medical School at Houston; Chief of Emergency Services, Memorial Hermann Hospital; Attending Physician, Department of Emergency Medicine, Lyndon B. Johnson General Hospital, Houston, Texas

Sepsis

Christopher R. King, MD, FACEP

Associate Professor of Emergency Medicine and Pediatrics, University of Pittsburgh School of Medicine, UPMC Presbyterian Hospital, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Local and Regional Anesthesia

Niranjan Kissoon, MD, FRCP(C), FAAP, FCCM, FACPE

Professor and Associate Head, Department of Pediatrics, Faculty of Medicine, University of British Columbia; Senior Medical Director, Acute and Critical Care Program, BC Children's Hospital, Vancouver, British Columbia, Canada

Jaundice

Craig A. Kizewic, DO

Pediatric Emergency Medicine Fellow, Department of Emergency Medicine, University of Florida Health Science Center—Shands Jacksonville, Jacksonville, Florida

Gastrointestinal Foreign Bodies

Ann Klasner, MD, MPH

Associate Professor of Pediatrics, University of Alabama at Birmingham; Co-Director, Pediatric Emergency Fellowship Program, and Attending Physician, Emergency Department, The Children's Hospital of Alabama, Birmingham, Alabama

Brain Tumor

Terry P. Klassen, MD, MSc, FRCPC

Professor and Chair, Department of Pediatrics, University of Alberta; Regional Program Clinical Director, Department of Child Health, Stollery Children's Hospital, Capital Health, Edmonton, Alberta, Canada

Upper Airway Disorders

Stephen R. Knazik, DO, MBA

Clinical Associate Professor of Pediatrics and Emergency Medicine, Wayne State University School of Medicine; E.D. Medical Director and Chief of Pediatric Emergency Medicine, Children's Hospital of Michigan, Detroit, Michigan

Chest Pain

Paul Kolecki, MD, FACEP

Associate Professor, Department of Emergency Medicine, Thomas Jefferson University; Consultant, Philadelphia Poison Control Center, Philadelphia, Pennsylvania

Adverse Effects of Anticonvulsants and Psychotropic Agents

Baruch Krauss, MD, EdM

Assistant Professor of Pediatrics, Harvard Medical School and Children's Hospital, Boston, Massachusetts

Procedural Sedation and Analgesia

Kelly L. Kriwanek, MD

Attending Physician, Children's Hospital Central California, Madera, California

Peripheral Neuromuscular Disorders

Nathan Kuppermann, MD, MPH

Professor of Emergency Medicine and Pediatrics, University of California, Davis, School of Medicine, Sacramento, California

Diabetic Ketoacidosis

Kenneth T. Kwon, MD, FACEP, FAAP

Associate Clinical Professor, Department of Emergency Medicine, University of California, Irvine, School of Medicine, Irvine; Director of Pediatric Emergency Medicine, Department of Emergency Medicine, University of California, Irvine, Medical Center, Orange, California

Electrical Injury

Steve Levi, MD

Assistant Clinical Professor of Medicine, Robert Wood Johnson School of Medicine; Chief, Electrophysiology, Our Lady of Lourdes Medical Center, Camden, New Jersey

Pacemakers and Internal Defibrillators

Deborah A. Levine, MD

Clinical Assistant Professor of Pediatrics and Emergency Medicine, New York University School of Medicine; Attending Physician, Bellevue Hospital Center, New York, New York

Bronchiolitis

Stuart Lewena, MBBS, BMedSci, FRACP

Honorary Fellow, Department of Pediatrics, Melbourne University, Melbourne; Pediatric Emergency Physician, Royal Children's Hospital, Victoria, Australia

Central Nervous System Vascular Disorders; Vaccination-Related Complaints and Side Effects

Erica L. Liebelt, MD

Associate Professor of Pediatrics and Emergency Medicine, University of Alabama at Birmingham School of Medicine; Director, Medical Toxicology Services, Children's Hospital and University of Alabama at Birmingham Hospital, Birmingham, Alabama

General Approach to Poisoning

Marc Y. R. Linares, MD

Director, Pediatric Emergency Fellowship Program, and Attending Physician, Emergency Department, Miami Children's Hospital, Miami, Florida

Gallbladder Disorders

Robert Luten, MD

Professor of Pediatrics and Emergency Medicine, Department of Emergency Medicine, University of Florida School of Medicine, Shands Hospital, Jacksonville, Florida

Approach to Resuscitation and Advanced Life Support for Infants and Children

Sharon E. Mace, MD

Associate Professor, Department of Emergency Medicine, The Ohio State University School of Medicine, Columbus; Faculty, and Emergency Medicine Residency, MetroHealth Medical Center, Cleveland; Director, Pediatric Education/Quality Improvement, and Director, Observation Unit, Cleveland Clinic, Cleveland, Ohio

Triage

Charles G. Macias, MD, MPH

Associate Professor of Pediatrics, Baylor College of Medicine; Attending Physician, Emergency Department, Texas Children's Hospital, Houston, Texas

Bone, Joint, and Spine Infections; Overuse Syndromes and Inflammatory Conditions

Ian Maconochie, MBBS, FRCPCH, FCEM

Honorary Senior Lecturer, Imperial College; Lead Clinician, Paediatric Emergency Department, St. Mary's Hospital, St. Mary's Trust, London, United Kingdom

Dehydration and Disorders of Sodium Balance

William K. Mallon, MD, FACEP, FAASM

Associate Professor of Clinical Emergency Medicine, Keck School of Medicine of University of Southern California; Director, Division of International Emergency Medicine, Department of Emergency Medicine, Los Angeles County + University of Southern California Medical Center, Los Angeles, California

Neck Trauma

Courtney H. Mann, MD

Adjunct Instructor, University of North Carolina at Chapel Hill, Chapel Hill; Medical Director, Pediatric Emergency Department, WakeMed Health and Hospitals, Raleigh, North Carolina

Vomiting and Diarrhea

Deborah J. Mann, MD

Assistant Professor, Emergency Medicine, State University of New York Upstate Medical University, Syracuse, New York

Common Pediatric Overdoses

Jonathan Marr, MD

Pediatric Emergency Medicine Fellow, University of Texas Southwestern Medical School, and Children's Medical Center Dallas, Dallas, Texas

Monitoring in Critically Ill Children; Seizures

Nestor Martinez, MD

Fellow, Pediatric Emergency Medicine, Miami Children's Hospital, Miami, Florida

Gallbladder Disorders

Andrew D. Mason, MD

Division of Pediatric Emergency Medicine, Hospital for Sick Children, Toronto, Ontario, Canada

Enterostomy Tubes

Todd A. Mastrovitch, MD

Instructor of Emergency Medicine in Clinical Pediatrics, Weill Medical College of Cornell University, New York; Academic Pediatric Emergency Medicine Attending, and Director, Pediatric Education, Department of Emergency Medicine, New York Hospital Queens, Flushing, New York

Failure to Thrive

Thom A. Mayer, MD

Chairman of Emergency Medicine, Fairfax Medical Center, Fairfax, Virginia

Triage

James J. McCarthy, MD, FACEP

Assistant Professor, Department of Emergency Medicine, University of Texas at Houston Medical School; Medical Director, Emergency Center, Memorial Hermann Hospital, Houston, Texas

Sepsis

Maureen McCollough, MD, FACEP

Associate Professor of Emergency Medicine and Pediatrics, Keck School of Medicine of University of Southern California; Medical Director, Department of Emergency Medicine, and Director, Pediatric Emergency Department, Los Angeles County + University of Southern California Medical Center, Los Angeles, California

The Critically Ill Neonate

Ryan S. McCormick, BS, EMT-P

Director, Office of Emergency Management, and Director, Center for Healthcare Preparedness, Saint Barnabas Health Care System, West Orange, New Jersey

Disaster Preparedness for Children

Barbara E. McDevitt, MD

Director of Pediatric Emergency Services, Saint Barnabas Medical Center, Livingston, New Jersey

Thoracic Trauma; Vomiting, Spitting Up, and Feeding Disorders

William M. McDonnell, MD, JD

Assistant Professor of Pediatrics, Division of Pediatric Emergency Medicine, University of Utah School of Medicine; Primary Children's Medical Center, Salt Lake City, Utah

High Altitude-Associated Illnesses

Mark S. McIntosh, MD, MPH, FAAP, FACEP

Clinical Assistant Professor, Department of Emergency Medicine, University of Florida, Jacksonville, Florida

Valvular Heart Disease

Francis Mencl, MD, MS, FACEP

Associate Professor of Emergency Medicine, Northeastern Ohio Universities College of Medicine, Rootstown; Director of EMS, and Attending Emergency Department Staff, Summa Health Systems, Akron, Ohio

Urinary Tract Infections in Children and Adolescents

Russell Migita, MD

Clinical Assistant Professor, Division of Emergency Medicine, Department of Pediatrics, University of Washington School of Medicine; Clinical Director, Emergency Services, Children's Hospital and Regional Medical Center, Seattle, Washington

Ventriculoperitoneal and Other Intracranial Shunts

Angela M. Mills, MD, FACEP

Assistant Professor, University of Pennsylvania School of Medicine; Attending Physician, Department of Emergency Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania

Pregnancy-Related Complications

Lilit Minasyan, MD

Fellow, Pediatric Emergency Medicine, Loma Linda University Children's Hospital and Medical Center, Loma Linda, California

Lower Extremity Trauma

Rakesh D. Mistry, MD, MS

Assistant Professor of Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Division of Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Urinary Tract Infection in Infants

Ameer P. Mody, MD, MPH

Assistant Professor of Emergency Medicine and Pediatrics, Loma Linda University School of Medicine, Loma Linda; Clinical Director, Pediatric Emergency Medicine, Emergency Medicine Specialists of Orange County, Children's Hospital of Orange County, Orange, California

Trauma in Infants; The Steroid-Dependent Child; Addisonian Crisis; Thyrotoxicosis

Cynthia J. Mollen, MD, MSCE

Assistant Professor, Pediatrics, University of Pennsylvania; Attending Physician, Emergency Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Sexually Transmitted Infections

James A. Moynihan, MS, DO, FAAP

Assistant Residency Director for Pediatric Emergency Medicine Fellowship, and Assistant Professor of Emergency Medicine, Division of Pediatric Emergency Medicine, Department of Emergency Medicine, Loma Linda University School of Medicine; Assistant Medical Director, Department of Emergency Medicine, Loma Linda University Medical Center and Children's Hospital, Loma Linda, California

Snake and Spider Envenomations

Antonio E. Muñoz, MD, FACEP, FAAP, FAAEM

Associate Professor of Emergency Medicine and Pediatrics, The University of Texas Medical School at Houston; Medical Director of Pediatric Emergency Medicine, Children's Memorial Hermann Hospital, Houston, Texas

Stridor in Infancy; Neonatal Skin Disorders; Erythema Multiforme Major and Minor; Henoch-Schönlein Purpura; Classic Viral Exanthems; Dermatitis; Infestations; Other Important Rashes

Stacey Murray-Taylor, MD

Associate Director, Adult Emergency Department, Newark Beth Israel Medical Center, Newark, New Jersey

Conditions Causing Increased Intracranial Pressure

Preface

Societies are often judged by the care they provide for the young and the weak. The quality of care for injured and ill children has grown tremendously since the formation and growth of pediatric emergency medicine as a subspecialty within the pediatric and emergency medicine communities. The body of knowledge that defines pediatric emergency medicine is deep in breadth and wide in scope. Those who practice it are energetic, intelligent, and caring. They come from diverse backgrounds and share the common goal of providing safe, comprehensive, high quality, cost-effective care. Because children are treated in many venues ranging from the prehospital setting, to urgent care clinics, community hospital emergency departments, academic medical centers and pediatric specialty care hospitals, the provision of excellent pediatric emergency care is of great interest to many.

This text is designed to meet the needs of anyone who cares for childhood emergencies. It is a highly practical and clinically useful reference organized in a logical fashion – according to the way one would think and problem solve when confronted with any emergency in a child. The emphasis is on information that has an impact in real-time care at the bedside and therefore helps the emergency practitioner at the moment help is most required. The book includes 200 chapters replete with clinical algorithms, tables, photos, figures, and expert commentary. The information is presented in a format which highlights key points, important clinical features, potential pitfalls, and delineates the diagnostic approach and specific management for a myriad of pediatric emergency problems.

The sections of the book are divided according to the typical way that one experiences patients in an emergency department – by level of acuity, type of disease, and patient characteristics. Section I: *Immediate Approach to the Critical Patient* addresses life-threatening presentations of medical and surgical disease and contains crucial information on providing immediate and life-saving therapies. Section II: *Approach to the Trauma Patient*, provides similar information when dealing with acute injury as well as definitive management recommendations for a wide range of traumatic conditions. Section III: *Approach to Unique Problems of Infancy* highlights important clinical features and critical management information for conditions which specifically affect this high-risk population of emergency patients. Sections IV and V: *Approach to the Acutely Ill Patient and Approach to Envi-*

ronmental Illness and Injury cover the wide spectrum of conditions encountered on a regular basis in the emergency care of children. Section VII: *Procedures, Sedation, Pain Management and Devices*, provides step by step techniques, important clinical considerations, and helpful illustrations for performing procedures and managing devices in children in the emergency department.

Several unique features of this text will prove invaluable to busy clinicians. Section VI: *The Practice Environment*, explicitly discusses difficult issues such as triage, the care of minors, end of life care, and family presence during resuscitation and offers practical and workable solutions. Section VIII: *Quick Looks*, offers an immediate differential diagnosis to common pediatric emergency department symptom-oriented complaints ranging from abdominal pain and cyanosis to jaundice and lymphadenopathy. The text is extensively cross referenced to provide the most rapid and useful assistance to the reader.

The creation of the first edition of *Pediatric Emergency Medicine* was borne out of the desire to synthesize and disseminate the evidence based practice of emergency care for children, where such evidence exists. There has been an explosive amount of research in the last several years on many aspects of pediatric emergency medicine, with findings that challenge current practices on a regular basis. Much is still to be learned, however, each year therapies based on anecdotal evidence or opinion are replaced with evidence based guidelines and validated decision rules. When evidence to support a particular diagnostic strategy or treatment could not be found, this text makes the best possible recommendation based on current literature and expert opinion or consensus, referencing statements in text for our readers' convenience. It also highlights controversies, cutting edge developments and areas that are in need of further study.

Our goal is to assure that a scientifically sound rationale is used as the basis for the management of ill and injured children. We hope to further such care on a regular basis in emergency departments everywhere to individuals of all backgrounds who provide pediatric emergency care. It is our intention that this first edition of *Pediatric Emergency Medicine* will become an invaluable resource in this capacity. With the knowledge and insight gained from the experts who have written on these pages, we sincerely hope that this text will promote and advance excellent emergency care to the young and vulnerable.

We gratefully acknowledge the work of Joanie Milnes, our developmental editor. Joanie was the ultimate professional, gently guiding us through every stage of publication. She was tough and persistent when we needed her to be but always kind, and remarkably hard working. We also appreciate the guidance and assistance of other Elsevier staff, particularly Todd Hummel who gave us a great start, and Maria Lorusso who gave us a great finish.

Ran D. Goldman, our pharmacology editor, did us a tremendous service and we are indebted to him for providing an efficient and thorough review of our chapters and for checking every medication dose and reference contained within. Ran, we thank you for that extra reassurance and for your tremendous hard work.

We pay tribute to all our contributors who authored chapters and put up with many requests and deadlines. Their level of excitement about the project as well as their knowledge and commitment to creating a high quality, thoroughly referenced work was unsurpassed. Several colleagues volunteered above and beyond the call of duty to author multiple chapters and we are indebted to them for the volume of work they embraced in a short period of time.

We especially thank our colleagues at The Children's Hospital of Philadelphia, the Hospital of the University of Pennsylvania, Saint Barnabas Health Care System, Loma Linda University Medical Center and Children's Hospital, and Orlando Regional Healthcare for their willingness to become authors and for the daily privilege of working with them in our respective emergency departments.

And finally, the motivation to create this book comes in large part, from our patients. They are a constant source of learning and inspiration and we thank them for the opportunity to care for them. It is our intention and hope that this text will improve the health and well being of those we are privileged to serve.

Approach to Resuscitation and Advanced Life Support for Infants and Children

Robert Luten, MD and Steven G. Rothrock, MD

Key Points

Both shock and respiratory failure can be diagnosed and treated in a timely fashion utilizing simple bedside clinical parameters.

With the exception of infants with cardiac failure, clinicians are most likely to under-resuscitate infants and children with shock (i.e., they do not administer enough fluids in a timely manner).

A clear understanding of technique and equipment for BVM ventilation *before*, and maintenance of endotracheal tube position *after*, intubation is crucial.

Eliminate unnecessary mental activity so that time can be used for assessing the priorities of resuscitation. Use printed material or cards to facilitate dosing and equipment selection and age-specific algorithms to improve management of resuscitation and evaluation of critically ill infants and children.

The practice of fundamental mock scenarios and treatment modalities can provide confidence when addressing the rare critically ill child.

failure and shock as its principal resuscitative thrust. The treatment of pediatric cardiac arrest, although included, needs to be seen in perspective relative to the larger picture, the priority for recognition of and resuscitation from shock and respiratory failure. Although the science of resuscitation therapy is continually evolving and requires periodic review, management of a pediatric resuscitation is a skill that changes little over time. Certain practical issues that are inherent in the treatment of respiratory failure, shock, and cardiac arrest in children are discussed in this chapter.

Survival with normal neurologic function following in-hospital cardiac arrest is 14% to 15% and less than 3% after out-of-hospital pediatric cardiac arrest.¹⁻⁵ Studies have delineated markers for poor outcome and no survival. It is helpful to know these probability markers to guide appropriateness of ongoing resuscitation and to quickly prepare and console parents in dealing with the death of their child. Also, in an effort to prevent cardiac survival in the presence of probable devastating neurologic outcome, it is helpful to have guidelines for termination of resuscitative efforts. Most authors agree that, in the absence of extenuating circumstances such as profound hypothermia, resuscitative efforts beyond two to three doses of epinephrine are unlikely to be successful.^{3,6,7} Other markers for poor probability of survival include drowning requiring chest compressions and advanced life support medications at the scene, lack of cardiac activity on arrival to the emergency department (ED), and prolonged (>30 minutes) resuscitation.^{3,6,7}

Introduction and Background

Survival following cardiac arrest in children is poor. As opposed to adults, in whom cardiac arrest is frequently a primary event brought on by ischemic heart disease, in children cardiac arrest is a secondary phenomenon, usually the result of profound metabolic disturbances from untreated shock or respiratory failure. In the early 1980s, the American Heart Association, through the creation of the Pediatric Advanced Life Support (PALS) course, aimed its educational emphasis at the recognition and treatment of respiratory

Approach

A recent review of the pediatric resuscitation process attempted to define elements of the mental (cognitive) burden of providers when dealing with critically ill children.⁸ An increase in logistical time is inherent in pediatric resuscitation compared to adult resuscitation. One of the reasons for this increased logistical time is the age- and size-related variations unique to children, which introduce the need for more complex, “nonautomatic” mental activities, such as calculating drug doses and selecting equipment. These activities

may subtract from other important mental activities such as assessment, evaluation, prioritization, and synthesis of information, which can be referred to in the resuscitative process as “critical thinking activity.” Summation of these logistical difficulties leads to inevitable time delays, and a corresponding increase in the potential for decision-making errors in the pediatric resuscitative process. This is in sharp contrast to adult resuscitation. One way of understanding this difference is to examine the adult resuscitation process. Medications used frequently (e.g., epinephrine, atropine, glucose, bicarbonate, and lidocaine) are packaged in prefilled syringes containing the exact adult dose, making their ordering and administration “automatic” (i.e., not requiring mental effort beyond the decision to order one ampule or one unit dose of the drug). The same concept is seen in equipment selection, where the usual necessary equipment is laid out for immediate access and use. It is also common to have preprinted algorithms readily available to guide drug selection, drug dosing, equipment selection, and administration decisions, even though the provider frequently has a good working knowledge of these issues. The end result is that the adult provider’s time is freed up for critical thinking, and is not occupied with these other decisions.

The use of resuscitation aids in pediatric resuscitation can significantly reduce the cognitive load caused by obligatory calculations of dosage and equipment selection. These aids relegate these activities to a lower order of mental function. In other words, the use of resuscitation aids in pediatric resuscitation transforms nonautomatic activities into automatic activities, decreasing logistical time, thereby increasing critical thinking time. An example is the Broselow-Luten system that codifies children to a color by a single length measurement. The color then serves as a code for preselected equipment, precalculated medications, and other age/size-related variables such as fluids and ventilator settings (Fig. 1–1).

Evaluation and Management

The ABCs

Standard preliminary treatment is usually initiated prior to arrival of critically ill or arrested children in the ED. Laypeople and emergency medical services (EMS) providers have been shown inaccurate at detecting breathlessness and the presence of a pulse in patients with cardiac arrest.⁹ For this reason, a complete cardiopulmonary re-evaluation is essential upon patient arrival in the ED. Head tilt and chin lift (jaw thrust without head tilt if cervical spine injury is possible) are initiated to open an obstructed airway while rescue breaths are given for apneic patients. Upon ED arrival, more advanced airway techniques, subsequently described, are applied. As respiratory failure is the most common precipitating event in childhood cardiac arrest, attention to properly opening the airway, adequate ventilation, and oxygenation are key resuscitation techniques.

Clinicians should be aware that the infant’s heart is below the lower third of the sternum in 88% of cases.¹⁰ For this reason, chest compressions over the lower third of the sternum generate a higher mean arterial pressure compared to the midsternum¹¹ (Fig. 1–2). Additionally, using both hand to encircle the chest while applying chest compressions to

infants (<1 year old) results in a higher arterial pressure than two-finger compressions during CPR.¹² For rescuers who are on their own, compression of the sternum with two fingers may be an appropriate alternative to allow for rapid transition between ventilation and compressions.¹³ While estimates of appropriate compression depths for different ages are suggested (Table 1–1), an increase in end-tidal CO₂ (ETCO₂) is seen with more effective chest compressions and may guide the efficacy of these efforts.¹⁴

Expert recommendations and advanced life support courses require a considerable amount of memorization of specific time intervals, depth of compression, and frequency of ventilation and chest compression, contributing to an excess cognitive burden during resuscitation efforts (Table 1–1). In reality, no specific ventilation rate or ratio has been shown to result in superior outcome during cardiopulmonary resuscitation (CPR). In fact, during bystander CPR, chest compressions may be all that are required to ensure adequate ventilation.^{15,16} Moreover, recommended compression rates of 100 beats/min in infants and children may be too low as rates of compression of 120 beats/min result in higher aortic and coronary perfusion pressures, and these rates barely approach normal heart rates at their recommended ages.^{17,18} Realistically, attention to properly opening the airway and to appropriately located and rapid compressions augmented by monitoring ETCO₂ will provide the best chance for intact survival in cardiac arrest while limiting the cognitive burden of adhering to a set of rigid, inflexible ratios and numbers that have limited scientific validity.

Two additional tools that may aid in the diagnosis and management of patients in cardiac arrest include ETCO₂ monitoring and ultrasonography (US). During CPR, a sudden rise in ETCO₂ to greater than 15 mm Hg predicts a return of spontaneous circulation (ROSC), while persistence of ETCO₂ less than 10 mm Hg for 20 or more minutes predicts a near-zero probability of ROSC.^{18,19} ETCO₂ also may discriminate between true pulseless electrical activity (PEA) and patients with true cardiac activity and a low blood pressure with nonpalpable pulses.²⁰ Bedside US in the ED can be used to identify cardiac activity during cardiac arrest. Adults with any cardiac activity on US during resuscitation have a 26% rate of survival to hospital admission compared to 3% for those with no cardiac activity.²¹ While this study has not been replicated in children, it is likely that US has some ability to predict survivors in this population. Ultrasonography has been used to detect ventricular fibrillation in patients initially thought to have asystole and, thus, guide appropriate management.²² Like capnography, US can be used to discriminate between patients with true PEA and those with a low blood pressure.²¹

After ED arrival, the first few seconds of evaluation determine the priorities and management over the next few minutes. Referred to as the “ABCs,” the initial clinical evaluation of the airway (A), breathing (B), and circulation (C) determines whether the child is suffering from respiratory failure (abnormal A and B), shock (abnormal C), or cardiopulmonary failure or arrest (abnormal or absent ABC). The presence of normal ABCs in the unresponsive patient eliminates respiratory failure (CO₂ retention and narcosis) and shock (decreased cerebral perfusion) as causes of the altered mental status and also eliminates the majority of critical pediatric diseases since children tend follow the pathways of

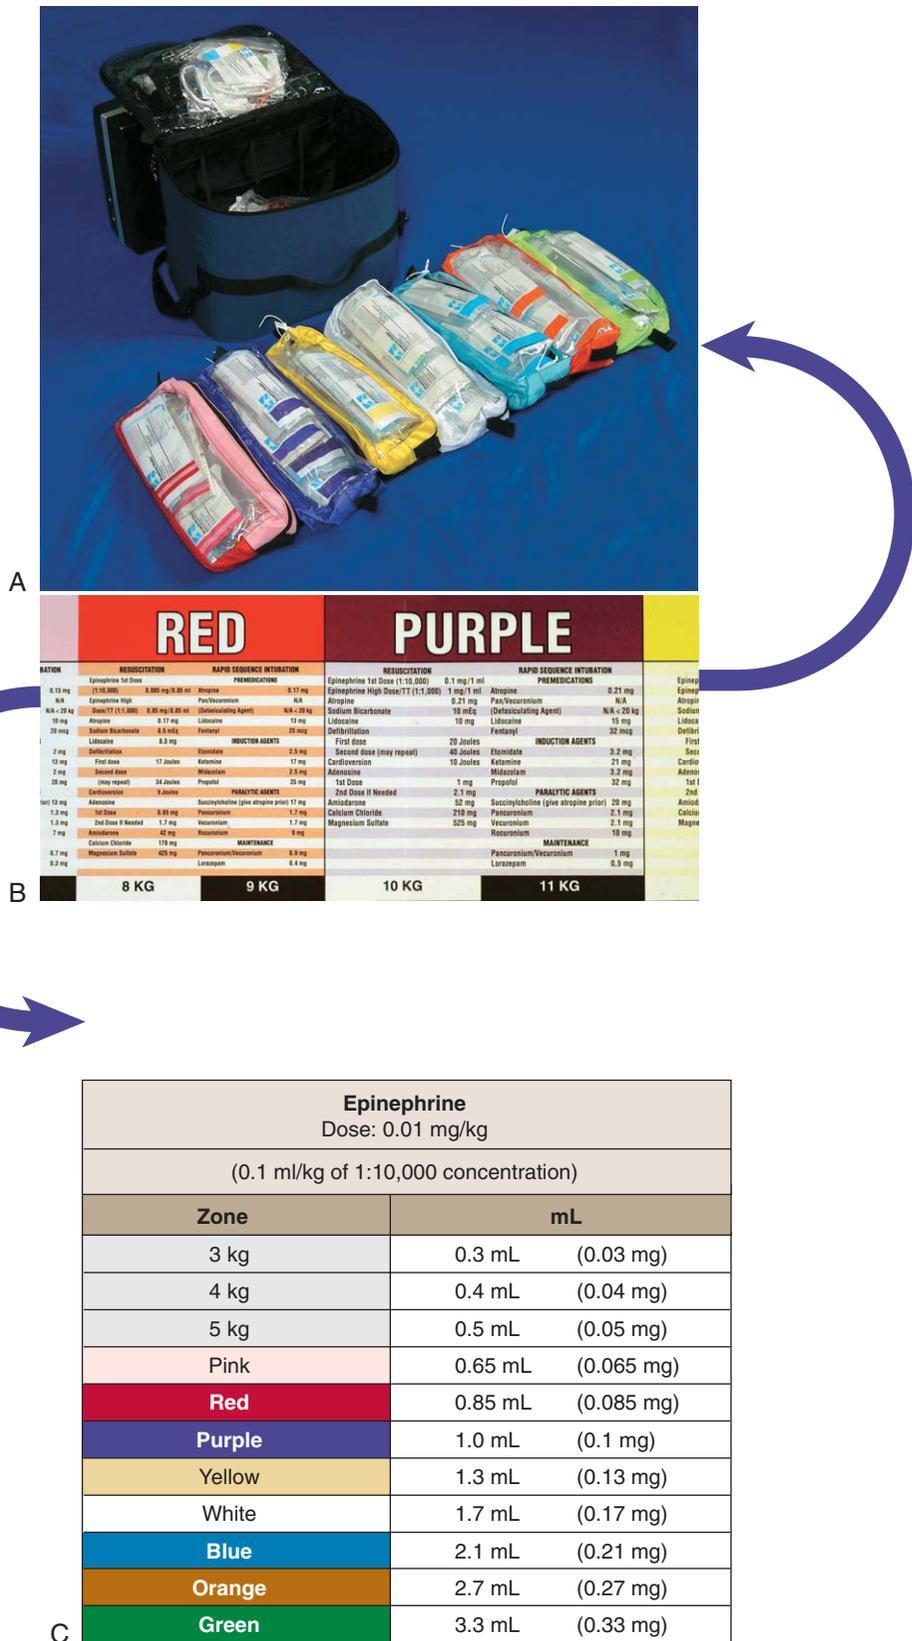

FIGURE 1-1. For situations in which a patient cannot be weighed, an accurate prediction of a patient’s color zone can be determined using the Broselow tape. Once a color has been obtained, it references precalculated drug doses and drug volumes as well as appropriately preselected equipment. **A**, Equipment storage system. **B**, Broselow tape. **C**, Medication label, the Broselow-Luten system.

respiratory failure or shock to cardiac arrest. Once these causes are eliminated, central nervous system disorders need to be addressed (e.g., head trauma, medication overdose, and, probably most common in the pediatric emergency setting, the postictal state).

Brief, structured observation of breathing difficulty to assess airway (patency), pulse oximetry to assess breathing (adequacy), and assessment of pulses and capillary refill to

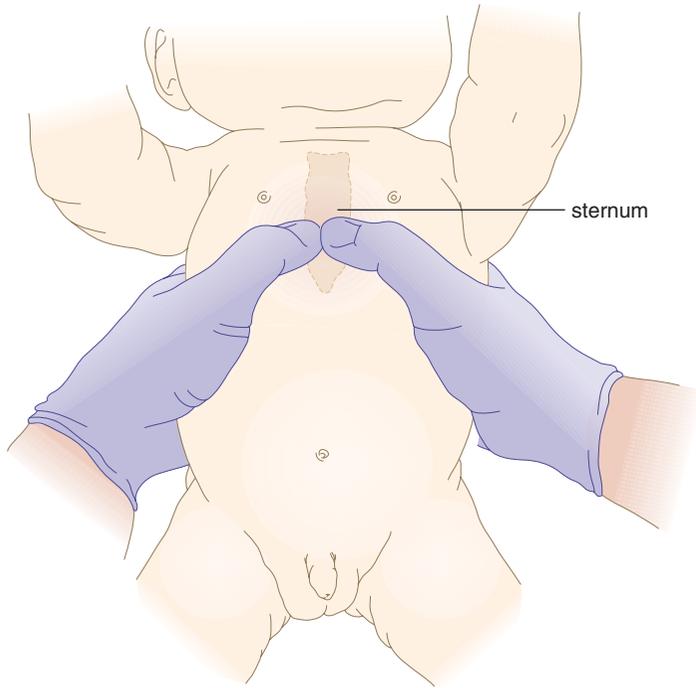

FIGURE 1-2. Optimum cardiac compressions (with two-person CPR) in infants (<1 year old) with thumbs compressing lower third of sternum and hands encircling chest.

assess circulation (perfusion) quickly determines whether respiratory failure or shock is present. Once recognized, subsequent therapeutic interventions are simple but effective if appropriately applied:

Respiratory Failure → O₂/BVM ventilation → Intubation

Shock → Vascular access → Fluids, ± pressors or antibiotics or blood

Arrest → BVM ventilation → intubation → chest compressions → defibrillation → vascular access → fluids/medications

Anywhere in the treatment, from the initial diagnosis to subsequent unexpected changes in clinical course, regardless of the disease, the mnemonic DOPE must be considered following patient deterioration. DOPE refers to **D**islodgement of the endotracheal tube (ET) into the esophagus or a main-stem bronchus, **O**bstruction of the ETT from debris or kinking, **P**neumothorax, or **E**quipment malfunction. A sequential approach to evaluation and treatment using the mnemonic (1—disconnecting the patient from mechanical ventilation and 2—auscultation of the lungs, followed by 3—suctioning of the ETT and visual inspection of the glottic opening) may be warranted in a more structured setting such as an intensive care unit. In the ED, immediate extubation and reintubation is more efficient and eliminates all causes except a tension pneumothorax, which can then be decompressed with the confidence that all other etiologies have been addressed.

Specific therapy will depend upon etiology (e.g., β-agonists for the wheezing of respiratory failure or antibiotics and steroids for septic shock). Details of these therapeutic interventions are found in other chapters. The following sections deal with some of the major practical issues and pitfalls in the initial treatment of the critically ill child based on evaluation of the ABCs. Many etiologies traditionally are listed in the differential diagnosis of the critically ill child, some of which are extremely rare. The approach described herein

Table 1-1 CPR Maneuvers and Techniques in Newborns, Infants, and Children

Maneuver	Newborn/Neonate	Infant (<1 yr)	Child (1-8 yr)
Open Airway Breathing	Head tilt–chin lift (jaw lift without head tilt if trauma)—all ages		
Initial	May require 30–40 cm H ₂ O pressure	Two breaths to make chest rise	Two breaths to make chest rise
Subsequent if no CPR	30–60 breaths/min	12–20 breaths/min	12–20 breaths/min
during CPR	30–60 breaths/min	8–10 breaths/min	8–10 breaths/min
Circulation*			
Check pulse	Umbilical/brachial	Brachial or femoral	Carotid
Compress at	Lower 1/2 sternum	Lower 1/2 sternum	Lower 1/2 sternum
Compress with	Two thumbs, encircling chest with hands	Two thumbs, encircling chest with hands	Heel of one hand
Depth	One third to one half of depth of chest for all listed ages		
Rate [†]	120/min @ 3 : 1	100/min 15 : 2	100/min @ 15 : 2
Ratio [‡]	3 : 1 (interposed breath)	15 : 2 (interposed breaths)	15 : 2 (interposed breaths)
Foreign Body Airway Obstruction[§]	Back blows Chest thrusts	Back blows Chest thrusts	Abdominal thrust (Heimlich maneuver). Chest thrust or back blow is acceptable alternative.

*Also check for normal breathing, movement, or coughing. Laypeople do not check pulse.

[†]Total number of events: compressions plus breaths.

[‡]Ratios are for two-person CPR.

[§]Only if the obstruction is severe, such that the victim is unable to make a sound.

From Rothrock SG (ed): Pediatric Emergency Pocketbook, 5th ed. Lompac, CA: Tarascon Publishing Inc, 2007.

addresses the physiologic derangements common to multiple causes. Some etiologies, although uncommon, become apparent within the context of the evaluative process or "secondary survey" (e.g., hypothermia, hyperthermia, hyperkalemia).

Respiratory Failure—The Basics

The major advance in the emergency management of respiratory failure in children is the implementation by emergency physicians of rapid sequence intubation (RSI), the use of potent sedatives and muscle relaxants in a defined procedure that facilitates intubation while reducing complications of intubation such as aspiration. Children requiring resuscitation from cardiac arrest are not intubated with RSI, however, as this procedure is usually reserved for patients not in cardiac arrest (see Chapters 2, Respiratory Distress and Respiratory Failure; and Chapter 3, Rapid Sequence Intubation). Appropriate bag-valve-mask (BVM) ventilation, ETT placement, and maintenance of ETT position are important components of successful advanced resuscitation.

Why Is BVM Ventilation So Important in Children and Why Is It Recommended in Arrest from "Total Airway Obstruction"?

BVM ventilation is a proven technique. In emergencies, for providers who rarely encounter critically ill children, it may be as effective as endotracheal intubation as a short-term rescue/temporizing measure. In fact, some subsets of infants and children undergoing prehospital endotracheal intubation (e.g., those with head trauma) have a worse outcome compared to those receiving only BVM ventilation. Importantly, BVM ventilation also can be effective in children with airway obstruction. Efforts by the patient to alleviate airway obstruction can cause worsening of the obstruction (i.e., forced inspiration worsens obstruction as *negative* extrathoracic pressure is generated, collapsing the airway). A respiratory arrest occurs secondary to fatigue from increased work of breathing (note, *not* from total obstruction as the obstruction has both a fixed and a dynamic and reversible component in children). Application of *positive* pressure via BVM causes the opposite effect by stenting or relieving the dynamic component of obstruction. Hence, experts recommend BVM ventilation as a temporizing measure even if the patient arrests from obstruction. Case reports of successful resuscitation after respiratory arrest from epiglottitis have borne this out.

BVM Size and Safety Features

For emergency airway management, a self-inflating BVM is preferred over an anesthesia ventilation bag. The BVM apparatus should have an oxygen reservoir so that a fraction of inspired oxygen of 90% to 95% is obtained when 10 to 15 L of oxygen is administered. The smallest bag that should be used is the 450-mL BVM device. Neonatal bags that are smaller (250 mL) do not provide effective tidal volume for small infants. Many BVM devices have a pop-off valve. The pop-off valve is usually set around 35 to 45 cm of water and is used to prevent barotrauma by providing a release of excessive pressure generated during BVM ventilation. Since a higher respiratory pressure is needed to ventilate a patient in some emergent airway situations, the bag should either have no pop-off valve or a valve that is easily adjusted or occluded. A new "old problem" occurs because of lack of familiarity by

staff with this safety feature. If the bag is stored with the valve unoccluded (i.e., as packaged from the manufacturer), it is common for staff to begin ventilating with the valve set in that position. As a result of the higher pressures required for initial ventilation, either because of increased lung compliance or poor positioning of the airway, oxygen escapes from the valve and is not delivered to the patient.²³ Critical time is lost until staff realize what is happening since the sensation of a leak from a poor seal of the mask over the face is lost as oxygen escapes from the valve. Another, even more dangerous possibility is the escape of oxygen from an unoccluded manometer port, as the resistance is much lower than 35 to 45 cm H₂O. Both possibilities can be prevented if providers perform a "leak test," similar to checking laryngoscope blade lights before intubation. This test is performed by compressing the bag with one hand while simultaneously occluding the patient connection port with other. If the pop-off valve, and other valves are in the occluded position, no air can be expressed and the bag remains full or tight, avoiding the pitfall of failure to deliver oxygen to the patient. A flow of at least 10 to 15 L/min of oxygen must be maintained into a reservoir attached to a pediatric bag, and at least 15 L/min must be supplied for an adult bag.

Many infants and children requiring mask ventilation will ultimately require endotracheal intubation, in many cases using RSI. Advanced airway techniques and maintenance of a controlled airway are described in Chapter 2 (Respiratory Distress and Respiratory Failure) and Chapter 3 (Rapid Sequence Intubation).

Achievement and Maintenance of Endotracheal Tube Position

Ideal placement of the ETT in the trachea is approximately midway between the vocal cords and the carina. A common occurrence when intubating a child is right mainstem intubation. Once correctly positioned, maintenance of the desired postintubation position is challenging in children. One method used to prevent mainstem intubation is to place one of the ETT insertion lines (near the distal tip of the tube) at the level of the cords during intubation. If the tube is maintained at that level, it will be positioned correctly. This placement, however, does not always occur in emergency intubations. Even if the tube is placed at one of the ETT distal insertion lines and it becomes dislodged during treatment, there is no simple method to detect this displacement or realign the tube at the insertion line without repeat laryngoscopy. Cole's formula for ETT size and depth, a more reliable method, is to insert the tube until the lip-to-tip distance is reached (a defined centimeter mark for each tube size), and secure the tube at that level. The lip-to-tip distance is approximately three times the internal diameter of the tube size in centimeters for a given patient. For example, the lip-to-tip distance for a 3.5-mm tube is approximately 10.5 cm. The actual distance is a range that can be obtained from reference materials. When a smaller size tube is used for a given patient—for example, in a patient with subglottic stenosis—the lip-to-tip distance for that tube would be the distance of the tube that would fit in a patient without the stenosis. That is, if a 3.0-mm tube is used instead of a 3.5-mm tube, which is the normally recommended tube for the patient, then the lip-to-tip distance would be still be 10.5, even though the patient is intubated with the smaller tube. A word of caution:

This formula may overestimate ETT depth in infants and children under age 2 by 0.5 to 1.0 cm.

Following intubation, two factors lead to ETT dislodgement. The first is the ease with which the tube slides in and out, since it is not anchored by an inflated cuff as in the adult, and the second is the movement of the tube within the trachea as a consequence of the large range of movement of the head and neck. Anesthesiologists have evaluated the average movement of the ETT with head movement in young infants. In 16- to 19-month-old infants, flexion of the neck by 30° to 45°

causes insertion of the ETT 0.9 to 1.7 cm deeper into the trachea, while extension by 30° causes the tube to move out of the trachea by a mean 1 cm.²⁴ Others have found that head flexion in children weighing more than 10 kg produces a mean downward displacement of the ETT by 1 cm, and head extension produces a mean upward displacement of 1.4 cm.²⁵ As the trachea is short at this age, this amount of head or neck movement can lead to extubation or mainstem intubation (Fig. 1–3). To ensure the tube does not slide in and out, adequate securing of the tube at the mouth is required.

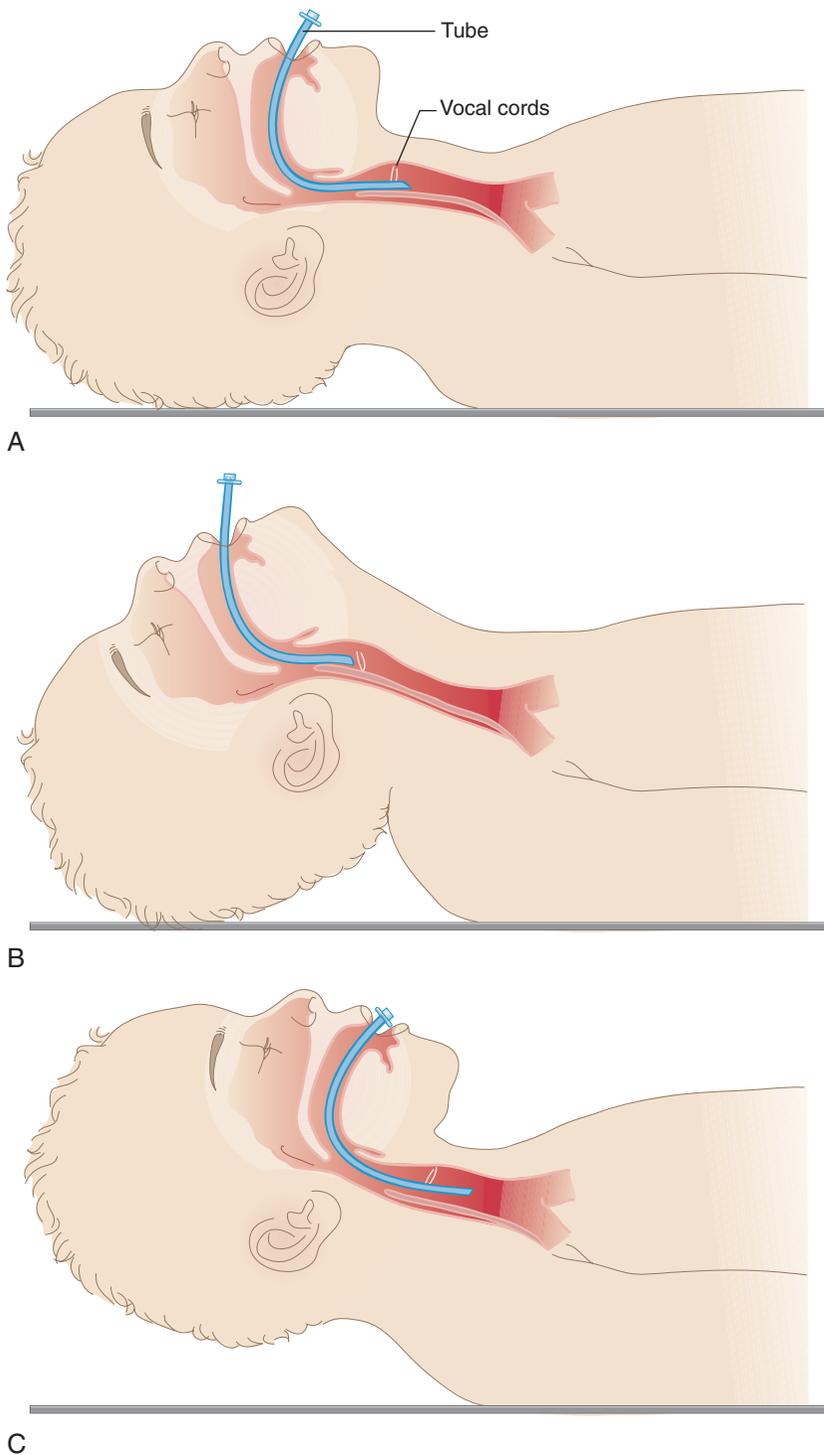

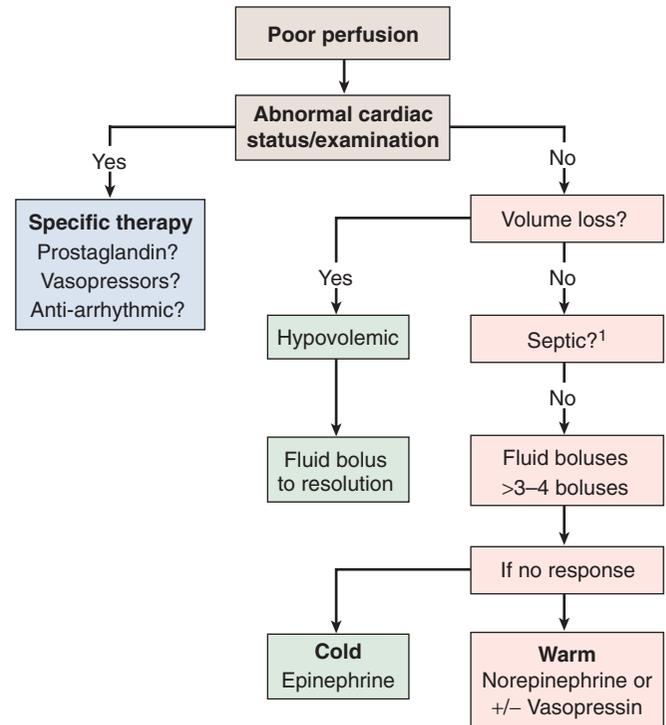

FIGURE 1–3. Position of endotracheal tube in normal position (A), with head and neck extended (B), and with head and neck flexed (C).

Inexperienced providers can apply commercial tube holders, which hold the tube adequately. Movement of the tube secondary to head and neck movement can be prevented by application of a cervical collar. Once the head and neck are immobilized, the most common complications of pediatric intubation (extubation and mainstem intubation) can be minimized.

Shock—The Basics

The recognition and treatment of shock has been identified as a pediatric resuscitation priority since the initial PALS effort.²⁶ Early studies identified adequate fluid resuscitation as a key to enhanced survival.²⁷ This concept, as well as aggressive intensive care management, has dramatically reduced mortality from septic shock.²⁸ The emergency physician's role is that of early recognition, initial aggressive management, and transfer to a higher level of care. Initial fluid and pressor therapy is guided by clinical determination of the type of shock and appropriate therapy. One of the misconceptions of pediatric care in general is that clinicians must be very cautious with fluids in children. In the setting of noncardiogenic shock, fluid needs are often great, especially in small children. A barrier to effective treatment is the tendency to “err on the side of less, rather than more” during fluid resuscitation. The patient in shock, hypovolemic and septic, may require repeated boluses totaling 100 to 200 mL/kg in the stabilization process (the total blood volume of a child is approximately 80 mL/kg).

The first steps in the resuscitative process for shock are simultaneous vascular access for the administration of an initial isotonic fluid bolus of 20 mL/kg and clinical evaluation to determine the cause of shock. Because fluid administration may be detrimental in cardiogenic shock, this condition must be excluded prior to initiation of large volumes. Cardiogenic shock can usually be ruled out most easily by the presence of a large liver on palpation, and to a lesser extent by the presence of rales in the lungs, and probably least often by the presence a murmur. A chest radiograph with normal lung fields and a normal-sized heart also makes cardiogenic shock unlikely. The second decision point comes when shock persists despite three to four boluses of isotonic fluid (Fig. 1–4). This state is sometimes referred to as “fluid-refractory” shock. This step is the clinical differentiation of septic versus hypovolemic shock, which determines which patients would benefit from pressor support in addition to aggressive fluid resuscitation (septic) and which patients require fluid (or blood) management alone (hypovolemic) (see Fig. 1–4). This differentiation becomes especially important when massive volumes of fluid are required to reverse a poorly perfused state. Importantly, the distinction between septic and hypovolemic is arbitrary in the sense that both can be considered hypovolemic, requiring large fluid volumes as part of the therapy. The term *hypovolemic* generally refers to the state of intravascular and interstitial fluid depletion usually resulting from fluid loss (e.g., diarrhea). The clinical signs associated with hypovolemic shock correlate with the severity of the interstitial fluid deficit, and permit a reliable clinical diagnosis. The term *septic* refers to the state of hypovolemia resulting from vascular permeability and fluid leakage, leading in many cases to interstitial hypervolemia manifested early on by warm skin and strong central pulses associated with intravascular depletion and late hypotension

¹Administer empiric antibiotics and consider steroids.

FIGURE 1–4. Clinical differentiation of shock types and initial management.

and more obvious signs of shock. Anaphylactic shock and spinal cord injury also manifest features of early hyperdynamic shock as seen in early sepsis. (See Chapter 8, Circulatory Emergencies: Shock, for a more detailed review of shock.)

Vascular Access

Although central venous access is ideal during critical resuscitations, it is rarely feasible. Most resuscitations occur in the prehospital or ED environment where rapid peripheral access may be problematic, limiting the ultimate success of resuscitation. The intraosseus (IO) route provides a rapid, reliable, alternate method of gaining vascular access when peripheral access cannot be achieved rapidly. IO access can usually be rapidly achieved even in relatively inexperienced hands.²⁹ A new intraosseus innovation has the potential to make mastery of this technique even more certain.³⁰ The Bone Injection gun (BIG) IO device is a spring-loaded cylinder that, when activated, “injects” the IO needle into the bone at a predetermined adjustable level (see Chapter 161, Vascular Access). If time permits, central venous (e.g., femoral vein) access may be an appropriate alternative. Ultrasound guidance can improve speed of this technique and decrease complications related to central venous access.

ABCDs of Resuscitation from Cardiac Arrest in Children

The most common causes of pediatric cardiac arrest include sudden infant death syndrome (SIDS), trauma, submersion, cardiac disorders, and sepsis.⁷ While knowledge of the specific precipitant resulting in cardiac arrest is important, attention to airway management and early CPR are vital to increasing the probability of ROSC regardless of cause. In

preparing for patient management, clinicians should be aware that the vast majority of nontraumatic cardiac arrest cases occur in the first year of life, with most in infants ages 3 months and younger.^{7,31} Most cases are unwitnessed, and most do not receive bystander CPR. Thus late initiation of resuscitation contributes to the poor outcome.⁷

When comparing the ABCDs (ABCs plus drugs/defibrillation) in pediatric and adult resuscitation, major practical differences are present. A major advance in adult resuscitation has occurred over the years, with new drugs and defibrillation leading to improved outcome for adults. Moreover, the ABCs are straightforward in adults and do not present significant barriers to successful resuscitation (see Table 1–1). The reverse is true in the care of children. Drug treatment of cardiac arrest has changed little over the last 25 years, with epinephrine representing the mainstay of the treatment. Unfortunately, little has changed in terms of outcome from cardiac arrest as well.

The management of cardiac arrest in a child can be perceived as daunting. However, excluding child-specific issues, the management follows the general principles of adult cardiac arrest, specifically the recognition and management of rhythm disturbances. Pediatric-specific issues that have been alluded to in this chapter or are discussed elsewhere include

- Eliminating age- and size-related issues, which can cause error, time delay, and confusion
- The rapid recognition and aggressive treatment of respiratory failure and shock (preventing cardiac arrest)
- The psychological overlay of dealing with a critically ill child

Once the ABCs have been addressed in critically ill or arrested patients, subsequent therapy (Ds) relates to the management of the cardiac rhythm. The goal of rhythm therapy is the achievement of adequate cardiac output (CO). Utilizing the formula $CO = \text{heart rate (HR)} \times \text{stroke volume (SV)}$ as a guide, one can see that rhythm disturbances that alter either HR or SV and thus affect CO must be changed, and this usually done with drugs. Rhythm disturbances can be classified as fast, slow, or absent (collapse) rhythms (Table 1–2). In an unstable patient, slow rhythms must be “sped up,” and they are generally all treated the same way, regardless of specific rhythm. Fast rhythms need to be “slowed down,” and in general, treatment in unstable patients consists of electrical cardioversion. Collapse rhythms must be converted to viable rhythms, and the treatment of these is specific, though not complicated. If perfusion remains poor in spite of rate normalization, a vasopressor may then be initiated.

For the purposes of resuscitation, rhythms in childhood cardiac arrest can be divided into shockable (ventricular fibrillation [VF] and ventricular tachycardia [VT]) and non-shockable (asystole and PEA) arrhythmias (Fig. 1–5). Asystole is by far the most common cardiac arrest rhythm noted in children, accounting for nearly two thirds of all cases.³ In general, asystole outcome is dismal as this rhythm occurs late and rarely responds to interventions. PEA is the second most common pediatric arrest rhythm and is the initial rhythm found in nearly one quarter of out-of-hospital pediatric cardiac arrest cases.³ PEA is defined as organized electrical activity on a cardiac monitor without pulses or any detectable cardiac output. Reversible causes of PEA include the 4 Hs (hypovolemia, hypoxia, hypothermia, hyperkalemia and other metabolic disorders), and the 4 Ts (tension pneumothorax, pericardial tamponade, thromboembolism and toxins).³² Importantly, $ETCO_2$ and cardiac US can be used to identify a subset of patients with cardiac activity that is not evident on physical examination who may respond to fluids, acute intervention (pericardiocentesis, needle thoracotomy), or pressure support. Management consists of airway support, ventilation, chest compressions, and reversing any identifiable cause (see Fig. 1–5). Epinephrine is also recommended to increase cardiac activity, coronary perfusion, and diastolic blood pressure, which are associated with improved ROSC. The recommended dose of epinephrine is 0.01 mg/kg intravenously (IV) or IO or 0.1 mg/kg intratracheally repeated every 3 to 5 minutes. Earlier studies that evaluated escalating doses of epinephrine have not been supported by evidence of improved outcome and cannot be recommended. Importantly, above 8 years, adult PEA and asystole algorithms are recommended. The primary difference is the use of vasopressin (40 units IV), which may improve survival to hospital discharge compared to epinephrine for the subset of adult cardiac arrest patients with asystolic cardiac arrest.

Shockable rhythms (VF or pulseless VT) are present in nearly 10% of out of hospital pediatric cardiac arrest cases.³ If cases of SIDS are excluded, this number may be as high as 19% to 24%.³³ These rhythms have the highest rate of neurologically intact survival of all arrest rhythms in children.³³ Ideally, patients with these rhythms are identified as early as possible and treated with immediate defibrillation at 2 joules/kg. If unsuccessful, they are defibrillated with another 2 to 4 joules/kg, then with 4 joules/kg. Either a monophasic or biphasic shock may be administered.¹³ To achieve appropriate variable dose, a manual defibrillator or an automated external defibrillator (AED) that can recognize pediatric VT and VF and that is equipped with dose attenuation can be used

Table 1–2 Classification of Arrest/Prearrest Rhythms by Heart Rate

Heart Rate	Cardiac Output	HR × SV	Example	Rationale
Fast	↓	↓	SVT, VT	HR is too fast for diastolic filling of heart
Slow	↓	Normal	Blocks and bradycardia	Self-explanatory
Absent	↓	↓	PEA* and VFib	Self-explanatory

*This classification is based on pulse rate, the absence of which gives the clinical diagnosis of pulseless electrical activity (PEA). PEA due to an ischemic, hypoxic myocardium or electromechanical disassociation (EMD) has no pulse and an almost universally poor prognosis. In a poorly perfused infant or child, pulses are difficult to palpate and the child's rhythm may not be truly pulseless. Cardiac activity with a low blood pressure may be present, with an improved prognosis mandating aggressive therapy compared to a patient who is truly in PEA. Abbreviations: HR, heart rate; PEA, pulseless electrical activity; SV, stroke volume; SVT, supraventricular tachycardia; VFib, ventricular fibrillation; VT, ventricular tachycardia.

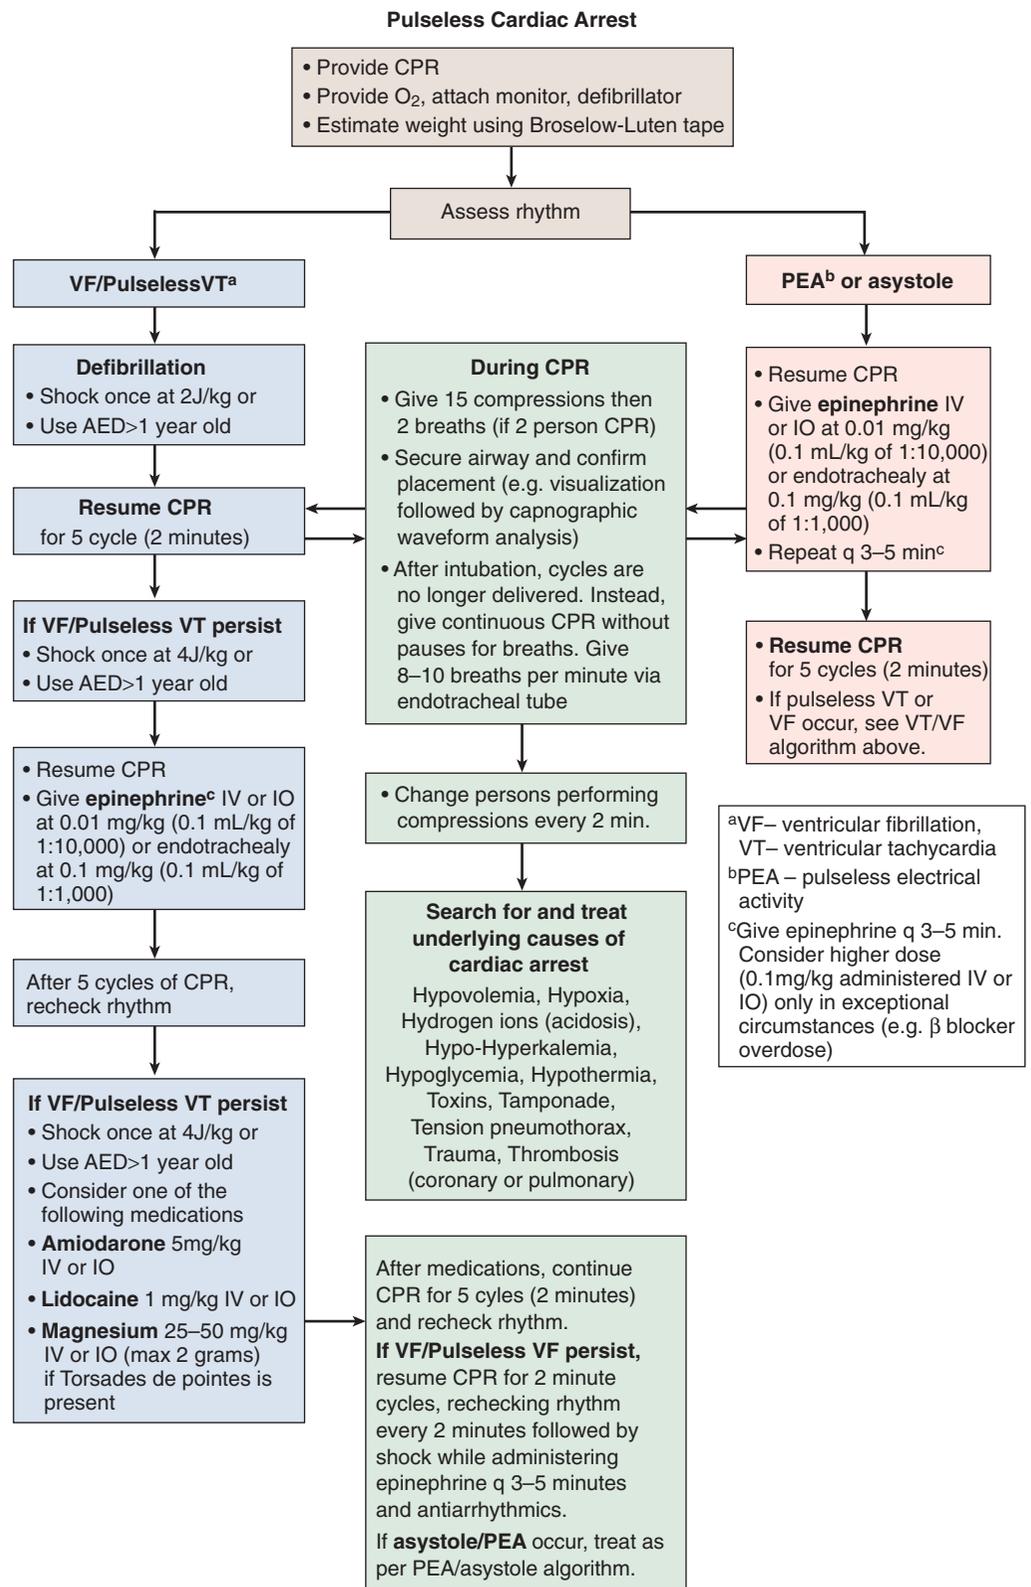

FIGURE 1–5. Pulseless cardiac arrest management.

in children 1 to 8 years old. Subsequently, ventilation and cardiac compressions are initiated and medications, including epinephrine and antiarrhythmics, are given. As for asystole and PEA, adult arrest protocols are recommended for children over 8 years old with VF/pulseless VT, the primary

difference being the use of vasopressin for these arrest rhythms instead of or in addition to epinephrine. Following drug administration, repeat defibrillation at 4 joules/kg is followed by CPR and further drug administration (see Fig. 1–5). Clinicians need to be aware of prehospital provider

recommendations for use of AEDs in cardiac arrest in children 1 year of age or older. AEDs are 96% sensitive and 100% specific at identifying VF/VT at this age.³⁴ In general, delivery of adult defibrillator doses to children over 1 year old has been shown safe, although use of pediatric algorithms, pads, and cables for adult AEDs is preferred.³³

In the postarrest state, besides careful attention to ETT positioning and maintenance, frequent monitoring of vital signs is essential. Vasoactive medications are frequently required, at least transiently, to maintain perfusion as myocardial depression as well poor vascular tone are common in this scenario. The use of these drugs requires careful monitoring as clinical response is very patient specific and can also vary at different infusion rates.

Summary

Therapy for pediatric cardiopulmonary arrest has changed little in the past decade. As a result, outcome for cardiac arrest has not improved. Currently, studies are underway to evaluate preventative techniques for at-risk infants and children, earlier prehospital interventions (e.g., specific pediatric AEDs), and postresuscitation neurologic preservation (e.g., therapeutic hypothermia).

Recognition of disorders leading to respiratory and cardiac arrest and prompt aggressive management have the potential to minimize morbidity and mortality in critically ill infants and children. The decision tree for simultaneous recognition, differentiation and management is clinical, requiring minimal ancillary studies. Once cardiac arrest occurs, CPR and advanced life support techniques are employed using standard algorithms. Drug dosing, equipment selection, and patient management is enhanced by use of length-based cognitive resuscitation aids (e.g., Broselow-Luten system) and printed management guides. Newer techniques of US and ET_{CO}₂ may aid in rapid diagnosis and management of patients with viable arrest rhythms and may predict return of spontaneous circulation.

Respiratory Distress and Respiratory Failure

Patricia S. Padlipsky, MD and Marianne Gausche-Hill, MD

Key Points

Pediatric airway differences are most pronounced in infants. By 8 years of age the pediatric airway is anatomically like the adult airway.

Respiratory distress is a state of increased work of breathing, whereas respiratory failure is a state of inadequate oxygenation or ventilation. Respiratory failure may or may not be preceded by respiratory distress.

Assessment of the respiratory status of an infant or child begins with the Pediatric Assessment Triangle. A rapid general impression directs immediate airway management.

Infants and children have unique clinical scenarios and conditions that may lead to a difficult airway.

Introduction and Background

Respiratory problems or complaints are one of the most common reasons for infants and children seeking medical care in an emergency department (ED). Children represent about 10% of all prehospital care transports, and of these about 10% are due to respiratory complaints.¹⁻³ In the ED, respiratory complaints account for approximately 10% to 20% of the pediatric visits.⁴ Respiratory compromise is the leading cause of death in children less than 1 year of age. Children often go through a period of respiratory distress prior to respiratory failure, but respiratory failure may exist without signs of respiratory distress. The survival of children from cardiopulmonary arrest (9%) is dismal compared to those in respiratory failure alone (80%); therefore, it is imperative that the emergency physician anticipate and recognize early signs and symptoms of respiratory failure and intervene quickly to prevent further deterioration to cardiopulmonary failure/arrest.^{5,6}

Recognition and Approach

There are anatomic, physiologic, and behavioral differences between the adult and pediatric airway that affect the risk of airway obstruction, the risk of the development of respiratory compromise, and the approach to management. The transition from neonatal to adult airway anatomy is completed by 8 to 10 years of age. By this time the airway is similar to that of the adult, only smaller. Anatomic, physiologic, and behavioral differences with their impact on patient care are summarized in Table 2-1.

Anatomic Differences

Neonates (defined as < 1 month of age) have large heads in relation to their body size. The relatively large occiput can result in natural flexion of the neck when lying supine, which can lead to airway obstruction. A towel roll placed under the infant's shoulders will elevate the patient's torso and result in a neutral position (Fig. 2-1). The neonate's chest muscles are not well developed, and the diaphragm and abdominal muscles are the main muscles of respiration. Abdominal breathing is normal in infants, but it often becomes exaggerated and faster as the infant has increasing respiratory difficulty. With increasing respiratory distress, the abdominal muscles may become fatigued, leading to seesawing respirations that may precede respiratory failure. Also, factors that impede diaphragmatic excursion, such as a distended gastric air bubble, severe pneumoperitoneum, or ascites, can also result in respiratory failure.

The differences in anatomy of the upper airway in infants and children versus adults result in increased susceptibility to respiratory distress and failure. For example, children have a relatively *larger volume of tongue* intraorally, which can lead to airway obstruction especially if there is loss of muscle tone and the tongue relaxes in a posterior position, obstructing the upper airway. This obstruction can be overcome by making sure that the head is repositioned to the midline and in the sniffing position. If necessary, an airway adjunct (oropharyngeal or nasopharyngeal) can be inserted. The *narrow upper airway* passage can also be obstructed by a foreign body or an infection that may cause inflammation and excess secretions. The *large mass of tonsillar and adenoidal tissue* can result in trauma to these tissues during nasotracheal

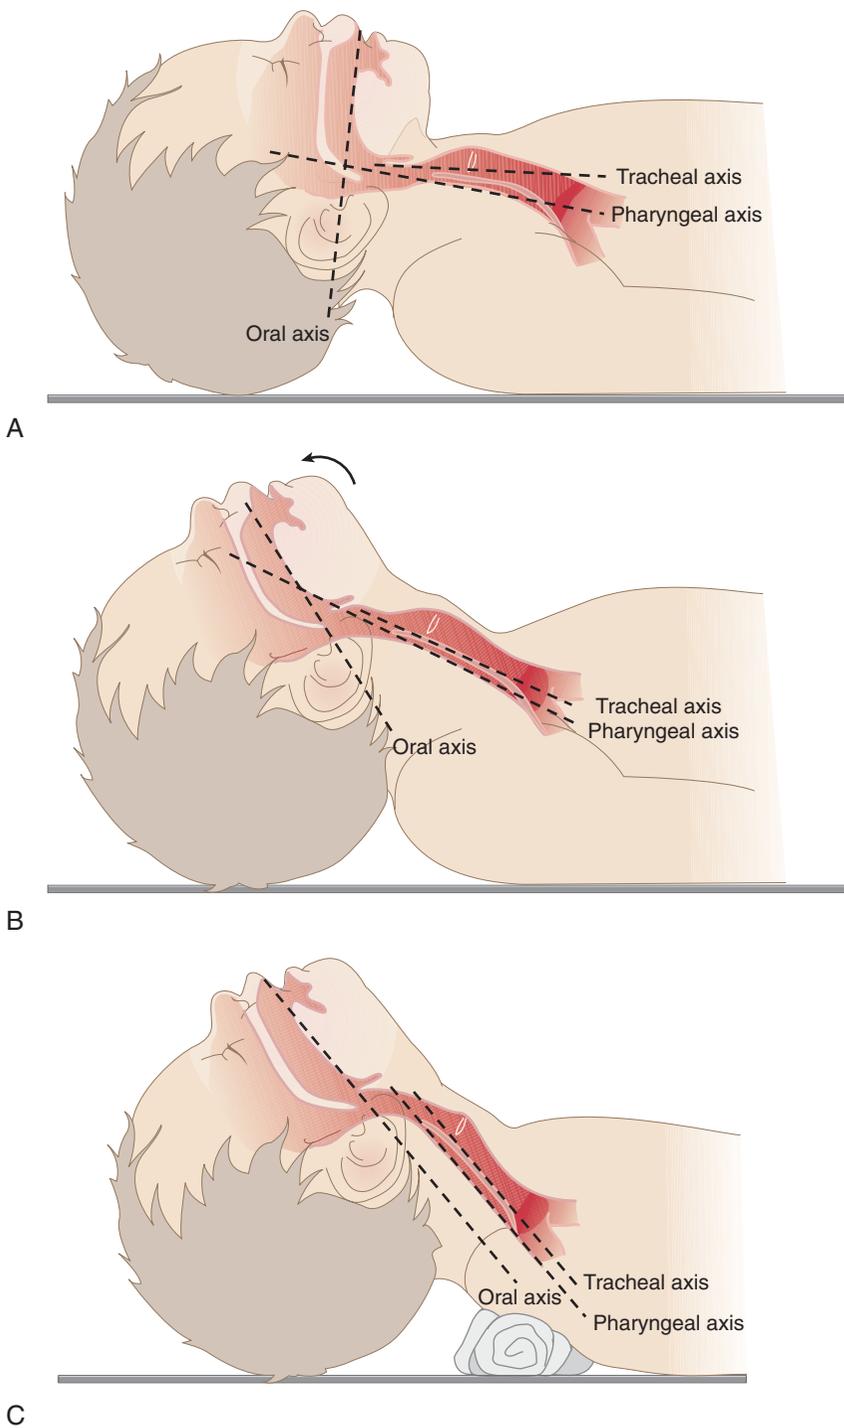

FIGURE 2-1. Alignment of the tracheal, pharyngeal, and oral axes. **A**, Alignment of airway axes with neck flexion. **B**, Alignment of airway axes with head extension and neck flexion—the “sniffing position.” **C**, Alignment of airway axes in supine position. (From Hazinski MF [ed]: PALS Provider Manual. Dallas: American Heart Association, 2002, p 95.)

intubation or nasopharyngeal airway placement. Therefore, emergency nasotracheal intubation is rarely performed in infants and children, and caution must be exercised in placing a nasopharyngeal airway in an infant.

Other airway differences that can result in additional challenges to successful endotracheal intubation include the following: 1) the pediatric *epiglottis is floppy, soft, and omega or U-shaped* as compared to the adult epiglottis, and 2) the *larynx is higher and more cephalad* (the glottis is located at C3-4 in the newborn, at C4-5 by 2 years of age, and at C5-6

for an adult) (Fig. 2-2). Use of a Miller or Wis-Hipple laryngoscope blade is often helpful in these situations. A straight laryngoscope blade is used in young children during laryngoscopy because of the acute epiglottic angle and shallow vallecula (Fig. 2-3). The straight blade is recommended for use until approximately 3 to 5 years of age but may be used in any age child or adolescent. Also, placing a towel under the patient’s shoulders until age 2 years and under the head in older children (with head in the sniffing position) will help align the tracheal, pharyngeal, and oral axes, facilitating

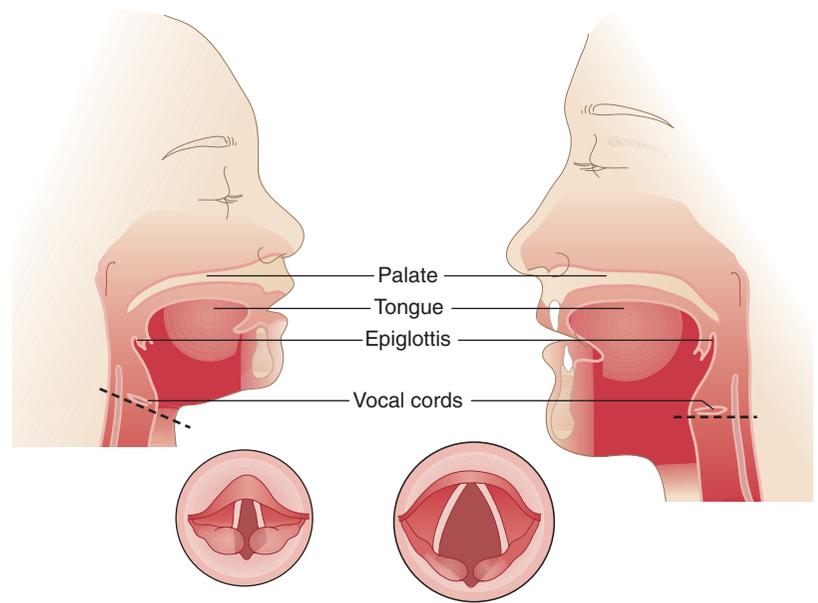

FIGURE 2-2. Comparison of adult and pediatric airway structures. (Modified from Riazz J): The difficult pediatric airway. In Benumof JL [ed]: Airway Management: Principles and Practice. St. Louis: Mosby Year Book, 1996, p 587.)

Table 2-1

Anatomic and Physiologic Airway Differences between Children and Adults That Impact Emergency Airway Management

	Impact	Action
Anatomic Differences		
Large occiput	Flexion of the neck with possible airway obstruction	Reposition head, towel under shoulders
Large tongue	Airway obstruction, especially with loss of muscle tone	Reposition head, sniffing position, towel under shoulders, airway adjuncts
Larger adenoids and tonsils	May obstruct airway, hemorrhage into the airway if injured	Caution with use of nasopharyngeal airway; reposition head
Floppy and long epiglottis	Visualization of vocal cords difficult	Use straight blade to intubate
Larynx cephalad and anterior	Vocal cords more difficult to visualize	Positioning and use of straight blade
Narrowest portion of larynx at the cricoid ring	Use of cuffed tubes may cause pressure damage to cartilage	Use uncuffed tubes until about 8 years of age or, if cuffed tube used, do not overinflate cuff
Narrower tracheal diameter, shorter distance between rings	Needle cricothyrotomy preferred surgical airway in infants and small children	Consider needle cricothyrotomy if cannot bag-mask ventilate, intubate, or use LMA
Shorter tracheal length	Intubation of the right mainstem; dislodgement	Use length-based resuscitation tape for ETT size and depth of ETT placement, or estimate by 3 times the ETT size; reassess frequently
Narrower airway	Greater airway resistance	Suction liberally; remove foreign material; use bronchodilators for lower airway obstruction
Fewer alveoli	Increase respiratory rate to increase minute ventilation	Provide supplemental oxygen; assist ventilation when respiratory rates too slow
Underdeveloped chest and abdominal muscles	Easy fatigability, increased abdominal breathing, increased respiratory rate	Early oxygen with signs/symptoms of respiratory distress, bag-mask ventilation with poor tidal volume or respiratory failure
Physiologic Differences		
Preferential nose breathers	Mucus or blood may obstruct nares, causing respiratory distress	Suction nares liberally
Increased metabolism and reduced FRC*	Shortened period of protection from hypoxia	Oxygenate; bag-mask ventilation and cricoid pressure may be necessary prior to intubation
Immature immune system	At greater risk for respiratory infections	Assess for infections with fever or signs of respiratory illness
Behavioral Differences		
Inability to verbalize distress or pain	Practitioner must rely on signs based on developmental milestones	Recognize signs of respiratory distress and failure

*Functional residual capacity is the lung volume at the end of a normal expiration, when the muscles of respiration are completely relaxed; at FRC, and at FRC only, the tendency of the lungs to collapse is exactly balanced by the tendency of the chest wall to expand (see Johns Hopkins School of Medicine Interactive Respiratory Physiology website at http://oac.med.jhmi.edu/res_phys/Dictionary.html). Abbreviations: ETT, endotracheal tube; LMA, laryngeal mask airway.

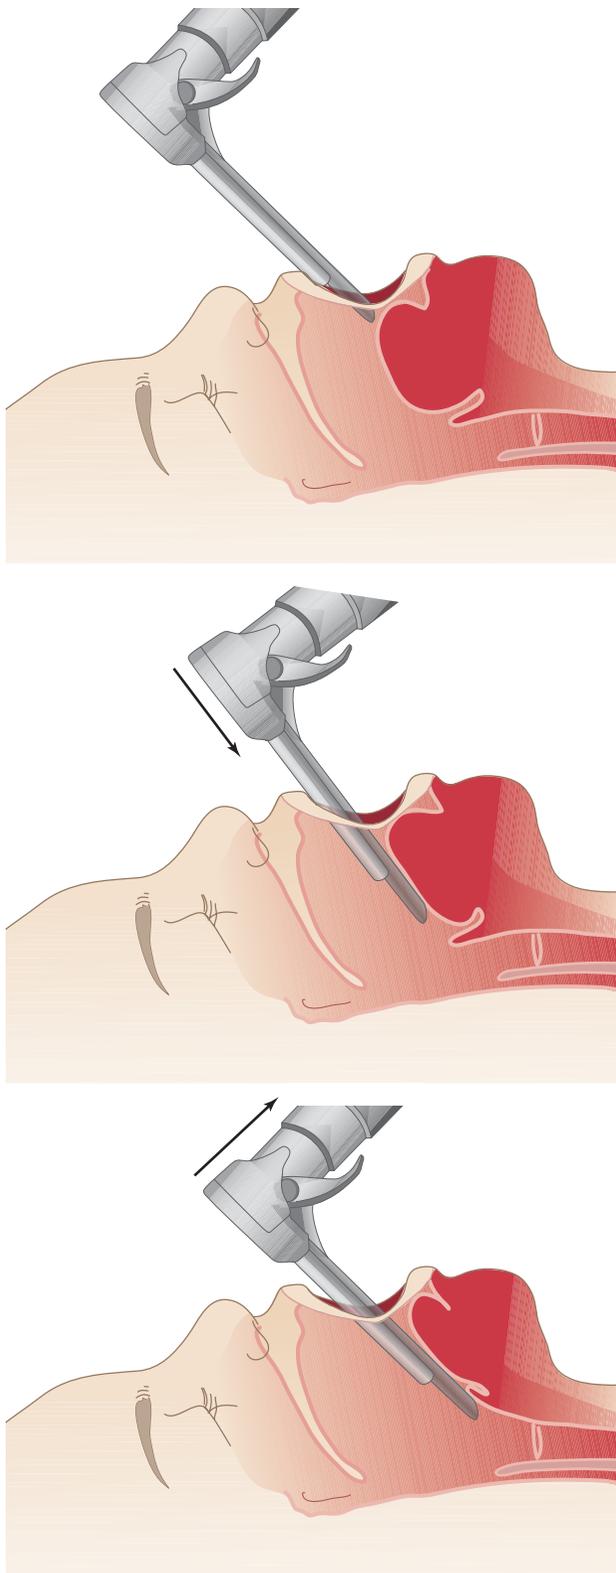

FIGURE 2-3. Proper use of and blade position for laryngoscope. (Modified from Gausche-Hill M, Henderson DP, Goodrich SM, et al [eds]: *Pediatric Airway Management for the Prehospital Professional*. Sudbury, MA: Jones & Bartlett, 2004, p 84.)

visualization of the glottis with intubation (Fig. 2-1). *The pediatric larynx is funnel shaped*, with the narrowest portion at the cricoid ring (below the vocal cords), whereas the adult larynx is cylinder shaped, with the glottis being the narrowest portion. Therefore, uncuffed rather than cuffed endotracheal tubes (ETTs) are often used in children younger than 8 years of age or until a size 6.0-mm ETT is needed. The use of an inflated cuff on the ETT can put pressure on the cricoid ring, which may limit blood supply and lead to pressure necrosis of the cartilage. This complication of cuffed tube use is probably less important than once believed, and now there is expanded use of cuffed ETTs in children who require high pressures to ventilate (e.g., asthma, submersion injury). The *shorter tracheal length* predisposes the child to complications of endotracheal intubation such as intubation of the right main bronchus or ETT dislodgement. Therefore, it is important to know how to estimate depth of placement of the ETT (three times the interior diameter of the ETT or by use of the Broselow tape), to check placement by auscultation or capnography, and to reassess the patient's clinical status frequently. The *narrower trachea and shorter distance between tracheal rings*, as well as the short neck and increased subcutaneous tissue in infants and young children, result in greater difficulty in locating anatomic landmarks to perform surgical cricothyrotomy and in increased likelihood of severe complications such as creation of a false tract, pneumomediastinum, infection, or bleeding. Needle cricothyrotomy is recommended in these infants and children if an immediate surgical airway is needed.

Differences between the adult and pediatric airway are also seen in the lower airways and in the lung. The *large airways of the pediatric patient are narrower* than those of an adult. This leads to greater susceptibility to obstruction by mucus, edema or foreign bodies, which then leads to greater airway resistance. This is explained by looking at Poiseuille's law, which states that resistance to flow (R) is inversely proportional to the fourth power of the radius (r) of the lumen ($R = 1/r^4$). Therefore, if the radius is halved, the resistance increases by 16-fold. This is especially true for children with a tracheostomy because insertion of the tracheostomy tube narrows the airway opening further. Therefore, the tracheostomy lumen can easily become blocked by secretions.⁷ It is important to suction all patients liberally, particularly if they are producing large amounts of secretions. In the lung, *infants and children have less alveoli* than adults. Several studies have shown that neonates have only one third to one half of the number of alveoli in the adult human lung. The number of alveoli reaches adult values by age 8.^{8,9} The fewer number of alveoli results in decreased area for gas exchange. Because they do not have extra alveoli for recruitment, young children increase their respiratory rate to increase minute ventilation and oxygenation, and to eliminate carbon dioxide, making tachypnea a hallmark sign of respiratory distress. This is more pronounced in children with lung disease (e.g., reactive airway disease, bronchopulmonary dysplasia). Early intervention with supplemental oxygen and bronchodilators and support of ventilation with a bag-mask device may prevent progression of the clinical status to respiratory failure.

Physiologic Differences

It has been demonstrated that neonates and infants (1 month to 1 year) may be *preferential nose breathers*,¹⁰ thus making

them susceptible to nasal obstruction (choanal atresia, mucus, blood). Miller and colleagues¹¹ noted that 8% of infants at 30 to 32 weeks' postconceptual age and 78% of term infants were capable of oral breathing in response to nasal occlusion. The ability to tolerate complete nasal occlusion occurs in most infants by 5 months of age. Therefore, if a neonate or infant is having any respiratory difficulty, it is important to suction out both nares to relieve any obstruction.

Children have a *basal oxygen consumption rate two to three times that of adults*.^{12,13} Adults consume 2 to 3 mL of oxygen per kilogram per minute under normal basal conditions. Infants and young children metabolize 4 to 9 mL of oxygen per kilogram per minute.^{12,13} Infants and young children also have a diminished functional residual capacity as compared to adults. This is quite significant because it means that, during apnea, children will maintain “normal” oxygenation for less than half the time of an adult; in other words, children will experience desaturation with shorter times of apnea. Therefore, it is important to supply oxygen to all children showing any signs of respiratory distress. It is also probable that bag-mask ventilation may be required to maintain “normal” oxygenation during periods of apnea prior to intubation.¹⁴

Behavioral/Developmental Issues

Infants and young children are not able to communicate like an older child or an adult. They cannot tell you how they feel or verbalize that they are short of breath or in pain. Therefore, attainment of knowledge of normal behavioral milestones is imperative so that an alteration of these behaviors may be recognized and signs of respiratory failure managed promptly.

Evaluation

Evaluation of a child in respiratory distress must begin with understanding of physiologic states of respiratory compromise and characterization of the anatomic site of that compromise.

Respiratory distress: A condition characterized by increased work of breathing. It is often associated with increase in respiratory rate, but in later stages rates may fall and be less than normal. Signs of airway obstruction such as change in body positioning, nasal flaring, grunting, retractions, stridor, or wheezing may be present. Non-specific signs of anxiety, restlessness, and irritability with any of the previous signs may be seen and can indicate the need for immediate intervention to avoid the progression to respiratory failure.

Respiratory failure: A condition in which the compensatory mechanisms are no longer able to maintain adequate oxygenation or ventilation. Respiratory failure is characterized by poor appearance, including decrease in muscle tone, poor interactiveness, “glassy-eyed” stare and inability to focus, and weak or absent speech or cry. Changes in skin color may occur and vary from pale to cyanotic.

Respiratory arrest: A condition characterized by absence of respiratory effort (prolonged apnea).

Upper airway obstruction: Obstruction of the flow of air/oxygen from the oropharynx to the carina of the trachea.

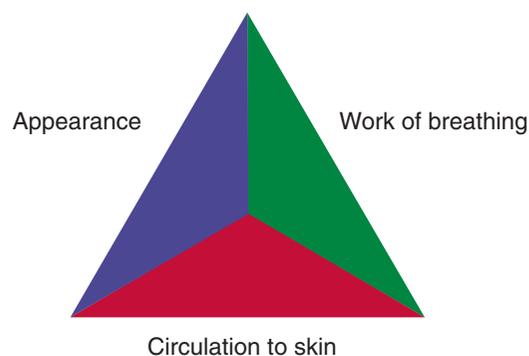

FIGURE 2-4. Pediatric Assessment Triangle. (From Gausche-Hill M, Henderson DP, Goodrich SM, et al [eds]: *Pediatric Airway Management for the Prehospital Professional*. Sudbury, MA: Jones & Bartlett, 2004, p 15.)

Lower airway obstruction: Obstruction of flow of air/oxygen within the bronchi and/or bronchioles from distal to the mainstem bronchi to the aveoli.

Diseases of the lung: Inflammation, infection, or scarring of the aveoli or interstitium of the lung.

Assessment

Any child with respiratory complaints, or any child about whom the parent expresses concerns regarding respiratory status, however mild, requires a rapid and thorough evaluation. The initial overall evaluation should contain two parts: the Pediatric Assessment Triangle (PAT), which is used to obtain an immediate general impression of the seriousness of the illness or injury, and the initial physical assessment. Based on these assessment steps, the examiners, within seconds, will have a general impression of how ill the child is and whether they need to intervene with treatment immediately or if they can continue further evaluation with the focused history and physical examination.^{14,15}

The PAT offers an orderly approach that can be used to assess children of all ages. It allows one to gather visual and auditory clues without touching the child. This “hands-off” assessment can allow the examiner to gather critical information from a distance without upsetting the child with an invasive physical examination.¹⁴ The PAT focuses on general appearance, work of breathing, and the circulatory status of the patient (Fig. 2-4).

General Appearance

How a child appears to an examiner demonstrates in part the adequacy of ventilation, oxygenation, brain perfusion, body homeostasis, and central nervous system function. The components of the assessment of the general appearance are summarized in the TICLS (pronounced “tickles”) mnemonic: **t**one, **i**nteractiveness, **c**onsolability, **l**ook/gaze, and **s**peech/cry.¹⁴

These five characteristics (TICLS) offer a quick way to assess a patient’s general appearance. If the patient’s appearance seems normal, then it is likely that oxygenation, ventilation, and brain perfusion are at least adequate. However, if a child’s general appearance is grossly abnormal, immediate efforts must be made to assess and treat abnormalities in oxygenation, ventilation, and perfusion while completing the initial assessment. There is still the potential for serious illness, so frequent reassessment is mandatory (Table 2-2).

Table 2–2 Findings of the PAT Used to Form a General Impression of the Physiologic State

PAT General Impression	Appearance	Work of Breathing	Circulation to the Skin
Stable	Normal	Normal	Normal
Respiratory Distress	Normal	Abnormal Nasal flaring Grunting Stridor Wheezing Retractions	Normal
Respiratory Failure	Abnormal Poor tone Combative Listless Lethargic	Abnormal Grunting Stridor Retractions Tachypnea Bradypnea Apnea	Normal/abnormal* Pale Cyanotic
Shock	Normal/abnormal* Poor tone Listless Lethargic	Normal	Abnormal Pale Mottled
CNS/Metabolic Disorder	Abnormal Poor tone, interactivity Inconsolability Abnormal speech or cry	Normal	Normal
Cardiopulmonary Failure	Abnormal Unresponsive	Abnormal Apneic	Abnormal Cyanotic

*In early stages will be normal and later progresses to abnormal.

Work of Breathing

Work of breathing reflects the child's attempt to compensate for abnormalities in oxygenation and ventilation. Assessing work of breathing requires looking for signs of increased work of breathing and listening for abnormal airway sounds.

VISUAL SIGNS

Abnormal positioning, respiratory rate, retractions, head bobbing and nasal flaring, are all visual signs that indicate increased work of breathing in an effort to improve oxygenation and ventilation. A few postures indicate compensatory efforts to increase airflow. A child who is in the "sniffing" position (child sits leaning forward) is trying to open up his or her airway and increase airflow. It is usually a result of severe upper airway obstruction (retropharyngeal abscess, foreign body, epiglottitis). A child who refuses to lie down or who leans forward on outstretched arms (tripod position) is attempting to use accessory muscles to improve breathing (severe bronchoconstriction; asthma, bronchiolitis).

Respiratory rate changes with sleep and wake states, and normal rates vary with age. The goal of the PAT assessment of respiratory rate is to determine if the rate is slow, fast, or absent.

Retractions are a common physical sign of increased work of breathing. They represent the use of accessory muscles to help breathing. **Retractions can be easily missed unless they are looked for with the child undressed.** They can occur in the supraclavicular area, intercostal area, and substernal area. When a child is approaching respiratory failure, retractions can decrease. This is an ominous sign and occurs when a child has exhausted compensatory mechanisms.

Head bobbing is the use of accessory neck muscles in infants to increase inspiratory pressure and improve breathing. The child extends the neck while inhaling, then the head falls

forward during exhalation. This visual sign suggests moderate to severe hypoxia.

Nasal flaring is the exaggerated opening of the nostrils during labored breathing and indicates another form of accessory muscle use that reflects significant increase in the work of breathing.

AUDIBLE AIRWAY SOUNDS

Abnormal airway sounds provide information about breathing effort and anatomic location of airway obstruction. Normally, the movement of air in and out of the airway cannot be heard without a stethoscope. Airway sounds that can be heard without the use of a stethoscope are abnormal and indicate obstruction to the passage of air through the airway structures. The type of abnormal airway sound is related to the location of the disease process. Table 2–3 lists abnormal airway sounds and their location, causes, and possible interventions.¹⁵

Circulatory Status

The third part of the PAT is a rapid evaluation of the circulatory system to determine the adequacy of cardiac output and perfusion of vital organs. The most important part of this assessment is to observe the skin. When there is inadequate blood volume or when the heart is unable to maintain output to the body, blood supply to vital organs is conserved by shunting blood away from less essential areas of the body such as the skin and mucous membranes, resulting in mottling, pallor, and/or cyanosis. Patients in respiratory failure may also show changes in skin color. Pallor is seen in early stages and cyanosis in late stages.

Using the PAT gives the clinician a rapid overall impression of whether the child's illness or injury is severe and life threatening before a more thorough hands-on evaluation is done.

Table 2–3 Abnormal Airway Sounds: Possible Causes and Immediate Management

Airway Sound	Description	Location	Causes	Immediate Management
Gurgling	Heard without a stethoscope; gurgling or bubbling	Posterior pharynx Upper airway	Inability to clear secretions or excessive fluid in upper airway	Provide oxygen; suctioning
Snoring	Heard without a stethoscope; low-pitched nasal sound	Upper airway	Oropharynx partially obstructed by tongue or soft tissues (adenoids, tonsils)	Head positioning; airway adjuncts
Muffled Speech	Heard without a stethoscope; “hot potato” voice	Upper airway	Peritonsillar abscess; epiglottitis	Head positioning; support ventilation as needed
Hoarse Speech	Heard without a stethoscope; raspy voice with changes in volume and pitch	Upper airway	Glottic inflammation from URI; croup, nodules, GE reflux	No immediate treatment needed. Specific treatment dependent on cause
Stridor	High-pitched sound usually heard during inspiration; may also be heard on expiration	Upper airway	Air passing through narrowed laryngeal or subglottic areas; foreign body, obstruction, croup, epiglottitis, allergic reaction	Allow patient to stay in position of comfort; provide oxygen. Support ventilation if in respiratory failure or severe distress. Specific treatment dependent on cause.
Rhonchi	Low-pitched musical, rough, rattling sounds	Upper airway; mainstem bronchus	Secretions, fluids, or narrowing in the large airways	Provide oxygen; suctioning. Observe for adequate oxygenation and ventilation. Bronchodilator
Grunting	Brief, vocalization on expiration against a partially closed glottis. Low-pitched sound.	Upper or lower airway	Produces positive end-expiratory pressure (PEEP) to keep alveoli open; pneumonia, pulmonary contusion, pulmonary edema	Usually indicative of moderate to severe hypoxia. Provide oxygen. Support ventilation as needed.
Wheezing	Whistling, musical sound usually present on expiration but may also be present on inspiration	Lower airway; bronchioles; alveoli	Partially obstructed lower airway; edema, secretions, spasm. Asthma most common cause, infection, reactive airway disease, pneumonia, allergic reaction	Provide oxygen. Bronchodilator with MDI or by nebulization. Steroids. Support of ventilation as needed.
Rales (Crackles)	Fine, high-pitched crackling sounds heard mid to late inspiration	Alveoli	Fluid or mucus in air sacs. Pneumonia most common cause; also pneumonitis.	Provide oxygen. Observe for adequate oxygenation and ventilation
Absence of Breath Sounds	No sound on auscultation	Severe partial or complete airway obstruction; severe lung disease	Obstructed airway due to foreign body or airway disease	Provide oxygen. Foreign body removal maneuvers. Trial of bronchodilator. Support of ventilation as needed.

Abbreviations: GE, gastroesophageal; MDI, metered-dose inhaler; URI, upper respiratory infection.

A child, who is alert and anxious, is breathing rapidly, and has retractions and normal skin color is a child in respiratory distress. If this child’s appearance becomes abnormal (i.e., listless, lethargic), then the child’s condition has deteriorated to respiratory failure. The PAT helps to determine how rapidly intervention is needed and what treatments may be needed immediately. For example, a child with respiratory failure or cardiopulmonary failure will need immediate support of ventilation and oxygenation, whereas a child who has respiratory distress initially may require only supplemental oxygen.

The ABCDEs

The second part of the initial assessment includes a physical evaluation of the ABCDEs: airway, breathing, circulation, disability, and exposure.^{14,15} After the PAT and the physical examination, it should be evident whether the patient is

stable or unstable. As one proceeds through the ABCDE evaluation, it is often necessary to start interventions prior to completing the evaluation. This can be done by delegating the task while the examination is being completed.

A—Airway

The PAT may identify the presence and possibly the location of airway obstruction but not necessarily the degree of obstruction. It is during this “hands-on” part of the initial evaluation that one assesses the severity of the illness. If the airway is not open, one must immediately perform maneuvers to attempt to open the airway.

B—Breathing

During the PAT, the child’s rate of breathing is assessed as either slow, fast, or absent. During the breathing examina-

tion, the number of breaths per minute is determined and the child's chest is auscultated with a stethoscope. When determining an infant's respiratory rate, it is important to actually count the number of respirations for at least 30 to 60 seconds because infants often have periodic breathing. *Increased respiratory rate* can indicate a number of conditions, including respiratory illness, and is a sign of respiratory distress. However, in and of itself respiratory rate can be misleading. Pain, cold, exercise, anxiety, and fever can lead to an increase in respiratory rate in the absence of hypoxia. For example, for every degree in temperature elevation, respiratory rate can increase up to 5 respirations per minute. Respiratory rate can also be increased in metabolic acidosis as a buffering mechanism and might not represent a primary respiratory abnormality at all. It is also important to realize that a child who has been showing evidence of increased work of breathing and who now has a normal respiratory rate may be becoming fatigued. Because respiratory rates may vary with external or internal stimuli, recording several rates may be more useful. The trend of the results is often more accurate than the initial documented rate. A normal respiratory rate must be placed in context with other clinical signs to determine if breathing is adequate. Finally, the normal respiratory rate slows as the patient ages (Table 2–4). Increases in vital capacity allow for increased tidal volume with growth and therefore slower rates to maintain minute ventilation. Unfortunately, most references have defined normal respiratory rates for well children without anxiety, pain, respiratory complaints (without pneumonia), or fever. Moreover, the cutoffs for defining tachypnea are much higher than most published standards.¹⁶ In fact, the cutoffs for defining an abnormal respiratory rate indicative of pneumonia are much higher. The World Health Organization defines tachypnea as ≥ 60 breaths per minute (bpm) for neonates (birth to 30 days), ≥ 50 bpm for infants 1 month to 1 year old, and ≥ 40 bpm for children 1 to 5 years old.¹⁷ Others have evaluated febrile children and found that a respiratory rate ≥ 59 at birth to 6 months old, ≥ 52 at 6 to 12 months old, and ≥ 49 at 1 to 2 years old was the optimum cutoff for predicting pneumonia in febrile infants and children.¹⁸

Minute ventilation is equal to tidal volume times respiratory rate ($MV = TV \times RR$). Generally, young infants respond by increasing respiratory rate but have a limited ability to increase tidal volume. As respiratory rates increase in

response to hypoxia, there is not enough time during a respiratory cycle to achieve adequate tidal volume or to allow oxygen to move from the alveoli into capillaries, and respiratory failure ensues.

During *auscultation*, it is important to note the absence of breath sounds or any abnormal lung sounds during inhalation or exhalation. It is also important to evaluate air movement and effectiveness of the work of breathing (see Table 2–3). Absence of breath sounds may indicate severe airway obstruction (upper or lower), consolidation, effusion, or pneumo- or hemothorax.

C—Circulation

A general impression of the circulatory status of the patient is made from looking at the skin during the PAT. A more in-depth “hands-on” assessment is then made by measuring the rate and quality of the child's pulse, skin temperature, capillary refill time, and blood pressure. The environmental temperature must be considered when evaluating skin temperature, capillary refill time, and skin color in children. Young children and infants are very susceptible to changes in temperature. It has been documented that capillary refill time is prolonged in cool temperatures, even in children with normal circulatory status.¹⁹

D—Disability

Assessment of disability is the evaluation of the child's neurologic status. This evaluation includes level of consciousness, motor movements, and typically pupillary status. Hypoxia, hypercarbia, and poor perfusion along with acute central nervous system injury can result in altered levels of consciousness. Assessments of level of consciousness in children are age dependent and may include the use of the AVPU (Alert, responsive to Voice, responsive to Pain, Unresponsive) scale or the modified Glasgow Coma Scale (GCS).^{14,15,20} Children who are only responsive to pain or who are unresponsive on the AVPU scale, and certainly children with a GCS score less than 9, if as a result of trauma, should undergo rapid sequence intubation (RSI) to control their airway, and provide neurologic resuscitation as needed to avert herniation. Children with a medical condition resulting in severe alteration of consciousness should be considered for RSI if their condition is not quickly reversible (see Chapter 3, Rapid Sequence Intubation).

E—Exposure

The PAT requires that the child's clothing be removed enough to evaluate their face, chest, and skin. When completing the initial assessment, during the ABCDE evaluation, the clothing needs to be removed enough so the child can be fully evaluated for other physiologic and anatomic abnormalities.

Ancillary Studies

Assessment is ongoing and, depending on patient stability, includes a secondary assessment, focused history, and complete physical examination. For children who require stabilization or resuscitation, initial assessment and critical interventions take place simultaneously. Tools such as the Broselow-Luten tape have been developed to provide a rapid and accurate method of estimating weight, necessary drug dosages, and sizes of airway equipment.^{21,22}

Table 2–4 Normal Respiratory Rates in Children*

Age	Respiratory Rate (per minute)
0–6 month	30–55
6–12 months	24–50
1–3 years	16–46
4–6 years	14–36
7–9 years	12–40
10–14 years	15–32
14–18 years	14–32

Adapted from Hooker EA, Danzl DF, Brueggmeyer M, Harper E: Respiratory rates in pediatric emergency patients. *J Emerg Med* 10:407–410, 1992.

*Cutoffs for febrile infants and children may be slightly higher.

Pulse Oximetry

Pulse oximetry can be used to determine the child's oxygen saturation level (SaO₂) and estimates the adequacy of the child's oxygenation. It does not reflect ventilation. Its use is indicated in any patient with cardiopulmonary arrest; in unstable or critically ill patients; in patients with cardiopulmonary disease; and in patients with or without the potential for hypoxia, apnea, respiratory distress/failure, or shock. Continuous pulse oximetry is recommended in the care of critically ill or injured patients, as well as those patients for whom the potential for respiratory failure exists, as it has been shown that health care providers cannot detect hypoxemia by clinical examination alone.²³ A pulse oximetry reading above 94% indicates oxygenation is probably adequate; however, a child in respiratory distress or early respiratory failure might be able to maintain oxygenation by increasing work of breathing and respiratory rate. Interpretation of pulse oximetry readings should be combined with the assessment of respiratory rate, work of breathing, and chest auscultation to obtain an accurate idea of respiratory status. Chapter 5 (Monitoring in Critically Ill Children) discusses the utility of and pitfalls associated with pulse oximetry in more detail.

Carbon Dioxide (CO₂) Detection/Monitoring

End-tidal CO₂ detectors are often used to confirm placement of an ETT in the trachea. If the ETT is placed correctly, as the patient is ventilated the CO₂ detector should turn from its baseline purple color to yellow with expiration, and return to purple when 100% oxygen passes across the filter paper. These detectors have been shown to be reliable in non-cardiac arrest states and can be used in infants weighing as little as 2 kg.²⁴ A pediatric-size detector should be used for infants and children who weigh 2 to 15 kg. For children who weigh more than 15 kg, an adult-size detector should be used. If an adult-size detector is used in an infant, it can be used to confirm tracheal placement of the ETT but must not be left in-line as the device has a large amount of dead space (38 mL), which could lead to hypoventilation in the small infant²⁵ (see Chapter 5, Monitoring in Critically Ill Children).

Capnography

Capnography or continuous end-tidal CO₂ monitoring is a non-invasive method for continuously assessing the level of CO₂. Carbon dioxide is produced during cellular metabolism, transported to the heart, and exhaled via the lung. Continuous monitoring of end-tidal CO₂ can provide information on adequacy of ventilation, metabolism, and circulation. Capnography has most commonly been used to verify ETT placement and monitor ventilation in the emergency department, operating room, and intensive care unit and during transport of critically ill patients.²⁶⁻²⁹ During cardiopulmonary resuscitation (CPR), continuous end-tidal CO₂ concentrations vary directly with cardiac output produced by precordial compressions.³⁰ During effective CPR, end-tidal CO₂ correlates with the efficacy of cardiac compressions and identifies the return of spontaneous circulation and likelihood of survival.^{31,32} Continuous CO₂ monitoring also may assist in detecting hypercapnic episodes and episodes of ETT dislodgement in mechanically ventilated patients.³³ Finally, end-tidal CO₂ measurement may provide an earlier indica-

tion of respiratory failure versus that provided by pulse oximetry or measure of respiratory rate alone during procedural sedation.³⁴

Arterial Blood Gas Measurement

As the use of pulse oximetry monitoring has become standard in most emergency departments, there is much less need for arterial blood gas measurement. Arterial blood gases are rarely needed in the evaluation of children for respiratory failure but may assist in assessment of shock states or presence of acidosis (metabolic or respiratory).

Radiography

In the emergency department, chest radiographs are often obtained on children with asthma, acute lower respiratory infections, foreign bodies, and hypoxia and to check ETT placement. Chest radiographs are of overall limited value and should be ordered and interpreted in the context of a complete medical history and physical examination. For example, experts have found that there is no evidence that chest radiography improves the outcome of ambulatory children with acute lower respiratory infection.^{35,36} In children with foreign bodies, the sensitivity and specificity of the chest radiograph in identifying the presence of an airway foreign body are 73% and 45%, respectively.³⁷ Therefore, one should not rely on chest radiography for making a diagnosis if the clinical suspicion is high.

Chest radiographs are often ordered in children with wheezing. Most children with wheezing have normal chest radiographs, and those with positive findings on chest radiograph have either increased respiratory rate, increased pulse, localized rales, or decreased breath sounds.³⁸ Dalton found that only 14% of asthmatics have abnormal radiography findings that may change management and concluded that chest radiographs should be taken in children with asthma only if the child does not respond to initial therapy.³⁹ Lastly, routine chest radiographs in infants with bronchiolitis are usually unnecessary; fever ($\geq 38^\circ\text{C}$) and oxygen saturation less than 94% were findings most often associated with infiltrates on radiographs in this population.⁴⁰

Chest radiography has also been utilized to evaluate children with high fever. Bachur et al. demonstrated that pneumonia was diagnosed by chest radiography in 38 of 146 children (26%) with fever ($>39^\circ\text{C}$) and an elevated peripheral white blood cell (WBC) count ($>20,000/\mu\text{L}$). Of note is that these children with occult pneumonia did not have hypoxia or tachypnea.⁴¹

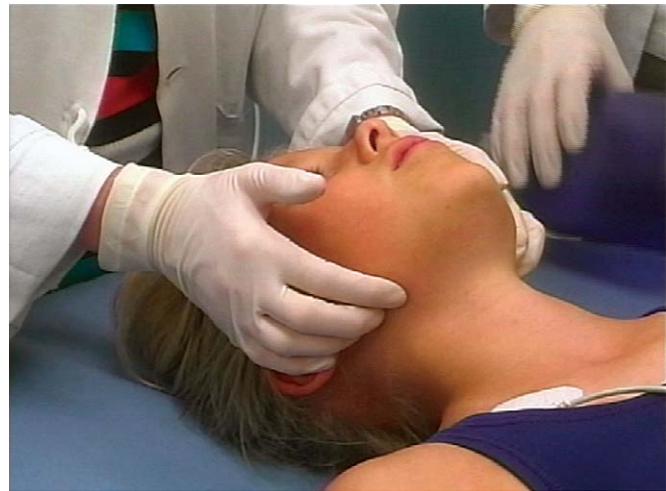

Routine chest radiographs for asthma or acute respiratory infections without other signs (e.g., tachypnea, tachycardia, hypoxia, fever, elevated WBC) are unnecessary unless a patient is failing management, has chronic symptoms, has localized symptoms, or is at high risk (e.g., very young, immunocompromised).

Etiologies of Respiratory Distress or Failure

Many different diseases and conditions can lead to respiratory distress and/or failure. These processes often involve the respiratory system, but many systemic and neurologic processes can also lead to respiratory distress and/or failure. These etiologies are listed in Table 2-5. Many of these processes are discussed in detail in other chapters throughout this book.

Table 2–5 Etiologies of Respiratory Distress and Failure in Infants and Children

Upper Airway	Lower Airway
Laryngotracheobronchitis (croup)	Asthma
Epiglottitis	Reactive airway disease
Foreign body aspiration	Bronchiolitis
Adenotonsillar hypertrophy	Tracheobronchomalacia
Peritonsillar, parapharyngeal, or retropharyngeal abscess	Foreign body aspiration
Subglottic stenosis, web, hemangiomas	α_1 -Antitrypsin deficiency
Tracheomalacia	Hydrocarbon aspiration
Laryngoedema	
Congenital anomalies	
Anaphylaxis	
Disease of the Lung	Systemic
Bronchopulmonary dysplasia	<u>Central Nervous System</u>
Cystic fibrosis	Status epilepticus
Submersion injury	Encephalopathy
Congestive heart failure	Meningoencephalitis
Pneumonia	Brain abscess, hematoma, tumor
Pneumonitis	Brain stem injury
	Drug intoxication
	Arnold-Chiari malformation
	Medication induced
Chest Wall Conditions	<u>Spinal/Anterior Horn Cell</u>
Diaphragmatic hernia	Poliomyelitis
Pneumothorax/hemothorax/chylothorax	Guillain-Barré disease
Severe kyphoscoliosis	Wernig-Hoffmann disease
Severe pectus excavatum	
Other Diseases	<u>Neuromuscular junction</u>
Cardiac disease	Myasthenia gravis
Sepsis	Botulism

**FIGURE 2–5.** Jaw-thrust maneuver to open the airway.

The initial diagnostic evaluation is used to determine if the patient is stable or unstable and to identify the category of respiratory disorder. If the patient is stable, then the physician can continue with the secondary assessment, complete history, and physical examination. Interventions may proceed based on physiologic dysfunction and category of respiratory dysfunction. It is important to reassess the patient frequently so that, if the patient becomes unstable, immediate management occurs. If the patient is unstable (respiratory distress, respiratory failure, respiratory arrest, cardiopulmonary failure or cardiopulmonary arrest), then the physician should begin immediate interventions to support oxygenation and perfusion.

Management

Management proceeds based on assessment of need and in a logical fashion from the least to most invasive and complex interventions. These interventions may include all or some of the following:

1. Positioning of the head in the midline position with a towel under the shoulders or head.

2. Opening the airway by performing a head tilt–chin lift in the medical patient or a jaw-thrust maneuver in the trauma patient (Fig. 2–5).
3. Suctioning the airway if the patient has oral or nasal secretions or blood.
4. Providing oxygen supplementation, either by low-flow systems such as a nasal cannula, or by simple face masks, which provide a low fraction of inspired oxygen (F_iO_2) (but greater than ambient F_iO_2), or systems that provide inspired oxygen levels of 95% or greater. These systems include partial non-rebreather masks for infants or full non-rebreather masks for older children.
5. Placing airway adjuncts such as a nasopharyngeal airway (can be used in the semiconscious patient) or an oropharyngeal airway (only used in the unconscious patient without a gag reflex).
6. Performing bag-mask ventilation to support ventilation and oxygenation for patients requiring assisted ventilation or neurologic resuscitation.
7. Considering advanced airway techniques when the management techniques listed previously do not improve the patient's clinical status: RSI, and laryngoscopy and foreign body removal with Magill forceps.
8. Placing a laryngeal mask airway or performing cricothyrotomy (needle or surgical) for patients who cannot be ventilated with bag-mask ventilation or whose airway cannot be secured by endotracheal intubation (see Chapter 3, Rapid Sequence Intubation; and Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts).

Initial intervention will include *positioning the head, opening the airway, and providing supplemental oxygen*. Suctioning may be added for signs of increased secretions or blood in the airway. If positioning and suctioning do not open the airway, one should consider upper airway obstruction from a foreign body and perform age-specific obstructed airway techniques (back blows and chest thrusts for infants or abdominal thrusts for children > 1 year of age). Consider *direct laryngoscopy with Magill forceps* for possible foreign body removal. If airway obstruction continues, a surgical airway can be attempted with *needle or surgical cricothyrotomy*.

FIGURE 2-6. Placement of an oropharyngeal airway.

For patients *without* foreign body obstruction but who are unable to maintain a patent airway with positioning, the physician should place an airway adjunct such as a *nasopharyngeal airway* or an *oropharyngeal airway*. Nasopharyngeal airways are used in semiconscious patients and should be avoided in young infants, patients with bleeding disorders, or those with craniofacial injury. *Oropharyngeal airways* are used in unconscious patients without a gag reflex to keep the airway open, usually during bag-mask ventilation. Figure 2-6 demonstrates placement of the oropharyngeal airway in a pediatric patient.

Bag-mask ventilation is indicated for the initial support of ventilation and oxygenation when compensatory mechanisms fail and the patient is in respiratory failure. If positioning, suctioning, adding airway adjuncts, or providing supplemental oxygen are not successful in improving a patient's condition and assisted ventilation is needed, then bag-mask ventilation should begin without delay. The first step is to ensure the correct size of face mask is used. The correct size mask will measure from the bridge of the nose to the cleft of the chin. Once the mask is attached to the elbow adapter on the bag, a "C" is formed with the physician's thumb and index finger. The mask is placed on the patient's face, the physician's thumb is wrapped around the mask at the end of the mask that lies on the bridge of the nose, and the index finger is placed around the lower part of the mask at the chin. The third, fourth, and fifth digits are placed along the angle of the patient's jaw, forming an "E," and the chin is pulled into the mask to ensure a seal. The entire hand position is called the "EC clamp" (Fig. 2-7).⁴² It is important *not* to place the "E" fingers in the soft tissue under the chin as pressure in this area can compress the airway or cause the tongue to fall back against the posterior pharynx, leading to airway obstruction. The Sellick maneuver (cricoid pressure) may be used if significant pressure is needed to ventilate, but it is possible to place too much pressure on the cricoid membrane and collapse the airway, leading to airway obstruction. To begin ventilation, the physician squeezes the bag for 1 to 2 seconds and with only enough force to cause chest rise, then releases the pressure on the bag. It is important to realize that the volume of air needed to provide adequate chest rise is

FIGURE 2-7. Bag-mask ventilation on a child; note hand position (EC clamp).

between 8 and 10 mL/kg. For a neonate only about 30 mL (2 tablespoons) of air is needed to cause adequate chest rise; a 1-year-old requires only about 105 mL (7 tablespoons). Excessive volume instilled with the bag-mask device can lead to gastric insufflation and vomiting.⁴³

Gausche and colleagues showed that using the "squeeze, release, release" technique for bag-mask ventilation, versus using endotracheal intubation to ventilate infants and children in the prehospital setting, can lead to improved outcomes for children in respiratory failure.⁴⁴ The person providing bag-mask ventilation should allow for slightly longer inspiratory times and then the patient is allowed time to passively exhale. The respiratory rate should be between 30 and 40 breaths/min in a neonate, 20 and 30 breaths/min in an infant, and no more than 20 breaths/min in a child. Modifications of this technique can be considered in patients when it is difficult to maintain a seal with one hand. In these cases, a two-person technique, with one person holding the mask with the EC clamp using both hands and the other squeezing the bag-mask device, may be used. In a case of upper airway obstruction, it has been shown that bag-mask ventilation with the patient in the prone position may be useful.⁴⁵

Endotracheal intubation and RSI are utilized in patients requiring long-term support of oxygenation and ventilation; in patients requiring neurologic resuscitation (GCS score < 9); in patients requiring airway protection, such as those with burns, anaphylaxis, or overdose; and in patients in whom bag-mask ventilation fails to support oxygenation and ventilation. (Endotracheal intubation and RSI are discussed in more detail in Chapter 3 Rapid Sequence Intubation; and Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts.)

The Difficult Airway

When dealing with children in an emergency department setting, it is imperative that one be able to anticipate a potentially difficult airway and have a backup plan if bag-mask ventilation and endotracheal intubation are unsuccessful. It is also necessary to have backup management plans when one comes across an unanticipated difficult airway.

Unlike the adult difficult airway, evaluation and management strategies for the difficult airway in children are not well described. This section discusses the evaluation, history, and physical examination of a patient prior to airway management to look for features that may indicate a difficult airway.

History

The American Society of Anesthesiologists Task Force on Management of the Difficult Airway stated that, although there is insufficient published evidence to evaluate the effect of a bedside medical history on predicting the presence of a difficult airway, there is suggestive evidence that some features of a patient's medical history (congenital syndromes, acquired or traumatic disease states, or history of prior difficult intubation) may be related to the likelihood of encountering a difficult airway.⁴⁶ Therefore, it is recommended that an airway history, whenever feasible, be conducted. Table 2–6 lists features that may be evident from the history that can indicate the possibility of encountering a difficult airway. Importantly, there are multiple congenital disorders and syndromes associated with anatomic and physiologic disorders that make airway management difficult (e.g., micrognathia, macroglossia, cervical spine disorders, hypotonia, midface disorders).⁴⁷

Physical Examination

According to the American Society of Anesthesiologists Task Force, an airway physical examination should be conducted, whenever feasible, prior to the initiation of airway manage-

ment in all patients. The intent of this examination is to detect physical characteristics that may indicate the presence of a difficult airway.⁴⁶ Physical findings that may predict airway difficulty are listed in Table 2–7, and some are discussed below.^{47–52}

The oropharyngeal examination is the first step to examining the airway. If possible, the patient's oral cavity should be examined with his or her mouth open and tongue maximally protruded. If the patient is uncooperative or too young to cooperate, this can be done with a tongue blade with the patient lying down. The degree of mouth opening and the size of the tongue in relation to the oral cavity are assessed. Mallampati et al.⁵³ classified airways on the basis of the degree of visualization of the faucial pillars, soft palate, and uvula. This classification has been used extensively in adults to predict the degree of difficulty with endotracheal intubation. Whether it can successfully predict difficulty in children is not known. Other findings in the oropharyngeal examination that may suggest difficult laryngoscopy and intubation are outlined in Table 2–7.

After the oropharyngeal examination, the ability to extend the patient's neck should be assessed. Neck extension is often necessary during laryngoscopy to be able to visualize the vocal cords. Obviously, neck extension should not be evaluated in a trauma patient when cervical spine trauma is suspected. However, the inability to extend the neck as a result of trauma or congenital syndromes, such as trisomy 21 or Goldenhar and Klippel-Feil syndromes, or acquired conditions, such as juvenile rheumatoid arthritis or prior cervical spine fixation, is a predictor of the possibility of difficult laryngoscopy and intubation.^{49,51} A short mandible, micrognathia, or a small oral cavity make visualization of the airway challenging due to the anterior location of the airway

Table 2–6 Historical Features That May Indicate a Difficult Airway

Feature	Anatomic Correlate
Prior history of difficult intubation	Narrow epiglottic angle; anterior vocal cords
Snoring/noisy breathing/obstructive sleep apnea	Enlarged adenoidal/tonsillar tissue
Difficulty feeding secondary to cough or cyanosis	Possibly reduced oxygen reserve
Difficulty breathing with URI	Enlarged adenoidal/tonsillar tissue
Recurrent croup	Narrow glottic area, hemangioma
Juvenile rheumatoid arthritis	Limited mouth opening
TMJ syndrome	Limited mouth opening
Acquired conditions	Normal anatomy is altered, usually by swelling, leading to upper airway obstruction
Croup	
Epiglottitis	
Retropharyngeal abscess	
Ludwig's angina	
Thermal injury	
Caustic ingestion	
Facial or neck trauma	Variety of reasons: obstruction, loss of landmarks, blood in airway, cervical spine stabilization
Foreign body	Upper airway obstruction

Abbreviations: TMJ, temporomandibular; URI, upper respiratory infection.

Table 2–7 Findings on Physical Examination That May Predict a Difficult Airway

Trauma

Facial and/or neck trauma
Blood in airway
Facial or oral burns

Oropharyngeal

Mallampati class III and class IV
Macroglossia
Small mouth
Prominent central incisors
Limited mouth opening (e.g., limited TMJ mobility, trismus from deep space infections, maxillofacial trauma)
Laryngeal edema (e.g., infection, inhalation injury, caustic ingestion)
Enlarged tonsils
High-arched palate
Foreign body
Secretions in upper airway
Swelling of intraoral structures (e.g., anaphylaxis, congenital syndromes)

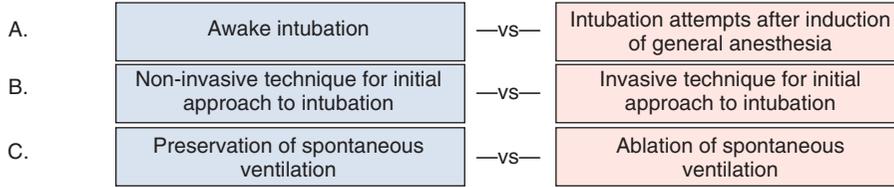

Other

Short neck
Limited neck extension or flexion
Micrognathia (short mandible)
Obesity

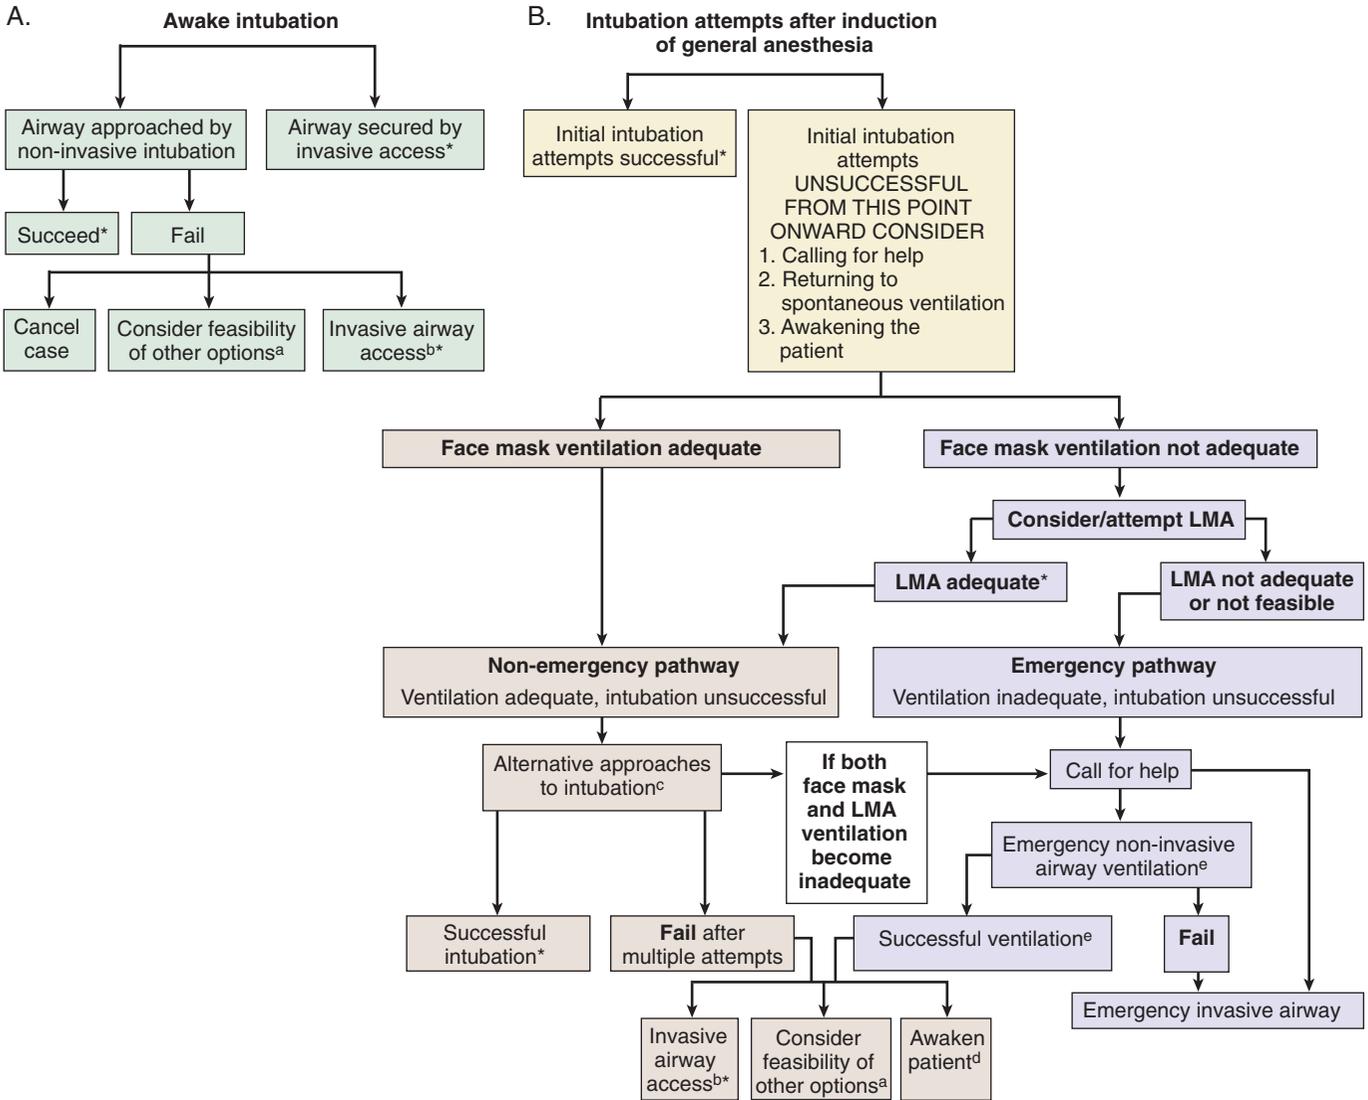

Abbreviation: TMJ, temporomandibular.

Difficult Airway Algorithm

1. Assess the likelihood and clinical impact of basic management problems.
 - A. Difficult ventilation
 - B. Difficult intubation
 - C. Difficulty with patient cooperation or consent
 - D. Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies.

^a Other options include (but are not limited to): surgery utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

^b Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

^c Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

^d Consider re-preparation of the patient for awake intubation or canceling surgery.

^e Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal combitube ventilation, or transtracheal jet ventilation.

FIGURE 2–8. Guideline for management of the difficult airway. (Adapted from American Society of Anesthesiologists Task Force on Management of the Difficult Airway: Practice guidelines for management of the difficult airway. an updated report. *Anesthesiology* 95:1269–1277, 2003.)

Table 2–8 Suggested Equipment for the Difficult Airway Cart^{46,49,50}

Exhaled CO₂ detector (adult and pediatric)
 Face masks (neonate to adult)
 Laryngoscope blades of all sizes and styles
 Magill forceps
 Local anesthetics
 All sizes of naso- and oropharyngeal airways
 Suction equipment and catheters
 Self-inflating resuscitation bags
 Endotracheal tubes of all sizes, cuffed and uncuffed
 Endotracheal tube guides:
 Semirigid intubation stylets
 Light wand
 Forceps designed to manipulate the distal portion of the tracheal tube
 Gum elastic bougie
 Laryngeal mask airways, assorted sizes
 Flexible fiberoptic intubation equipment
 Emergency nonsurgical ventilation (at least one):
 Transtracheal jet ventilation
 Hollow jet ventilation stylet
 Tracheoesophageal Combitube
 Emergency surgical airway access:
 Cricothyrotomy equipment
 Commercially available cricothyrotomy kit for children

The items listed represent only suggestions as some of these items will be available in standard intubation/airway trays. The contents of the difficult airway cart should be customized to meet the needs, preferences, and skills of the emergency department physicians.⁴⁶

From Behringer EC: Approaches to managing the upper pathway. *Anesthesiol Clin North America* 20:813–832, 2002.

and the small area in which to manipulate the structures with laryngoscopy. Micrognathia is a prominent feature in Treacher-Collins and Pierre Robin syndromes.^{49,51} Micrognathia can also make it difficult to achieve an adequate seal during bag-mask ventilation.

Although it is uncommon to encounter a difficult airway in a child, it is critical to be able to predict a difficult airway before using induction agents and neuromuscular blockade. Failure to predict a difficult airway and failure to have an alternative plan when encountering an unanticipated difficult airway can result in a life-threatening situation in which ventilation and oxygenation are impossible. It is imperative that emergency physicians have access to a difficult airway cart that contains additional equipment used to perform or facilitate intubation or to establish an airway. A list of suggested equipment is found in Table 2–8.^{46,48,49,51} It is also important to remember that calling early for assistance from anesthesia or otolaryngology when a difficult airway is anticipated is highly recommended. The American Society of Anesthesiologists Task Force has established a difficult airway algorithm to help with difficult airway management (Fig. 2–8).⁴⁶

Summary

Early recognition of respiratory distress and failure in an infant or child with appropriate interventions will optimize outcomes. Additional research is needed to identify factors leading to respiratory failure and devices that may accurately predict the need for early intervention. The role of the laryngeal mask airway in emergency settings is ill-defined at this

point in time, but this airway must be investigated as a possible tool to initially manage patients with respiratory failure. Evaluation of factors and examination techniques that can predict a difficult airway in children should be explored. Finally, optimal and cost-effective ways to maintain airway management skills for physicians who rarely perform these life-saving techniques on children need to be studied.

Chapter 3

Rapid Sequence Intubation

Steven G. Rothrock, MD

Key Points

Immaturity of the autonomic nervous system in neonates and infants increases their propensity to develop bradycardia with airway manipulation, hypoxia, and succinylcholine use.

Unique anatomic and physiologic properties require a different approach, medication dosing, and techniques for rapid sequence intubation in neonates, young infants, children, and adolescents.

Preoxygenation for 2 minutes with 100% oxygen allows for only 2 minutes of apnea before desaturation occurs in healthy infants and even less time in ill infants.

To ensure success, clinicians must use a consistent stepwise methodology for intubation that includes personnel and patient preparation, medication and equipment selection, procedural performance, confirmation of correct tube placement, and advancement to rescue techniques when appropriate.

Introduction and Background

Airway manipulation during endotracheal intubation is associated with adverse cardiovascular effects (hypertension, bradycardia, tachycardia, arrhythmias) and increased intracranial, intraocular, and intragastric pressure in addition to airway trauma and hypoxia. Rapid sequence induction is the process of providing rapid sedation during general anesthesia in unprepared patients at risk for aspiration. Rapid sequence intubation (RSI) is used to describe rapid sequence induction using sedation and paralysis during endotracheal intubation while minimizing trauma, time to airway control, and complications of intubation and airway manipulation. Emergency medicine and pediatric emergency medicine physicians using RSI have $\geq 99\%$ success rates for controlling an airway in children with traumatic and medical disorders without requiring surgical rescue techniques.¹⁻³

Recognition and Approach

Several features make the technique of rapid sequence induction more difficult in infants and children compared to adults. Infants and young children have less rigid support to their major airway structures.⁴ The soft palate and epiglottis obstruct the airway more commonly than the tongue in patients with an altered level of consciousness and in those undergoing anesthesia.⁵⁻⁷ In infants and children, these structures have less cartilaginous support than found in adults, increasing the propensity to collapse and obstruct during sedation. The tongue also encompasses a proportionately larger amount of the oropharynx, increasing the difficulty of mask ventilation and passage of airway devices. Immature diaphragmatic and intercostal muscle composition and positioning lead to more rapid fatigue and respiratory decompensation, accelerating the need to make airway decisions in the very young.⁴

The physiologic response to hypoxia and laryngeal manipulation is exaggerated in young infants. The neonatal cardiac conduction system has predominant intrinsic sympathetic activity within the sinus and atrioventricular nodes, resulting in a high resting heart rate.⁸ In contrast, little sympathetic innervation of the ventricles and bundle branches exists in neonates and young infants.⁹ The absence of nerves that directly supply the ventricles makes them less electrically stable and exaggerates the cardiac response to stress.⁸ This effect is offset by a predominant vagal nerve influence mediated by cholinergic fibers that directly supply the atrial and ventricular conduction systems.^{8,10} This autonomic imbalance predisposes the heart to profound accelerations and decelerations with stress. Bradycardia is induced by airway manipulation, hypoxia, and succinylcholine administration in infants ≤ 1 year old. By 1 year, autonomic imbalances diminish, limiting these adverse effects and limiting the theoretical basis for using atropine as a premedication.^{11,12}

Neonates and young infants differ from older children and adults in their responses to many anesthetic agents. In the neonate, relatively larger extracellular fluid volume and blood volume, smaller muscle mass and fat stores, and greater blood flow to the central organs influence the effect and metabolism of drugs.⁸ Drug metabolism is less effective in neonates than in children due to incompletely developed hepatic enzyme systems and glomerular filtration. These factors contribute to increased toxicity and sensitivity to a variety of agents used during airway management (e.g.,

benzodiazepines and narcotics) and a requirement for different drug doses. A smaller muscle mass and a larger volume of distribution require use of higher relative doses of succinylcholine at younger ages.¹³ Knowledge of these physiologic differences allows for selection of safer, rational choices during RSI.

Prior to performing RSI, patients are preoxygenated with 100% O₂ to create an oxygen reservoir. In healthy adults, the effect of this nitrogen washout is a maintenance of oxygen saturation greater than 90% for up to 8 minutes of apnea.¹⁴ Infants and young children consume more oxygen and have a smaller functional residual capacity compared to older children, adolescents, and adults.^{12,15} For this reason, infants and children will desaturate more quickly, resulting in a shortened window of opportunity for endotracheal intubation before hypoxia occurs.¹⁴

Selection of patients requiring RSI is one of the most important decisions made in the emergency department (ED). This technique should be considered in every patient requiring definitive airway control (e.g., respiratory failure, shock, altered mental status) in an emergency fashion in whom no contraindications exist.

Evaluation

If time permits, obtain a brief history including allergies, prior problems with anesthesia, medications, time of last meal, and associated medical conditions. Disorders placing patients at risk for complications from RSI require immediate identification. Subacute or chronic burns and neurologic or muscle disease (e.g., muscular dystrophy) increase the risk of fatal hyperkalemia following succinylcholine administration and require use of nondepolarizing agents.¹⁶ Children with prior reactions to anesthetics or a family history of malignant hyperthermia or neuroleptic malignant syndrome should not receive succinylcholine.¹⁶ The presence of an upper respiratory infection or airway irritation (e.g., trauma, blood) increases the risk of laryngospasm and decreases the time to desaturation.¹⁷

Prior to paralysis, clinicians must make a determination of their ability to manually intubate and ventilate the patient based upon history, clinical features, and anatomic variables. Authors have analyzed the ability of intraoral (incisor-to-incisor) distance, mandibular length, Mallampatti score, and thyromental distance to predict difficult intubations in adults undergoing general anesthesia. These parameters have poor utility in the ED. Only an intraoral distance less than 2.5 cm is statistically associated with difficult intubations in adult ED patients.¹⁸ No studies have analyzed the ability of any of these criteria to predict difficult intubations in infants or children. Children at risk for difficult intubations include those with a history of micrognathia, macroglossia, prominent dentition, cleft palate, limited temporomandibular joint mobility or congenital cervical spine disorders. Acquired abnormalities associated with difficult intubations include any disorder that distorts the neck, oral, or facial anatomy (e.g., burns, edema, blood, vomitus, infection), temporomandibular joint immobility (e.g., lateral airway abscess or trauma), or potential cervical spine trauma requiring immobility. Intrinsic or acquired airway and lung disease may make bag-mask ventilation difficult in patients who are sedated and paralyzed. Depending upon the urgency for airway control,

immediate surgical or alternate airway techniques (e.g., awake intubation, bronchoscopy) may be required in patients at risk for difficult intubations. A significant number of children with difficult intubations have no identifiable risk factors; therefore, rescue devices and alternative techniques must be prepared for every patient undergoing RSI (see Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts).

Management

Equipment Preparation

Equipment preparation prior to patient arrival is essential to satisfactory completion of RSI. Every ED should be equipped with appropriate ventilation and bag-mask devices, oxygen masks, laryngoscope blades, oral airways, suctioning devices, endotracheal tubes (ETTs), laryngeal mask airways, and other rescue devices for all ages and sizes. A color-coded system (e.g., drawers in a cart or wall shelving) based on weight and age helps to rapidly select appropriately sized equipment. Monitoring devices, including cardiac monitors, pulse oximetry, and ETT placement confirmation devices (e.g., end-tidal CO₂ monitors), should be available and checked systematically for proper functioning. Length-based estimates (e.g., Broselow-Luten tape) are a rapid and accurate means of equipment selection (Table 3–1).

Age-based equipment selection may be employed, although this technique may be slightly less accurate than length-based estimates (Table 3–1). Straight laryngoscope blades are used until age 2 years, with either curved (e.g., McIntosh) or straight blades used above this age. For the youngest infants (<1 year old), straight laryngoscope blades with the widest flange (e.g., Oxford, Wis-Hipple, Wisconsin, Flagg) are best for controlling the relatively large tongue.^{19,20} Above 1 year, blades with a narrower flange (e.g., Miller) can control the tongue and decrease trauma to the gingiva and teeth.²⁰ Further modification with a curve at the tip allows for the options of either direct elevation of the epiglottis via the blade or blade insertion into the vallecula (e.g., modified Miller, Phillips) in older infants.²⁰

Cole's age-based formula can be used to select an appropriate-sized ETT, although length-based estimates will select tubes less likely to produce an air leak.²¹ Preterm neonates require ETTs with an internal diameter (ID) of 2.5 to 3.0 mm, birth to 3-month-olds require 3 to 3.5 mm ID, 3- to 9-month-olds require 3.5 to 4.0 mm ID, greater than 9-month-olds to 18-month-olds require 4 to 4.5 mm ID, and 18- to 24-month-olds require 4.5 to 5 mm ID. Above 24 months, an appropriate tube size can be estimated by using the formula: [age (in years) ÷ 4] + 4 mm (Table 3–1).²¹ Modification of Cole's formula to [age (in years) ÷ 3] + 4 mm identifies cuffed ETTs that can be inserted (with or without blowing up the balloon) to decrease the amount of air leak compared to uncuffed tubes.²² Alternate methods for estimating ETT sizes (e.g., fifth finger width, fifth finger diameter, fifth finger nail width, naris diameter) are all less accurate than length-based and age-based formula estimates and should not be used.²³ In general, uninflated or uncuffed ETTs are used for children ≤ 8 years old. At this age, the area below the vocal cords, the cricoid ring, is the narrowest part of the airway, precluding the need for a cuff and leading to pressure-induced complications if a cuff is used. New low-pressure, high-volume cuffs (using Cole's formula minus 0.5 to 1.0 mm ID for ETT size)

Table 3–1 Rapid Sequence Intubation Protocol*

Preparation of Equipment			
Apply cardiac monitor, pulse oximeter, spine immobilization devices.			
Ready suctioning devices, postintubation confirmation device.			
Ready backup devices (laryngeal mask airway, bougie, surgical equipment).			
Ready appropriate-size blades and endotracheal (ET) tubes (and tubes 1/2 size above/below with stylets).			
Age	Laryngoscope [†]	ET tube (mm) [‡]	ET depth (cm) [§]
Premature	0 straight	2.5–3.0	8
Newborn	0–1 straight	3.0–3.5	9–10
3 mo	0–1 straight	3.0–3.5	9–10
6 mo	1–1.5 straight	3.5–4.0	10
1 yr	1–1.5 straight	4.0–4.5	11–12
2 yr	1–2 straight or curved	4.0–4.5	11–13
5 yr	2 straight or curved	5.0–5.5	15–16.5
12 yr	3 straight or curved	6.5–7.0	19–21
Preparation of Personnel			
Identify personnel for directing intubation, monitoring, applying cricoid pressure, medication, and ventilation.			
Preparation of Patient and Medications			
Immobilize cervical spine.			
Preoxygenate—3 min of 100% O ₂ or 4–8 deep breaths over 30–60 sec			
Premedication/medications* (calculate and prepare doses in labeled syringes): atropine, lidocaine, sedatives, cardioprotective agents, defasciculating or priming agent, paralytic			
Sedation and Paralysis and Timing of Events: (–) signifies time agent given prior to laryngoscopy*			
(–) 7 min	Preoxygenation for 3 min if spontaneously breathing		
(–) 4 min	Atropine (esp. ≤1 year old, ketamine use, second dose succinylcholine)		
(–) 4 min	Defasciculating/priming agent (optional) (Observe for rare respiratory depression)		
(–) 3 min	Lidocaine (esp. if weaker sedating agent)		
(–) 2 min	Sedation or induction agent and application of cricoid pressure		
(–) 1 min	Succinylcholine or paralytic agent (administer 90 sec preintubation if defasciculating or priming agent used)		
0 min	Laryngoscopy and intubation		
Postintubation Evaluation			
Confirm ET tube position—capnographic waveform analysis is most accurate. Alternately, use colorimetric end-tidal CO ₂ device or, in adolescents, esophageal detection device.			
Reexamine patient and obtain chest radiograph. Secure ET tube with taping that ensures tube will not move when head and neck move, and consider administration of sedative or sedative with paralytic.			
*See Table 3–2 for medication dosage and timing.			
[†] French size of laryngoscope blades.			
[‡] ET tube internal diameter (ID) is estimated by: [age (in years) ÷ 4] + 4 if age >2.			
[§] Distance from incisors or gum line to midtrachea in centimeters. If patient is ≥2 years, ET ID × 3 estimates correct ET tube depth in centimeters.			

may reduce these complications and provide a safe alternate to using uncuffed ETTs.^{24,25}

Personnel Preparation

Prior to patient arrival, personnel are to intubate, apply cricoid pressure, immobilize the neck, bag-mask ventilate,

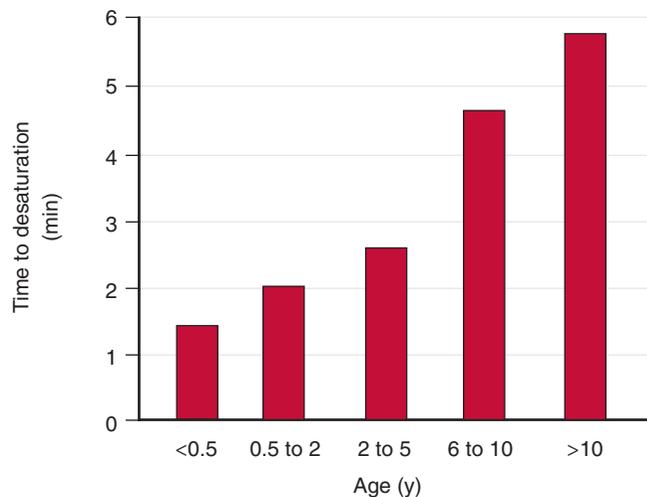

FIGURE 3–1. Time to arterial desaturation (<90% SaO₂) in apneic healthy infants and children preoxygenated at 100% O₂ for 2 to 3 minutes.^{14,30,31}

handle equipment (e.g., ETT, suction devices, rescue devices), watch monitoring devices, confirm intubation, and prepare and administer medications (see Table 3–1).

Patient Preparation and Preoxygenation

Upon patient arrival and during initial resuscitation, the patient's spine is immobilized if trauma is suspected. A cardiac monitor and pulse oximeter are applied and one or more intravenous cannulas inserted. Apneic patients require bag-mask ventilation with 100% oxygen, whereas those in cardiac arrest require endotracheal intubation without the RSI technique.

If time permits, patients who are spontaneously breathing require administration of 100% oxygen with a tight-fitting non-rebreather mask. This will assist in displacing nitrogen and creating an oxygen reservoir for patients subjected to prolonged apnea due to sedation and paralysis during RSI. Under optimum conditions, the alveolar oxygen saturation rises to at least 87% to 90%.²⁶ With application of 100% oxygen via a tightly sealed mask and an anesthesiology closed system that actively removes expired gases, this target is reached within 2 minutes in almost all healthy infants and children breathing spontaneously.²⁷ In the ED, a tight-fitting non-rebreather mask with at least 10-L/min oxygen flow will lead to an adequate alveolar saturation within 3 minutes.^{28,29} This will allow for maintenance of arterial saturation greater than 90% during apnea for 1.5 to 2 minutes in healthy infants ≤6 months old, 2 to 3.5 minutes in 7-month-old to 5-year-old children, 3.5 to 5 minutes in 6- to 10-year-old children, and over 6 minutes in children and adolescents older than 10 years (Fig. 3–1).^{14,30,31} For obese or ill children (e.g., those with lung disease or higher oxygen consumption), the time to desaturation will be shorter. For apneic patients, ventilation with 100% oxygen (applying cricoid pressure) will build oxygen reserves in a similar fashion and allow for some degree of apnea during sedation, paralysis, and intubation but will increase the risk of vomiting and aspiration.

Premedication

Laryngoscopy and endotracheal intubation can lead to a variety of adverse physiologic effects, including increased

intracranial pressure, increased intragastric pressure with vomiting, increased intraocular pressure, elevated blood pressure, tachycardia or bradycardia, laryngospasm, and bronchospasm. Many of these effects are exacerbated by administration of succinylcholine. To diminish these effects, a variety of medications can be given prior to sedation and paralysis (Table 3–2).

Atropine has been used for over 50 years to decrease salivation and prevent bradycardia associated with airway manipulation and succinylcholine use. Initial studies that evaluated the cardiovascular complications of endotracheal intubation and succinylcholine use demonstrated that most of these

complications were due to volatile anesthetics (e.g., halothane) or hypoxia that occurred during intubation.^{32–34} Children ≤ 1 year old have a more pronounced bradycardic response to intubation and to succinylcholine administration. At this age, atropine use prior to intubation (especially if succinylcholine is used) is often recommended.^{35–37} Many experts also recommend use of atropine in older children (i.e., up to 5 to 10 years).^{20,35–37} Reasons for this recommendation are less clear. The sympathetic-parasympathetic imbalance disappears in the first year of life.³⁸ When less cardioactive anesthetic agents (e.g., isoflurane) are administered to children receiving succinylcholine, the typical response is an

Table 3–2 Medications Used for Rapid Sequence Intubation

	Intravenous Dose*	Onset† (min)	Duration (min)	Indications	Select Contraindications (Relative and Absolute)	Prominent Side Effects
Premedication						
Atropine	0.02 mg/kg	2–4	>120	Infants ≤ 1 yr old, all requiring >1 dose of succinylcholine	Extreme tachycardia or tachycardic arrhythmia	Agitation, tachycardia, arrhythmias, seizures, hyperthermia, urine retention
Lidocaine	1.5–2.0 mg/kg	3	Only useful 3 min before intubation	Head injury suspected and weak sedative given	High-degree atrioventricular block, amide anesthetic allergy	Bradycardia, heart block, seizures, altered mental status, respiratory depression
Defasciculating or priming agent	1/10th paralytic dose below	3–4	N/A	Consider if >5 yr & possible increased intracranial pressure	See succinylcholine and nondepolarizing agents below	Respiratory arrest; see paralytic side effects below
Induction						
Etomidate	0.3–0.4 mg/kg	0.25–0.5	5–15	Trauma, head injury, hypovolemia	Adrenal suppression, underlying seizures	Painful injection, myoclonus, vomiting, adrenal suppression
Thiopental	3–5 mg/kg	0.5–1.0	10–30	Head injury, normal blood pressure	Hypotension, barbiturate allergy, porphyria	Hypotension, bronchospasm (esp. if asthma), local necrosis
Ketamine (with atropine)	1–2 mg/kg	0.5–1.0	10	Asthma, noncardiac hypotension	Head injury, glaucoma, cardiogenic shock	Vomiting, hypersalivation, hypertension, tachycardia
Midazolam	0.1–0.3 mg/kg	1–5	20–30	Absence of shock (do not use in preterm infants)	Shock, hypersensitive to midazolam, narrow-angle glaucoma	Hypotension, bradycardia
Propofol	2.5 mg/kg	0.5–1.0	3–10	Useful if paralytics contraindicated, age ≥ 3 years, and blood pressure is OK	Hypotension; hypersensitive to sulfites, soybean oil, egg yolk, or egg lectithin	Hypotension, bradycardia, flushing, acidosis, muscular twitching, pain on injection
Paralytic						
Succinylcholine	0–1 year: 2–3 mg/kg 1–5 year: 1.5–2 mg/kg >5 years: 1–1.5 mg/kg	0.5–1	3–8	Rapid paralysis	Cannot ventilate, neurologic or muscle disease, subacute-chronic burn, hyperkalemia	Hyperkalemia; increased intracranial, gastric, and ocular pressure; fasciculations
Rocuronium	0.6 mg/kg (0.9 mg/kg)	1–1.5 (<1)	30–45 (>60)	Priming or defasciculating agent, cannot use succinylcholine	Unable to mask ventilate; use half dose if liver disease	Hypotension, tachycardia or bradycardia, arrhythmias, bronchospasm
Mivacurium	0.15–0.25 mg/kg	2–2.5	10–20	See above	Unable to mask ventilate	See above
Vecuronium	0.1–0.2 mg/kg	2–5	30–45	See above	Unable to mask ventilate	See above

*Dose for rapid sequence intubation.

†See Table 3–1 for exact timing of medication administration.

increased heart rate or tachycardia in 88% to 95%, with a decreased heart rate in 12% and bradycardia in 0 to 2%³⁹⁻⁴¹ In contrast, use of halothane with succinylcholine in children leads to bradycardia in 14% to 30% of cases.^{32,40,42} Addition of atropine to succinylcholine may increase the overall number of dysrhythmias compared to use of succinylcholine alone.^{17,43} Adding sedatives to the intubating regimen further diminishes the cardiovascular response and side effects from laryngoscopy and succinylcholine. Other important considerations include the ability of atropine to mask significant physiologic changes (e.g., assessing shock management, intracranial pressure changes, airway complications, pain, sedation level). Moreover, atropine increases temperature and the risk of malignant hyperthermia, increases ventricular arrhythmias, relaxes the lower esophageal sphincter with increased risk of aspiration, lowers the seizure threshold, induces confusion, and increases urinary retention. Atropine also has a narrow therapeutic index, increasing the potential for dosing errors.^{39,43,44}

Despite prior recommendations, atropine use is no longer considered routine in infants and children undergoing intubation among many neonatologists and anesthesiologists in the United States, Canada, Europe, and Australia.⁴³⁻⁴⁷ As no controlled studies have proven when atropine is beneficial, evidence-based recommendations cannot be given. Atropine should always be readily available with appropriate dosing calculated prior to all intubations as its use may become necessary. If no contraindications exist prior to intubation, atropine should be administered to all infants ≤ 1 year old, to all patients receiving a second dose of succinylcholine regardless of age, and to all patients receiving ketamine, an agent that causes prominent airway secretions. Moreover, children who are already bradycardic require atropine prior to intubation, especially when succinylcholine is used. For all other cases, ED personnel should be prepared to administer atropine if bradycardia develops during or after intubation with the realization that bradycardia may be a clue to a coexisting physiologic derangement (e.g., airway blockage, hypoxia, increased intracranial pressure, profound shock) or prolonged airway manipulation. The correct dose of atropine is 0.02 mg/kg intravenously (IV), with a minimum of 0.1 mg and maximum of 0.6 mg per single dose.

Lidocaine is a cardioactive agent that has been recommended by some experts to reduce intracranial pressure in patients with possible head trauma or space-occupying intracranial lesions who require endotracheal intubation.^{36,48,49} This recommendation has been based, in part, on adult studies that evaluated the intracranial pressure response to endotracheal suctioning in patients with tumors or a recent neurosurgical procedure.⁵⁰⁻⁵³ Lidocaine has been shown to suppress the cough reflex, and this mechanism may explain its benefit during endotracheal suctioning.⁵⁰⁻⁵² Others have examined the effect of IV lidocaine administration on hemodynamic parameters during intubation, assuming that blunting the hemodynamic response to intubation would correlate with a diminished intracranial pressure response. Conflicting studies have found that IV lidocaine either has no effect on blood pressure⁵⁴⁻⁶³ or heart rate^{55-57,60-64} or attenuates a rise in blood pressure⁶⁵⁻⁶⁸ and heart rate^{58,59,65-68} during laryngoscopy and intubation. Upon further analysis of these studies, it appears that the addition of lidocaine to a strong sedating agent (e.g., thiopental, propofol) has minimal

to no additional hemodynamic blunting effect.^{57-59,61,63-65,69,70} A hemodynamic blunting effect is more likely when agents with less sedating or less cardiovascular effects are used (e.g., midazolam, etomidate).^{61,71,72} The optimum lidocaine dose is 1.5 to 2 mg/kg IV.^{66,68,73-75} To be effective, lidocaine must be given precisely 3 minutes prior to laryngoscopy.^{67,76} If given at 1, 2, or 5 minutes preintubation, its effects are diminished or absent.^{67,76} Lidocaine should be considered in patients who receive etomidate or midazolam as induction agents.

Other cardioactive agents (especially β -blockers, calcium channel blockers, and short-acting narcotics) have been used to blunt the heart rate and blood pressure response to endotracheal intubation and lower the intracranial pressure response to intubation. Of these, esmolol has been shown most useful at blunting hemodynamic parameters.^{55,62} However, no pediatric studies have shown this to be a safe addition to RSI in the ED setting. Short-acting narcotics (e.g., fentanyl, alfentanil, sufentanil) also increase intracranial pressure and should be avoided during RSI if a head injury is possible.^{77,78}

A “defasciculating” dose of a neuromuscular blocking agent is often administered prior to succinylcholine in adults to diminish side effects during RSI. Generally, this involves administration of a 1/10th intubating dose of a nondepolarizing agent or a 1/10th dose of succinylcholine IV 3 to 4 minutes prior to administration of a full dose of succinylcholine to decrease muscle fasciculations and intracranial, intragastric, and intraocular pressure. Children 5 years old and younger have less muscle mass and have minimal to no risk of fasciculations with succinylcholine administration. Thus, defasciculating agents are not recommended at this age. For children older than 5 years, use of a defasciculating agent is controversial. Importantly, experts have found that it is not the fasciculations that determine the cerebral response to succinylcholine. Instead, it is the effect of succinylcholine on muscle spindle afferent fibers that correlates with peak cerebral pressure and flow responses regardless of whether or not fasciculations occur.⁷⁹ It is unclear if this muscle afferent signal is blocked by administration of a defasciculating agent.^{79,80} Moreover, administration of a defasciculating dose of a paralytic rarely can cause paralysis, adds to the multi-drug cocktail given for RSI and thus increases the risk for dosing errors, and increases the time to intubation during RSI with succinylcholine. This technique is best reserved for relatively stable patients older than 5 years when a 3- to 4-minute delay will not affect outcome.

Alternately, a similar priming dose (1/10th of paralytic dose) of a nondepolarizing agent can be administered 3 to 4 minutes prior to the intubating dose of a nondepolarizing paralytic agent. This priming dose will decrease the time required to wait for complete paralysis by nearly one half depending upon which agent is administered.

Medications (Sedatives and Paralytics)

Multiple drugs can be used to induce anesthesia or unconsciousness during RSI. Clinicians need to be fully aware of indications, contraindications, side effects, and dosing for each of these medications (see Table 3-2).

Sodium thiopental is a barbiturate that depresses the patient’s reticular activating system. This agent has a rapid uptake within the brain, producing a rapid onset, usually

within 30 seconds. It also causes cerebral vasoconstriction, decreasing blood flow and intracranial pressure. It is ideal for patients with isolated increased intracranial pressure without hypotension. It should be avoided in patients with hypotension, hypovolemia, or cardiovascular instability.³⁵

Etomidate is a carboxylated imidazole with sedative-hypnotic properties that produces unconsciousness within 15 to 30 seconds of administration. It is not an analgesic, has little effect on blood pressure, and causes a slight decrease in systemic vascular resistance, cerebral blood flow, and intracranial pressure.^{37,81} Due to its cardiovascular and central nervous system protective effects, it is an ideal induction agent in trauma patients with and without head injury.⁸² Side effects include pain on injection, adrenocortical suppression (minimal with a single dose), hypertonicity, coughing, laryngospasm, hiccoughing, vomiting, occasional involuntary muscle movements, and muted ability to blunt blood pressure and heart rate responses to laryngeal manipulation.^{37,81} Due to these effects, many experts recommend adding other cardioprotective agents (e.g., benzodiazepines, lidocaine) when etomidate is used as an induction agent.^{37,81} The typical RSI dose is 0.3 to 0.4 mg/kg IV.^{81,82}

Ketamine is a dissociative sedative that produces profound analgesia and amnesia. When used alone, it results in protective airway reflexes, spontaneous respirations, and cardiopulmonary stability. Its bronchodilating effects make it an ideal agent for intubation of asthmatics. Its hemodynamic protective effects allow for use in patients who are hypotensive due to volume depletion. Prominent salivation requires coadministration with atropine, although ketamine's catecholamine stimulatory effects limit bradycardia when coadministered with succinylcholine. Ketamine raises intracranial pressure and intraocular pressure and should be avoided if either of these effects is a concern. Ketamine may have adverse effects if cardiogenic shock is present and should be avoided in most patients with cardiac-related hypotension. A typical IV dose is 1 to 2 mg/kg (administered with atropine), with an onset of less than 1 minute.⁸³

Midazolam is a rapid-acting benzodiazepine that can be used as an induction agent in select cases. It has no analgesic properties and may worsen hypotension. It is most appropriately used in hemodynamically stable patients. Its dose should be reduced or an alternate agent selected in patients with severe cardiovascular instability. The typical induction dose is 0.1 to 0.3 mg/kg IV.³⁵

Propofol is an IV anesthetic that can be used as an induction agent. It has a rapid onset (<30 seconds) and brief duration of action. A major side effect limiting its use is hypotension. For this reason, it should be avoided in patients with multi-system trauma, hypovolemia, cardiac compromise, or hypotension from any cause. Due to prominent relaxation of pharynx and laryngeal reflexes, some authors recommend propofol in patients in whom neuromuscular blockade cannot be used.³⁷ Intubating conditions with propofol alone (i.e., no paralytics) are superior to those obtained while using thiopental alone for RSI.⁸⁴ Others have found that administration of a short-acting narcotic (e.g., alfentanil 20 or 40 mcg/kg IV) prior to propofol improves intubating conditions to near those of RSI with paralytic agents.⁸⁵ Since experience with propofol alone or coadministered with alfentanil is limited in the ED setting, this regimen cannot be recommended as routine at this time. The typical dose of propofol

used with RSI is 2.5 mg/kg IV given 30 to 60 seconds prior to succinylcholine.

Neuromuscular Blocking Agents

Succinylcholine is a neuromuscular blocking agent that acts by depolarizing the neuromuscular end plate and sympathetic and parasympathetic ganglia.¹⁶ Initial muscular contractions may cause fasciculations followed by muscle relaxation until the muscle membrane repolarizes following hydrolysis of succinylcholine by plasma cholinesterase. Muscle contraction and muscle spindle afferent activity can cause increased intracranial, gastric, and ocular pressure. Hyperkalemia with cardiac arrest can occur in patients who are susceptible, including those with myopathies, neuromuscular disease, denervation injuries, shock, metabolic acidosis, crush injuries, renal failure, and subacute or chronic burns.^{16,20} Patients who deteriorate immediately after succinylcholine administration require confirmation of ETT position and function. If tube function and position are adequate, treatment should be directed at reversing hyperkalemia (IV calcium, sodium bicarbonate, glucose, and insulin). Bradycardia also is prominent in children ≤ 1 year old, and in children at all ages receiving more than one dose. In these instances, atropine is administered prior to succinylcholine. Disorders that affect plasma cholinesterase levels (e.g., liver disease, hereditary deficiency, anemia, renal failure, connective tissue disorders, or pregnancy) increase the duration of action of succinylcholine. The recommended dose of succinylcholine is 2 to 3 mg/kg in neonates and young infants (<1 year), 1.5 to 2 mg/kg at 1 to 5 years, and 1 to 1.5 mg/kg above 5 years.^{16,81} If a defasciculating agent is administered, the higher end of the dosing range should be administered. A final alternative for patients requiring rapid airway control without IV access (e.g., patients with laryngospasm) is 4 mg/kg administered intramuscularly (IM). Maximum paralysis with IM dosing occurs in 3 to 4 minutes with a duration of 19 to 23 minutes.³⁷

Rocuronium is a nondepolarizing neuromuscular blocking agent. It has a rapid onset (70 to 90 seconds) and relatively short duration (≤ 45 minutes) following a 0.6 mg/kg dose.¹⁶ The time to onset is comparable to succinylcholine (<60 seconds) if a higher dose (0.9 mg/kg) is administered, although this regimen results in a longer duration of action (>60 minutes).^{86,87} Alternately, the typical RSI dose may be split into a priming dose (1/10th original dose) and an intubating dose (9/10th original dose). The priming dose of 0.06 mg/kg can be given 3 minutes prior to the intubating dose (0.54 mg/kg) with an onset of paralysis in less than 1 minute after administration of the intubating dose.³⁷ Care must be used with this technique as the priming dose rarely can cause neuromuscular depression requiring mask ventilation, as well as anxiety and aspiration. In general, this drug has few hemodynamic effects making it relatively safe in critically ill patients. Since rocuronium is metabolized hepatically, duration of action is up to 50% longer if liver disease is present.¹⁶

Mivacurium is a short-acting nondepolarizing neuromuscular blocking agent. The recommended dose of mivacurium for RSI is 0.15 to 0.25 mg/kg IV.^{16,37} Onset is 1 to 2 minutes with a typical duration of 15 to 20 minutes.^{12,88} It is rapidly hydrolyzed by plasma cholinesterase, resulting in a shorter duration of action compared to other nondepolarizing

neuromuscular blockers. Administration of a priming dose (0.025 mg/kg) followed 3 minutes later by an intubating dose (0.225 mg/kg) results in a more rapid onset of paralysis (~1 minute).⁸⁹ An important side effect that occasionally occurs with higher doses is cutaneous flushing and mild hypotension due to histamine release.

Vecuronium is a nondepolarizing neuromuscular blocking agent with few hemodynamic effects. A dose of 0.1 to 0.2 mg/kg IV produces adequate paralysis within 2 to 2.5 minutes, with a duration of greater than 60 minutes in infants and 25 to 55 minutes in children and adolescents.⁹⁰ A 0.01-mg/kg priming dose followed in 3 minutes by 0.15 mg/kg produces adequate paralysis in 90 seconds.

Techniques and Sequencing

All spontaneously breathing patients require preoxygenation with 100% oxygen via tight-fitting non-rebreather mask for at least 2 to 3 minutes. For patients requiring atropine, this agent should be administered 4 minutes prior to anticipated laryngoscopy (see Table 3–1). Priming or defasciculating doses of neuromuscular blocking agents, if used, are given 3 minutes prior to administration of the intubating dose of paralytic (~4 minutes prior to intubation). For optimum effect, if administered, lidocaine must be given 3 minutes prior to intubation. Sedating agents are administered 2 minutes prior to intubation, with succinylcholine or nondepolarizing paralytic administered approximately 1 minute prior to intubation (90 seconds prior to intubation if a defasciculating agent is used) (see Table 3–1). Once sedatives are injected, cricoid pressure is applied and maintained until intubation is confirmed. Spontaneously breathing patients who are able to maintain an oxygen saturation of 100% do not require assisted ventilation. Bag-mask ventilation, in this instance, may cause vomiting and aspiration. Patients who are hypoxic, in respiratory distress, or hypoventilating prior to medication administration require bag-mask ventilation while waiting for maximum sedation and paralysis.

Several techniques assist in visualization of the vocal cords and passage of the ETT. If cervical spine trauma is not a concern, the patient is placed in a sniffing position (depending upon occiput size and patient age) for a more direct view of the glottic structures. If a cervical collar is in place, removal of the collar with manual immobilization of the cervical spine allows for more movement of the mandible. Use of the BURP technique (**backward, upward, rightward pressure** on the larynx) by an assistant will increase glottic visualization. Moreover, external laryngeal manipulation with the nonintubating hand by the intubator allows for a more direct view of the vocal cords. During intubation, the physician should limit intubation attempts to 30 seconds and prevent and treat hypoxia via bag-mask ventilation if attempts are unsuccessful. Tube insertion is stopped once the double lines at the end of the ETT pass the vocal cords. Correct tube depth (distance from incisors or gum line to midtrachea) can be estimated by multiplying the ETT internal diameter by 3, although this formula may cause ETTs to be placed 0.5 to 1.0 cm too deep in infants less than 2 years old (see Table 3–1).

Disposition (Postintubation)

Following intubation, placement of the ETT should immediately be confirmed. The most accurate method for confirma-

tion is capnographic waveform analysis. The presence of a waveform assures tube placement within the trachea.⁹¹ Alternately, a colorimetric end-tidal CO₂ detection device can be attached to the endotracheal tube. A color change from purple to yellow with each breath after an initial six breaths confirms tracheal tube placement.⁹¹ A false positive (permanent yellow) is seen if acid (vomit) or epinephrine contaminates the colorimetric device. While ventilating, the physician should listen over the stomach for bowel sounds with bagging, and over the lateral aspects of the chest for bilateral breath sounds. Clinicians should be aware that auscultation can be inaccurate (especially in younger children) and will reveal bilateral breath sounds at the axilla in up to 15% and vapor condensation of the ET tube in 85% with esophageal intubations.⁹² An alternate confirmation device that may be used in older children and adolescents is the esophageal detector device. With this device, clinicians attempt to aspirate 10 mL of air from the endotracheal tube. Ten milliliters is easily aspirated from the trachea, but will cause collapse of the esophagus and inhibit aspiration of air. After tube confirmation, the tube is immediately taped in place so that it will not move with head movement. Sedation is continued in all patients, and paralysis is considered if indicated.

Clinicians need to be prepared for deterioration before, during, and after intubation. If a patient cannot be intubated or ventilated following administration of sedating and paralytic agents, a stepwise approach must be taken.⁹³ The first step is to attempt insertion of a laryngeal mask airway (LMA) with ventilation via the mask. If successful, endotracheal intubation can be attempted via a conduit present in intubating LMA devices. If the patient still cannot be intubated or ventilated, trans-tracheal jet ventilation or an alternate surgical airway procedure will be required depending upon the patient's age and clinical circumstances (see Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts).

Borland detailed the most common complications during pediatric intubations. These include hypoxia (4.3%), laryngospasm (2.3%), hypotension (0.6%), and cardiac arrest, aspiration, wrong drug administration, dislodged ETT, and dental injuries (0.1% to 0.2% each).⁹⁴ Prevention of these complications involves adequate preoxygenation, appropriate medication dosing, and intensive monitoring. Capnography can aid in diagnosis of many of these conditions. Tube dislodgement causes a loss of the waveform, whereas hypotension causes a gradual decrease in the height of the waveform. Malignant hyperthermia causes an increasing end-tidal CO₂ and increased height of the capnographic waveform in addition to the typical signs of dark urine, increased temperature, and muscle rigidity.

Summary

Successful rapid sequence intubation requires a stepwise algorithmic approach to preparation, patient monitoring, medication selection, dosing and administration, procedural performance, and confirmation of completion. A complete understanding of every step and every medication is essential to successful completion of this procedure. Clinicians must be prepared for deterioration at any time and the inability to intubate or ventilate after medication administration. A thorough knowledge of each of these factors will protect the patient and ensure the best possible outcome.

Intubation, Rescue Devices, and Airway Adjuncts

Aaron J. Donoghue, MD, MSCE and Ron M. Walls, MD

Key Points

Preservation of oxygenation of the brain and vital organs is the most important step in pediatric resuscitation.

The most prominent anatomic differences of a pediatric airway are the relatively large tongue, the superior larynx, and the narrowest point of the airway being at the cricoid cartilage. Respiratory physiologic differences in young children result in a greater tendency for hypoxemia.

Failure of oral intubation is uncommon, but several rescue devices and alternative approaches exist and are well validated.

Indications

The emergency physician is responsible for airway management for patients in the emergency department (ED), and therefore has a responsibility for the decision making, drugs, and techniques that constitute the armamentarium of modern airway management. The challenge in caring for the acutely ill or injured child lies in determining which interventions are needed, and in balancing the risks and benefits of these interventions. The need for intubation can be obvious, as when the child presents in cardiopulmonary arrest, but it is in the more subtle cases that the judgment of the provider is most important. In general, intubation is safe and highly effective, with a low rate of adverse events, and patient outcome is more often threatened by a delay in intubation than by an intubation that might have been unnecessary or undertaken too early. The key management decision is whether, and when, to intubate the patient with serious illness, but whose airway or respirations have not yet failed. There is no easy way to determine which patients should be intubated, or when; however, the decision to undertake intubation or another form of active airway management is based

on an assessment of the patient with respect to three central issues:

- I. Failure of airway maintenance or protection
 - A. Coma
 - B. Loss of intrinsic tone of airway musculature (e.g., from critical illness, intoxication)
 - C. Loss of airway protective reflexes
 1. Inability to swallow/expectorate secretions adequately (more reliable measure than the gag reflex)
 2. Inability to cough
 3. Inability to keep airway patent (upper airway obstruction from tongue, foreign body, inflammatory or infectious process)
- II. Failure of oxygenation or ventilation
 - A. Ventilatory failure that is not reversible by other means (e.g., opioid respiratory depression is reversible by administration of naloxone)
 - B. Hypoxemia that is not responsive to supplemental oxygen (e.g., pneumonia with persistent hypoxemia despite high-flow oxygen)
- III. Anticipatory management: What is the patient's anticipated clinical course? Is it likely that deterioration will occur, and threaten either the airway or the patient?
 - A. Injury/illness with foreseeable need to control airway (e.g., septic shock with concern for metabolic debt and work of breathing, anterior neck injury with potential for worsening airway obstruction, multiply injured trauma patient with shock or need for multiple invasive procedures)
 - B. Need for diagnostic or interventional procedure requiring patient cooperation (e.g., computed tomography, magnetic resonance imaging, painful procedures) when procedural sedation is not possible or is contraindicated (e.g., patient too ill or unstable for sedation without airway control)
 - C. Securing of airway for interfacility transport or transport to an area of the hospital where resuscitation will be difficult if the patient deteriorates (e.g., computed tomography, magnetic resonance imaging)

A recent summary of pediatric data from the National Emergency Airway Registry (NEAR) project reported on the

indications for intubation in 156 pediatric patients in 11 hospitals. A total of 77 (49%) were intubated as a result of trauma (38 of 77 sustained traumatic brain injury), 25 (16%) were intubated during management of status epilepticus, and 9 (6%) were intubated during management of a toxic ingestion. Other diagnoses included asthma, congestive heart failure, sepsis, pneumonia, and coma (Table 4-1).¹

Contraindications

- There are no contraindications for airway management in general, but patient condition might dictate which approach is best.
- Cricothyrotomy is contraindicated in children under 10 years old, in whom it is technically difficult. In this age group, needle cricothyrotomy is preferable when access from above the glottis is not possible.
- Identification of attributes that predict difficult intubation (Box 4-1), especially when accompanied by attributes of difficult bag-mask ventilation, is a relative

Box 4-1 The Intubation Difficulty Scale*

- Number of intubation attempts > 1
- Number of intubators > 1
- Number of alternative techniques used
- Cormack glottic visualization score (0 = complete, 3 = nonvisualization)
- Lifting force for laryngoscopy (0 or 1)
- External laryngeal pressure to visualize cords (0 or 1)
- Vocal cords abducted? (0 or 1)

*An ideal intubation would receive a score of zero.

From Sagarin MJ, Chiang V, Sakles JC, et al: Rapid sequence intubation for pediatric emergency airway management. *Pediatr Emerg Care* 18:417-423, 2002.

contraindication for rapid sequence intubation (RSI; see Chapter 3 Rapid Sequence Intubation), unless as part of a double setup in which the backup, or rescue, maneuver is planned for and readily available.

Preparation/Consent

Pertinent Past Medical History

It is often impossible to obtain detailed historical information before intubating a critically ill child. If time permits, however, a past medical history should focus on whether the patient has been intubated before and if any problems were experienced. The patient's birth history may be contributory: former premature infants have a higher incidence of subglottic stenosis and of chronic respiratory insufficiency. Patients with certain genetic syndromes (e.g., Down syndrome, mucopolysaccharidoses) may be predisposed to distorted airway anatomy. It is essential to seek any history compatible with muscular dystrophy, the presence of which contraindicates the use of succinylcholine. If the current indication for endotracheal intubation (ETI) is trauma, maintaining cervical spine immobility is paramount, and an additional operator will be required for ETI. Likewise, certain preexisting diagnoses (e.g., Down syndrome) may predispose the patient to atlantoaxial instability, in which case cervical spine precautions should be employed. A list of preexisting medical diagnoses that should alert the emergency physician to the possibility of a difficult airway is provided in Table 4-2.²

All patients should be assumed to have a full stomach, and planning should account for this. In the absence of an identified difficult airway, RSI is the procedure of choice.

Table 4-2 Preexisting Conditions That May Predispose to Difficult Airway Management in Children

Newborn Period	Trauma
Tracheal agenesis	Cervical spine injury
Laryngeal atresia	Face/neck trauma
Congenital fusion of jaws	Burn/inhalational injury
Congenital laryngeal stenosis	Mass Lesions
Laryngeal web	Head/neck tumors
Congenital ankylosis of temporomandibular joint	Hematoma/hemangiomas
Cystic hygroma	Lingual thyroid, epiglottic cyst
Craniofacial Dysmorphism	Metabolic/Musculoskeletal
Cleft lip/palate	Disorders

From Frei FJ, Ummenhofer W: Difficult airway in pediatrics. *Paediatr Anaesth* 6:251-263, 1996.

Anatomy

Pediatric intubation is, in general, easily accomplished, and the incidence of difficult intubation is less than in adults, who have many more acquired conditions that make intubation difficult. Important anatomic differences, however, distinguish the pediatric intubation from the adult, and, to a lesser degree, intubation of the infant from that of the older child. Age-related variations in size also mandate careful equipment selection and drug dosing. Specific considerations related to pediatric intubation are as follows:

- **Size**—airway structures are smaller and the field of vision with laryngoscopy is more narrow
- **Adenoidal hypertrophy** is common in young children, leading to:
 - Greater difficulty with nasotracheal intubation
 - Greater risk for injury to adenoidal tissue with resultant bleeding in the hypopharynx when laryngoscopy is performed
- The **tongue is large** relative to the size of the oropharynx.
- **Superior larynx** (Fig. 4–1)—often imprecisely referred to as “anterior,” the laryngeal opening in infants and young children is actually located in a *superior* position (in infants, the larynx is opposite C3-4 as opposed to C4-5 in adults). This makes the angle of the laryngeal opening with respect to the base of the tongue more acute and visualization by direct laryngoscopy more difficult.
- The **hyoepiglottic ligament** (connects base of tongue to epiglottis) is more elastic in young children; thus, a laryngoscope blade in the vallecula may not elevate the epiglottis as efficiently as in an adult.
- The **epiglottis** of children is narrow and angled acutely with respect to the tracheal axis; thus the epiglottis covers the tracheal opening to a greater extent and can be more difficult to mobilize.
- The **narrowest point** of the young child’s airway occurs at the level of the *cricoid cartilage* instead of at the level of the glottic opening itself.

Physiology

Respiratory Physiology

LUNG

Infants have fewer and smaller alveoli than young children, and their overall gas exchange surface area is disproportionately small. Surface area reaches proportions similar to adulthood by 8 years of age. Channels for collateral ventilation (pores of Kuhn and Lambert’s channels) are absent in infancy. The overall effect of these phenomena is a greater tendency for alveolar hypoventilation and for the development of atelectasis during a respiratory illness.³

RESPIRATORY MECHANICS

The pediatric thoracic skeleton is largely cartilaginous and much more compliant than the adult skeleton. Elastic recoil of the chest wall in the young child is essentially absent. A given change in thoracic pressure will result in a larger change in lung volume, similar to the physiology seen in an adult with emphysema. A given change in volume is associated with little or no change in pressure, so that a greater amount of work is required to generate a tidal breath.

The high compliance of the pediatric chest wall results in a closing volume (CV) (volume at which terminal bronchioles collapse because they are no longer supported by elastic recoil) that can be elevated with respect to functional residual capacity (FRC). If the already diminished elastic recoil is impaired (e.g., by supine positioning), CV can exceed FRC to an even greater extent, resulting in the absence of ventilation of some lung segments during normal tidal breathing. Young patients therefore have a greater tendency for intrapulmonary shunting and hypoxemia with the positioning required for airway management.

Accessory respiratory muscles in young children are composed of a lower percentage of slow-twitch muscle fibers and are more susceptible to fatigue compared to the diaphragm. Also, the architecture of the pediatric thorax (horizontal rib orientation with extensive cartilage composition) is such that

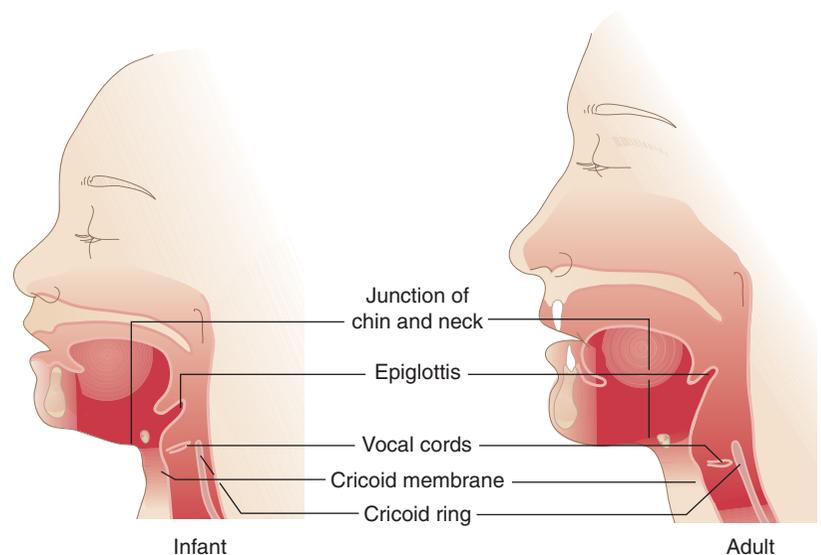

FIGURE 4–1. Relative position of the pediatric larynx in the neck compared to that in the adult. (Adapted from Walls RA [ed]: *Manual of Emergency Airway Management*. Philadelphia: Lippincott Williams & Wilkins, 2000.)

intercostal and suprasternal muscles are poorly recruited to assist in respiratory effort.

AIRWAY

Airway diameter and length increase with age. The distal airway (bronchioles) lags in growth behind the proximal airway during the first few years of life. Poiseuille's law states that airway resistance is inversely proportional to the fourth power of the radius of the airway. Thus young children have higher resistance to airflow at baseline in their lower airways, and a change in airway diameter of a given dimension will have a much more profound effect on airway resistance in a small child than in an older child or adult. Such a change can occur as a result of edema, obstruction, or excess secretions. Illnesses that affect the caliber of small airways (such as asthma and viral bronchiolitis) produce a disproportionate increase in work of breathing in infants and children.³

CELLULAR OXYGENATION

Resting oxygen consumption in the newborn is twice that of an adult (6 mL/kg/min vs. 3 mL/kg/min), and increased adipose tissue provides a greater mass per volume of FRC than in the adult. Oxygen consumption in infants is extremely sensitive to physiologic derangements such as fever and hypothermia. The oxyhemoglobin dissociation curve for young infants is shifted to the left (greater affinity of hemoglobin for oxygen and poorer tissue oxygen delivery) by the presence of elevated amounts of fetal hemoglobin.³

Combined Effects of Respiratory Physiologic Factors

The summary effects of the various respiratory physiologic phenomena described previously are a greater tendency for hypoxemia and arterial desaturation. Figure 4-2 shows a

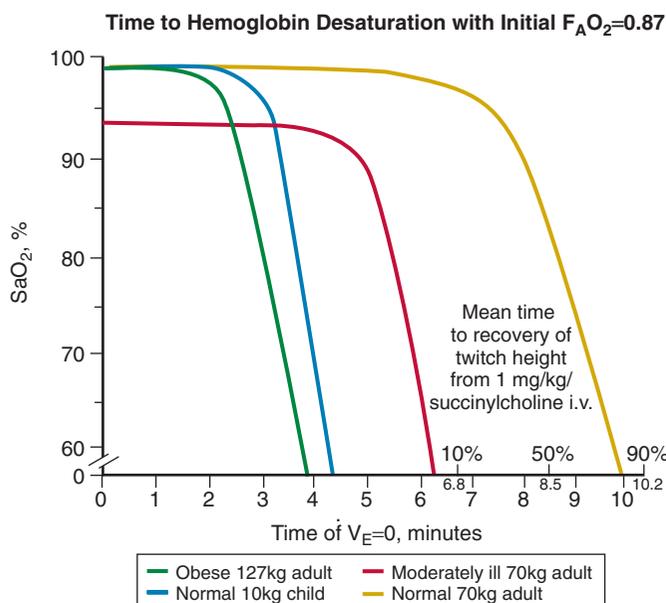

FIGURE 4-2. Time to hemoglobin desaturation with initial $F_AO_2 = 0.87$. (From Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine [see comment]. *Anesthesiology* 87:979–982, 1997.)

model of oxyhemoglobin desaturation⁴ to demonstrate the time to critical desaturation of several classes of patients, including children. According to this model, a healthy 10-kg child will desaturate to 90% after approximately 3 minutes of apnea, much more quickly than healthy or even moderately ill adults.⁵ This rapid desaturation is a product of two attributes: the greater oxygen consumption in children (described earlier) and the greater body mass index of young children, placing a greater relative demand on their pulmonary oxygen capacity. Desaturation rates vary with age. Infants preoxygenated with 100% oxygen for 2 minutes can maintain their oxyhemoglobin saturation above 90% for approximately 2 minutes, compared with almost 2.5 minutes for toddlers and over 4 minutes for children greater than 3 years of age. The time required for the saturation to fall from 95% to 90% is significantly shorter in infants than older children as well (8 seconds compared with 16 seconds).⁶ The rate of oxyhemoglobin desaturation has not been determined for children with varying degrees of systemic or pulmonary illness or injury, but it is logical to assume that it is even more rapid than described here, reinforcing the requirement for continuous monitoring of oxyhemoglobin saturation during intubation, as during all phases of the management of a seriously ill or injured child. When oxyhemoglobin saturation falls to 90%, intubation attempts are paused to permit bag-mask ventilation to restore adequate (>95%) oxygen saturation.

Cardiovascular Physiology

Children have higher vagal tone than older patients, so laryngoscopy has a much greater tendency to produce vagally mediated bradycardia in young children. Succinylcholine, which is formed by joining two acetylcholine molecules, can have significant cardiac muscarinic effect in children, aggravating the vagal effects of the laryngoscopy. Atropine, 0.02 mg/kg, should be administered to children under 10 years of age who are to receive succinylcholine for intubation. Children have a limited ability to vary stroke volume in order to maintain cardiac output, and, as a result, tachycardia is often the sole compensatory mechanism in low cardiac output states. Vagally mediated bradycardia can have a significantly deleterious effect on cardiac output.

Neonatal Physiology

Neonates in particular have significantly fragile cardiopulmonary adaptive mechanisms. Hypoxia is very poorly tolerated and causes paradoxical bradycardia. Additionally, neonatal respiratory control is immature and uncoordinated, with newborns typically exhibiting periodic breathing (absence of respiratory effort for up to 15 seconds) for up to several weeks of life. Minute ventilation does not increase sufficiently in response to hypercarbia, so hypoxemia results in transient hyperventilation and actually progresses to respiratory depression as oxygen tension falls.

Equipment

One of the challenges in airway management of children is the range of sizes of equipment necessary for safely and effectively caring for patients throughout the pediatric age range. Several rules of thumb have been designed and validated to minimize confusion pertaining to this issue; among the most

prevalently used is the length-based equipment selection, commonly accomplished through use of the Broselow-Luten tape and color-coding system. This and other sizing schema are discussed in more detail in this section as well as in Chapter 2 (Respiratory Distress and Respiratory Failure).

Ventilation Equipment

Bag-Valve-Mask Devices (Anesthesia vs. Self-inflating)

Bag-valve-mask (BVM) devices fall into two broad classes. Self-inflating bags, or Ambu bags, are semirigid plastic elliptical bags that return to their original shape spontaneously after being compressed. A properly configured self-inflating bag has a one-way exhalation valve, requiring the bag to replenish itself from a high-flow oxygen supply, often combined with a reservoir system, to deliver high concentrations of oxygen (>90%). These bags can also deliver high concentrations of oxygen during active breathing by the patient.

Anesthesia circuits consist of collapsible bags connected to an expiratory limb and a venting mechanism, most often a one-way valve allowing the egress of exhaled gases. Advantages to the use of anesthesia bags include the ability to provide 100% oxygen without a reservoir and a greater sensitivity to detect changes in airway pressure, with both spontaneous and assisted breaths. Most anesthesia circuits have an adjustable valve incorporated into the venting mechanism, allowing the operator to adjust the maximum amount of inspiratory pressure delivered to the patient; this may enable the operator to minimize barotrauma from elevated inflating pressures. Disadvantages of anesthesia circuits include the fact that they are more difficult to use by inexperienced personnel and the fact that they cannot be used in the absence of an air or oxygen source.

Suctioning

Ideally two separate suction devices should be available and opened to maximal suction. One should have a rigid tonsillar suction (Yankauer) tip attached for suctioning the mouth and oropharynx, and the second should have a smaller caliber flexible catheter for suctioning thin secretions in the hypopharynx or via the endotracheal tube, after intubation. If only one suction source is available, both suction tip devices should be at hand so that they can be interchanged if necessary.

Endotracheal Intubation

Laryngoscope

The two predominant types of laryngoscope blades used in pediatric airway management are the straight (Miller, Wisconsin) and curved (MacIntosh). Both types can be used in children and adults successfully depending on operator experience. Most pediatric practitioners favor the use of straight blades when intubating young children because of the laxity of the supporting structures of the epiglottis discussed previously. For infants less than 1 year, straight laryngoscope blades with the widest flange (e.g., Wis-Hipple, Wisconsin, Flagg) are best for controlling the relatively large tongue.^{7,8} For older children, blades with a narrower flange (e.g., Miller) can control the tongue and decrease trauma to the gingiva and teeth. Further modification with a curve at the tip allows for the options of either direct elevation of the

Table 4–3 Laryngoscope Blades and Sizes

Laryngoscope Blade	Patient Age	Patient Length (Broselow-Luten Tape Color)
Miller 0	Newborns up to 2.5 kg	NA
Miller 1	0–3 mo	60.75–85 cm (pink, red, purple)
Wis-Hipple 1.5 Miller 2	3 mo–3 yr >3 yr	85–132.5 cm (yellow, white, blue, orange)
Miller 3	Large adolescents	137.5–155 cm (green)

epiglottis via the blade or blade insertion into the vallecula (e.g., modified Miller, Phillips) in older infants.⁸ Appropriate sizes of blades for children of different ages, according to both age and Broselow-Luten sizing, are shown in Table 4–3.

When properly inserted, the tip of a straight laryngoscope blade rests underneath the tip of the epiglottis, and, when upward force is applied, the blade physically lifts the epiglottis out of the way to expose the glottic opening, as depicted in Figure 4–3A. The curved blade can be used in exactly the same manner, but usually the blade is positioned such that the tip lies in the vallecula, anterior to the epiglottis, and upward traction pulls the epiglottis up and exposes the glottic opening, as shown in Figure 4–3B.

Endotracheal Tubes

The two most commonly applied rules of thumb for sizing of endotracheal tubes (ETTs) are the age-based rule and selection based on body length (the Broselow-Luten tape). The age-based rule is

$$[\text{Age in years}/4] + 4 = \text{ETT size}$$

The Broselow-Luten tape selects the size of ETT based on the length of the patient. Both age- and length-based rules have been shown to be accurate in the majority of patients, and both can be used depending on operator preference. Some data have shown that the age-based rule tends to overestimate ETT size, whereas the Broselow tape tends to underestimate it.^{9–12} Application of age-based sizing criteria to children younger than 2 years of age is less accurate; recommendations for ETT sizing in this age range are detailed in Chapter 2 (Respiratory Distress and Respiratory Failure).

Another unvalidated “rule” that is often applied to children is that the diameter of a child’s airway is approximately the same diameter as the child’s fifth digit, and that an ETT with an outer diameter of that same size is an accurate choice of size. This simple guideline has unfortunately not stood up to validation testing, and cannot be recommended. It may be that the width of the *nail* of the fifth digit is a more accurate predictor of ETT size than the diameter of the finger itself.^{11,13}

As mentioned earlier, the narrowest point in the airway of the young child occurs at the level of the cricoid cartilage, below the insertion of the vocal cords. In these patients, uncuffed endotracheal tubes are often the most appropriate

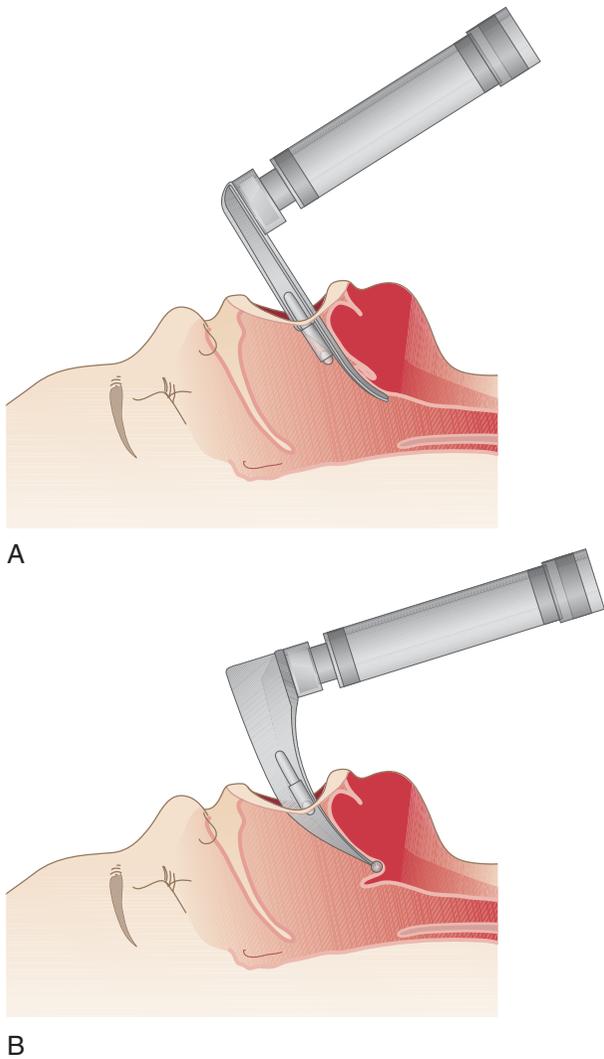

FIGURE 4-3. **A**, Correct position and exposure of glottic opening with a straight laryngoscope blade. **B**, Correct position and exposure of glottic opening with a curved laryngoscope blade.

tubes to achieve easy passage through the upper airway and the ability to ventilate effectively without excessive air leak. The conformation of the airway approximates that of an adult by about age 8 years; children beyond that age most often require cuffed endotracheal tubes to achieve a good fit in the trachea. Multiple studies have shown that cuffed ETTs can be safely used in small children, and that the likelihood of postextubation stridor is not significantly increased by their use; additionally, anesthesia studies have shown decreased need for gas flow with cuffed ETT use, suggesting a better fit to the tracheal lumen with cuffed than uncuffed ETTs.^{14,15} Current recommendations state that “cuffed endotracheal tubes . . . may be appropriate under circumstances in which high inspiratory pressure is expected.”¹⁶

Airway Adjuncts (Oral Airways, Nasopharyngeal Airways)

Oropharyngeal (OP) and nasopharyngeal (NP) airways can be used to maintain airway patency, particularly during

BVM ventilation, but provide no airway protection. In general, a patient who requires a device to maintain airway patency may also require intubation for airway protection. Both devices exist in a range of sizes suitable for all pediatric ages. The correct size of an OP airway for a patient can be estimated by the distance from the patient’s central incisors to the angle of the mandible; for NP airways, the correct size is estimated by the distance from the naris to the earlobe. OP airways, when properly positioned, tend to rest against the base of the tongue and, in conscious patients, can induce gagging and vomiting so they should be used only in the unconscious patient. An OP airway should always be used when an unconscious patient is undergoing bag-mask ventilation.

Alternative Airway Techniques¹⁷

A number of devices and techniques have been used successfully in the operating room for ventilation during general anesthesia, and have also been used for both primary and rescue airway management in emergency patients. Some are specific devices that are placed into the airway, and these can be thought of as supraglottic (e.g., laryngeal mask airway [LMA]), infraglottic (e.g., Combitube), or surgical (e.g., percutaneous transtracheal jet ventilation, cricothyrotomy), to distinguish them from the glottic placement of an endotracheal tube. Other devices assist in the placement of an ETT by improving visualization of the glottic aperture, and include fiberoptic (both flexible and rigid) and video devices. LMAs (see discussion of use later) are available in multiple sizes and from multiple manufacturers to accommodate patients from newborn through adulthood. The Combitube (see discussion of use later) is available in sizes appropriate for patients of at least 48 inches in height. Newer supraglottic devices such as the cuffed oropharyngeal airway (COPA), the laryngeal tube (King LT), and the pharyngeal-tracheal lumen (PTL), exist in sizes appropriate for use in larger patients.

Monitoring

A patient undergoing emergency ETI is potentially critically ill, and should have single-lead electrocardiography, oximetry, and blood pressure monitoring. Many operators find it helpful to have the tone of the oximeter made audible so that a change in heart rate (cadence) or saturation (pitch of tone) can be appreciated without viewing the readout. Bradycardia during laryngoscopy is usually caused by vagal influence, but hypoxemia must always be excluded by oximetry. Monitoring should continue from the preparatory phases through the intubation and throughout the period of postintubation care.

Detection of exhaled carbon dioxide is the standard of care for confirmation of tracheal placement of an ETT, and should be performed in every case. This can be done using a colorimetric device, or by continuous capnography. Capnography can be useful in circumstances in which noninvasive continuous monitoring of alveolar ventilation is desirable (e.g., status asthmaticus, traumatic brain injury).

In cases of prolonged cardiac arrest, when CO₂ exchange has ceased, end-tidal CO₂ (ETCO₂) detection can be falsely negative, indicating esophageal placement when the tube is in the trachea. In cardiac arrest resuscitation, if ETCO₂ is detected and the tube is inserted to the proper depth, tracheal

placement is assured. When ETCO_2 detection is negative during circulatory arrest, alternate means of tube placement confirmation are required.

Techniques

Orotracheal Intubation

Airway Positioning

ANATOMIC ASPECTS

Numerous anatomic features unique to children must be recognized with regard to airway positioning. Elevation of the occiput with respect to the shoulders, commonly employed in adults and adolescents, may worsen the view of the glottic opening in infants and toddlers. The infant or toddler should be supine on a flat surface with the head in a neutral position or with a small degree of extension at the neck. Excessive flexion or extension can result in airway obstruction in small children.

CERVICAL SPINE PRECAUTIONS

When necessary, cervical spine immobilization requires the presence of an assistant maintaining the head in a neutral position. This can be performed by kneeling or standing at the intubator's side and holding the child's head from above the patient, or by standing at one side of the patient and reaching from below to hold the sides of the head. The purpose of the immobilization is to both prevent and detect any movement that might be occurring during that intubation that is changing the relationship between the head, neck, and torso. During intubation, the front of the cervical collar is opened to prevent restriction of jaw opening produced by the collar.

JAW THRUST AND CHIN LIFT

Maintaining a patent airway in the supine patient involves displacing the mandibular block of tissue (jaw, floor of mouth, and tongue) anteriorly away from the posterior oropharynx. This can be accomplished by one or a combination of numerous techniques. Most commonly applied are the jaw thrust, in which the operator applies upward pressure behind the angle of the mandible on one or both sides of the patient, and the chin lift, in which the apex of the mandible is grasped and lifted upward. These techniques can be applied with one or two hands and with or without a mask in place. Difficulty maintaining airway patency with these techniques may be indicative of the need for an airway adjunct, or (worst case) a surgical approach to the airway.

Preoxygenation

As discussed previously, the time to desaturation of healthy, fully preoxygenated children is on the order of 2 to 3 minutes. Critically ill children have a shorter desaturation time. Preoxygenation is essential for children undergoing ETI, unless it is not possible. Despite adequate preoxygenation, a critically ill child can desaturate very quickly after apnea is induced, and continuous oximetry is essential. Critically ill children may require assisted ventilation during their apneic period to maintain arterial saturation, which makes good BVM technique as well as properly applied cricoid pressure (see next) of paramount importance.^{5,6,18,19}

Cricoid Pressure/Laryngeal Manipulation

The technique of cricoid pressure was initially described by Sellick in 1961 as a technique to prevent aspiration of regurgitated gastric contents during anesthesia induction and intubation.²⁰ Sellick's maneuver also prevents insufflation of air into the stomach with positive pressure ventilation. The technique is performed by applying firm pressure on the cricoid ring, displacing it backward to occlude the posterior esophagus. Sellick's maneuver is applied as soon as the patient loses consciousness and is continued vigilantly until the endotracheal tube is placed, with the cuff inflated (if applicable) and position confirmed by ETCO_2 detection. The generally accepted standard in adults is to apply 10 pounds (4.5 kg, 44 N) of pressure continuously. Published reports have shown that cricoid pressure is often applied incorrectly or ineffectively, and cases of vocal cord and glottis distortion and even airway obstruction due to improperly performed cricoid pressure maneuvers have been reported.²¹⁻²³ Those performing the maneuver should be trained to do so.

Current literature has not specifically examined the use of cricoid pressure for RSI in the ill child. While it is logical to extrapolate that decreased pressure is required for children, no data exist as to the optimal pressure required to occlude the pediatric esophagus. The pressure typically applied by anesthesiologists has been shown to be less than for adults (5 to 5.5 pounds), but whether this pressure is clinically appropriate is unknown.²⁴ The theoretical rationale for the use of cricoid pressure in pediatric intubation is very strong. In addition to reducing the likelihood of gastric regurgitation with aspiration during intubation, Sellick's maneuver also minimizes entry of air into the stomach during bag-mask ventilation. It is very often necessary to support ill children with positive pressure ventilation during RSI, and the prevention of gastric insufflation with cricoid pressure can be of great importance to minimize gastric distention and risk of regurgitation of gastric contents.

Application of backward-upward-rightward pressure on the larynx—commonly referred to as “BURP”—optimizes the view of the glottic opening in cases of difficult laryngoscopy.²⁰ An assistant applies direct pressure on the thyroid cartilage, displacing it dorsally, rostrally, and to the patient's right. The BURP maneuver is superior to simple cricoid pressure in improving glottic visualization in difficult laryngoscopy cases.²⁵ External laryngeal manipulation is a technique wherein the intubator uses his/her right hand to maneuver the laryngeal structures while maintaining his/her own line of sight with the airway opening.²⁶ Once an optimal position is found, the intubator ensures that an assistant maintains that position of the larynx while the patient is intubated. This technique has been validated using videographic imaging in adults intubated by emergency medicine interns.²⁷

Neither of these techniques has been studied in children, but both could be logically extrapolated to the pediatric patient as long as gentle external forces are used, as the amount of pressure needed to occlude or distort the pediatric airway is likely much less than that needed for an adult.

Laryngoscopy (see Table 4-2, Fig. 4-1)

The laryngoscope is held in the intubator's left hand and the right hand is used to open the mouth. The blade is advanced into the oropharynx in such a way as to sweep the tongue to

the left side of the mouth and hold it there. Passing the blade to a midline position and gently down the esophagus will allow the intubator to visualize the glottis during gentle withdrawal of the blade. As the blade is withdrawn, the first structure that comes into view is the glottis, with the epiglottis held in an anterior position by the blade. Figure 4–3A and Figure 4–3B show the proper positioning of straight and curved laryngoscope blades. In the former case, the tip goes under the epiglottis, lifting it out of the way; in the latter, the tip rests in the vallecula and upward traction pulls the epiglottis up out of the line of sight. The curved blade can also be used to actively lift the epiglottis if necessary.¹⁶

Tube Insertion

The ETT is held by the right hand and inserted while line of sight to the glottic opening is maintained with the laryngoscope. It is important not to allow the tube to obstruct the intubator's view of the vocal cords. A common error that leads to obstruction of the line of sight during direct laryngoscopy is sliding the tube along the channel of the blade instead of at the right side of the mouth away from the blade. If a video laryngoscope is used (e.g., DCI Video MacIntosh, Karl Storz North America), the tube is placed by passing it along the channel of the blade and through the glottis under video visualization. In children with small mouths, an assistant can stretch the right corner of the mouth laterally to provide more space for the ETT. Midtracheal placement of the ETT tip is usually assured when the “double black line” (marked on the outside of an uncuffed ETT) is aligned with the vocal cords. Additionally, multiplying the inner diameter of the ETT by a factor of 3 gives the depth of insertion in centimeters (measured at the lip) that usually gives proper midtracheal positioning (this rule of thumb may incorrectly overestimate depth of placement in children younger than 2 years old).

Confirmation of Placement

ETCO₂ detection is the standard of care to confirm proper ETT placement. Several types of ETCO₂ detectors are commercially available. Most EDs use disposable colorimetric devices, which register exhaled CO₂ by a change in color of an indicator, but some use capnometry, which digitally displays the exact partial pressure of exhaled CO₂, or capnography, which provides a waveform.

Several studies have supported the specificity and sensitivity of confirmation of placement of ETTs using ETCO₂ in infants and children.^{28,29} In the patient in cardiopulmonary arrest, the absence of pulmonary blood flow may limit the amount of carbon dioxide in the alveoli, making ETCO₂ prone to false-negative results (the tube is in the trachea, but the test indicates the tube is in the esophagus), but this occurs in only a subset of patients. Persistent detection of CO₂, however, reliably indicates that the tube is in the airway.³⁰ Concomitant physical examination will address the possibility that the tube, while in the airway, has been inadvertently placed in the supraglottic larynx, or in a mainstem bronchus.

The imperfect specificity of ETCO₂ in the arrested patient occasionally will require use of alternative devices to confirm ETT placement. Air aspirators, or esophageal detection devices (EDD), are one common class of such devices. The principle behind the use of the EDD relies on the collapsibility of the esophagus compared to the cartilage-reinforced

trachea. EDDs attempt to aspirate air from the endotracheal tube by negative pressure (examples include a syringe-like device and a semirigid plastic bulb that reinflates when squeezed). If negative pressure is applied to a tube in the trachea, the reinforced trachea will resist collapse and the EDD will fill with air, confirming that the tube is in the trachea. Negative pressure applied to a tube in the esophagus, on the other hand, will collapse the esophagus around the end of the tube and result in slow or incomplete filling of the EDD with air.

EDDs have been shown to be accurate in older children.³¹ Some studies have shown their accuracy to be poor in children under 1 year of age and when used with uncuffed ETTs.^{32–34} At present, no recommendations exist for the routine use of EDDs in children, and these devices should be used only when there is uncertainty about tube position after use of ETCO₂ detection.

There is no method of confirming proper placement of an ETT that is 100% reliable. A combination of the techniques described here and clinical examination will provide the correct information in the vast majority of cases. Physical examination should not be used to overrule a “negative” ETCO₂ detection (tube in esophagus) unless the patient is in cardiac arrest and clinical evidence strongly supports tracheal placement.

Securing the ETT

Securing an ETT is most often accomplished by one of two methods. Strips of adhesive tape can be torn longitudinally to allow half of each piece to attach to the patient's face and the other to the shaft of the ETT. Alternatively, a number of prefabricated tube devices are commercially available. In the conscious or responsive patient, it may be necessary to place an adjunctive device between the incisors (a “bite block”) to prevent the patient from biting against the tube and occluding it. Oropharyngeal airways may be used for this purpose, along with rolls of gauze or other prefabricated devices.

Alternative Intubation Techniques

Blind Nasotracheal Intubation

Blind nasotracheal intubation (BNTI) has little role in the modern ED, particularly in children, in whom it is more difficult than in adults because of the wider discrepancy between the pharyngeal and laryngeal axes, as well as the presence of large adenoidal tissue. BNTI is reserved for those cases in which oral intubation is deemed to be unlikely to succeed and alternative techniques, including fiberoptic intubation, are not available. The patient must be cooperative and spontaneously breathing to allow appreciation of breath sounds through the ETT as the tip is blindly inserted through one naris and advanced to just above the glottic opening. Pediatric experience with this technique is extremely limited. The anterosuperior location of the glottic opening with respect to the nasopharynx in infants and young children make the blind placement of a tube through a naris and into the trachea extremely difficult. Therefore, this technique is not recommended in children less than 10 years old.

Lighted Stylet

The lighted stylet relies on the characteristic appearance of light transilluminating the larynx through the anterior neck.

The ETT is threaded over the light wand, which is bent almost to a right angle to direct the lighted tip anteriorly toward the glottic opening. The wand-tube combination is then advanced blindly over the tongue and directed anteriorly toward the vocal cords. When the visible illumination goes from a diffuse circle of light to a more focused and clearly delineated outline of the glottic opening (sometimes called “coning”), the tube is advanced off the device into the trachea. Both reusable and disposable light wand devices exist that can accommodate ETTs down to infant and pediatric sizes. Literature on the emergent use of this technique is limited.

Fiberoptic Intubation

Equipment for fiberoptic laryngoscopy exists in sizes small enough that fiberoptic techniques can be employed in any age of patient. Fiberoptic intubation requires training and experience, and can be acquired as a skill through training courses or in a simulation laboratory. It is uncommonly used in children, but offers the added advantage of a detailed airway examination that may avert intubation altogether (e.g., in smoke inhalation).

Digital Intubation

This technique, which also has little role in modern airway management, is performed by advancing the index finger of one hand into the patient’s mouth and palpating the tip of the epiglottis. The intubator then pushes the epiglottis anteriorly with that fingertip while sliding an ETT along the side of the finger with the opposite hand. There is very little human, and even less pediatric, experience with this method.

Retrograde Intubation

This technique is rarely used in the ED in pediatric or adult patients, and involves percutaneously inserting a needle through the cricothyroid membrane and inserting a guide-wire cephalad through the needle lumen until it can be pulled through the patient’s open mouth. An ETT is then threaded over the wire and advanced into the trachea. There is virtually no experience or study related to the use of this approach in the pediatric age group.

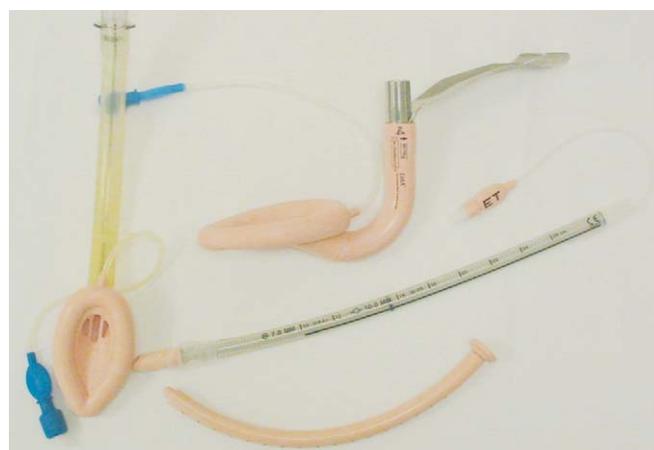

Rescue Devices

Rescue devices are those that are used when intubation has failed or the operator judges that further attempts at orotracheal intubation are likely to be futile.

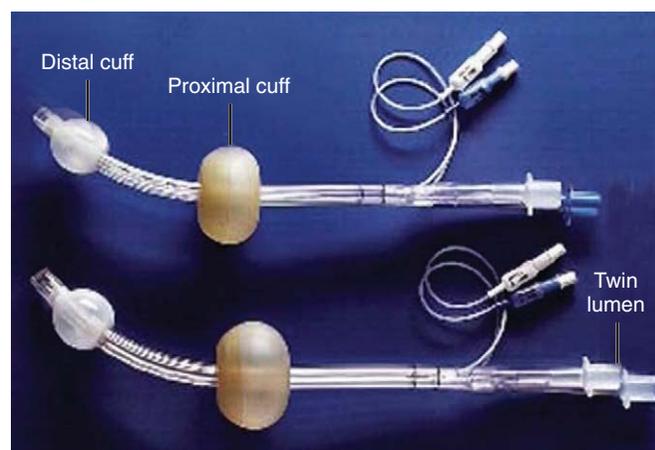

Laryngeal Mask Airway

The LMA consists of a teardrop-shaped inflatable cuff surrounding a fenestrated latex window that faces the glottic opening when properly positioned (Fig. 4–4A). The device is inserted into the open mouth of the patient and advanced until resistance is felt, at which point the cuff is inflated. Studies of the use of the LMA by various classes of personnel have shown that it is easy to place and rarely associated with significant complications.^{35,36} LMAs are made in a range of sizes that are appropriate for all ages from neonate to adult. A summary of appropriate sizes and cuff volumes for LMAs is given in Table 4–4.

The LMA does not result in the placement of a cuffed ETT in the trachea, so it is generally believed that the device does not protect against aspiration. It appears that aspiration

A

FIGURE 4–4. Rescue devices. **A**, LMA classic (left) and the Fastrach intubating LMA. The former is available in sizes from neonate to large adult. The intubating LMA should only be used in patients over 30 kg. **B**, The Combitube is available in two sizes, SA (small adult) on left, and standard on right. Patients must be over 48 inches tall if a Combitube is to be used.

Table 4–4 Laryngeal Mask Airway Sizes

Size	Patient Weight	Amount of Air in Cuff (mL)
1	<5 kg	4
1½	5–10 kg	7
2	10–20 kg	10
2½	20–30 kg	14
3	Children >30 kg; small adult	20
4	Normal adult	30
5	Large adult	40

risk may approximate that when bag-mask ventilation is employed.³⁷ Data comparing LMA use to ETI and BVM ventilation are children is limited¹⁶; nonetheless, LMAs are widely used in operating room settings, EDs, and by some prehospital care communities.¹⁷ The patent for the original LMA has run out, and numerous products are now available, some claiming improvements over the original design.

Combitube

The Combitube consists of a dual-lumen tube with two inflatable cuffs. It is inserted blindly through the oropharynx and passes almost universally into the esophagus. Both cuffs are inflated, with a smaller cuff securing the distal end in either the esophagus or, rarely, the trachea (depending on where the device comes to lie) and a larger cuff filling the oropharynx so as to provide a seal. Ventilation is provided through sidestream ports in the tube, positioned just above the glottis. If the tube is placed in the trachea, sidestream ventilation will be unsuccessful, and the alternative lumen is used, ventilating the trachea directly through the distal end of the tube. The Combitube has a high rate of successful placement by hospital and prehospital personnel in patient simulators and adults.^{38,39} Combitubes are made in two sizes, and only the “SA” (small adult) size is suitable for pediatric use (Fig. 4–4B). The Combitube is restricted to patients greater than 48 inches in height, (typical size and weight of a 10 year old). No sizes of Combitube currently exist for pediatric patients of younger age.⁴⁰ The PTL tube is a device similar to the Combitube, inserted via a blind technique and shown to be relatively easy to use.³⁹ The PTL is also unavailable in pediatric sizes. Both the PTL and Combitube are safe to use in adolescent patients.

Surgical and Transtracheal Airway Procedures

Emergency surgical airway management is rare, and particularly so in pediatrics. In the first phase of the multihospital NEAR study, only 1 of 156 emergency pediatric airways was managed by cricothyrotomy.¹ The small size of the cricothyroid membrane, incomplete development of the normal external laryngeal landmarks, excessive mobility of the airway, and lack of rigidity of the structures make surgical airways particularly challenging in small children. Although tracheostomy is possible in even very small neonates under highly controlled conditions, emergency airway management accesses the airway through the cricothyroid membrane. Cricothyrotomy can be performed using an open surgical technique, percutaneously using a Seldinger technique, or by using a cricothyrotome (an instrument designed to access the membrane and provide an airway, usually in one or two steps.) There is no evidence in support of using any of the cricothyrotomes, including those represented as being specially designed for the pediatric airway. In general, such devices should be avoided. For children greater than 10 years old, surgical cricothyrotomy can be performed, particularly in older children, whose airway dimensions approach those of adults. Under age 10 years, needle cricothyrotomy is preferable; this can be accomplished using an angiocatheter of reasonable size. Jet ventilation requires the use of a special apparatus that incorporates a regulator to control pressure to limit barotrauma, and can be provided through this catheter. In infants less than 1 year old, bag ventilation is performed through the catheter by incorporating the ETT adaptor from a 3-mm ETT. Use of the bag in the small child minimizes the risks of barotrauma.

There are no studies to clearly delineate the role of emergency transtracheal ventilation in pediatric patients, and the technique is rarely if ever used. It is relatively simple, however, and may be valuable in those small patients for whom a surgical airway is not feasible.

The Difficult Pediatric Airway

Difficulty in intubation in children can be due to chronic or acute conditions as discussed briefly earlier (see Table 4–2). A recent clinical review provides a detailed list of conditions that may predispose a child to a difficult intubation.² Anticipating that a child will be difficult to intubate is hard to do with any degree of specificity or sensitivity. Predictors shown to be useful in adults, such as Mallampati and Cormack and Lehane scoring, have not been shown to be specific in children for predicting difficulty in ETI. Some empiric observations such as inability to move the neck (rheumatic disease, Klippel-Feil syndrome, arthrogyrosis) or potential for morbidity from neck motion (trauma, Down syndrome), a small or distorted mandibular space (Pierre-Robin syndrome, Treacher-Collins syndrome), and tongue size are of predictive value for children in need of airway management.

The difficult pediatric airway is a very rare clinical phenomenon. This very fact also means that not even experienced emergency medicine practitioners frequently manage the difficult pediatric airway. The need for fiberoptic or surgical management of a pediatric airway is most commonly encountered in the operating room, and therefore it is those subspecialists that frequently manage children via these techniques (anesthesiologists, otorhinolaryngologists) that are most likely to have enough experience to intervene in a facile manner.

Two mnemonics often used for identifying difficult intubation in adults are presented here. The abnormalities identified by these rules of thumb are uncommon in children, but the general principles of signs of potential difficulty can be applied in a manner nonspecific to age. Thinking through these mnemonics may help the emergency medicine practitioner to identify children for whom paralysis (RSI) should be avoided or subspecialist assistance might be warranted.^{41,42} It must be noted that these mnemonics are derived from adult studies and have not been shown to be specific or sensitive in children. In general, when developing a system for identification of a potentially difficult intubation, sensitivity is much more important than specificity; that is, it is more valuable to identify every difficult airway at the expense of considering some to be difficult when they are not. The mnemonics are presented here as a representative framework for anticipating difficulty with a pediatric airway.

Lemon

- Look externally for signs of procedural difficulty (facial/oral characteristics, habitus, etc.) and potential difficulty with bag-mask ventilation (obesity, poor mask seal, airway obstruction, high ventilatory resistance [e.g., asthma])
- Evaluate the “3-3-2” rule (the interincisor gap of an open mouth should approximate three of the patient’s finger breadths; the distance from the mentum to the hyoid bone should also be three of the patient’s finger breadths; the distance from the thyroid notch to the floor of the mouth should be two of the patient’s finger breadths). While these measurements are not specifically validated in small children, they can serve as a guide to judge the accessibility of the upper airway for direct laryngoscopy.
- Mallampati score (Fig. 4–5)

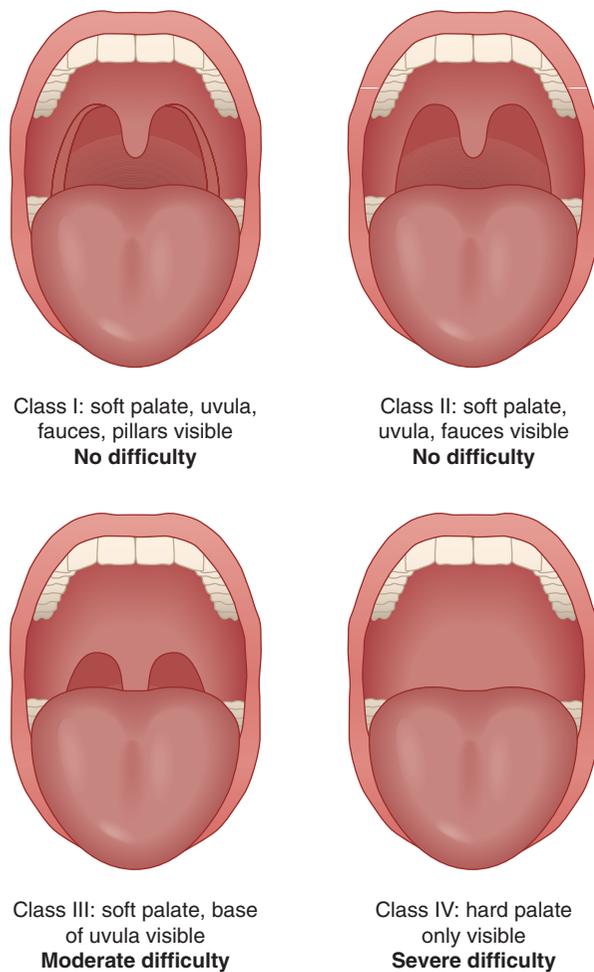

FIGURE 4-5. Mallampati scoring system for visualization of pharyngeal structures. Easy intubation is anticipated by a score of 1 or 2, some difficulty is expected with a score of 3, and great difficulty or impossible intubation is associated with a score of 4. (From Whitten CE: *Anyone can Intubate*, 4th ed. San Diego: Mooncat Publications, 2004.)

- Obstruction (any evidence/suspicion for airway obstruction)
- Neck mobility (i.e., reduction of neck mobility that limits the ability to put the neck in extended position for direct laryngoscopy)

The Four Ds

- Distortion of facial/neck/oral anatomy by disease process
- Disproportion of neck, mandible, submandibular space
- Dysmobility of jaw, neck
- Dentition—edentulous adults are difficult to maintain a sealed bag-valve mask on; this seldom is true for edentulous infants

Success Rates and Complications

Incidence of Complications

Estimates of the incidence of complications of ETI vary.⁴³⁻⁴⁵ The definition of “complication” related to ETI is inconsistent across studies, encompassing such phenomena as predictable changes in physiology, imperfect fit of selected

equipment, and adverse events attributable directly to the process of laryngoscopy and ETI placement. The NEAR registry has employed a strict definitional scheme to differentiate between “true” complications (resulting from the procedure itself) and “technical problems” (cuff leak, detected ETI, equipment failure, etc.) or “physiologic alteration” (changes in physiology during or after ETI that may or may not be attributable to the intubation).¹ This new nomenclature, while sensible, was not available at the time of publication of most other studies. Such phenomena as mainstem intubations, gastric distention, and failure to place a gastric tube for stomach decompression are cited as complications in other studies, resulting in misleading reports of complication rates that are higher than would have occurred had only true complications been included.

Failure of Procedure

Failure of laryngoscopy and ETI in children varies with the setting, patient age, and training and experience of the intubator. Prehospital studies of ETI in children have found success rates varying from 18% to 30% in infants and young children and 71% to 90% in older children and adolescents.^{46,47} ED-based studies of pediatric ETI show that success rates vary with age as well. Data from the NEAR study found that the first intubation attempt was successful in 60% of patients less than 5 years old, while success rates for older children ranged from 71% to 85%. In the same study, the first intubator was successful in 74% to 79% of children less than 5 years old and in 86% to 94% of children 6 to 18 years old.¹

A landmark study comparing BVM ventilation to ETI in the prehospital management of children in need of respiratory support demonstrated no benefit of ETI over BVM, although the paramedics studied rarely undertook pediatric intubation in the large, urban center studied. In that study, unrecognized esophageal intubation occurred in 15 children, and 14 of these children died.⁴⁸ Uniform use of ET_{CO}₂ detection is meant to reduce the occurrence of this event.

Trauma (Oral, Pharyngeal, Laryngeal)

Trauma to the oropharynx, teeth, lip, tongue, and larynx have been reported with ETI, but is uncommon and generally mild. The NEAR study identified direct trauma in only 1 of 156 intubation attempts; other studies of prehospital and ED pediatric intubations found a range of similarly infrequent incidences (0.5% to 4%).^{45,48,49} Young children have primary teeth, which are easily injured and avulsed and can pose an aspiration risk. Primary teeth overlie secondary tooth buds that can be damaged by forces exerted on primary teeth. Other pertinent anatomic features in children include the small mouth, large tongue, and prominent adenoidal tissue.

Respiratory Complications (Aspiration, Air Leak Syndrome/Pneumothorax)

The conversion from native negative pressure breathing to positive pressure ventilation via an ETT is associated with a significant increase in intrathoracic pressure, particularly in clinical situations in which lung or chest wall compliance is decreased. Complications from barotrauma, such as pneumothorax, interstitial emphysema, and subcutaneous air, can result from positive pressure ventilation. It is difficult to determine whether such phenomena, when observed, result

from the intubation or from the condition for which intubation was required.

Emesis and aspiration of gastric contents are uncommon but significant events that can occur before, during, or after ETI. The common use of BVM ventilation for preoxygenation and for maintenance of arterial oxygen saturation during RSI may put small children at a greater risk of these complications. The use of cricoid pressure to prevent both gastric insufflation and regurgitation is designed for the prevention of these complications.

Physiologic Complications

Vagally mediated bradycardia related to laryngoscopy in children is discussed earlier in this chapter and in Chapter 2 (Respiratory Distress and Respiratory Failure).

Cardiopulmonary interactions following the conversion from spontaneous negative pressure ventilation to positive pressure ventilation involve an increase in intrathoracic pressure resulting in a decrease in preload and possibly left ventricular afterload. The compliance of the chest wall in small children results in the need for greater changes in pressure to yield a given tidal volume, and so it can be extrapolated that the resultant preload changes may be more dramatic in young children. Left ventricular function in young children is affected more drastically by metabolic disturbances (hypoglycemia, acidosis, hypocalcemia), states that commonly accompany clinical situations in which ETI is necessary. Additionally, lower respiratory illnesses such as bronchiolitis and pneumonia, common indications for pediatric ETI, result in increased pulmonary vascular resistance, increased right ventricular diameter, and consequently (via ventricular interdependence) decreased left ventricular preload.⁵⁰ Anyone performing ETI on a critically ill child should be wary of the concurrent presence of any disease state resulting in decreased preload (hypovolemia, capillary leak, blood loss), as well as whether the metabolic milieu can be optimized prior to ETI.

Equipment-Related Complications

Children who undergo intubation with ETTs of the wrong size or type can experience difficulty with maintaining appropriate oxygenation and ventilation. The rules of thumb commonly used for selection of types and sizes of equipment related to ETI are imperfect and yield estimates that are incorrect in certain circumstances. Additionally, and probably more commonly, availability of or practitioner familiarity with appropriate equipment is suboptimal. ETTs of incorrect size have been shown to be frequently used by both ED physicians and prehospital care providers, although such equipment variances have not been correlated with adverse patient outcomes.^{45,49}

Postprocedural Care and Disposition

A chest radiograph should be obtained following all intubations to confirm that endobronchial intubation is not present, and that the tube is well positioned below the glottis. Placement of the tip of an ETT either too deep (right mainstem bronchus) or too shallow (high in the trachea near the glottis) can predispose the patient to complications such as tube dislodgement, obstruction, and barotrauma.

Table 4–5 Postintubation Sedation and Neuromuscular Blockade

Drug	t _{1/2} (hr)	Clearance (mL/kg/min)
Sedatives and Analgesics		
Midazolam	1.7–2.6	6.4–11
Lorazepam	11–22	0.8–1.8
Diazepam	20–50	0.2–0.5
Fentanyl	1.7–2.6	6.4–11
Morphine	2–4	10–40
Meperidine	2–5	10–20
Drug	Duration of Blockade (min)	
Neuromuscular Blocking Agents		
Rocuronium	20–30 (dose dependent)	
Vecuronium	30–60	
Pancuronium	40–75	

Monitoring of pulse oximetry, heart rate, and blood pressure should be maintained until the patient is transferred from the ED or resuscitation efforts are terminated. When possible, continuous monitoring of ET_{CO}₂ is a useful adjunct, both for complications related to the ETT and ventilation system and for underlying disease processes.

Issues Related to Transport

Transport of the intubated child is a difficult task requiring expertise with airway management and the use of sedation and neuromuscular blockade in children. Sedatives, analgesics, and neuromuscular blocking agents are routinely employed in transport of the critically ill child. Some characteristics of commonly employed agents for these purposes are shown in Table 4–5; which agent is appropriate will depend on the individual child's situation.

Monitoring in transport can be more difficult due to the inability to auscultate heart and breath sounds, as well as the presence of movement artifacts in electrocardiography leads. Continuous monitoring of pulse oximetry, heart rate, blood pressure, and neurologic status are essential to safely transporting such patients. Bhende and colleagues examined the use of colorimetric ET_{CO}₂ detection for evaluating placement of ETTs in 58 intubated children while in transport; in all cases in which tube position was checked while en route, the location of the tube was correctly identified.²⁸ Transport teams caring for intubated children must be able to at least intermittently (if not continuously) monitor the presence of ET_{CO}₂ as evidence of correct placement of the ETT.

Chapter 5

Monitoring in Critically Ill Children

Jonathan Marr, MD and Thomas J. Abramo, MD

Key Points

Cyanosis is not an early or reliable indicator of hypoxemia in anemic children.

Pulse oximetry is accurate when saturations are greater than 70%.

Capnographic end-tidal CO₂ is the most reliable method for confirming endotracheal tube placement.

Oscillometric blood pressure measurements are accurate in pediatric patients.

Introduction

Improved EMS systems and the development of transport medicine have increased the need for real-time information. Caring for the ill or injured child can be difficult since invasive blood draws (e.g., arterial blood gas) are not always easy to obtain and may not be tolerated if performed multiple times. Thus a noninvasive means of patient monitoring is a promising area of emergency pediatrics. Physicians must be aware of how new devices impact their clinical decision making and of the limitations of the information these devices provide.

Noninvasive monitoring of critically ill children in the emergency department (ED) includes pulse oximetry, capnography, cardiac telemetry, and oscillometric blood pressure measurement. In the ED, invasive monitoring is usually limited to blood gases and occasionally continuous indwelling arterial pressure monitoring. Central venous pressure and mixed venous oxygen monitoring may become more common in the future.

Recognition and Approach

Identification of the seriously ill and injured child in the ED requires rapid cardiopulmonary assessment and has become

the foundation of pediatric advanced life support. Goals are to assess for respiratory failure, shock, and the impact on end-organ function. An orderly approach that assesses the triad of respiratory effort, perfusion, and mental status will allow for early identification of critically ill children (see Chapter 2, Respiratory Distress and Respiratory Failure; Chapter 8, Circulatory Emergencies: Shock; and Chapter 9, Cerebral Resuscitation). Addition of noninvasive and invasive monitoring techniques will allow for early recognition of patient deterioration and rapid determination of response to therapy.

Evaluation and Management

Noninvasive Monitoring

Pulse Oximetry

Pulse oximetry has become an essential tool in the ED and is often referred to as the fifth vital sign. Furthermore, continuous evaluation of arterial oxygen saturation remains an important monitoring technique during stabilization and transport since providers cannot reliably detect hypoxemia by clinical examination alone.¹ Historically, the pulse oximeter has been utilized in research since 1935. The principle of pulse oximetry is based on the Beer-Lambert law, which states that the concentration of an absorbing substance in solution can be determined from the intensity of light transmitted through that solution.² Simply stated, arterial oxygen saturation is based on the differential absorption of red and infrared photons by oxyhemoglobin and deoxyhemoglobin measured by the pulse oximeter.

Two light-emitting diodes (LEDs) in the pulse oximeter probe each emit light of specific wavelength from one side of the oximeter that passes through locations such as the digits or earlobe, with cutaneous *pulsatile* blood flow. Other possible monitoring sites include the nares, the cheek at the corner of the mouth, and the tongue.³ A photodiode detector at the far side of the oximeter measures the intensity of transmitted light at each wavelength. Oxygen saturation is derived from calibration curves that associate the absorbance ratios to arterial oxygen saturation.

Initial calibration curves were derived from Beer-Lambert calculations, but more accurate calibration curves have come

Table 5–1 Sources of Errors in Pulse Oximetry

Light interference	Venous pulsations
• Ambient light	• Obstructed venous return
• Penumbra effect	• Severe right heart failure
Optical shunting	• Tricuspid regurgitation
• Probe malposition	• Dependent limb
• Oversized probe	• Tourniquet constriction
Motion artifact	• High positive pressure ventilation
Low signal-to-noise ratio	
• Shock	
• Cardiac arrest	
Dyshemoglobinemias	
• Carboxyhemoglobin	
• Methemoglobin	
• Sickle cell anemia (crisis)	
Dyes	
Other	
• Anemia	
• Blue or black nail polish	

from experimentally derived data. These curves are based on measurements in healthy young volunteers after induction of hypoxemia with coincident determination of oxygen saturation by both pulse oximeter and in vitro laboratory co-oximeter.² Due to limitations in the degree of hypoxemia induced in volunteers, levels below 75% to 80% are extrapolated and thus subject to significant bias as oxygen saturation decreases. In general, pulse oximeters are accurate to within $\pm 3\%$ at arterial saturations greater than 70%.^{4,5}

Pulse oximetry error can come from a variety of sources (Table 5–1). The most common cause of an erroneous reading is related to false signals caused by the detection of nontransmitted light. Ambient light is a major source of interference, and sources include fluorescent lighting, surgical lamps, infrared heating lamps, fiberoptic instruments, and sunlight.^{6,7} Optical shunting occurs when light reaches the photodetector without passing through an arterial bed, and takes place when probes are malpositioned or oversized. This is also called the *penumbra effect*,⁸ and yields a calculated saturation in the low 80s despite normal saturations. In hypoxic patients, however, the penumbra effect from ambient light and optical shunt will lead to *overestimation* of their oxygen saturation.⁹

Movement creates high-amplitude signals that are mistaken for arterial pulsations and cause erroneous calculations in saturation values. The net effect of motion artifact is to factitiously lower pulse oximeter saturation. Internal algorithms in newer generation oximeters have attempted to attenuate errors due to motion artifact. Similarly, states of venous pulsation causing congestion also cause false signals that artificially lower oxygen saturation readings.¹⁰ These states include obstructed venous return, severe right heart failure, tricuspid regurgitation, measurements in a dependent limb, constrictive tourniquets, and high positive pressure ventilation.

States of absent or low-amplitude pulses create a low signal-to-noise ratio, causing the pulse oximeter to “search” for a saturation reading. This will occur in the seriously ill patient, in whom such information is essential. Fortunately, in most instances the failure to detect signal is more often due to local vasoconstriction rather than systemic hypotension. Earlobe probes have been suggested to produce better

signals compared to digit probes.¹¹ Their use is supported by evidence that the earlobe is less vasoactive than the nail bed and thus less susceptible to vasoconstrictive effects.¹²

Carboxyhemoglobin and methemoglobin are *dyshemoglobinemias* not capable of carrying oxygen and thus affect oxygen-carrying capacity. Hemoglobin exists in varying states: bound to oxygen (oxyhemoglobin or O₂Hb), unbound to oxygen (reduced hemoglobin or Hb), bound to carbon monoxide (carboxyhemoglobin or COHb), and altered to a ferric state (methemoglobin or MetHb). Dyshemoglobinemias absorb light used by the pulse oximeter and will produce false absorptions attributed to O₂Hb and Hb. High levels of COHb will cause pulse oximeter saturations to be overestimated.^{13–15} Methemoglobin, formed as iron is oxidized to the ferric state, occurs congenitally or from exposure to anesthetics, sulfa drugs, or nitrites.² Increasing levels of MetHb lead to concomitant decreases in pulse oximetry saturations to a plateau of 82% to 85%.^{16,17}

Intravenous dyes are known to cause falsely low measured oxygen saturations by pulse oximeter. Methylene blue has been documented to cause profound decrease in measured oxygen saturations with pulse oximetry.¹⁸ Indocyanine green is used in angiography of the retina, and indigo carmine to evaluate for dysplasia in ulcerative colitis. These dyes can cause falsely low pulse oximeter readings that occur 35 to 40 seconds after dye administration.¹⁸

Pulse oximetry readings have reportedly underestimated the degree of hypoxemia in severe anemia,¹⁹ but one study found pulse oximetry to be accurate down to a Hb level of 2.3 g/dl in nonhypoxic adult patients.²⁰ Skin pigmentation has had variable effects on pulse oximetry and likely has negligible effects on accuracy. Nail polish, specifically black or blue colors, demonstrated the most interference with pulse oximeter readings, lowering oximetry values by 6% in one study.^{2,16} Solutions to this problem include removing the nail polish or placing the probe sideways to remove the nail from the transmission path.

In the ED, pulse oximetry serves to detect arterial hypoxemia from respiratory, cardiac, infectious, and metabolic etiologies while facilitating timely intervention before a patient deteriorates. Furthermore, pulse oximetry is used to monitor patients who are sedated for imaging or who undergo procedural sedation and analgesia for painful procedures. The Joint Commission on Accreditation of Healthcare Organizations has recognized the need for noninvasive monitors to improve patient safety.

Current-generation pulse oximeters have improved algorithms that improve accuracy with patient movement while continuing to use *transmitted* light to determine saturations. Other advances include recent Food and Drug Administration approval of a new method for continuous, noninvasive measurement of carbon monoxide in blood (<http://masimo.com/Rainbow/rb-overview.htm>). *Reflectance* oximeters provide innovative technology that detects “backscatter” of light from LEDs and estimates arterial oxygen saturations. Testing of reflection oximetry of retinal blood to measure cerebral oxygenation and perfusion has been in development for the last decade.²¹ Unfortunately, reflectance oximeters lack accuracy and have increased susceptibility to noise, and have remained inappropriate for current clinical practice. Near-infrared technology is a noninvasive and relatively low-cost optical technique that is used to measure tissue O₂ saturation,

Color	Percent CO ₂	Memory Aid
Purple	<0.5%	Purple = Problem

*Normal expired end-tidal CO₂ is 5%.

changes in hemoglobin volume, and, indirectly, brain/muscle blood flow and muscle O₂ consumption.²² Currently, this technology remains in development with ongoing research.^{23,24}

Capnography/End-Tidal CO₂

While pulse oximeters measure oxygenation, the other functional component of the respiratory system that can be non-invasively measured is ventilation, or elimination of CO₂. Diseases that cause respiratory distress or failure interfere with exchange of oxygen and carbon dioxide via ventilation/perfusion mismatch, loss of lung compliance, increased airway resistance, or impairment of respiratory drive.

End-tidal CO₂ (ETCO₂) monitoring is a noninvasive means for following levels of CO₂ in the exhaled breath.²⁵ Carbon dioxide can be measured qualitatively by colorimetric CO₂ detectors or quantitatively by infrared capnometers.^{26,27} Since CO₂ is the by-product of cellular metabolism and is transported by the circulatory system to be eliminated via exhalation, measurement by capnometry provides an indirect measure of systemic metabolism, cardiac output, and ventilation.^{28,29}

Either colorimetric detector or infrared spectroscopy achieves confirmation of CO₂ in the ED. Colorimetric devices have a pH-sensitive paper that produces a reversible color scale based on the concentration of CO₂ (Table 5-2).³⁰ Accuracy is affected by humidity, secretions, or contamination with gastric contents or acidic drugs, but is safe in brief use in infants and children greater than 1 kg.²⁶ Colorimetric detectors are semiquantitative and cannot detect hypo- or hypercarbia, right mainstem bronchus intubation, or oropharyngeal intubation in a spontaneously breathing patient.²⁶ False-negative results occur during cardiac arrest, severe airway obstruction, pulmonary edema, and severely hypocarbic infants. Despite these limitations, colorimetric detectors have shown prognostic value in pediatric cardiopulmonary resuscitation (CPR), while a capnometric or capnographic rise in ETCO₂ to greater than 15 mm Hg precedes return of spontaneous circulation in adults.³¹

Carbon dioxide molecules absorb infrared radiation at a specific wavelength; thus, when filtered infrared light passes through a CO₂-containing sample and is compared with a known standard, the concentration of ETCO₂ is obtained.^{26,27} A capnogram is a graphic display of the CO₂ waveform over time (Fig. 5-1).

ETCO₂ measurement has been found to be the most reliable method of confirming endotracheal tube position and can distinguish between endotracheal and esophageal intubation.^{26,29,32,33} Furthermore, continuous ETCO₂ monitoring can detect airway obstruction and inadvertent extubation more rapidly than pulse oximetry.³⁴ Thus, the American Heart Association guidelines require secondary confirma-

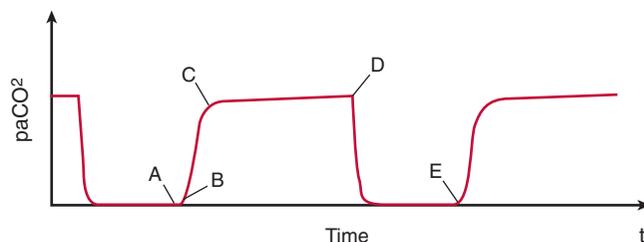

FIGURE 5-1. Capnogram showing the typical curves and loops seen in mechanical ventilation.⁸⁷ Point A, end of inhalation; point B, beginning of expiration; segment B–C, appearance of CO₂; segment C–D, flow in uniformly ventilated alveoli with near-constant CO₂; point D, end-tidal CO₂; segment D–E, inspiratory phase. Abnormal shapes can provide clues to clinical findings. A rising segment C–D with no plateau is suggestive of prolonged expiration and differential emptying of alveoli, as noted with asthma or partially obstructed endotracheal tubes (ETTs). Sudden decrease in CO₂ with no waveform suggests dislodged ETT, esophageal intubation, obstructed ETT, or ventilator disconnection.

tion of proper tube placement in all patients with a perfusing rhythm by capnography or exhaled CO₂ detection immediately following intubation and during transport.³⁵

Although an exponential decrease in ETCO₂ occurs in cardiac arrest or severe sudden hypotension, it remains a valuable clinical tool during CPR. During effective CPR, ETCO₂ has been shown to correlate with cardiac output,³⁶ efficacy of cardiac compression, return of spontaneous circulation (ROSC), and survival.³⁷ ETCO₂ greater than 10 mm Hg during the first 20 minutes was shown to be associated with ROSC,³⁸ whereas a value less than 10 mm Hg at 20 minutes predicted death.³⁹ Following ROSC, ETCO₂ values return to normal.^{40,41}

Recently, continuous ETCO₂ monitoring in *nonintubated* pediatric patients has been shown to be useful for monitoring respirations during seizures^{42,43} and sedation and monitoring acid-base status in diabetic ketoacidosis.⁴⁴ Other studies have shown that ETCO₂ correlates with arterial partial pressure of CO₂ (Pco₂) measurements.⁴⁵⁻⁴⁷

Blood Pressure Oscillometry

Oscillometry is based on the principle that the artery wall oscillates when blood flows through an artery during cuff deflation.⁴⁸ The rapid increase in oscillation amplitude estimates *systolic* pressure, while the sudden decrease in oscillation approximates *diastolic* pressure; the period of maximal oscillation is used to estimate *mean* intra-arterial blood pressure.⁴⁹ The estimation of systolic and diastolic values is determined indirectly from an empirically derived manufacturer-specific algorithm.⁵⁰ Noninvasive oscillometric (automated) blood pressure measurements are as accurate as auscultatory measurements, with less interobserver variability in children.⁵¹

Oscillometry-derived blood pressures have limitations. Large differences in estimated pressure readings between various manufacturers' devices are thought to be secondary to proprietary algorithms that provide blood pressure estimates. However, systolic blood pressure can average as much as 10 mm Hg above that obtained by auscultation, while diastolic blood pressure measurements are 5 mm Hg higher in children.¹² For this reason, standard blood pressure tables that define normal values for children may not apply to blood

pressure measurements obtained by oscillometric methods.⁵² Others note poor correlation with diastolic blood pressures. In addition, the devices do not perform well in the presence of limb movement or dysrhythmias.⁵³ Finally, mean arterial pressures may be significantly underestimated in patients with widened pulse pressures.⁵⁴

Ultrasonic Doppler devices for blood pressure measurement have recently been developed, but have not become established in clinical practice. The probe is placed over an extremity artery while a proximal cuff is slowly deflated; systolic pressure is estimated with appearance of the first Doppler signal, and diastolic pressure is read when the strength and quality of the signal decrease.⁵⁵ This technique may be helpful for intermittent blood pressure measurements when the oscillometric device is not able to provide pressure readings and an arterial line is not available.

Another method to estimate systolic blood pressure includes the *needle-bounce technique*, which is used by anesthesiologists and flight nurses/physicians and obviates the need to auscultate Korotkoff sounds.⁵⁵ Using a sphygmomanometer, the inflated cuff is slowly deflated and the first visible bounce of the needle correlates with systolic blood pressure. Pulse oximetry can estimate systolic blood pressure by the reappearance of waveforms during deflation⁵⁶ or by the disappearance of waveform during inflation.⁵⁷ Inflation and deflation, however, must be performed slowly (2 to 3 mm Hg/sec) in order for this technique to be accurate.²

A continuous partial radial artery compression device has been developed utilizing an oscillometric technique to indirectly measure blood pressure. Continual variable pressure is placed over the radial artery, and pulse pressure waveforms are measured and recorded in real time. This information is processed through a proprietary algorithm generating systolic, diastolic, and mean pressures. A recent study demonstrated that this device performed as well as oscillometric assessment and arterial line pressures.⁵⁸ Pediatric studies are currently ongoing.

Continuous ECG Monitoring

Continuous electrocardiographic (ECG) monitoring is required in all patients at risk for cardiac, pulmonary, or neurologic deterioration in the ED. All systems use electrodes that transmit potentials from the heart through the tissues. The ECG signal is then amplified, filtered, and displayed on an oscilloscope. Three- and five-lead systems are available. Lead II can be used to detect most arrhythmias, while the CM5 configuration (right arm electrode at the manubrium, left arm at the V₅ position, and final lead at the left shoulder) detects most left ventricular ischemic events.

Electrical interference and artifacts can occur from several sources (any electrical device powered by alternating current, shivering, movement). Placement of electrodes over bony prominences reduces some of the artifacts. High skin impedance is another common cause of poor signals. Removing skin oils with alcohol diminishes this interference.

Tissue Perfusion Monitoring

The assessment of perfusion status in critically ill patients traditionally has been obtained by global indices such as blood pressure, heart rate, urine output, and mental status. These indices, however, are delayed in exhibiting *early* signs of severe perfusion defects.⁵⁹ Early detection of tissue hypo-

perfusion by regional monitoring is based on the concept that blood flow is the primary determinant of tissue carbon dioxide.⁶⁰ Gastric tonometry indirectly assesses the splanchnic circulation, which receives up to 25% of cardiac output and contains 20% to 25% of the systemic blood volume.⁶¹ During low-flow states (i.e., shock), large areas become hypoperfused, increasing anaerobic metabolism, lactate, and CO₂ production.⁶² Tonometry measures the partial pressure of CO₂ that freely diffuses across gastric mucosa, providing early and accurate information about tissue perfusion.⁶³ Pediatric studies, however, are limited and gastric tonometry has not been widely implemented in younger age groups due to technical and artifact problems.

Sublingual capnometry has emerged as an alternative to monitoring tissue perfusion. The carbon dioxide-sensing optode (optical sensor) forms carbonic acid upon exposure to carbon dioxide. The pH change causes a shift in the fluorescence of the indicator and is converted to a carbon dioxide concentration. Multiple studies have suggested that sublingual capnometry is predictive of severity of shock⁶⁴ and outcome.⁶⁵ These studies are small and primarily reflect adult findings. Nonetheless, sublingual capnometry has emerged as a promising technique of noninvasive monitoring of perfusion and hemodynamic disturbances.

Invasive Testing/Monitoring

Critical Lab Monitoring

Arterial blood gas (ABG) analysis is the most commonly used tool for monitoring the effectiveness of oxygenation, ventilation, quantification of acid-base status, and response to therapy. Measured variables are partial pressures of oxygen (Po₂) and carbon dioxide (Pco₂) and hydrogen ion concentration (pH), while other values, such as concentration of total hemoglobin (tHb), O₂Hb saturation, saturations of the dyshemoglobins (COHb and MetHb), plasma bicarbonate, and base excess/deficit, are calculated.⁶⁶ In clinical practice, Pco₂ is the best measure of ventilation and adequacy of breathing. The Po₂ represents oxygen dissolved in the blood and can be low secondary to low atmospheric pressure (e.g., high altitude), hypoventilation, lung disease causing ventilation/perfusion (V/Q) mismatch (e.g., asthma, pneumonia), loss of pulmonary architecture (e.g., emphysema), and shunt (e.g., cyanotic heart disease). Distinguishing between hypoventilation and V/Q mismatch can be accomplished by calculating the alveolar-arterial (A-a) gradient using the fraction of inspired oxygen (FiO₂), Po₂, and Pco₂:

$$FiO_2 \times \text{air pressure (713} \times 0.21 \text{ or 150 at sea level, room air)} - (Po_2 + Pco_2/0.8)$$

Contemporary research has shown comparable accuracy of venous blood gases with ABGs for measuring pH and bicarbonate (HCO₃) in adult diabetic ketoacidosis.⁶⁷ Studies also have shown a correlation between arterial and capillary pH and Pco₂ in acutely ill children.^{68,69} Others have shown a correlation between pH, Pco₂, base excess (BE), and HCO₃ in ABG, capillary blood gas, and venous blood gas values.⁷⁰

The accuracy of arterial blood gases is influenced by air bubbles within the sample; the resultant gas equilibrium between air and arterial blood lowers arterial carbon dioxide pressure and increases arterial oxygen pressure.⁷¹ Time and

temperature are other variables that affect accuracy. If the sample cannot be analyzed quickly, it should be placed on ice and cooled to 5°C, at which it can be stored for up to an hour. Complications associated with arterial punctures include pain, arterial injury, thrombosis, hemorrhage, and aneurysm formation.

The BE has traditionally been used to assess acid-base status and estimate unmeasured anion concentrations (Table 5–3). First, *standard bicarbonate* is calculated from measured blood gas pH using the Henderson-Hasselbalch equation; the PCO₂ is kept constant at 40 torr to isolate the metabolic contribution and remove the respiratory component.⁷² Next the difference between standard bicarbonate and 22.9, multiplied by a factor of 1.2, calculates the BE.⁷³ A BE values ≤–5 is considered a clinically significant metabolic acidosis. Moreover, BE values ≤–8 predict a higher mortality (23% vs. 6% if BE >–8) in pediatric trauma victims.⁷⁴ One limitation is that the calculations of BE assume normal water content, electrolytes, and albumin; these values are more than likely altered in critically ill children and are more apt to introduce error.

The presence in critically ill patients of metabolic acidosis based on BE values was thought to reflect elevated lactic acid levels, poor perfusion, and concomitant organ dysfunction. This principle has since been challenged^{75–77} because hyperchloremia skews the BE to suggest false acidosis,⁷⁸ and BE poorly correlates with lactic acidosis.^{72,77}

In adults, a strong ion gap (SIG) greater than 2 mEq/L is more accurate than BE in detecting true tissue acidosis,⁷⁷ identifying patients with lactic acidosis and splanchnic hypoperfusion with multiorgan dysfunction, and predicting mortality.⁷² The SIG represents a complex calculation that measures the difference between strong anions and strong cations and is the mathematical difference between the apparent strong ion difference (SIDa) and the effective strong ion difference (SIDe).⁷⁹ An elevated SIG greater than 2 mEq/L signifies that unmeasured strong anions are present in the bloodstream:

$$\text{SIDa} = [\text{Na}^+ + \text{K}^+ + \text{Ca}^{2+} + \text{Mg}^{2+} - \text{Cl}^- - \text{lactate} - \text{urate}]$$

$$\text{SIDe} = [\text{albumin} \times (0.123 \times \text{pH} - 0.631)] + [\text{PO}_4 \times (0.309 \times \text{pH} - 0.469)] + \text{HCO}_3$$

$$\text{SIG} = \text{SIDa} - \text{SIDe} \text{ (abnormal SIG is } > 2 \text{ mEq/L)}$$

In the absence of oxygen, lactate is a by-product of glycolysis to maintain energy production (ATP) when pyruvate cannot enter the Krebs cycle.⁸⁰ Lactate abruptly increases when oxygen delivery falls to a critical level and concomitant decrease in oxygen extraction occurs.⁸¹ Clearance occurs via the liver and kidneys, and normal arterial lactate levels are between 0.5 and 1 mEq/L. Traditionally, elevated blood lactate levels in hemodynamically unstable patients are thought to reflect circulatory shock, arterial hypoxemia, or both. Elevated lactate levels are described in circulatory shock, acute lung injury, sepsis, and multiorgan failure, and are an indicator of severe inflammatory cascade. Increasing lactate levels are associated with organ dysfunction, adverse events, and mortality in adult patients with shock, trauma, and sepsis.⁷⁶ Nonetheless, lactate levels remain useful indicators for indirectly monitoring perfusion and oxygen delivery/consumption.

Continuous Indwelling Arterial Monitoring

Patients requiring close arterial blood pressure monitoring or frequent arterial blood gas analysis may require arterial cannulation for continuous monitoring. The transducer that translates the blood pressure into a waveform can be set to alarm if specific high or low values for mean arterial pressure, systolic blood pressure, or diastolic blood pressure are reached. The dicrotic notch signifying aortic valve closure should be greater than one third of the height of the systolic pressure unless cardiac output is depressed (Fig. 5–2A). The slope of the upstroke reflects myocardial contractility, with a diminished slope indicating shock (Fig. 5–2B). Formulas can be used to estimate stroke volume by measuring the area from the beginning of the upstroke to the dicrotic notch. Multiplying this value by the heart rate will estimate the cardiac output. Finally, the downward slope during diastole indirectly assesses resistance to cardiac outflow. Vasoconstriction causes a slow fall in this slope. Importantly, mean arterial pressure will be higher when measured at the periphery (e.g., distal lower extremity) compared to more centrally obtained pressures. Auscultatory measurements may give a slightly lower value than continuous indwelling catheter measurements. Falsely lowered values may be present if vasoconstriction occurs (e.g., severe shock, hypothermia, or vasopressor administration). Importantly, loss of a normal waveform or any distal extremity problems (pain, blanching, loss of pulse) may indicate thrombotic obstruction and the need to remove the cannula. A dampened waveform (increased diastolic and decreased systolic blood pressure) can be due to air bubbles, blood clots, soft tubing, or a soft diaphragm within the pressure transducer.

Central Venous Pressure Monitoring

Central venous pressure monitoring is used in critically ill patients who are in circulatory failure, require massive fluid or blood replacement, or have a compromised cardiovascular system. New interest in goal-directed therapy for septic shock

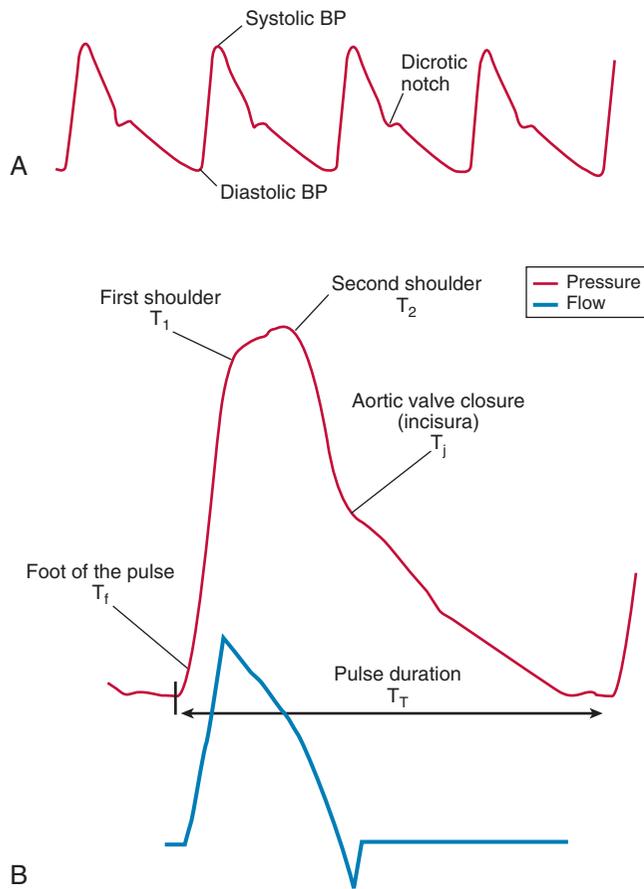

Figure 5-2. A, Blood pressure (BP) translated to waveform during continuous BP monitoring. B, Correlation of blood pressure and arterial blood flow.

has increased the potential use of this tool in critically ill infants and children presenting to the ED.⁸²

Following placement of a central venous catheter (see Chapter 161, Vascular Access), measurement of central venous pressure (CVP) can be used to diagnose disorders and guide treatment. A normal CVP is 5 to 12 cm H₂O, with low values indicating a low right atrial pressure and hypovolemic or distributive shock. High values indicate cardiogenic shock, overhydration, pulmonary embolism, tension pneumothorax, valvular heart disease (e.g., pulmonary stenosis), pericardial tamponade, or restrictive pericarditis. Importantly, changes in CVP readings following infusion of a fluid bolus reflect intravascular volume and are more important predictors of volume abnormalities. Following a 10-ml/kg fluid bolus, the CVP is expected to rise 3 to 4 cm H₂O. If this number drops rapidly (in <5 to 10 minutes) to its baseline or only rises 1 to 2 cm with a fluid bolus, hypovolemia is probable and further fluid administration is usually indicated. A rise greater than 5 cm H₂O indicates overfilling and the potential for development of pulmonary edema.

During treatment of septic shock, one goal is to maintain a normal perfusion pressure (mean arterial pressure minus CVP) for an infant or child's age: 55 cm H₂O for infants up to 1 year old, 60 cm H₂O for those from 1 to 2 years old, and 65 cm H₂O for those who are greater than 2 to 15 years old⁸¹ (see Chapter 8, Circulatory Emergencies: Shock).

Inaccurate CVP monitoring can result from a malpositioned catheter tip within the internal jugular vein, subclavian vein, or right ventricle or migration between discordant locations. Radiographic confirmation can limit this complication. Readings must be obtained using the same reference level at the midaxillary line with the patient supine. Measurements are taken at rest and during exhalation. Coughing, straining, positive pressure ventilation, air bubble within the catheter, and possibly vasopressors can falsely raise CVP values. Falsely low readings occur with catheter obstruction or contact with the vessel wall.

Mixed Venous Oxygen Saturation

Superior vena cava or mixed venous oxygen saturation (SvO₂) can serve as a guide to therapy in septic shock. When oxygen saturation, oxygen consumption, and hemoglobin are stable, this parameter indirectly measures cardiac output. Patients in septic shock often have a low SvO₂ due to decreased cardiac output and increased consumption. One goal in managing septic shock is to achieve an SvO₂ greater than 70% using a combination of volume, vasopressors, vasodilators, and type III phosphodiesterase inhibitors depending upon the clinical scenario (see Chapter 8, Circulatory Emergencies: Shock; and Chapter 13, Sepsis). While interpreting SvO₂ values, clinicians should be aware that many parameters decrease this value, including low cardiac output, decreased arterial saturation, anemia, and increased oxygen extraction (e.g., early sepsis, agitation).

Pulmonary capillary wedge pressure monitoring for infants is generally not undertaken in the ED. As more accurate, less invasive means of monitoring cardiac output/cardiac index become available, it is expected that these tools will assist in diagnosing and managing critically ill patients in the ED.

Summary

Hemodynamic monitoring in the ED is vital, since the condition of an ill child may change quickly. Emergency physicians are multitasking and caring for multiple patients simultaneously, thus real-time information must be readily available and accessible. Recognition and rapid assessment can be accomplished in a few minutes using noninvasive monitoring techniques. Knowledge of the utility and limitations of critical monitoring techniques will enhance patient care and potentially improve outcome for seriously injured and ill children.

Chapter 6

Neonatal Resuscitation

Richard M. Cantor, MD and Steven G. Rothrock, MD

Key Points

Neonatal resuscitation rarely occurs within most emergency departments; therefore, appropriate personnel, equipment, and medications must be readily available.

More than 90% of newly born infants respond well to basic and standardized resuscitative efforts.

A decreasing heart rate is a sign of clinical deterioration; assisted ventilation is required if the heart rate is less than 100 beats per minute (bpm) and cardiac compression is required if it is less than 60 bpm.

Direct tracheal suction is required in newly born infants with absent or depressed respirations, poor muscle tone, or a heart rate less than 100 bpm.

Introduction and Background

When discussing neonatal resuscitation, it is important to define the age range that is being discussed. To avoid confusion with terminology, the International Liaison Committee on Resuscitation has defined “newly born” as an infant in the first minutes to hours after birth to focus attention on the needs of the infant who has just been born. A “neonate” is defined as being 0 to 28 days old, while the term *newborn* is no longer used.¹

There are approximately 4.1 million infants born each year in the United States. Ninety percent of newly born infants (first hours after birth) are capable of transitioning from intrauterine to extrauterine life without any difficulty. They will require little or no assistance to initiate spontaneous and regular respirations. Nearly 10% of newly born infants require some degree of assistance to begin breathing at birth.² Approximately 1% will require extensive resuscitative measures to survive.^{3,4}

The priorities of resuscitation in the newly born mimic those in adults. The airway must be open and clear. Breathing must be guaranteed, whether spontaneous or assisted. Oxygenated blood must adequately circulate centrally and to the

periphery. An additional stressor for the newly born involves the maintenance of thermal regularity. The large surface area of these infants combined with exposure to wet surfaces facilitates the development of hypothermia.

When considering procedures to initiate while attending the delivery, the following measures are listed in order of required frequency^{5,6}:

- Adequate assessment of the baby's response to birth
- Maintenance of thermal regularity
- Positioning, clearing the airway, stimulation to breath by drying, and the provision of oxygen if necessary
- Establishment of effective ventilation whether by bag, bag-mask, or endotracheal intubation
- Institution of chest compressions
- Administration of resuscitative medications

Recognition and Approach

Pathophysiologic Factors

Prenatally, only a small fraction of fetal blood passes through the fetal lungs. While in utero, the potential air sacs within the alveoli are filled with fluid rather than air. The pulmonary vasculature is constricted prenatally and diminished in importance. After delivery, the lungs expand with oxygen and there is global relaxation of the pulmonary vascular network.

Three major changes take place within seconds after birth:

- Fluid in the alveoli is absorbed into lung tissue and replaced by air.
- Clamping of the umbilical arteries and vein results in a dramatic increase in systemic blood pressure.
- As a result of utilization of the alveolar potential space, the blood vessels in the lung tissue relax. This facilitates a decrease in flow through the ductus arteriosus. The eventual closure of the ductus is directly related to the rapidly rising partial pressure of oxygen in neonatal blood.

At the completion of this normal transition, the infant's initial cries and deep breaths will assist the movement of fluid from the airways.⁷ This facilitates the resolution of any cyanosis in the child into an oxygenated state. There is a gradual improvement in oxygenation and pH over the first 24 hours, while there is relatively high hematocrit (Table 6–1).

An infant may encounter difficulty before labor, during labor, or after birth. Processes that began in utero usually

manifest themselves in compromised blood flow within the placenta or the umbilical cord. Fetal bradycardia will often be present in the distressed newly born. Problems that occur after birth are more likely to involve the infant's airway. Specifically, the infant may not manifest a sufficient breath to adequately force fluid from the alveoli.⁸ In addition, foreign material, such as meconium, may block air from entering the alveoli. In any event, the lungs will not fill with air and the body will be deprived of oxygen. A relatively rare complication of a term delivery is the existence of persistent pulmonary hypertension. This entity represents an intrauterine lack of oxygen, which results in sustained constriction of the pulmonary arterials. This manifests itself with profound cyanosis.

Multiple risk factors are associated with the need for resuscitation in the newly born (Table 6–2). Infants who are compromised may exhibit one or more of the following symptoms and signs:

- Cyanosis
- Bradycardia
- Hypotension
- Depression of the respiratory drive
- Poor muscle tone

To identify hypotension, clinicians must be aware of age- and weight-based normal blood pressures for newly born infants

(Table 6–3). The mean arterial pressure for premature newly born infants should be greater than their gestational age in weeks.

Personnel Required at Anticipated Delivery

At every delivery, there should be one identified person primarily responsible for initiating resuscitation. This person should have the skills necessary to perform a complete resuscitation, including endotracheal intubation and supervision of emergent medications. When resuscitation is necessary, it must be initiated immediately.

If a high-risk delivery is anticipated, at least two people must be present solely to manage the baby—one with the full compliment of resuscitation skills and the other to provide assistance. In high-risk cases, the primary resuscitator will serve as the leader of the team and will be responsible for opening the airway and intubation if necessary. Other personnel will be needed to assist with positioning, suctioning, drying, administering oxygen, ventilating, or applying chest compressions. One staff member should be available for drawing up and administering medications.⁶ In all cases, personnel must observe appropriate precautions to protect against exposure to infectious agents.

All necessary equipment for a complete resuscitation must be readily available and operational at all times (Table 6–4).

Table 6–1 Normal Arterial Blood/Hct Values in Full-Term Newly Born

Age	PaO ₂	PaCO ₂	pH	Base Excess	Hct (vol %)
1 hr	63 mm Hg	36 mm Hg	7.33	–6.0 mEq/L	53
24 hr	73 mm Hg	33 mm Hg	7.37	–5.0 mEq/L	55

Abbreviations: Hct, hematocrit; PaCO₂, arterial partial pressure of carbon dioxide; PaO₂, arterial partial pressure of oxygen.

Evaluation

In general, determining the need for resuscitative efforts begins immediately after birth. Most newly born infants respond to the extrauterine environment by demonstrating a vigorous cry, movement of all extremities, and a strong respiratory effort. With these responses in place, early cyanosis improves to duskiness and finally to a pink color. Infants who do not meet these criteria require intervention (Fig. 6–1).

Table 6–2 Risk Factors Associated with the Need for Neonatal Resuscitation

Antepartum Factors

Maternal diabetes (esp. if poor control)
 Preeclampsia or eclampsia
 Chronic hypertension
 Chronic anemia or isoimmunization (if Rh–)
 Prior late fetal demise or neonatal death
 Late-trimester bleeding
 Maternal infection or fever
 Maternal underlying disease (e.g., heart, lungs, kidney, thyroid, or neurologic)
 Polyhydramnios
 Oligohydramnios
 Premature rupture of membranes
 Postterm gestation

Intrapartum Factors

Emergency cesarean section or general anesthesia
 Assisted delivery (forceps or vacuum extraction)
 Breech or other abnormal lie/presentation
 Premature labor
 Precipitous delivery
 Chorioamnionitis
 Prolonged rupture of membranes (>18 hr before delivery)
 Prolonged labor (>24 hr)
 Prolonged second stage of labor (>2 hr)

Multiple gestation
 Size-dates discrepancy
 Medication & drug use
 Illicit drugs (e.g., cocaine, amphetamines)
 Lithium carbonate
 Sedatives, narcotics
 Magnesium
 Adrenergic blocking drugs
 Maternal cigarette or alcohol use
 Fetal malformation
 Diminished fetal activity
 No prenatal care
 Age <16 or >35 yr

Fetal bradycardia
 Abnormal fetal heart rate patterns
 Uterine tetany or atony
 Maternal narcotics administration within 4 hr of delivery
 Meconium-stained umbilical cord
 Placental abruption—stained amniotic fluid
 Prolapsed uterus
 Placenta previa

Table 6-3 Normal Blood Pressure (BP) for Different Birth Weights

	Weight			
	<1 kg	1–2 kg	2–3 kg	>3 kg
Systolic BP (mm Hg)	40–60	50–60	50–70	50–80
Diastolic BP (mm Hg)	15–35	20–40	25–45	30–50

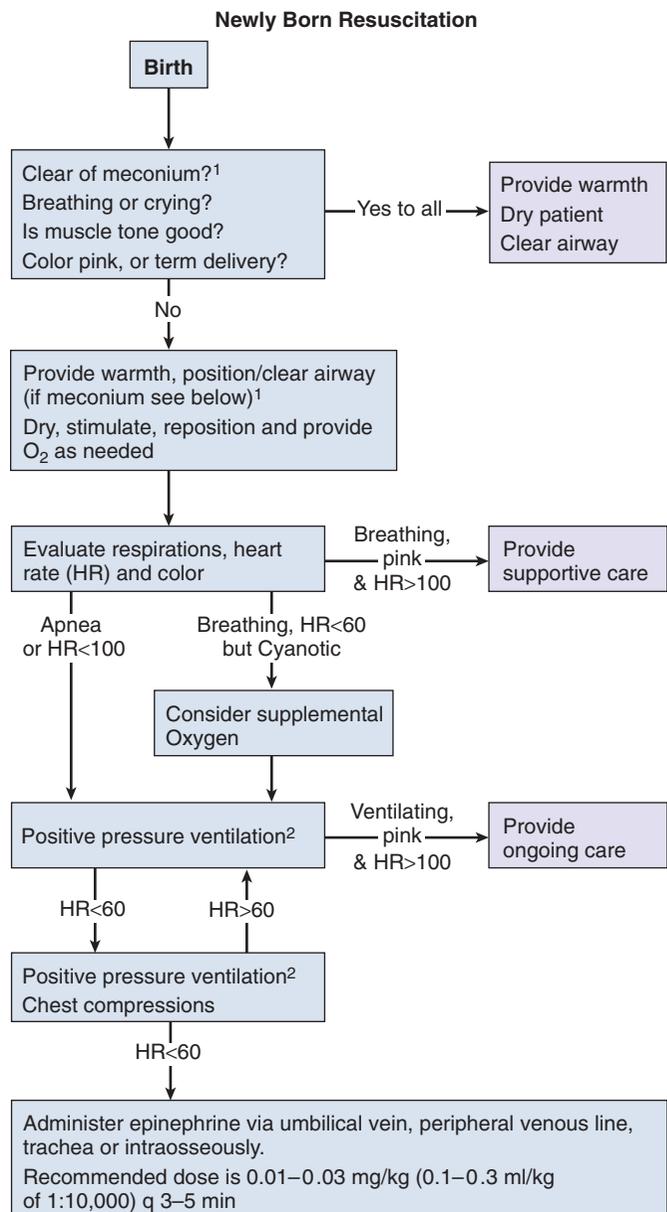

Table 6-4 Equipment and Supplies Used during Resuscitation

Self-inflating bag with reservoir or flow-inflating bag and mask with an oxygen source
 Masks (term and preterm sizes)
 Laryngoscope straight blades (0, 1)
 Endotracheal tubes (2.5, 3, 3.5 internal diameter)
 Oxygen source
 Bulb suction, or DeLee suction trap and meconium aspirator
 Wall suction device with attachments
 1-, 3-, and 20-ml syringes
 Three-way stopcock
 3.5F or 5F umbilical catheters
 5F feeding tube or catheter with connector to accommodate syringe (for endotracheal medicines)
 Normal saline flush
 Povidone-iodine applicator (or similar sterilizing fluid)
 Sterile gloves
 Umbilical tape and scissors
 Scalpel handle and blade
 Curved hemostat
 Forceps
 Normal saline for volume expansion
 Dry, warm blankets
 Radiant warmer
 Medication labels
 Code sheet for recording medication

In a fairly rapid manner, the healthy newly born infant should establish regular respirations sufficient to maintain a heart rate greater than 100 beats per minute (bpm). The need for assisted ventilation is indicated by the presence of gasping, apnea, or a heart rate less than 100 bpm.

The heart rate can be estimated by listening directly to the precordium or feeling pulsations at the base of the umbilical cord. Central and peripheral pulses in the neck and extremities are often difficult to feel in infants.^{9,10} An additional benefit to palpating the umbilical base is the avoidance of interference with respiratory assistance. The heart rate should consistently remain above 100 bpm. Any changes in the heart rate may indicate improvement or deterioration of the clinical status.

A stable, fully perfused newly born infant should maintain a pink color in the mucous membranes without supplemental oxygen. The face, trunk, and mucous membranes are examined for central cyanosis. Acrocyanosis is considered a normal finding at birth and is not a reliable indicator of central hypoxemia. In most cases it is more a sign of cold stress. Decreased cardiac output, severe anemia, hypovolemia, and acidosis are associated with the development of pallor. Capillary refill should not be relied upon to diagnose hypovolemia or shock at this age. Normal newly born capillary refill time can be greater than 3 to 4 seconds.¹¹

¹Meconium management: *Intrapartum*—Suctioning the mouth, pharynx, and nose is no longer recommended after delivery of the head.

Following delivery—Perform immediate direct laryngoscopy with suctioning ONLY if (1) depressed respirations (2) absent of diminished muscle tone or (3) HR < 100 beats/minute. Repeat until little meconium is recovered or HR < 60–80 (indicating need for resuscitation). Perform tracheal suctioning before initiating positive pressure ventilation (PPV). If patient becomes severely distressed, positive pressure ventilation may be required even if all of meconium is not suctioned out.

²Consider endotracheal intubation if positive pressure ventilation is ineffective at this step.

FIGURE 6-1. Decision chart for newly born resuscitation.

Management

Thermal Regularity

Cold stress will increase oxygen consumption and impede effective resuscitation.¹² The goal is to avoid overshoot hyperthermia since it may favor the development of respiratory depression. It is important to provide a warm, draft-free environment for the infant. Normothermia is facilitated by

placing the infant under a radiant warmer, drying the skin, removing wet linen, and wrapping the infant in prewarmed blankets. Plastic bags or plastic (food-grade, heat-resistant) wrapping applied to neonates placed under a radiant heat source will aid in maintaining temperature.¹³ An additional mechanism for the prevention of heat loss involves placing the infant directly on the mother's chest or abdomen.

Positioning of the Airway

The newly born infant is placed supine or lying on one side with the head in a neutral position. It is important at this point to rule out airway obstruction as manifested by respiratory effort without air movement. In this case, the head position is readdressed by placing a blanket or towel under the shoulders to facilitate air entry.

Suctioning

In most deliveries, there is enough time to suction the infant's nose and mouth with a bulb syringe. Secretions are wiped from the nose with gauze or a towel. If suctioning is necessary, first the mouth and then the nose is suctioned with a bulb syringe or a suction catheter. Aggressive pharyngeal suction must be avoided since this may cause laryngeal spasm and bradycardia, delaying the onset of spontaneous breathing.^{14,15}

Meconium Aspiration

Approximately 12% to 14% of deliveries are complicated by the presence of meconium in the amniotic fluid. There is evidence from a randomized trial that intrapartum (after delivery of the head) suctioning of meconium does not reduce the incidence of meconium aspiration syndrome. For this reason, routine intrapartum oropharyngeal and nasopharyngeal suction of neonates with meconium-stained fluid is no longer recommended.¹³ Tracheal suctioning is recommended after delivery *if cardiorespiratory depression is present*. If meconium and depressed respirations are present, direct laryngoscopy is performed immediately after birth for suctioning of residual meconium from both the hypopharynx and the trachea. Suctioning is then applied directly to the tracheal tube as it is withdrawn from the airway. This combination of intubation and suctioning is repeated until little additional meconium is removed or bradycardia precludes any further interventions. In cases in which severe bradycardia or bradypnea is present, it may be necessary to begin positive pressure ventilation despite the presence of meconium in the airway. In contrast, clinical studies have suggested that tracheal suctioning of the vigorous infant does not improve outcome and may cause complications. Therefore, acute interventions are reserved for those infants who have signs of cardiopulmonary depression.

Physical Stimulation

In most cases, drying and suctioning produce enough stimulation to begin effective respirations. If these maneuvers fail, flicking the soles of the feet may initiate spontaneous respiration. If these efforts are unsuccessful, positive pressure ventilation is begun. It is important to avoid forms of stimulation that may be hazardous to the infant (Table 6–5).

Ventilation

A bag and mask will often be sufficient in ventilating infants who require positive pressure breaths.¹⁶ Proper ventilation

Table 6–5 Forms of Stimulation That May Be Hazardous to the Newly Born

Harmful Actions	Potential Consequences
Slapping the back Squeezing the rib cage	Bruising Fractures, pneumothorax, respiratory distress, death
Forcing thighs onto abdomen Dilating anal sphincter	Rupture of liver or spleen Tearing of anal sphincter
Using hot or cold compresses or baths	Hyperthermia, hypothermia, burns
Shaking	Brain damage

may be one of the most important skills required for resuscitating newly born infants. One study found that improper ventilation was the cause of or contributed to neonatal cardiorespiratory depression in more than 60% of newly born infants requiring chest compressions.⁴ Indications for positive pressure ventilation include apnea or gasping respirations, a heart rate below 100 bpm, and persistent central cyanosis. Failure to improve or deterioration during ventilation should prompt immediate reassessment of airway positioning and ventilation techniques.

When delivering the first several breaths, it is important to consider utilizing higher inflation pressures (30 to 40 cm H₂O in full-term and 20 to 25 cm H₂O in preterm newly born infants). Lower pressures can be used with subsequent breaths. If pressure is not being monitored, the minimal inflation needed to increase the heart rate should be used.¹³ A rate of 30 to 60 breaths/min should be attempted. Adequate ventilation is demonstrated by bilateral expansions of the lungs and improvement of heart rate and skin color. It is important to check the seal between the mask and face and clear any airway obstructions to assure the delivery of an adequate breath. Abdominal distention is an indication of air in the stomach, which can impede ventilatory sufficiency. It is important in this scenario to insert an 8-French orogastric tube and aspirate with a syringe. Subsequently the tube may be left open to air. If these maneuvers do not result in sufficient air entry, the patient must be endotracheally intubated.

Either a self-inflating bag, a flow-inflating bag or a T-piece mechanical device designed to regulate pressure can be used to ventilate a newly born infant. Clinicians should be knowledgeable about the use of devices they choose to use during resuscitation.

A T-piece connection to a face mask can deliver a flow-regulated, pressure-limited, oxygen supply to the baby and enable application of prolonged initial inflation breaths. Use of a T-piece connector more consistently delivers target pressures and prolonged inflation independent of the operator's expertise. Some experts believe that this technique can reduce the need for endotracheal intubation, although this opinion has not been formally investigated in any subsequent studies.¹⁷

Resuscitation bags larger than 750 ml should be avoided. Self-inflating bags refill independently of gas flow based on surface tension of the bag. When using self-inflating bags, to assure the delivery of high concentrations of oxygen, an oxygen reservoir is attached. The pressure release valve is set at a pressure of approximately 30 to 35 cm of H₂O. An over-

ride feature should be in place to deliver higher pressures if necessary. As mentioned previously, self-inflating bags should not be used to deliver oxygen passively through the mask.

Flow-inflating (anesthesia) bags have a long history in neonatal resuscitation. They only inflate when compressed gas is flowing and the patient outlet is partially occluded. The appropriate use of this equipment requires a more complex skill set on the part of the care provider. Since high pressures can be delivered, a manometer is used at all times. High concentrations of oxygen may be moved passively through the mask of a flow-inflating bag.

With few exceptions, clinicians should avoid hypocarbia during newly born resuscitation after correcting hypoxia. Every 1 mm Hg drop in the partial pressure of carbon dioxide during ventilation decreases cerebral blood flow by 3%, potentially worsening cerebral ischemia associated with birth asphyxia.¹⁸ While the use of hyperventilation (and hypocarbia) for treating persistent pulmonary hypertension of the newborn is unproven, many centers employ modest hyperventilation in this instance.¹⁹ Hypocarbia also may benefit a subset of neonates with worsening cerebral edema and intracranial bleeding. However, benefits from this practice are small and transitory.¹⁸

Endotracheal Intubation

Fortunately, most newly born infants will respond to bag-valve-mask ventilation alone.²⁰ Relative indications for endotracheal intubation include ineffective bag-valve-mask ventilation, prolonged need for positive pressure ventilation, meconium clearance, and the administration of resuscitative medications. Guidelines for choosing airway equipment size exist (Table 6–6). An additional method for determining endotracheal tube (ETT) size is to divide the gestational age (in weeks) by 10. Most practitioners favor the orotracheal route for intubation. In more than 10% of newly born infants who deteriorate and require chest compression, an improperly placed ETT (esophageal or mainstem intubation) is the cause.⁴ The “1,2,3, . . . 7,8,9” rule is used to estimate proper depth of the ETT in centimeters at the lip. For a 1-kg infant, the proper ETT depth is 7 cm, while a 2-kg infant requires an 8-cm depth and a 3-kg infant requires a 9-cm depth at the lips.¹⁸ Proper positioning must be ascertained by direct auscultation, chest wall movements, end-tidal capnography, and radiography. Clinicians should be aware that there are two sizes of colorimetric end-tidal CO₂ devices: one is used in children greater than 15 kg (Easy Cap II, Nellcor) and one is used in young children and infants 1 to 15 kg (Pedi-Cap).²¹ False-negative colorimetric end-tidal CO₂ confirmation can occur with very small neonates (<1 kg) and neonates who are

in shock (see Chapter 5, Monitoring in Critically Ill Children). Once the ETT position is confirmed, the tube must be securely taped in place.

If bag-mask ventilation and tracheal intubation are unsuccessful, a laryngeal mask airway (LMA) can be inserted during resuscitation. A size 1 LMA can be used in neonates up to 5 to 6.5 kg.

Oxygen Administration

Experts have found that air is as effective as 100% oxygen for most resuscitations following delivery. There is evidence that 100% oxygen has detrimental effects on breathing physiology and cerebral circulation, and causes damage from oxygen free radicals.¹³ For this reason, adequate lung inflation, ventilation, and support of cardiac output should take priority. Supplemental oxygen should be considered for neonates with persistent central cyanosis. If administered, blow-by oxygen may be delivered through a face mask, an oxygen mask, or a hand cupped around oxygen tubing. Self-inflating bags cannot reliably deliver significant oxygen flow without compression. The goal is to deliver sufficient oxygen to achieve a resolution of cyanosis in the mucous membranes. Reliance on pulse oximetry to determine adequate oxygenation is problematic since it normally takes 20 to 60 minutes after birth to achieve an oxygen saturation above 95%.^{22,23}

Chest Compressions

The provision of adequate ventilation and oxygenation will restore vital signs in most newly born infants. Decisions to initiate chest compressions involve consideration of the heart rate, responsiveness of the heart rate, and the time elapsed after measures have been initiated. Ventilatory sufficiency must be assured before chest compressions are instituted.

Chest compressions should begin if the heart rate remains below 60 bpm despite adequate ventilation for 30 seconds. Ventilation is of paramount importance and should not be compromised by compressive efforts.

Compressions are delivered on the lower third of the sternum.²⁴ An accepted technique involves two thumbs on the sternum superimposed on or adjacent to each other depending on the size of the infant. The fingers should encircle the chest and support the back at the same time. An additional method involves two fingers of one hand placed on the sternum at right angles to the chest with the other hand supporting the back. Investigators have determined that the two-hand encircling technique may deliver improved systolic and coronary perfusion pressures.²⁵

The depth of compressions should approximate one third of the anterior-posterior diameter of the chest. Palpable

Table 6–6 Equipment Size by Weight

Weight (g)	Gestational Age (wk)	ETT Size (mm)	ETT Depth (cm)*	Suction Catheter (Fr)	Oral Airway	Laryngoscope Straight Blade
<1000	<28	2.5	6.5–7	5	000	0
1000–1250	28–30	2.5, 3.0	7	5, 6	000	0
1250–2500	31–36	3.0	7–8	6	00	0, 1
2500–3000	36–38	3.0, 3.5	8–9	6, 8	0	1
>3000	>38	3.5, 4.0	>9	8	0	1

*Depth at the lips.

pulses should be generated, and compressions and ventilations coordinated to avoid simultaneous delivery. A 3 : 1 ratio of compressions to ventilation is maintained, with 90 compressions and 30 breaths achieving 120 events per minute. Personnel must remember to reassess the heart rate approximately every 30 seconds. Chest compressions may be discontinued when the heart rate is over 60 bpm.

Medication and Fluid Administration

In general, bradycardia in the newly born is the result of inadequate lung inflation or hypoxemia. Medications are administered only when adequate ventilation and compressions fail.²⁶ Several potential routes for medication delivery exist, including tracheal, peripheral venous, umbilical vein, and intraosseous (IO) (see Chapter 161, Vascular Access). The tracheal route can be used for intubated patients to administer epinephrine and naloxone (although the subcutaneous route is recommended for naloxone administration if no intravenous [IV] line is available). However, absorption is variable and umbilical and peripheral venous routes are preferred if available. Umbilical vein cannulation is ideal for administration of fluids and resuscitation medications. For clinicians who rarely perform this procedure, the time to insertion may be unacceptably long. Therefore, if umbilical and peripheral routes are not easily achieved, IO access is an appropriate alternative for fluid and medication delivery.²⁷ Use of this route may cause fractures (especially in preterm newly born infants and neonates) and tissue damage if extravasation occurs. Therefore, the IO access should be removed as soon as an acceptable alternate site is obtained.

Epinephrine

Administer epinephrine when the heart rate remains less than 60 bpm after a minimum of 30 seconds of adequate ventilation and compressions. Asystole and profound bradycardia are the primary indications for the administration of epinephrine.

The recommended IV dose is 0.01 to 0.03 mg/kg of a 1 : 10,000 solution (0.1 to 0.3 ml/kg) repeated every 3 to 5 minutes.²⁸ The use of high-dose intravenous epinephrine is not indicated at this age. However, a higher dose (0.1 mg/kg) is recommended if the tracheal route is used for epinephrine administration.

Volume Expanders

Hypovolemic newly born infants require the administration of volume expanders. Clinical situations that suggest volume loss include heavy perinatal bleeding, cyanosis, pallor, apnea, extreme tachycardia or bradycardia, loss of muscle tone, and absence of response to other resuscitative measures (e.g., ventilation, oxygenation, drying, stimulation). Normal saline or lactated Ringer's solution is the fluid of choice for volume expansion. Large-volume blood loss may be corrected by the administration of O-negative blood. The use of albumin-containing solutions should be avoided.²⁹ The initial dose of volume expanders is 10 ml/kg given over 5 to 10 minutes. Volumes greater than this may result in complications such as intracranial hemorrhaging or volume overload in asphyxiated or premature neonates. The response and clinical scenario will dictate the need for additional fluids, blood, or pressors.

Glucose

Hypoglycemia is an important cause of clinical deterioration in newly born infants who are premature or who have diabetic mothers. Stressed neonates can quickly deplete their glycogen stores and develop hyperinsulinemia.³⁰ Neonates who have perinatal asphyxia also may develop hyperinsulinemia and have a worsened prognosis if they are hypoglycemic.^{31,32} Signs of hypoglycemia include irritability, hypotonia, seizures, depressed mentation, and shock. Normal values for glucose vary with the infant's gestational age. While debate exists as to the cutoff that defines hypoglycemia, most experts define any value less than 40 to 47 mg/dl as abnormal for a full-term infant.³³ As bedside glucose testing can be inaccurate, all values less than 50 mg/dl are considered abnormal. Management consists of 2 ml/kg of a 10% glucose solution administered intravenously. A continuous IV solution initially may be required, with conversion to oral solutions containing glucose once stabilized.

Bicarbonate

The routine of use of bicarbonate in resuscitation of the newly born is unsupported. It should only be given after full cardiopulmonary resuscitation is in progress and only after prolonged efforts. A dose of 1 to 2 mEq/kg (diluted to 0.5 mEq/ml in solution) may be given by slow IV push.

Naloxone

Naloxone hydrochloride is a pure narcotic antagonist. It will reverse respiratory depression in the newly born infant whose mother has received opioids within 4 to 6 hours of delivery. However, naloxone may exacerbate neurologic injury during asphyxia and cause seizures in infants born to mothers with opioid addiction. In adults and adolescents, arrhythmias, hypertension, and pulmonary edema have occurred following its use. For this reason, naloxone is not recommended during the initial resuscitation of newborns with respiratory depression. Before naloxone is administered, ventilation should be attempted first to restore heart rate and color. If used, the recommended dose of naloxone is 0.1 mg/kg given intravenously or intramuscularly. It is important to realize that repeated doses of naloxone may be necessary since the half-life of the offending agent is often prolonged.

Postresuscitation Care

After resuscitation, personnel must continue monitoring heart rate, respiratory rate, administered oxygen concentration, and arterial oxygen saturation. Blood pressure should be documented and the blood glucose level checked during stabilization after resuscitation. Chest radiography will help rule out any correctible complications (Tables 6–7 and 6–8), such as the presence of a pneumothorax.

One randomized prospective trial evaluated the effect of whole-body hypothermia on neonates with hypoxic-ischemic encephalopathy and acidosis or perinatal complications who required resuscitation at birth. Hypothermia (33.5°C for 72 hours) decreased the risk of death and disability in this population.³⁴ Confirmation of this study and implementation of a practical, widely available method for delivery of hypothermia may make this treatment standard in the future.

Table 6–7 Complications of Resuscitation

Complication	Possible Causes	Prevention or Corrective Action to Be Considered
Hypoxia	Taking too long to intubate	Preoxygenate with bag and mask. Provide free-flow oxygen during procedure. Halt intubation attempt after 20 sec.
Bradycardia/apnea	Incorrect placement of tube Hypoxia Vagal response from laryngoscope or suction catheter	Reposition tube. Preoxygenate with bag and mask. Provide free-flow oxygen during procedure.
Pneumothorax	Overventilation of one lung due to tube in right main bronchus	Oxygenate after intubation with bag and tube. Place tube correctly.
Contusions or lacerations of tongue, gums, or airway	Excessive ventilation pressures Rough handling of laryngoscope or tube Inappropriate “rocking” rather than lifting of laryngoscope	Use appropriate ventilating pressures. Obtain additional practice/skill
Perforation of trachea or esophagus Obstructed endotracheal tube	Laryngoscope blade too long or too short Too vigorous insertion of tube Stylet protrudes beyond end of tube Kink in tube or tube obstructed with secretions	Select appropriate equipment. Handle gently. Place stylet properly. Try to suction tube with catheter. If unsuccessful, consider replacing tube.
Infection	Introduction of organisms via hands or equipment	Pay careful attention to clean/sterile technique.

Table 6–8 Postresuscitation Considerations

Organ System	Potential Complication	Postresuscitation Action
Brain	Apnea Seizures	Monitor for apnea. Support ventilation as needed. Monitor glucose and electrolytes. Avoid hyperthermia.
Lungs	Pulmonary hypertension Pneumonia Pneumothorax Transient tachypnea Meconium aspiration syndrome Surfactant deficiency	Consider anticonvulsant therapy. Maintain adequate oxygenation and ventilation. Consider antibiotics. Obtain radiograph if respiratory distress is present. Consider surfactant therapy. Delay feedings if respiratory distress is present.
Cardiovascular	Hypotension	Monitor blood pressure and heart rate. Consider inotrope (e.g., dopamine) and/or volume replacement.
Kidneys	Acute tubular necrosis	Monitor urine output. Restrict fluids if oliguric volume and vascular volume are adequate.
Gastrointestinal	Ileus Necrotizing enterocolitis	Monitor serum electrolytes. Delay initiation of feedings. Give intravenous fluids. Consider parenteral nutrition.
Metabolic/Hematologic	Hypoglycemia Hypocalcemia; hyponatremia Anemia Thrombocytopenia	Monitor blood sugar Monitor electrolytes Monitor hematocrit Monitor platelets

Termination of Resuscitation

During resuscitation, clinicians must be aware of factors that are associated with high mortality and little chance of survival. Extreme prematurity (gestational age <23 weeks, or birth weight <400 g) and anomalies such as anencephaly and known trisomy 13 and 18 have been shown to have a uniformly poor prognosis, and experts do not recommend initiating resuscitation.¹³ In conditions with an unknown prognosis associated with borderline survival and high morbidity with a high burden to the child, experts recommend supporting the parent’s views regarding the initiation of resuscitation.¹³

For neonates who are born without signs of life, a uniformly poor prognosis is associated with a gestational age less than 26 weeks (even if there is return of spontaneous circulation), weight less than 750 g, or no signs of life after 10 minutes of resuscitation.^{35,36}

Summary

Neonatal resuscitation is a skill set that all emergency physicians must maintain. Most newly born infants will respond well to simple therapeutic interventions. Chest compression and medications are required in only a small subset of infants. Proper personnel, training, equipment and preparation, and

adherence to protocols, will prevent complications and optimize outcome for distressed newly born infants.

Chapter 7

The Critically Ill Neonate

Maureen McCollough, MD and Steven G. Rothrock, MD

Key Points

All emergency departments should be prepared to care for a critically ill infant, including having the appropriate-sized equipment.

Knowledge of the normal findings on examination, vital signs, and serum parameters will allow for early identification of neonates at risk for serious illness.

Understanding the anatomic and physiologic changes that occur in the first month of life will aid physicians in understanding the unique disease processes that occur at this age.

Early treatment to maintain normothermia and normal blood glucose levels is an important goal that is easily overlooked in critically ill neonates.

Introduction and Background

Knowing the anatomic and physiologic changes that occur in the first month of life is critical to understanding the pathophysiology of many neonatal disorders. For example, the ductus arteriosus that shunted blood away from the lungs during fetal development closes during the first few days of life. Pulmonary vascular resistance also falls for several weeks as blood flow improves to the lungs. This increased flow can unmask disorders placing neonates at risk for congestive heart failure (e.g., large ventricular septal defect).

Most term infants will lose weight (10%) during the first few days of life, but this will level off by day 5 to 7. Most will regain their birth weight by day 10 to 14, and then will gain 20 to 30 g ($\sim 1/2$ to 1 ounce) per day for the first few weeks of life. In general, the normal respiratory rate (RR) of a newborn is 30 to 40 breaths/min, although the World Health Organization defines an abnormal value as any RR ≥ 60 breaths/min. Neonates are obligate nose-breathers. Because of this nasal dependency, use of a nasal cannula can sometimes worsen a newborn's respiratory distress. A newborn infant's ribs are aligned horizontally, so in order to increase thoracic capacity, the infant must lower his diaphragm. If the stomach is

distended with air, the diaphragm will not function properly, leading to poor ventilation. A nasogastric or orogastric tube can decompress the stomach in order to improve ventilation.

Periodic breathing, which occurs during the first few months of life, is the cessation of breathing for 5 to 10 seconds followed by a burst of more rapid breathing with more than 50 to 60 breaths/min for 10 to 15 seconds. This pattern repeats over and over for a period of time. With periodic breathing, the cessation of breathing is not associated with cyanosis, bradycardia, limpness, or altered mental status. Because of periodic breathing, newborns should have respiratory rates recorded for at least 30-second intervals to avoid falsely high or low counts. Normal heart rates range from 90 to 180 beats per minute (bpm); the average is 120 to 150 bpm.¹ The normal systolic blood pressure is 60 mm Hg. For premature neonates, the mean arterial pressure is usually greater than or equal to their gestational age in weeks. Acrocyanosis (cyanotic distal extremities) is common. At birth, newborns have a relatively thick right ventricular wall and elevated pulmonary vascular resistance, with a rapid decrease by 6 to 8 weeks and a more gradual decrease to adult levels by age 6 years.

Guidelines have been published for interpreting the neonatal electrocardiogram (ECG), with normal values defined as all values between the 2nd and 98th percentiles.¹ The ECG normally will show a right axis deviation, ranging from +60 to +180 degrees.¹ The normal heart rate for a neonate is 90 to 180 while values >220 to 230 are associated with supraventricular tachycardia. Due to the normal right axis, tall R waves are normally seen in leads V₁, V₂, and rV₄. QRS and T waves show small voltages. The normal QRS interval is 0.02 to 0.08 seconds.¹ Since the normal QRS value is narrow, ventricular tachycardia may appear narrower than typically expected, leading to misinterpretation as supraventricular tachycardia. The normal value for a corrected QT interval (QTc) is 440 msec.¹

The normal point of maximal impulse where the left ventricle pushes against the chest is at the left lower sternal border. A normal early systolic murmur caused by the normal persistent patency of the ductus arteriosus may be heard in the first few days of life. An innocent pulmonary flow murmur can be heard radiating to sides of the chest and back, usually less than grade 2/6. Peripheral pulses, including a dorsalis pedis pulse, should be palpable in all normal neonates. On chest radiography, the normal cardiothoracic ratio is less

than 0.57 to 0.65 as both inspiration and the size of the thymus will affect this.^{2,3} The liver is palpable 1 to 2 cm below the right costal margin in newborns, and the spleen tip is often palpable.

Formula-fed newborns will consume 2 to 4 ounces every 3 to 4 hours by the end of the first week of life. Breast-fed infants will generally empty a breast within 7 to 8 minutes, so switching breasts is recommended. Young infants may stop middle-of-the-night feeds by 3 to 6 weeks of age, while others continue until 4 to 6 months of age. Clinicians should always ask about feeding parameters when assessing for adequate weight gain.

The first meconium stool should be passed within 24 hours of birth. If stool is not passed, Hirschsprung's disease, congenital colon disorders, or hypothyroidism may be present. After mild feedings begin, transitional stools will start on the third to fourth day that are greenish brown and may contain milk curds. Soon after, stools of breast-fed infants will become stringy, loose, yellow, and sweet smelling. Formula-fed babies will produce stool that is more pasty, homogeneous, yellow-brown, and more foul smelling. Stool frequency often corresponds to the number of feeds but is usually 3 to 5 per day. Breast-fed babies may stool after every feed. Infants born in the breech position, especially male infants, may have significant bruising to the genital area.

Normal hemoglobin values for a newborn range from 13 to 20 g/dl. This will generally decrease during the first month of life. Infants reach their "physiologic nadir" around 2 to 3 months old with hemoglobin values averaging 11.4 g/dl; then erythropoiesis resumes. The amount of fetal hemoglobin varies from infant to infant, disappearing by 7 months. The white blood cell (WBC) count may also range at birth from 8000 to 35,000, with a gradual decline over the first month. Cerebrospinal fluid (CSF) in a neonate may show up to 22 WBCs/mm³ with a predominance of lymphocytes.⁴⁻⁶

Recognition and Approach

Managing a critically ill neonate in the emergency department (ED) is challenging. Because of anatomic and physiologic changes that are occurring in the neonate, unique diseases will occur in the neonatal period (Table 7-1). Young neonates (<7 to 10 days old) who present to the ED have a particularly high incidence of serious illness, with 10% to 33% requiring hospital admission.^{7,8} The most common diagnoses in admitted patients include respiratory infections, sepsis, dehydration, congenital heart disease, bowel obstruction, hypoglycemia, and seizures.^{7,8}

Evaluation of a critically ill neonate who presents to the ED begins with placement of a cardiac monitor and pulse oximeter; assessment of vital signs, including blood pressure, temperature, heart rate, and respiratory rate; and bedside testing for blood glucose. The temperature must be determined as neonates may be hypothermic or hyperthermic. The temperature of the undressed neonate should be rechecked periodically as young infants have difficulty with temperature regulation due to large body surface areas. For this reason, radiant warming for normothermic and hypothermic neonates should be considered.

Delivery of oxygen by high-flow mask may be sufficient to reverse hypoxia in ill neonates. If not, intubation and assisted ventilation are required. Scalp veins can be used to deliver

Table 7-1

Important Causes of Critical Illness in Neonates

Infectious

Sepsis due to bacteria (*E. coli*, group B streptococcus, *Listeria*) or viruses (herpes, enteroviruses)
Meningitis
Omphalitis

Neurologic

Seizures
Central nervous system hemorrhage
Birth injury
Spontaneous (e.g., arteriovenous malformation)
Trauma—accidental and nonaccidental
Hydrocephalus

Respiratory Disease

Upper airway disorders (e.g., vocal cord paralysis, laryngomalacia, papillomas)
Lower airway disorders
Pneumonia (viral and bacterial)
Bronchiolitis
Bronchopulmonary dysplasia
Aspiration

Cardiac

Dysrhythmias
Congenital left ventricular outflow obstruction (e.g., hypoplastic left heart, critical aortic stenosis, interrupted aortic arch)
Congenital cyanotic heart defects
with diminished pulmonary flow (e.g., tetralogy of Fallot)
with increased pulmonary flow (e.g., transposition of the great arteries)
Congenital acyanotic heart defects (e.g., large ventricular septal defect)
Cardiomyopathies

Intestinal Disorders

Volvulus
Necrotizing enterocolitis
Hirschsprung's enterocolitis
Incarcerated hernias

Metabolic/Endocrine

Inborn errors of metabolism or other metabolic derangements—
hyponatremia, hypocalcemia, hypomagnesemia
Hypoglycemia
Congenital adrenal hyperplasia
Hypothyroidism
Formula mix-ups with electrolyte abnormalities (e.g., hyponatremia)

Other Disorders

Vitamin K deficiency (hemorrhagic disease of the newborn)
Toxins and other home remedies

both fluid boluses and medications. If no intravenous (IV) lines can be established, either an intraosseous (IO) line or umbilical vein catheter must be placed (see Chapter 161, Venous Access). For most physicians who do not frequently care for very young infants, an IO line may be easier to establish. Because of the limited ability for neonates to maintain normal glucose, a rapid bedside measure of serum glucose is mandatory. Blood glucose concentrations below 40 mg/dl are considered abnormal in neonates, while a blood glucose concentration between 40 to 50 mg/dl can be normal or abnormal (see Chapter 106, Hypoglycemia). Due to the inaccuracy of bedside tests, levels below 50 mg/dl mandate intervention. Management consists of 5 ml/kg of IV 10% dextrose (D₁₀). The serum glucose should be remeasured within 5 to 10

minutes to check for effectiveness of the glucose, and periodically during the resuscitation and ED stay.

If saline boluses are required, the clinician should begin with 20 ml/kg, and then reassess vital signs and clinical signs of perfusion (e.g., capillary refill, mental status). For premature neonates and neonates with asphyxia or suspected cardiac disorders, fluid boluses should be limited to 10 ml/kg. Maintenance fluids for normally perfused neonates can be sustained with 5% dextrose in $\frac{1}{4}$ normal saline (D₅1/4NS) at 4 ml/kg/hr while in the ED. If packed red blood cells, platelets, or fresh frozen plasma is needed, it should be administered in 10-ml/kg dosages. Early communication with a neonatal intensive care unit or pediatric intensive care unit will help expedite a potential transfer of the critically ill neonate, and a critical care team or personnel experienced with caring for young infants will be needed during transport.

Evaluation and Management

The presenting features of many serious neonatal disorders are nonspecific. Respiratory distress can signify both respiratory and nonrespiratory disease. Neurologic complaints, including altered mentation and seizures, can be due to serious intracranial disorders (e.g., bleeding, infection, hydrocephalus, encephalopathy) and non-neurologic disorders (e.g., metabolic disease, toxins, hypoxia, hypotension). The differential diagnosis of shock is extensive and includes sepsis, congenital obstructive left heart syndromes, arrhythmias, volume or blood loss, metabolic disease, and endocrine disorders. Vomiting may be due to multiple disorders, including gastrointestinal disorders, intracranial disease, infections, metabolic abnormalities, and toxins. Knowledge of typical and atypical presentations can improve the accuracy of diagnosis of critical illness in neonates.

Selected Disorders Causing Respiratory Distress in Neonates

Difficulty breathing and respiratory distress are among the most common reasons for ill neonates to be brought to the ED. Clinicians must be able to distinguish between upper airway disorders causing stridor, lower respiratory disorders (e.g., pneumonia, bronchiolitis, bronchopulmonary dysplasia), and nonrespiratory disorders (e.g., congenital heart disease).

Neonatal Stridor

Neonates with upper airway obstruction present with respiratory distress and stridor (see Chapter 34, Stridor in Infancy). Stridor is primarily inspiratory with supraglottic disorders (e.g., laryngomalacia), biphasic or inspiratory and expiratory with glottic and subglottic disorders (e.g., vocal cord disease, subglottic stenosis), and expiratory with tracheal disease (e.g., tracheomalacia).⁹ Contrary to classic teaching,⁹ the pitch is not a useful discriminator between diseases causing stridor and wheezing.¹⁰

Laryngomalacia is the most common cause of stridor in neonates.¹¹ Onset of stridor occurs within the first 2 to 4 weeks of life; stridor is worse with crying and agitation, and is relieved by lying in the prone position. Gastroesophageal reflux often accompanies laryngomalacia. The second most common cause of neonatal stridor is vocal cord paralysis,

with nearly one quarter of cases bilateral. Unilateral paralysis leads to a weak cry and aspiration since the affected vocal cord is abducted. If paralysis is bilateral, stridor is usually severe, the cry may be strong, and aphonia is present since the vocal cords are usually paralyzed in the midline. Bilateral vocal cord paralysis can cause apnea, severe stridor, and respiratory arrest. While most cases are idiopathic, vocal cord paralysis, especially if bilateral, may be due to intracranial disease (hemorrhage, hydrocephalus, Arnold-Chiari malformation, meningoencephalocele). Other less common causes of neonatal stridor include tracheomalacia, laryngeal webs, subglottic stenosis (postintubation), hemangiomas, papillomas, abscesses, and vascular slings.⁹

While management of stridor depends on the underlying cause, neonates with new-onset stridor require admission for diagnostic evaluation (e.g., laryngoscopy, bronchoscopy) and treatment. Although laryngomalacia is usually benign and self-limited, occasionally stridor is severe and requires emergent intervention. Pulling the tongue and mandible forward and placing the neonate in the prone position may improve symptoms. Bag-mask ventilation or endotracheal intubation also may be required.

Lower Respiratory Tract Infections

Respiratory infections are an important cause of severe illness in neonates (see Chapter 57, Bronchiolitis; and Chapter 58, Pneumonia/Pneumonitis). Early-onset pneumonia that occurs within 7 days of birth is most commonly due to group B streptococcus. Organisms causing early-onset pneumonia are contracted congenitally or via the intrauterine route (herpes simplex, cytomegalovirus, adenovirus, *Treponema pallidum*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*) or after birth (group B streptococcus, *Escherichia coli*, *Klebsiella pneumoniae*, *Ureaplasma urealyticum*). Risk factors include maternal amnionitis, prolonged rupture of membranes, low Apgar scores, prematurity, and placental abruption. Late-onset pneumonia in the discharged neonate begins more than 7 days after birth. In addition to the organisms causing early-onset pneumonia, late-onset pneumonia may be due to respiratory syncytial virus, *Streptococcus pneumoniae*, *Staphylococcus aureus* (often acquired nosocomially), and both nontypable and type B *Haemophilus influenzae*.

Manifestations of neonatal pneumonia include respiratory difficulty (e.g., tachypnea, retractions, grunting, respiratory distress, rales, wheezing, cyanosis) and nonspecific symptoms (e.g., temperature instability, feeding difficulty, irritability). Group B streptococcus can produce a rapid onset of respiratory distress and hypotension, often with coexisting sepsis and meningitis. Chest radiography may show diffuse bilateral granular infiltrates or patchy infiltrates with occasional pleural effusions. Respiratory syncytial virus (RSV) often causes bronchiolitis with wheezing, tachypnea, and feeding difficulty. Radiography may be normal or reveal hyperinflation, interstitial infiltrates, or atelectasis. This virus has the potential to cause severe disease in premature neonates, or those with underlying cardiac or pulmonary disease. *Chlamydia trachomatis* is an important cause of pneumonia in neonates 3 weeks old and older. Onset is insidious, fever is uncommon, and conjunctivitis is present in half of all cases.¹² Radiography typically shows bilateral interstitial infiltrates with hyperinflation. *Bordetella pertussis* may

be one of the most common causes of death from community-acquired infections in infants under 2 months old.¹³ Most cases of pertussis are acquired from an infected mother.¹⁴ The classic stages of pertussis (asymptomatic, catarrhal, and paroxysmal cough) often do not occur in neonates.¹⁵ The catarrhal stage (nasal discharge, sneezing) is often brief or absent.¹⁵ Most neonates do not develop a paroxysmal cough or inspiratory whooping. Symptoms include tachypnea, recurrent gagging, apnea, cyanosis, feeding difficulty, and post-tussive emesis.¹⁵ Radiography may show perihilar infiltrates and atelectasis. Pneumothorax, pneumomediastinum, and bronchiectasis may be seen. Lymphocytosis, which is common in older children and adults, is usually absent in neonates. Complications of pertussis include ventricular fibrillation, cardiac arrest, seizures, subarachnoid hemorrhage, rectal prolapse, hernias, and dehydration.¹⁵

Laboratory testing is often not useful in diagnosing neonatal pneumonia. An elevated serum WBC count is nonspecific, and blood cultures are positive in a minority of neonates with bacterial pneumonia.¹⁶ Urine latex agglutination testing for group B streptococcus is available but has limited sensitivity.¹⁶ A nasopharyngeal swab can be obtained and tested via enzyme immunoassay or polymerase chain reaction for RSV or direct fluorescent antibody (DFA) for pertussis. Serologic confirmation of pertussis can be performed via enzyme-linked immunoassay (ELISA). Any conjunctival discharge in a neonate with pneumonia should be tested for *Chlamydia trachomatis* via DFA or ELISA. However, neither test is as sensitive as a culture.

Management of lower respiratory infection (pneumonia and bronchiolitis) in neonates includes administration of oxygen and IV fluids, continuous cardiac monitoring, and pulse oximetry. For neonates who are wheezing, a trial of inhaled β -agonists or epinephrine may be useful. Use of steroids for wheezing is controversial. Broad-spectrum IV antibiotics are indicated for pneumonia, including ampicillin plus gentamicin or cefotaxime. *Chlamydia trachomatis* is treated with a macrolide. Treatment of pertussis may only be effective during the catarrhal stage, with antibiotic options including macrolides and trimethoprim-sulfamethoxazole.

Bronchopulmonary Dysplasia

By definition, infants with bronchopulmonary dysplasia (BPD) have required oxygen for at least 28 days after birth at least up to 36 weeks of age (gestational age at birth plus post-natal age). BPD usually develops in premature neonates being

treated with oxygen and positive pressure ventilation for respiratory insufficiency. Pulmonary damage causes increased airway resistance, decreased lung compliance, increased airway reactivity, and increased airway obstruction. Increased pulmonary vascular resistance, right and left ventricular hypertrophy, and systemic hypertension can also occur. Infants may present with respiratory distress, tachypnea, and wheezing. Congestive heart failure may also occur. Many infants have baseline hypoxemia and cannot maintain their oxygen saturation above 90% without supplementation. Arterial blood gas analysis may reveal hypoxia, elevated bicarbonate levels, or elevated partial pressure of carbon dioxide due to chronic respiratory insufficiency. Acute exacerbations of illness may be associated with viral infections (e.g., RSV) with an increased risk of respiratory failure, apnea, and pneumonia. Chest radiography may be difficult to interpret due to chronic changes. By the time patients are discharged home from their initial hospitalization, cystic lucencies, increased lung volumes, and fibrotic scarring are present on plain radiographs. It is important to compare current radiographs to prior films to assess for interval changes (e.g., new infiltrate). Treatment consists of bronchodilators (albuterol, ipratropium), and steroids for acute wheezing. If fluid overload is present, diuretics are administered. All infants with BPD and acute respiratory symptoms require hospital admission.

Cardiac Disease

Neonates with congenital heart disease (CHD) often present in the first month of life (see Chapter 30, Congenital Heart Disease). Congenital heart disease occurs in 8 of every 1000 live births. Most infants with cardiac emergencies who present in the neonatal period will have *cyanosis, cardiovascular collapse, congestive heart failure, or an arrhythmia*. Disorders causing these symptoms present at different times during the first month of life (Table 7–2).¹⁷

Structural abnormalities of the heart, if presenting during the neonatal period, will generally present in one of three ways: (1) cyanosis due to right-to-left shunting of blood within the heart; (2) a mottled or gray appearance due to outflow obstruction, with shock often mimicking sepsis; or (3) congestive heart failure due to left-to-right intracardiac shunting.

Chest radiography, arterial blood gases, and clinical evaluation can discriminate between disorders with these features. Left-to-right shunt lesions (e.g., ventricular septal defect) cause pulmonary congestion (Table 7–3) These patients will

Table 7–2 Most Common Congenital Cardiac Defects Diagnosed at Different Neonatal Ages

0–6 Days		7–13 Days		14–28 Days	
D-Transposition of great arteries	19%	Coarctation of aorta	16%	VSD	16%
Hypoplastic LH	14%	VSD	14%	Coarctation of aorta	12%
Tetralogy of Fallot	8%	Hypoplastic LH	8%	Tetralogy of Fallot	7%
Coarctation of aorta	7%	D-Transposition of great arteries	7%	D-Transposition of great arteries	7%
VSD	3%	Tetralogy of Fallot	7%	Patent ductus	5%
Other defects	49%	Other defects	48%	Other defects	53%

Abbreviations: LH, left heart; VSD, ventricular septal defect.

Table 7-3 Causes of Congestive Heart Failure in Neonates

Noncardiac disorders (the most common cause of CHF in the first 24 hr of life)
Severe anemia
Sepsis
Metabolic disorders (acidosis, hypothermia, hypoglycemia, hypocalcemia)
<u>Left-to-right</u> intracardiac shunt
Ventricular septal defect, large
Arteriovenous malformations
Complete atrioventricular canal
Patent ductus arteriosus, large
<u>Right-to-left</u> intracardiac shunts
Transposition of the great arteries
Total anomalous pulmonary venous return
Truncus arteriosus
Diminished left ventricular function or output (less common and often associated with shock)
Hypoplastic left heart syndrome
Critical aortic stenosis
Interrupted aortic arch
Cardiomyopathies
Tachyarrhythmias (most commonly supraventricular tachycardia)
Anomalous coronary artery origin
Coronary artery fistulas

usually be able to increase their partial pressure of oxygen (P_{O_2}) to greater than 60 to 70 mm Hg (saturation >90% to 95%) when 100% oxygen is administered for 10 minutes (hyperoxia test). In contrast, patients with cyanotic heart disease usually cannot increase their P_{O_2} above 60 mm Hg (85% to 90% saturation) during a hyperoxia test. Moreover, chest radiography in patients with cyanotic CHD may reveal oligemia (e.g., tetralogy of Fallot) or congestive heart failure (e.g., transposition of the great arteries or total anomalous pulmonary venous return). Management of left-to-right heart lesions causing congestive heart failure consists of oxygen administration, diuretics, vasopressors for hypotension, and vasodilators for afterload reduction (e.g., hypertension, vasoconstriction). Infants with right-to-left cyanotic heart disease with ductus-dependent pulmonary flow (e.g., tetralogy of Fallot, Ebstein's anomaly, critical pulmonary stenosis) or shock due to outflow obstruction require prostaglandin E_1 (see Chapter 30, Congenital Heart Disease).

Selected Disorders Causing Shock in Neonates

Sepsis

Any ill-appearing young infant should be considered septic until proven otherwise (See Chapter 8, Circulatory Emergencies: Shock; and Chapter 13, Sepsis). “Late-onset” sepsis usually occurs after 1 week of age, develops more gradually, and is less associated with perinatal risk factors. Meningitis is a common presentation, and thus a lumbar puncture is indicated in all septic-appearing neonates. Group B streptococcus is the most common bacterial cause of sepsis in the United States. *Listeria monocytogenes*, *E. coli*, *Klebsiella*, enterococcus, non-group D α -hemolytic streptococcus, and *H. influenzae* are other bacterial causes. Viral causes include herpes simplex, enteroviruses (coxsackievirus, ECHO virus), and adenovirus (liver and central nervous system [CNS] are usually involved). The mother of a newborn infected with herpes may be asymptomatic.

In an ill-appearing neonate, the diagnosis of sepsis is often straightforward. However, the clinical signs of sepsis may be more subtle. Lethargy, irritability, and decreased oral intake are common. Other clinical features include vomiting, diarrhea, temperature instability (high or low), abdominal distention or ileus, apnea, tachypnea, cyanosis, respiratory distress, tachycardia, bradycardia, jaundice, pallor, petechiae, and poor perfusion.

The evaluation of a critically ill-appearing neonate requires a physical examination to look for sources of infection such as herpes lesions or omphalitis. Neonates with herpes may present with a disseminated infection involving multiple organ systems, or encephalitis with or without a rash, or less commonly with disease localized to the skin, eyes, or mouth. If lesions are to be found, they will usually appear on the birth “presenting” portion of the baby. If the child was delivered head first, the scalp must be thoroughly examined for lesions, especially where a fetal scalp electrode may have been inserted. If the CSF has many WBCs or a predominance of red blood cells but no organisms on Gram stain, herpesvirus infection should be considered. If herpesvirus is suspected, a polymerase chain reaction assay for herpes can be obtained on a sample of the CSF. This test is more than 95% sensitive for herpes meningitis and encephalitis.¹⁸

Several serum parameters are elevated in neonatal sepsis. An immature neutrophil-to-total neutrophil ratio greater than 0.2 is 60% to 90% sensitive and 70% to 80% specific for diagnosing neonatal sepsis, while an abnormal C-reactive protein is 75% sensitive and 86% specific for this disorder.¹⁹⁻²¹ Limited studies have found that an elevated interleukin-6 level (100 or 135 pg/ml cutoff) is 81% to 93% sensitive and 86% to 96% specific, a procalcitonin level greater than 0.5 $\mu\text{g/L}$ is 93% to 100% sensitive and 92% to 98% specific, and an elevated tumor necrosis factor- α level is 72% to 95% sensitive and 43% to 78% specific for diagnosing neonatal sepsis.²²

Any ill-appearing infant who is considered septic needs all body fluids cultured, including CSF. Positioning the infant in a sitting position or lateral nonflexed position may be less likely to make the child hypoxic during lumbar puncture (LP). All young infants should be placed on a pulse oximeter during the LP. Be wary of performing an LP on a critically ill-appearing young infant as the risk of apnea is higher. It may be better to forego the LP, administer antibiotics, and examine the CSF when the infant is more hemodynamically stable. A urinalysis is insufficient to rule out a urinary tract infection in very young infants. A culture must be sent at the same time. A chest radiograph can be obtained but is unlikely to have significant findings if the child has no signs of respiratory or cardiac disease.

All critically ill-appearing neonates should be admitted to the hospital. Management includes correction of hypovolemia, hypoglycemia, electrolyte disorders, and hypothermia. If sepsis is a consideration, antibiotics should be administered in the ED. Ampicillin 200 mg/kg/day IV every 6 hours (to treat gram-positive organisms, *Listeria*, and enterococcus) plus gentamicin (synergism plus broad gram-negative coverage) are recommended in the treatment of neonatal sepsis. Gentamicin is nephrotoxic and ototoxic; therefore, the exact dosage depends on the neonate's gestational age and weight:

1. If the neonate is 0 to 4 weeks old and the birth weight was <1200 g, administer 2.5 mg/kg IV every 18 to 24 hours.
2. If the neonate is <1 week old and the birth weight was >1200 g, administer 2.5 mg/kg IV every 12 hours.
3. If the infant's age is >1 week and the birth weight was 1200 to 2000 g, administer 2.5 mg/kg IV every 8 to 12 hours.
4. If the infant is >1 week old and the birth weight was >2000 g, administer 2.5 mg/kg every 8 hours.

If the CSF is positive or suspicious for infection, then the infant should receive ampicillin (200 mg/kg/day divided q 6 hours) plus cefotaxime (100 mg/kg/day divided q 12 hours). A recent study questioned the use of ampicillin as *Listeria* did not seem to be a consideration today in septic neonates; however, the sample size was too small to definitively exclude *Listeria* as a pathogen.²³ Acyclovir 20 mg/kg per dose every 8 hours (every 12 hours if gestational age plus age in weeks = 34 weeks) IV is administered to cover herpesvirus infections in the following situations^{24,25}:

- WBCs or high protein but no organisms are found on CSF.
- CSF pleocytosis is present with vesicular rash on infant, focal neurologic signs, pneumonitis or hepatitis, or a maternal history of herpes.
- There is an elevated red blood cell count in the CSF.

Congenital Obstructive Left Heart Syndromes

Patients with congenital obstructive left heart syndromes (e.g., hypoplastic left heart, coarctation of the aortic, interrupted aortic arch) present dramatically with shock that is often mistaken for sepsis (see Chapter 30, Congenital Heart Disease). Importantly, 85% manifest cardiomegaly, 70% have diminished lower extremity pulses (and lower arterial saturation in the feet compared to the hands), and over half have a murmur noted on examination.²⁶ Clinicians must be aware that prostaglandin E₁ may be life saving in patients with ductus-dependent systemic flow (hypoplastic left heart, interrupted aortic arch, critical coarctation of the aorta, transposition of the great arteries with tricuspid atresia) and pulmonary flow (tetralogy of Fallot, Ebstein's anomaly, critical pulmonic stenosis, tricuspid atresia, and pulmonary valve atresia).

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) occurs in approximately 1 of every 15,000 live births (see Chapter 108, Addisonian Crisis). CAH is adrenal insufficiency resulting from deficient activity of one of the five enzymes required to produce cortisol. The most commonly deficient enzyme is 21-hydroxylase. This results in decreased conversion of 17-hydroxyprogesterone to 11-desoxycortisol in the glucocorticoid pathway. This decreased conversion leads to a *deficiency in cortisol* synthesis, which results in cardiovascular collapse. Hyperplasia of the adrenal gland develops as a result of overstimulation by adrenocorticotropic hormone (ACTH) (which has no negative feedback from cortisol).

Most infants affected by this enzyme deficiency have decreased conversion of progesterone to 11-desoxycorticosterone in the mineralocorticoid pathway. This leads to a *deficiency of aldosterone* synthesis with urinary salt wasting.

Aldosterone deficiency results in classic electrolyte findings and also contributes to cardiovascular collapse.

As a result of elevated ACTH stimulation, adrenal *steroid precursors accumulate* and are metabolized to *androgens*, resulting in the virilization of the external genitalia in female infants. Female infants are more likely to be found to have this disorder in the neonatal nursery because of the external findings. Since male infants' genitalia usually are not affected, this disorder may go unrecognized, putting male infants at greater risk for presentation to the ED.

Clinical signs include total body salt depletion, vomiting, and dehydration that may lead to circulatory collapse and death during the initial 2 to 3 weeks of life (commonly at the end of the first week of life). Females may have enlarged clitoris and fusion of labial folds; in some, the female infant may be mistaken for a male. An affected male infant may have a small phallus.

Laboratory tests may reveal hyponatremia, hyperkalemia, azotemia, and metabolic acidosis. Potassium levels can be as high as 9. Hypoglycemia can also be present. When blood is drawn for testing, an additional 5 ml should be saved (in a red-topped tube) so that blood can be sent for 17-hydroxyprogesterone, dehydroepiandrosterone, androstenedione, and testosterone levels. If possible, this sample should be drawn before giving hydrocortisone. Volume is restored with 0.9% normal saline boluses, and then D₅ 1/4 NS is administered at 1 to 1¹/₂ times the maintenance rate. Cortisol replacement is accomplished with hydrocortisone 1 to 2 mg/kg IV for term infants, then 25 to 100 mg/m²/day divided into three to four doses every 6 to 8 hours. Extreme hyperkalemia is usually well tolerated, and saline is usually the only measure needed to lower potassium. Intravenous 10% calcium gluconate, β-agonists, insulin, and glucose may be used if arrhythmias occur (see Chapter 114, Hyperkalemia). As in any critically ill infant, the temperature and glucose must be monitored throughout the resuscitation and ED stay.^{4,6}

Other important disorders causing shock in neonates include hypovolemia from gastroenteritis, gastrointestinal bleeding (see Chapter 75), arrhythmias (see Chapter 63), inborn errors of metabolism (see Chapter 29 and "Neurologic Presentation of Serious Illness in Neonates" later in this chapter), and abdominal catastrophes.

Serious Disorders Causing Gastrointestinal Complaints in Neonates

Vomiting (bilious and nonbilious), diarrhea, gastrointestinal bleeding, and jaundice are important clinical features that may indicate critical illness in neonates. It is important to differentiate between bilious and nonbilious vomiting. In a neonate, bilious vomiting is a surgical emergency until proven otherwise. Studies have shown that 20% to 50% of neonates presenting with bilious emesis within the first week of life have a surgical condition.²⁷⁻²⁹ For example, bilious vomiting is common symptoms in infants who have malrotation with volvulus.

Volvulus

Volvulus begins with congenital malrotation of the midgut portion of the intestine (see Chapter 83, Malrotation and Midgut Volvulus). During the fifth to eighth week of embryonic life, the embryonic intestine rotates 270 degrees. If there is no rotation or incomplete rotation, the intestine will not

be attached correctly at the mesentery. This puts the bowel at risk for volvulus or twisting of a loop of bowel about its mesenteric base attachment. This is a true surgical emergency because bowel necrosis can occur within hours of onset of the twisting.

Infants with malrotation can present with (1) a sudden onset of bilious vomiting and abdominal pain consistent with an acute volvulus; (2) duodenal obstruction due to obstructing Ladd bands; or (3) intermittent vomiting, constipation, and failure to thrive due to feeding intolerance from an internal hernia.³⁰⁻³³ Bilious vomiting in neonates is always worrisome and should be considered a true emergency until proven otherwise. Most neonates with volvulus are described as well appearing; however, if the bowel is already ischemic or necrotic, they may develop shock. The abdomen is usually not distended. The pain is a constant pain, not usually intermittent, although this finding is difficult to discern in neonates. Jaundice and hemochezia are late and ominous signs.

Laboratory tests in cases of volvulus may show dehydration and acidosis. With a volvulus, plain abdominal radiography may be normal or show a small bowel obstruction. If a duodenal obstruction is present, abdominal radiography may show the classic “double bubble sign” (a paucity of gas [airless abdomen] with two air bubbles—one in the stomach and one in the duodenum).

An upper gastrointestinal contrast study is the procedure of choice for diagnosing a volvulus. The small intestine is rotated to the right side of the abdomen with a midgut volvulus. Contrast will be seen to narrow at the site of obstruction (“cork-screwing”). Ultrasound may show spiraling of the small bowel about the superior mesenteric artery. Ultrasound may also show a distended, fluid-filled duodenum; increased peritoneal fluid; and dilated loops of small bowel to the right of the spine.³⁴⁻³⁶

The diagnosis of volvulus needs to be made rapidly. Rehydration of the infant is important, using 20-ml/kg boluses of normal saline as needed. A nasogastric tube is placed. Antibiotics effective against enteric organisms (e.g., ampicillin, clindamycin, gentamicin) should be administered if shock or peritonitis is present. When the diagnosis is being considered, a surgeon should be contacted immediately, prior to contrast imaging or ultrasonography. Some pediatric surgeons may take an ill-appearing neonate with bilious vomiting to the operating room directly without additional diagnostic radiologic tests.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is usually seen in premature infants but can be seen in term infants, usually in first 10 days of life. Often these infants have a history of an anoxic event or stress at birth. Infants with NEC can appear ill, with lethargy, irritability, anorexia, a distended abdomen, and bloody stools. Plain abdominal radiography usually shows pneumatosis cystoides intestinalis caused by gas in the intestinal wall. Antibiotics such as ampicillin, clindamycin, and gentamicin are administered to cover bowel flora. Admission to an intensive care unit and consultation with a pediatric surgeon are imperative. Surgery is generally indicated for perforation, abdominal wall cellulitis, portal vein gas, a fixed abdominal mass, or clinical deterioration indicating intestinal gangrene.

Intestinal Obstruction

Failure to pass meconium within 24 hours of birth, distention, refusal to feed, and bilious vomiting are signs of lower intestinal obstruction in neonates. While many of these infants are detected in the neonatal nursery, occasional cases are discharged home and present acutely to the ED in the first month of life. Disorders causing neonatal lower intestinal obstruction include Hirschsprung’s disease (see Chapter 77, Constipation), anorectal malformations, meconium plug syndrome, small left colon syndrome, hypoganglionosis, neuronal intestinal dysplasia, and megacystis-microcolon-intestinal hypoperistalsis syndrome. Management is medical or surgical depending upon the cause of obstruction.³⁷

Neonates with duodenal atresia can present in a manner similar to those with midgut volvulus. Vomiting is bilious in up to 85% of cases, since the duodenal web or the area of atresia is distal to the ampulla of Vater in most cases. The abdomen may be scaphoid due to a paucity of distal gas or may be distended due to a dilated duodenal loop. Plain abdominal radiography may reveal a double bubble with air in the stomach and in the proximal duodenal loop. Importantly, associated genetic (trisomy 21), congenital cardiac, and gastrointestinal disorders (e.g., imperforate anus) are present in a large number of cases. Preoperative management consists of nasogastric tube placement and fluid resuscitation.

Other disorders causing bowel obstruction in neonates include pyloric stenosis (see Chapter 76), jejunoileal atresia, and rarely appendicitis (see Chapter 73).

Incarcerated Hernia

Incarcerated hernias are more common in premature infants (see Chapter 84, Hernia). The parent may notice swelling in the groin area at the time of diaper change. Incarcerated hernias should be included in the differential diagnosis for an inconsolable crying infant. Gentle reduction (see Chapter 169, Hernia Reduction) can be attempted in the ED after administration of analgesia and sedation. If the hernia is not reducible or ischemic or necrotic bowel is suspected, consultation with a pediatric surgeon is required.

Jaundice

Hyperbilirubinemia with jaundice is an important clinical feature in certain neonates with serious illness. While elevated unconjugated bilirubin is usually physiologic, abnormally high levels can damage the brain, especially in neonates who are premature, or those with hypoxia, hypercarbia, and acidosis.³⁸ Exact levels of unconjugated bilirubin that are of concern at different gestational ages are discussed elsewhere (see Chapter 38, Jaundice). Moreover, pathologic causes of elevated unconjugated bilirubin exist, including ABO incompatibility, inherited red cell disorders, extravasated blood or hematomas, and bowel obstruction (e.g., pyloric stenosis, large or small bowel obstruction). Hemolytic disorders are often associated with anemia (hemoglobin <13 g/dl) and a reticulocyte count greater than 6%. If Rh or ABO blood type incompatibility is present, a Coombs test will be positive. Elevated conjugated bilirubin, defined as greater than 2 mg/dl or greater than 20% of the total bilirubin, is always abnormal. Serious underlying causes include biliary obstruction, infections (e.g., sepsis, urinary tract infections, TORCH

syndrome diseases), toxins, hypothyroidism, hypoadrenalism, and inherited metabolic disorders.³⁹ In addition to high unconjugated bilirubin, jaundice occurring before 24 hours or at greater than 1 week of age, or increasing more than 5 mg/dl/day, or associated with persistent vomiting, ill appearance, or suspected gastrointestinal tract obstruction requires a comprehensive evaluation to exclude serious pathologic causes.

Neurologic Presentation of Serious Illness in Neonates

Seizures

Generalized tonic-clonic, jacksonian march, and absence seizures are rarely seen in neonates (see Chapter 40, Seizures). Electrical discharges are incompletely spread and tend to remain localized due to anatomic and physiologic CNS immaturity. Many neonatal seizures involve subtle motor automatisms. “Electroclinical dissociation” is common as neonates may have clinical seizures without electroencephalographic (EEG) correlation. There are few idiopathic seizures in neonates; a search for the etiology is mandatory. Focal seizures can be caused by metabolic disorders in neonates, and do not necessarily imply a focal CNS lesion. Seizures occur in 0.2% to 1.4% of all newborns; mortality ranges from 15% to 40%.⁴⁰

Seizures may be subtle in the neonate and include multifocal movement, asynchronous bilateral clonic activity, motor automatisms, and the absence of generalized tonic-clonic seizures seen in older infants and children. Examples of motor automatisms include oral-buccal-lingual movements (e.g., lip smacking, tongue thrusting), progressive limb movements (stepping, bicycling, pedaling), and ocular movements (e.g., staring spells, prolonged eye deviation, nystagmus). Nonmotor seizure activity can include vasomotor changes, apnea, pallor, pupillodilation, changes in respiration, changes in heart rate, excessive salivation, and elevation in blood pressure. Clonic seizures may be focal and migratory (first one leg, then the opposite arm), and consciousness is usually maintained. The clonic movement of neonatal seizures is slower and more rhythmic than an older child’s clonic movements. Tonic seizure with hyperextension of the trunk, neck, or limbs is another variant. Neonatal jitteriness (nonseizure) will involve fast movements of all extremities; stimulation will induce movements, movements will stop with restraint or passive flexion, eye movement and gaze are normal, and rarely does jitteriness have autonomic signs or symptoms.

The list of disorders that can cause seizures is extensive (Table 7–4). Clues as to the etiology can be found based on the age of the infant at presentation. Seizures in the first 48 hours are usually due to birth trauma, pyridoxine dependency, hypoxic encephalopathy, or hypoglycemia. Benign familial neonatal seizures usually begin on the second or third day of life and resolve by 1 to 6 months. Infants who present at 4 to 7 days old may be hypocalcemic due to a high phosphate load from formula. Benign idiopathic “fifth day fits” start on the fifth day of life and cease by day 15. Seizures that present after 7 days of age are more likely due to infection.

The prenatal and intrapartum history are important in determining infection risks, prenatal STORCH (syphilis, toxoplasmosis, other infections, rubella, cytomegalovirus,

*Unique to or of particular concern in the neonatal period.

and herpes simplex) studies, substance abuse, perinatal asphyxia, or family history of seizures. Opiate withdrawal seizures can present up to several weeks postbirth. If the infant is bottle fed, it is important to ask how the caregiver mixes the formula. If the caregiver has supplemented or replaced the infant’s diet with free water or tea or other home remedies such as baking soda for colic, hyponatremic seizures can result.

The physical examination should include a blood pressure check for hypertension. An unusual odor of sweat or urine can indicate inborn errors of metabolism. A cranial bruit may be an indication of an intracranial arteriovenous malformation. The skin should be evaluated for jaundice, café-au-lait spots, or herpes vesicles (look at scalp electrode sites). The neurologic examination should include cranial nerves, motor nerves, and neonatal reflexes such as the Moro reflex. Laboratory tests should include glucose, sodium, calcium, and magnesium levels. Other tests to consider include hematocrit, electrolytes, blood urea nitrogen, phosphate, serum ammonia, arterial blood gases, and possibly blood cultures (bacterial and viral), and STORCH titers. Urine should be sent for urinalysis, culture, and toxicology screening. Suspicion of an inborn error of metabolism requires specialized testing (see Chapter 29, Inborn Errors of Metabolism). If another etiology is not found, then CSF will need to be sent

for glucose, protein, cell count, differential, Gram stain, bacterial and viral cultures, polymerase chain reaction for viruses (especially herpesviruses), lactate and pyruvate, and glycine. Cranial computed tomography (CT) is required if an obvious cause is not found on initial evaluation. Head ultrasound can be performed at the bedside to identify hemorrhage (e.g., intraventricular hemorrhage) and hydrocephalus. Magnetic resonance imaging can also identify most acute intracranial disorders; however, this test takes time and requires patient stability. Therefore, it usually not performed on critically ill neonates.

For actively seizing and postictal patients, management consists of first supporting the airway, breathing, and circulation. A bedside glucose must immediately be checked and, if low, corrected with a glucose bolus of 0.5 g/kg (5 ml/kg D₁₀). Standard anticonvulsant therapy, such as benzodiazepines, should be initiated, followed by phenobarbital or dilantin if there is no response to benzodiazepines (see Chapter 40, Seizures). Traditionally, phenobarbital has been preferred over phenytoin for treating neonatal seizures. However, limited studies suggest that both drugs are equally effective in treating neonatal seizures.⁴¹ Antiseizure drug treatment options for seizing neonates include the following:

1. Lorazepam (Ativan) 0.05 to 0.1 mg/kg IV or rectally over 2 to 5 minutes; may repeat 0.05 mg/kg IV once in 10 to 15 minutes
2. Phenobarbital 15 to 20 mg/kg IV (infuse no faster than 1 mg/kg/min); may repeat 5-mg/kg/dose every 15 to 30 minutes, up to total dose of 30 mg/kg
3. Diazepam (Valium) 0.1 mg/kg IV given over 3 to 5 minutes or every 15 to 30 min for two to three doses, or 0.5 mg/kg rectally
4. Phenytoin (or fosphenytoin PE) 15 to 20 mg/kg IV, infusing phenytoin no faster than 0.5 mg/kg/min and fosphenytoin no faster than 2 mg/kg/min

The clinician should use caution when administering benzodiazepines to neonates since they have greater respiratory depression compared to older infants and children. Calcium gluconate 10%, 50 to 200 mg/kg IV (0.5 to 2 ml/kg at 1 ml/min), should be administered if seizing persists after standard therapy and hypocalcemia is suspected or proven. If there is no response to calcium, a slow infusion of magnesium sulfate (25 to 50 mg/kg IV) should be considered since hypocalcemia may not be reversed until hypomagnesemia is corrected. Pyridoxine (vitamin B₆) 50 to 100 mg IV should be administered if the infant is still seizing after standard anticonvulsant therapy, glucose, and calcium infusion. Pyridoxine is a cofactor for the synthesis of the inhibitory neurotransmitter γ -aminobutyric acid. Infants whose mothers are on isoniazid are at risk for vitamin B₆ deficiency. Hypertension-induced seizures are treated with antihypertensive medications. EEG monitoring may be required during intensive anticonvulsant therapy to verify whether or not seizures are present. Antibiotics (i.e., cefotaxime and ampicillin) should be administered to septic neonates. Acyclovir 20 mg/kg per dose every 8 hours (every 12 hours if gestational age plus age in weeks = 34 weeks) IV should be considered if there are WBCs or high protein but no organisms on CSF assay, pleocytosis, vesicular rash on the infant, or focal neurologic signs; if pneumonitis or hepatitis is present; or if there is a maternal history of herpes. All

neonates with seizures require admission to a monitored bed.^{42,43}

Central Nervous System Disorders

Neonates with an intracranial bleed also can appear critically ill. Symptoms include vomiting, lethargy, seizures, and an altered mental status (see Chapter 42, Conditions Causing Increased Intracranial Pressure). Birth-related trauma can cause parenchymal and intraventricular hemorrhage, especially if the neonate was premature or underwent a precipitous delivery. Infarction occurs in up to 15% of neonates with intracranial bleeding.⁴⁴ Delayed development of hydrocephalus may occur in 5% of cases.⁴⁵ CT is required if bleeding or hydrocephalus is a concern, while magnetic resonance imaging may be required to make the diagnosis of infarction. Young infants also can be victims of nonaccidental trauma. CT findings suggestive of nonaccidental trauma include subarachnoid hemorrhage, interhemispheric subdural hematomas, and multiple skull fractures (especially in different stages of healing) (see Chapter 119, Physical Abuse and Child Neglect).

Hemorrhagic disease of the newborn can manifest as intracranial bleeding. At birth, neonates receive an intramuscular (IM) injection of vitamin K to combat the normal transient decrease in vitamin K–dependent coagulation factors (II, VII, IX, X) that occurs 48 to 72 hours after birth, with gradual return to normal by 7 to 10 days. This decrease is probably due to lack of free vitamin K in the mother and an absence in the newborn of bacterial intestinal flora normally responsible for synthesis of vitamin K. Infants born at home may not receive regular neonatal care, or the hospital nursery may fail to give vitamin K as an oversight. Breast milk has minimal vitamin K (15 mcg/ml); infant formulas are fortified with 50 to 100 mcg/ml. Breast-fed infants' intestines are colonized with lactobacilli, which are incapable of synthesizing vitamin K; formula-fed infants' intestines are colonized with *E. coli*, which produces vitamin K.

Neonates who do not receive IM vitamin K at birth are at risk for hemorrhagic disease of the newborn. Early presentation occurs at less than 24 hours of age and may be due to maternal drugs that interfere with vitamin K metabolism (phenobarbital, dilantin, rifampin, isoniazid, coumadin). These patients may present with umbilical or circumcision site bleeding.

Classic presentations occur on the second to fifth day of life and are found in breast-fed infants who did not receive vitamin K at birth. Infants present with spontaneous bruising and gastrointestinal, nasal, subgaleal, intracranial, or circumcision site bleeding. Late presentation develops after 2 weeks in breast-fed infants who did not receive vitamin K at birth. Infants can present as late as 1 to 2 months old with pallor, intracranial hemorrhage, deep ecchymosis, or nodular purpura, which may be mistaken for child abuse. During evaluation of infants with spontaneous bleeding, the clinician should examine the midhigh area for evidence of a vitamin K needle stick. Laboratory results include a normal platelet count, prolonged partial thromboplastin time, and prolonged prothrombin time. Resuscitation is directed at correcting respiratory insufficiency and hypovolemia with administration of packed red blood cells (type O, Rh negative), 10 ml/kg over 20 to 30 minutes. For severe bleeding, the coagulopathy is corrected with fresh frozen plasma,

10 ml/kg. The infant should be given 1 mg vitamin K and admitted for observation.⁴

Inborn Errors of Metabolism

Inborn errors of metabolism refer to the hundreds of hereditary biochemical disorders resulting in the alteration of a protein structure or the amount of a protein being synthesized (see Chapter 29, Inborn Errors of Metabolism). Inborn errors are usually caused by deficiency of an enzyme needed to convert one metabolite to another. This results in the accumulation in body fluids of a metabolic intermediate that is normally present in low concentrations. Normally these metabolic intermediates are not toxic, but high levels can cause serious effects. The usual target organ affected is the CNS, followed by the gastrointestinal tract, with up to 93% of infants manifesting signs and symptoms related to one of these systems.⁴⁶ Most inborn errors manifest themselves in the newborn period or soon after.

The most common inherited metabolic disorders presenting with acute, life-threatening encephalopathy are organic acidemias, urea cycle defects, and specific amino acid defects.⁴⁷ Hypotonia, lethargy, coma, seizures, cerebral edema, intracranial bleeding, or other neurologic abnormalities occur in 85% of cases. In addition to neurologic features, neonates frequently manifest gastrointestinal symptoms, including vomiting, hepatic dysfunction, feeding difficulty, and diarrhea.⁴⁶ Hepatomegaly, jaundice, and a coagulopathy may be present. Many of these infants will have a peculiar odor associated with a particular inborn error. In general, patients have either a metabolic acidosis, elevated ammonia, hyperglycemia, hypoglycemia, or a combination of these serum abnormalities (Table 7–5). More intensive testing will reveal elevated levels of a particular metabolite in the serum or urine (specific amino acids, pyruvate, organic acids, carnitine, galactose). Tissue biopsy, fibroblast culture for enzyme assay, and DNA studies may be required to confirm the diagnosis. Viral or bacterial infection, introduction of a new food, or high protein ingestion can trigger the presentation of the inborn error. Because these disorders run in families, the

clinician should ask about previous siblings, especially males, who died in infancy. A history of deterioration in a previously well neonate should be considered sepsis or an inborn error until proven otherwise. Specific management is directed at treating precipitants and reversing hypoglycemia, hypovolemia, and acidosis (administering vitamin B₁₂ for methylmalonic acidemia, biotin for carboxylase deficiency). Ammonia may be reduced by arginine in a urea cycle defect. Dialysis to lower ammonia levels may be needed.

Neonatal Hypocalcemia

Neonatal hypocalcemia is more often seen in the first few days of life but can occur later as a result of high phosphate levels in cow's milk formula, maternal hypoparathyroidism, maternal diabetes, congenital hypoparathyroidism, immature renal function, hypomagnesemia, or maternal vitamin D deficiency (see Chapter 115, Hypocalcemia). Hypocalcemia is defined as plasma calcium less than 7 mg/dl; clinical signs include jitteriness and poor feeding. Tetany may occur with increased muscle activity, twitching, vomiting, carpal pedal spasm, clonus, laryngospasm, or stridor (most classically, the neonate presents only with a weak cry, like a baby lamb.) Young infants with hypocalcemia do not have the classic hypocalcemic tetany signs as in adults. Hypocalcemia can account for up to 34% of neonatal seizures. These seizures can be multifocal or migratory clonic seizures. An ECG showing a QTc interval greater than 0.44 to 0.46 seconds supports the diagnosis of hypocalcemia. Serum calcium, magnesium, and ionized calcium levels should be determined before treatment if possible. Calcium gluconate 10%, 50 to 200 mg/kg IV (0.5 to 2 ml/kg at 1 ml/min), can be administered for hypocalcemic seizures. It should be infused slowly to prevent bradycardia, and repeated as needed. Hypomagnesemia (<1 mEq/L) can be treated with 25 to 50 mg/kg IV or IM magnesium sulfate.

Other Disorders Causing Neurologic Manifestations

Occasionally and unknowingly, a parent may be to blame for a child's seizures. Young infants can be exposed to a variety

Table 7–5 Laboratory Parameters in Inborn Errors of Metabolism

From Rothrock SG: Inborn errors of metabolism. In Rothrock SG (ed): Pediatric Emergency Pocketbook, 5th ed. Lompac, CA: Tarascon Publishing (www.tarascon.com), 2007, p 116, with permission.

of substances that can alter their electrolytes, calcium, or magnesium. Parents may also inappropriately mix formula, using more water than is needed. Infant formula comes in three standard preparations: ready-to-eat liquid, which should not be mixed with water; liquid concentrate, which should be mixed 1 : 1 with water; and powdered formula, which should be mixed 1 scoop to 2 ounces of water.

Home remedies for a variety of ailments may also be given to young infants, causing severe consequences. The clinician must ask about additional liquids, powders, herbs, or other substances given to the neonate since parents will not always volunteer this information. Examples of inappropriate substances given by parents include baking soda for colic or herbal teas for constipation or colic.⁴⁸

Unlike older children, infants can become colonized after ingesting spores of *Clostridium botulinum*. Botulism has been reported in neonates as young as 3 days old,⁴⁹ although the disease peaks in the 2- to 4-month age range. Risk factors include parents who work with soil and who live in a rural area. In the past, ingestion of honey was a common cause; however, educational efforts have diminished this risk factor in the United States. Symptoms are due to cholinergic blockade and include hypotonia, constipation, descending flaccid paralysis, autonomic instability, and absence of cranial nerve reflexes (with dilated pupils). While serum tests are available to aid in diagnosis, these tests are insensitive. Diagnosis is usually made by an assay performed on stool. This may need to be sent to a state health department. Management requires prolonged support of ventilation and nutritional support. Medications that prolong cholinergic blockade (e.g., gentamicin) should be avoided. Human botulinum immune globulin (Baby-BIG), pooled from adults immunized with pentavalent botulinum toxin, is available for infant botulism treatment and can decrease the length of hospitalization by over 50%. It is active against the type A and B toxin but not against types C through F. Trivalent equine immunoglobulin to toxins A, B, and E is available for adults, but is not recommended for use in infants due to a high hypersensitivity rate and short duration of action.⁴⁹

Summary

Managing a critically ill newborn is difficult. Understanding the anatomic and physiologic changes that are occurring can improve the ability to diagnose and manage many disorders at this age. Considering the unique disease processes that present in the neonatal period is also imperative. Preestablished communication between the ED and the neonatal or pediatric intensive care unit is vital for streamlining the transfer for ongoing critical care.

Chapter 8

Circulatory Emergencies: Shock

Christine S. Cho, MD, MPH and Steven G. Rothrock, MD

Key Point

Shock is an abnormal physiologic state of inadequate tissue perfusion that is a common end point for various diseases.

Physiologic subtypes of shock include hypovolemic, cardiogenic, distributive, and obstructive shock. Multiple subtypes of shock can be present with a single disease.

With the exception of cardiogenic shock, the most common mistake in management is not administering enough fluids in a timely fashion.

Use of goal-directed therapy for fluid-refractory septic shock improves outcome.

Introduction and Background

Shock is an abnormal physiologic state in which there is an inability to deliver adequate oxygen to meet the metabolic needs of the body. At the cellular level, impairment of oxygen delivery leads to ischemia, a transition from aerobic to anaerobic metabolism, lactic acidosis, and ultimately organ dysfunction and failure. If interventions are not made in a timely, aggressive manner, individual organ failure will progress to multisystem organ failure and eventual death.

Mortality from septic shock has decreased from 97% to 9% over the last 40 to 50 years due to improved hemodynamic monitoring, advanced life support, and the advent of critical care units.¹ However, infants (especially premature infants) continue to have the highest morbidity and mortality. Racial and regional disparities also exist in shock mortality.^{2,3}

The early recognition of shock can be challenging. Reliance on the development of hypotension before making the diagnosis of shock will lead to underrecognition. This is especially true in children because of their increased physiologic reserve and their ability to maintain a normal blood pressure despite moderate to profound hypovolemia. In fact, children can lose up to 25% to 30% of their blood volume

with only minimal changes in vital signs.^{4,5} The term *compensated shock* is used for patients with shock physiology, but preservation of normal blood pressure. *Decompensated shock* is used when the patient has hypotension, and is usually a late sign of shock. If untreated, decompensated shock will become irreversible, leading to eventual death.

Physiologic subtypes of shock include hypovolemic, cardiogenic, distributive, and obstructive shock. Hypovolemic shock is due to a deficiency in intravascular volume either through insufficient intake or excessive loss of fluid. Cardiogenic shock is due to failure of the heart to provide sufficient cardiac output. Distributive shock is defined as a change in vascular capacitance resulting in peripheral vasodilation and abnormal redistribution of blood flow. Obstructive shock is due to an obstruction of outflow from the heart. The differential diagnosis for each type of shock is extensive (Table 8–1).

While it is useful to distinguish between the physiologic subtypes of shock, recognition and treatment of the specific disorders that lead to shock is equally important. In addition, some diseases have multisystem involvement with several different subtypes of shock. For example, children with septic shock may be hypovolemic from fluid loss and inadequate intake, and may have sepsis-induced myocardial depression that directly limits contractility and cardiac output.

Recognition and Approach

Knowledge of physiologic compensatory responses can help clinicians identify shock subtypes and initiate appropriate management. Cardiac output is regulated by both the heart rate and the stroke volume of each contraction. Preload, cardiac contractility, and afterload determine stroke volume. Preload reflects both the absolute intravascular volume and changes in venous capacitance. Afterload is related to systemic vascular resistance. The primary physiologic response to compensate for shock is via the sympathetic nervous system. Baroreceptors in the carotid sinus and chemoreceptors in the aorta and carotid bodies sense hypovolemia and hypoxemia, respectively, and activate the sympathetic adrenergic response. The release of catecholamines activates α_1 receptors in peripheral vascular smooth muscle, causing peripheral vasoconstriction.⁶ Presynaptic α_2 receptors in the heart and vasculature are activated by norepinephrine released from sympathetic nerves and mediate negative feedback inhibition of further norepinephrine release.

Table 8–1 Differential Diagnosis of Shock by Physiologic Subtypes**Hypovolemic Shock****Decreased Intake****Increased Loss****Intravascular****Blood**

- External trauma (wounds, open fracture)
- Internal trauma (thorax, abdomen, pelvis, long bone fractures, nonaccidental trauma)
- Surgical blood loss
- Gastrointestinal bleed

Nonblood

- Vomiting
- Diarrhea

Beta-blocker

*Although sepsis is classically considered a form of distributive shock secondary to endotoxin-mediated vasodilation, septic shock also comprises elements of hypovolemia and cardiac dysfunction. In addition, septic shock can manifest with either low or high systemic vascular resistance.

Abbreviations: AVM, arteriovenous malformation; COLHS, congenital obstructive left heart syndromes; HLHS, hypoplastic left heart syndrome; SVT, supraventricular tachycardia; TAPVR, total anomalous pulmonary venous return; VSD, ventricular septal defect; WPW, Wolff-Parkinson-White.

Table 8–2 Adrenergic Receptor Actions as They Relate to Treatment of Shock

Receptor	Receptor Actions
α_1	Peripheral vascular, including pulmonary vascular, smooth muscle constriction
α_2	Presynaptic receptors in heart and vasculature are activated by norepinephrine released by sympathetic nerve and mediate negative feedback on further release of norepinephrine Postsynaptic receptors mediate vasoconstriction
β_1	Increased heart rate (chronotropy), AV node conduction (dromotropy), and cardiac contractility (inotropy)
β_2	Increased renin secretion Peripheral vascular and bronchiolar smooth muscle relaxation
β_3	Decreased cardiac contractility (inotropy)
D_1	Renal, coronary, and mesenteric vasodilation
	Stimulate natriuresis
D_2	Inhibit norepinephrine release from nerve endings

Abbreviations: α , alpha; β , beta; AV, atrioventricular; D, dopamine.

Postsynaptic α_1 and α_2 receptors in peripheral vessels mediate vasoconstriction. In the heart, β_1 receptors are activated to increase heart rate (chronotropy), conduction velocity (dromotropy), and contractility (inotropy). In the failing heart, β_3 receptors are upregulated and cause negative inotropic effects mediated by nitric oxide and cyclic GMP (Table 8–2). Peripheral dopamine₁ (D_1) receptors mediate dilation of coronary and mesenteric arteries and stimulate a natriuretic response. Dopamine₂ (D_2) receptors exist on nerve endings and inhibit norepinephrine release from synaptic nerve endings, inhibit release of prolactin, and induce vomiting. Stimulation of either D_1 or D_2 receptors suppresses gastrointestinal (GI) tract function and may precipitate an ileus. Phosphodiesterase (PDE) inhibitors increase contractility by increasing cyclic AMP and potentiating the delivery of calcium into myocardial cells. At the same time, PDE inhibitors dilate peripheral blood vessels. Knowledge of individual receptor functions and the mechanism of different vasoactive agents allows clinicians to tailor therapy to the specific disease (Tables 8–2 and 8–3).

Individual organs control delivery of oxygen by autoregulation of regional blood flow. Each organ has a critical perfusion pressure below which it cannot maintain adequate oxygen delivery through autoregulation. An important treatment goal in shock is to maintain an adequate perfusion pressure (mean arterial pressure–central venous pressure difference) (Table 8–4). Autoregulation also helps to preferentially perfuse organs that are more vital for survival (e.g., brain, heart, kidneys).

In addition to the sympathetic nervous system, endocrine-mediated mechanisms help maintain perfusion in shock. Atrial receptors in the heart sense decreased volume and stimulate the release of antidiuretic hormone, which acts as a peripheral vasoconstrictor and increases water reabsorption at the renal collecting ducts. The renin-angiotensin-aldosterone system is activated in shock when the kidneys release renin in response to decreased renal blood flow. Angiotensin II is a peripheral vasoconstrictor, and aldoste-

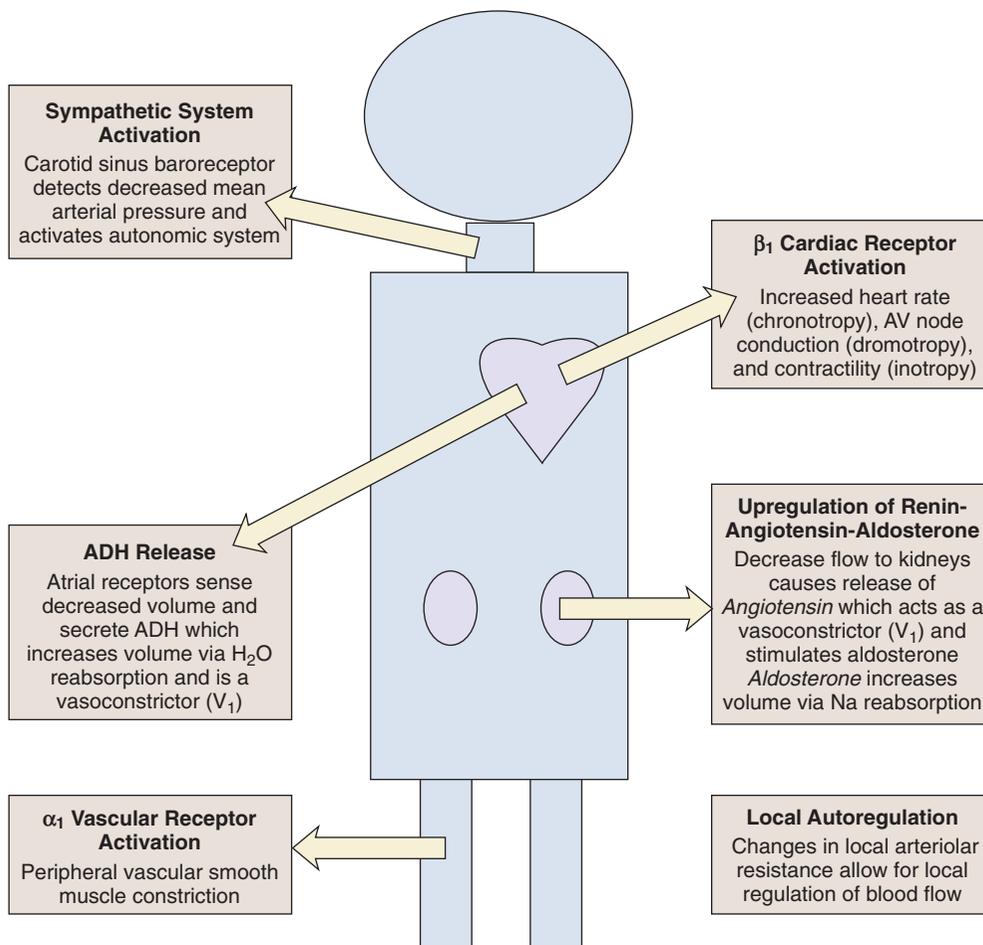

FIGURE 8–1. Physiologic changes in response to shock. Abbreviations: ADH, antidiuretic hormone; AV, atrioventricular; V₁, vasopressin receptor.

Table 8–3 Common Vasoactive Medications Used in Treatment of Shock

Drug	Receptor Activation*	Dose (mcg/kg/min)	Physiologic Result†
Dopamine	D ₁ , β ₁ , α ₁ (α at high doses)	<5 5–10 >10	Predominately increased renal, mesenteric, and coronary beds Cardiac stimulation (inotropy or contractility, heart rate) Peripherally vasoconstricts to increase blood pressure
Dobutamine	β ₁ , β ₂ >> α ₁	2–20	Cardiac stimulation, vasodilator
Epinephrine	β ₁ , β ₂ , > α _{1/2} (α at high doses)	Low: 0.01–0.3 High: >0.3	Cardiac stimulation Cardiac stimulation and vasopressor
Norepinephrine	α _{1/2} , β ₁	0.05–2	Vasopressor, cardiac stimulation
Isoproterenol	β ₁ , β ₂	0.1–2	Cardiac stimulation
Phenylephrine	α ₁	0.1–0.5	Vasopressor
Milrinone	PDE inhibitor	Loading: 50 mcg/kg Then 0.5–1	Cardiac stimulation, vasodilator
Nitroprusside	Activation of NO	0.3–10	Vasodilator

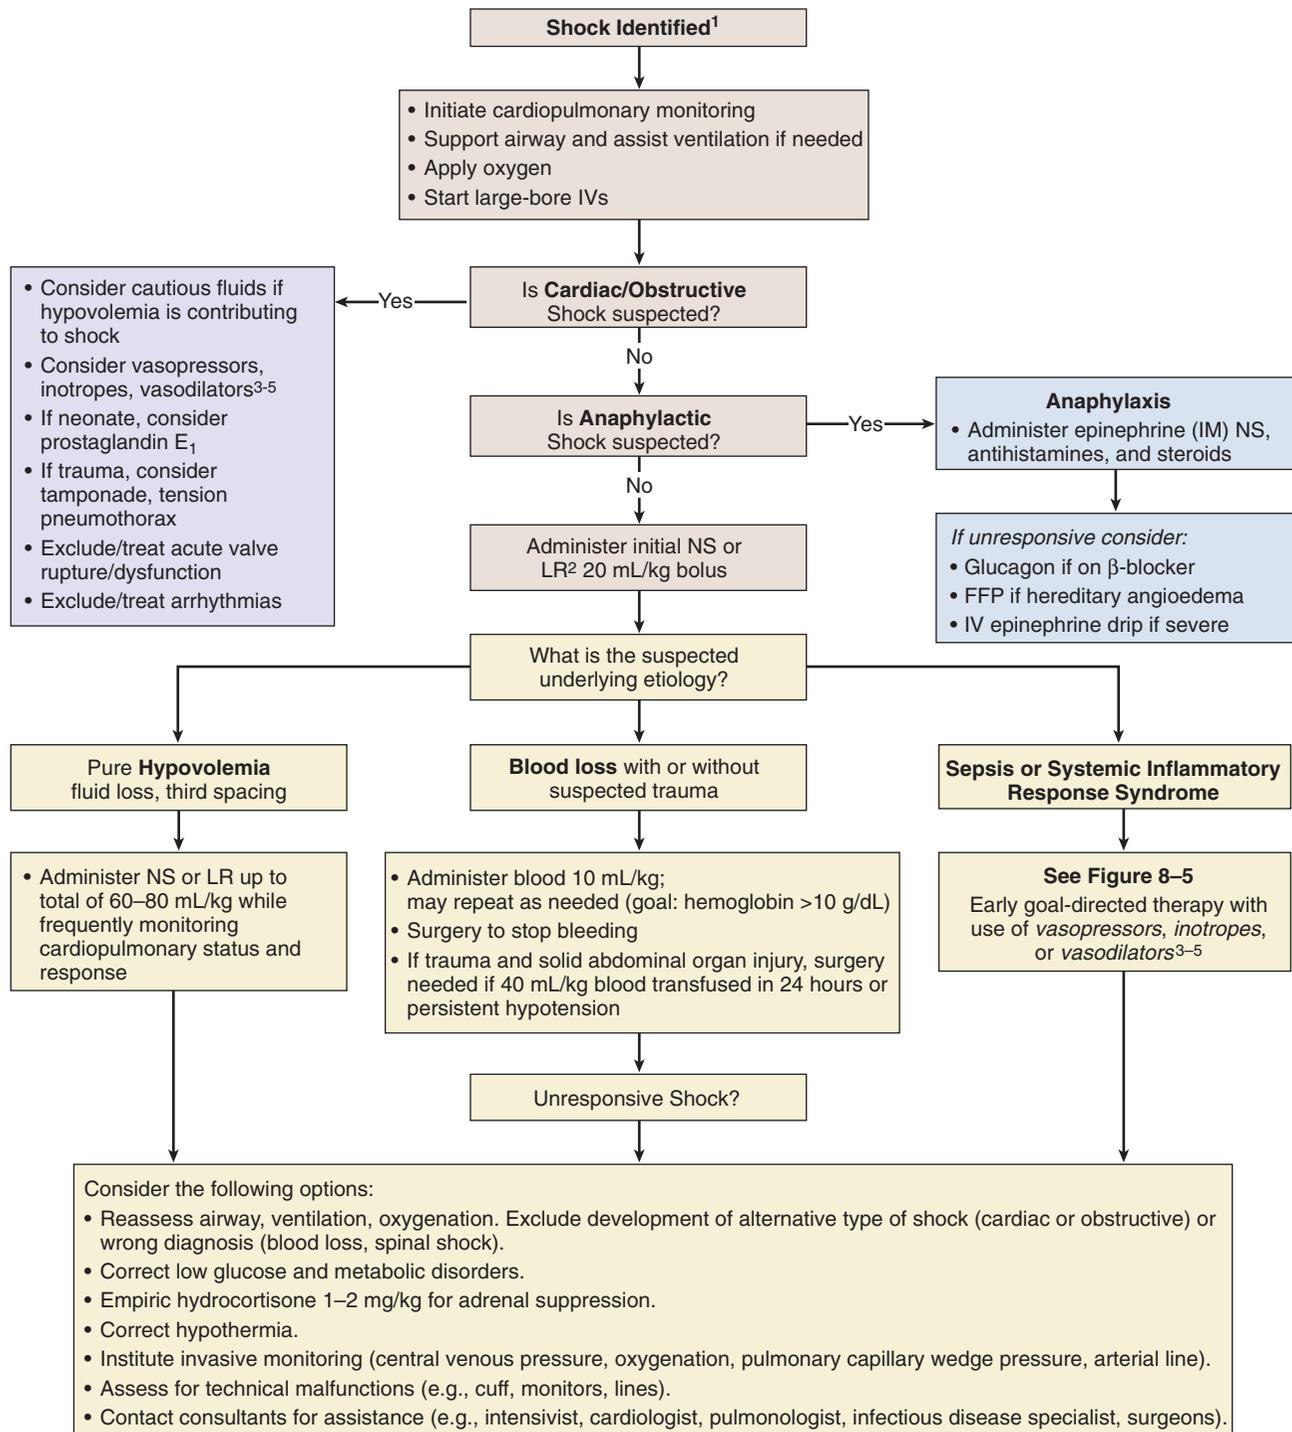

*β₁, Beta₁-adrenergic receptor; β₂, beta₂-adrenergic receptor; α₁, alpha₁-adrenergic receptor; α_{1/2}, alpha₁- and alpha₂-adrenergic receptors; D₁, dopaminergic receptor; PDE, phosphodiesterase; NO, nitric oxide.

†Cardiac stimulation: increases cardiac contractility, heart rate, and atrioventricular nodal conduction; Vasopressor: peripheral vasoconstriction (increasing systemic vascular resistance); Vasodilator: peripheral vasodilation (decreasing systemic vascular resistance).

rone will increase volume via sodium reabsorption at the kidneys (Fig. 8–1).

Various physiologic parameters can be directly or indirectly measured during shock resuscitation. If a central line is placed into the superior vena cava, central venous pressure

and venous oxygen saturation can be monitored. If a pulmonary artery catheter is placed, cardiac index and systemic venous resistance can be calculated to help in the selection of vasoactive agents (Figs. 8–2 and 8–3) (see Chapter 5, Monitoring in Critically Ill Children).

¹ Algorithm is a suggested general approach that does not cover all diagnoses, scenarios, and management options. Clinicians should use their judgment and frequently reassess the response to therapy.

² LR, Lactated Ringer's solution; NS, normal saline.

³ *Inotropes*: dopamine (5 and 10 mcg/kg/min), dobutamine, amrinone, milrinone, epinephrine (< 0.3 mcg/kg/min or > 0.3 mcg/kg/min with a vasodilator) to increase the cardiac index (CI) and reverse shock if CI < 3.3 L/min/m² after fluid resuscitation.

⁴ *Vasopressors*: dopamine (≥ 10 mcg/kg/min), norepinephrine, phenylephrine, epinephrine (> 0.3 mcg/kg/min), or vasopressin to increase systemic vascular resistance (SVR) and reverse shock if SVR < 800 dyne-sec/cm⁵/m² after fluid resuscitation.

⁵ *Vasodilators*: nitroprusside, nitroglycerin, or phentolamine to decrease SVR if there is a CI < 3.3 L/min/m² and an SVR > 1600 dyne-sec/cm⁵/m² after fluid resuscitation.

FIGURE 8–2. General approach to management of shock based on etiology. Abbreviations: FFP, fresh frozen plasma; IM, intramuscular; IV, intravenous.

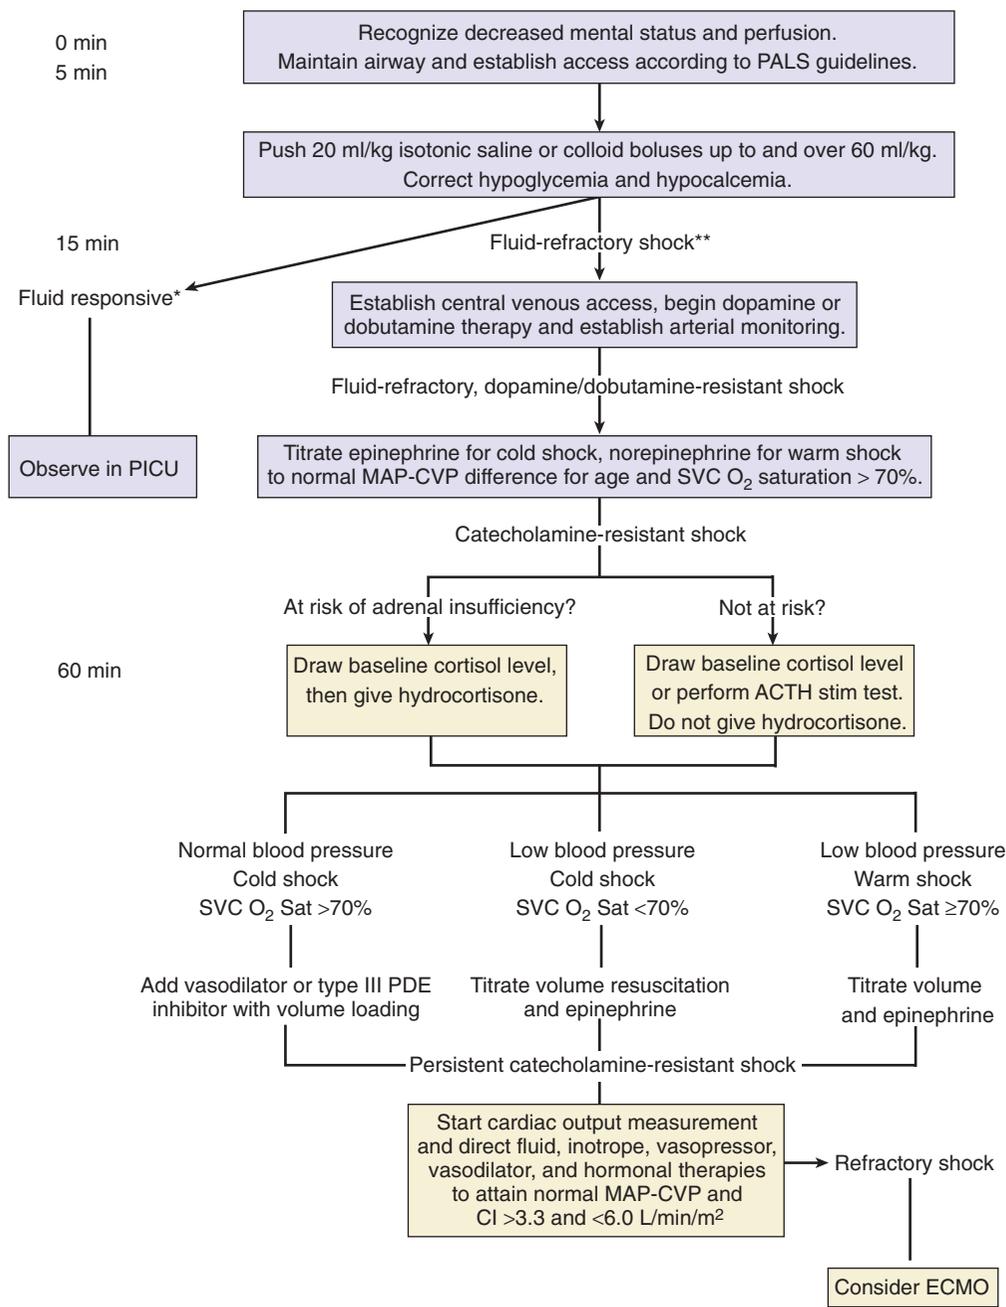

FIGURE 8-3. Algorithm for resuscitation of septic shock. Abbreviations: ACTH, adrenocorticotropic hormone; CI, cardiac index; ECMO, extracorporeal membrane oxygenation; MAP-CVP, mean arterial pressure–central venous pressure difference; PALS, Pediatric Advanced Life Support; PDE, phosphodiesterase; PICU, pediatric intensive care unit; stim., stimulation; SVC O₂, superior vena cava oxygen saturation. Evaluation

Symptoms of disorders causing shock are disease specific (e.g., wheezing and rash in anaphylaxis, abdominal pain in traumatic hemorrhagic due to solid organ injury). Other important symptoms include change in mental status, dyspnea, and decreased urine output. The list of symptoms of organ system dysfunction is extensive and eventually involves most organ systems (Table 8-5).

Vital signs are extremely variable in shock. While isolated tachycardia may be an early and sensitive sign of impaired oxygen delivery, it has poor specificity. Bradycardia is a late finding in shock and indicates impending cardiac or pulmonary arrest. Tachypnea is an early manifestation of shock that is easily overlooked. While hypotension is a poor indicator of early shock, a widened pulse pressure in the setting of a

Table 8–5 Systemic Signs and Symptoms of Impaired Perfusion/Shock

Organ	Early Impairment	Late Impairment
Brain	Change in mental status: irritability, anxiety, confusion, sleepiness, agitation	Lethargy, obtundation, coma
Kidney	Oliguria	Anuria
Liver	Transaminase elevation, hyperbilirubinemia	Liver failure, coagulopathy
Heart	Ischemia, tachycardia, widened pulse pressure	Dyspnea due to congestive failure, bradycardia, malignant arrhythmias
Gastrointestinal tract	Mucosal ischemia, emesis	Ileus, ascites, ischemia with bleeding
Lungs	Pulmonary edema, tachypnea, hypoxemia	Bradypnea, respiratory failure
Hematologic system	Mild bleeding due to coagulopathy, thrombocytopenia	Uncontrolled bleeding due to disseminated intravascular coagulopathy
Skin	Cool and pale, or warm (early sepsis)	Mottled, cold, pale, or purple discoloration

normal blood pressure may be a subtle early finding. Hyperthermia may be present in early septic shock, while hypothermia will eventually develop in all types of shock.

Physical examination findings consistent with shock vary depending on the primary etiology (see Table 8–5). Infants and children with early distributive shock (e.g., neurogenic, early sepsis, anaphylaxis) exhibit warm extremities, bounding peripheral pulses, and a brisk capillary refill time, while most other forms of shock lead to cool extremities, weak pulses, and a delayed capillary refill time. Capillary refill time should be interpreted within the context of the ambient room temperature. In one pediatric study, only 31% of healthy patients in a cold room had a normal capillary refill time.⁷ Capillary refill time also has poor interobserver reliability when assessed in ill children.⁸ In addition, a normal capillary refill time of ≤ 2 seconds is an inaccurate predictor of hemodynamic status in children in pediatric critical care units.⁹ Recognition of physical examination patterns can aid in determining the etiology of shock (Figs. 8–4 and 8–5).

Prompt recognition of shock is important so that aggressive treatment can be initiated. One study found that delayed reversal of septic shock was associated with a greater than twofold increase in mortality for every hour that passed without reversal.¹⁰ Knowledge of the limitations of the history and physical examination and of pattern recognition can assist in an early diagnosis of shock and can help identify the exact cause.

Hypovolemia

Hypovolemia is the most common cause of shock throughout the world. This is primarily due to the high incidence of and morbidity from dehydration due to gastroenteritis in developing countries. In addition to gastroenteritis, several other diseases result in excessive fluid loss and can lead to hypovolemic shock. Examples include hemorrhage from trauma or GI bleeding, as well as fluid loss from burns, diabetic ketoacidosis (DKA), and diabetes insipidus.

In gastroenteritis, a history of vomiting with diarrhea is typically present. Infants and children with shock will exhibit physical examination findings of severe dehydration: cool extremities, weak peripheral pulses, dry mucous membranes, a sunken fontanelle in infants, sunken eyes, diminished skin turgor, and a delayed capillary refill time (see Chapter 72, Vomiting and Diarrhea). The presence of three of four clinical features—ill appearance, dry mucous membranes, diminished capillary refill time, and absent tears—identifies most

children with $\geq 10\%$ dehydration, signifying a population at high risk for hypovolemic shock.¹¹

Patients with DKA are a unique population who often suffer from extreme dehydration. In young children, this can be particularly profound since symptoms of diabetes are difficult to recognize. In the past, there was concern that rapid correction of glucose, sodium, and serum osmolality might harm patients with DKA. However, development of cerebral edema is not associated with the rate of fluid administration or rate of change in serum glucose.¹² Children with DKA and hypotension require aggressive treatment with intravenous fluids in a manner similar to children with other types of hypovolemic shock (see Chapter 105, Diabetic Ketoacidosis).

In a patient who has suffered extensive full-thickness or deep partial-thickness burns, shock may result. The body has lost its protective shield and therefore has increased fluid losses. In addition, massive capillary leak of fluid leads to intravascular hypovolemia. Patients with burns may also have shock from infection and sepsis, although this is more likely in the subacute phase and not when the patient immediately presents to the emergency department (ED). All burns that total 15% of the total body surface area will require aggressive fluid management (see Chapter 26, Burns).

Another etiology of hypovolemic shock is massive GI bleeding. Causes include portal hypertension and esophageal varices from congenital or chronic liver disease, ulcer bleeding, platelet disorders, and coagulopathies. Bleeding from GI infection, inflammatory colitis, ischemic bowel, or surgical disorders (e.g., Meckel's diverticulum) may also lead to blood loss (see Chapter 75, Gastrointestinal Bleeding).

Septic Shock

Sepsis is an inflammatory state in the presence of infection. Five percent to 30% of children with sepsis will develop septic shock.¹³ The systemic inflammatory response syndrome (SIRS) leads to shock through an interplay of mechanisms. Hypovolemia exists from decreased intake prior to presentation. Disruption of vascular integrity and increased vascular capacitance from cytokines also decreases preload and compromises stroke volume. Myocardial dysfunction from endotoxins contributes to decreased organ perfusion and compounds shock.

Severe sepsis and septic shock, as defined by a recent consensus conference, are overlapping syndromes^{14,15} (Tables 8–6 and 8–7). Importantly, shock physiology can occur without hypotension.

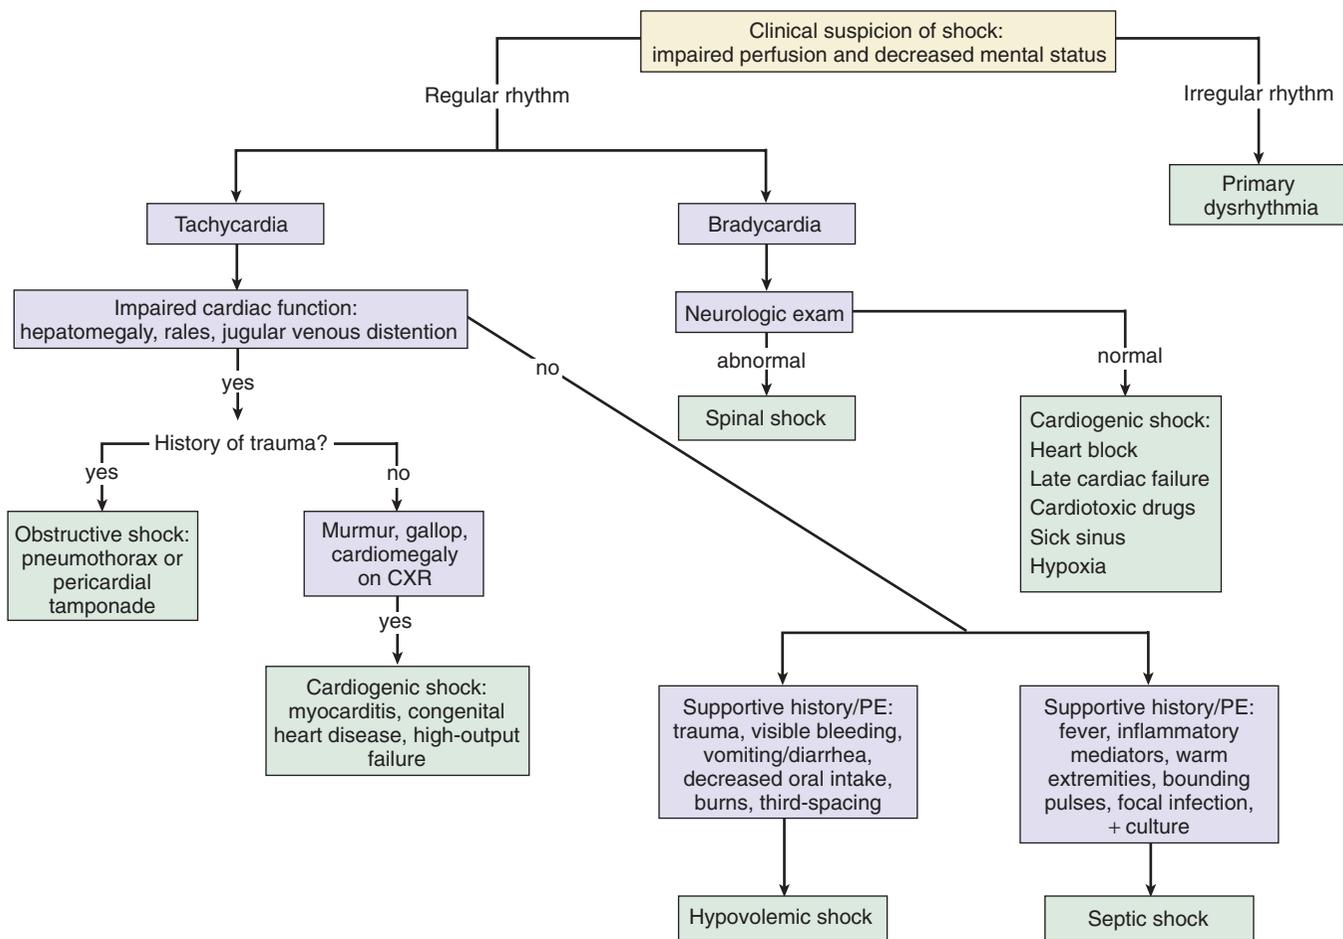

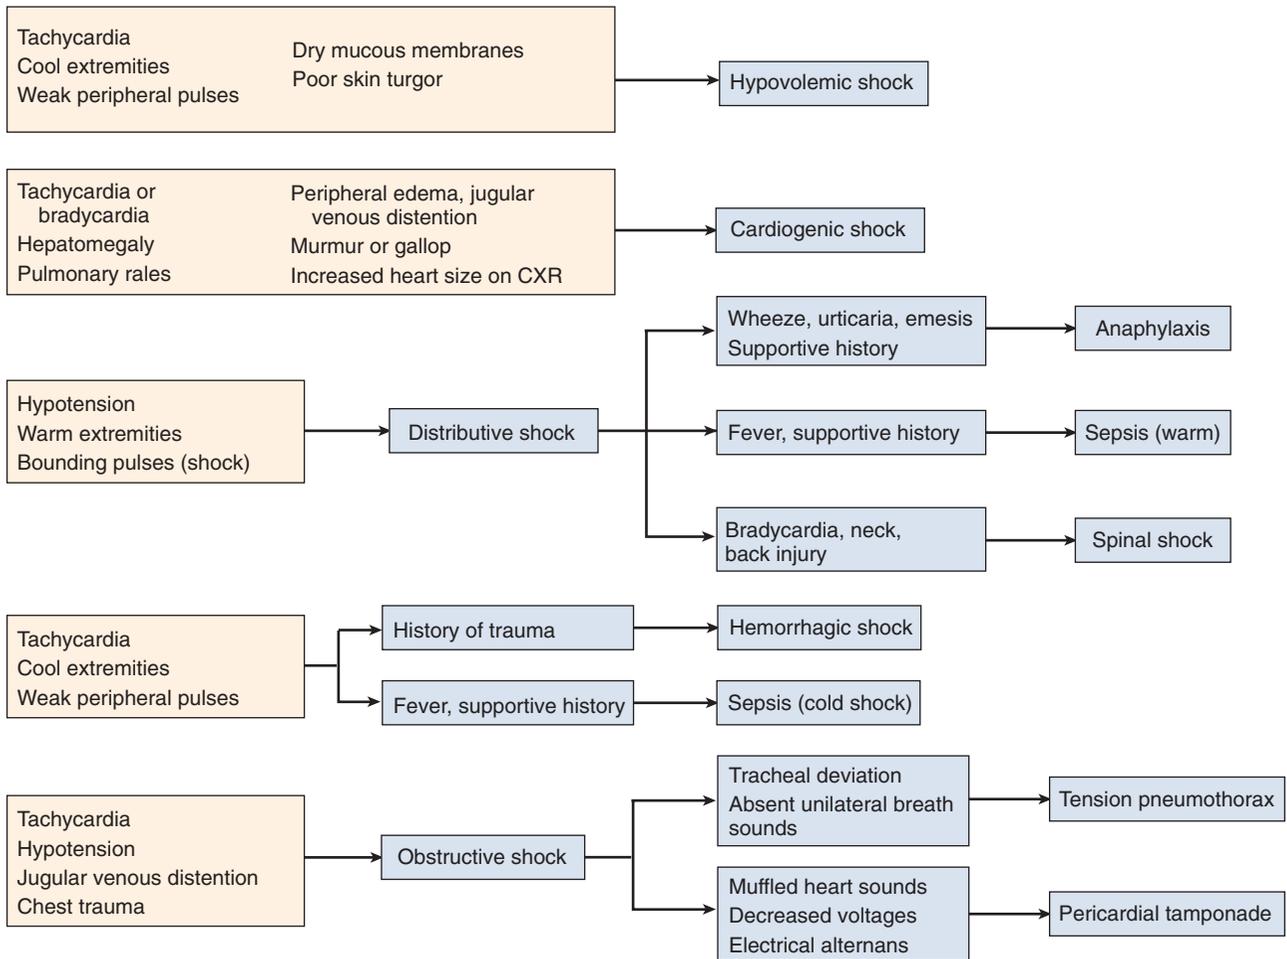

FIGURE 8-4. Algorithm for elucidating etiology of shock. Abbreviations: CXR, chest radiograph; PE, physical examination.

Table 8-6 Definitions of Sepsis-Related Terms	
SIRS (systemic inflammatory response syndrome)*	Presence of 2 of the following: <ul style="list-style-type: none"> • Core (rectal, bladder, oral) temperature <36° C or >38.5° C • Heart rate > 2 standard deviations above percentile for age, or otherwise unexplained, persistent elevation for 0.5–4 hr; if <1 yr old, bradycardia < 10th percentile for age • Respiratory rate > 2 standards deviations above percentile for age, or need for mechanical ventilation • White blood cell count elevated or depressed for age or >10% bands
Sepsis*	SIRS + presence of infection (positive culture or clinical evidence with high probability of infection)
Severe Sepsis*	Sepsis + presence of 1 of the following: <ul style="list-style-type: none"> • Cardiovascular organ dysfunction • Acute respiratory distress syndrome • Dysfunction of 2 or more other organs (see Table 8-7)
Septic Shock*	Severe sepsis + cardiovascular organ dysfunction (see Table 8-7)
Cold Shock†	Septic shock with decreased capillary refill time and mottled, cool extremities (epinephrine)
Warm Shock†	Septic shock with warm extremities; strong, bounding pulses; and instant capillary refill (norepinephrine)
Fluid-Refractory/Dopamine-Resistant Shock†	Persistence of shock despite ≥ 60 ml/kg of fluid resuscitation in first hour and dopamine infusion to 10 mcg/kg/min
Catecholamine-Resistant Shock†	Persistence of shock despite use of epinephrine or norepinephrine for fluid-refractory, dopamine-resistant shock
Refractory Shock†	Persistence of shock despite goal-directed use of inotropic agents, vasopressors, vasodilators, and maintenance of metabolic (glucose and calcium) and hormonal (thyroid and hydrocortisone) homeostasis

Recognize Shock: Poor Perfusion, Change in Mental Status, Decreased Urine Output**FIGURE 8-5.** Pattern recognition for different types of shock. Abbreviation: CXR, chest radiograph.

Differentiating the clinical presentation into warm (early) or cold (late) shock can assist in management. Cold shock is accompanied by decreased capillary refill time, weak peripheral pulses, and mottled, cool extremities. Children with warm shock present with warm extremities, strong, bounding pulses, and normal capillary refill time. Abnormal endotoxin-mediated vasodilation causes warm shock and is the basis for the major categorization of septic shock as a distributive-type shock.

Elevated troponin^{16,17} and B-type natriuretic peptide¹⁸ levels can be used as a marker for cardiac compromise during septic shock, although it is unclear whether cardiac dysfunction is a result of poor perfusion during septic shock, or if cardiac compromise is due to the underlying cause of sepsis. Echocardiography can be used to diagnose or confirm diminished cardiac function.

Various studies have attempted to find prognostic factors for septic shock. In adults, elevated levels of tumor necrosis factor (TNF) and interleukin-1B have been found to be associated with a poor outcome.^{19,20} High TNF levels are associated with higher probability of obtaining a positive blood culture in patients with shock.²⁰ Children with septic shock have higher levels of erythropoietin and interleukin-6^{21,22} compared to those without septic shock. A C-reactive protein

level greater than 8 mg/dl is 94% sensitive and 87% specific for SIRS in adults, although cutoffs are less well defined for children.²³ However, procalcitonin is a more specific marker for children with septic shock and correlates with higher morbidity.²⁴⁻²⁶ The median admission procalcitonin level for nonsurvivors with septic shock is significantly elevated (273 vs. 82 ng/ml) compared to survivors.²⁶ Children with shock have higher median levels of procalcitonin (39.1 vs. 15.0 ng/ml) compared to children without shock.²⁴

The most studied marker for severity of septic shock is arterial lactate.^{27,28} Normalization of lactate and base deficit has been associated with recovery from septic shock.²⁷ Noninvasive monitoring systems for impaired perfusion and shock include gastric tonometry and capnometry. In gastric tonometry, mucosal pH and partial pressure of carbon dioxide (Pco₂) are measured to identify splanchnic vasoconstriction, which occurs early in hypoperfused states. Importantly, adults and children with lower intramucosal pH have higher mortality,²⁷⁻²⁹ although tonometry is not a feasible measurement tool for the ED. Elevated end-tidal CO₂ is also a marker for impaired tissue perfusion. In adults, elevated sublingual capnometry has been used as another noninvasive method of estimating lactate and severe shock.³⁰ One study found that sublingual CO₂ greater than

Table 8–7 Organ Dysfunction Criteria

Cardiovascular	<ol style="list-style-type: none"> 1) Hypotension (blood pressure <5th percentile for age despite ≥ 40 ml/kg of fluid in 1 hr) OR 2) Need for vasoactive medication to maintain blood pressure OR 3) 2 of the following <ul style="list-style-type: none"> • Unexplained base deficit > 5.0 mEq/L • Arterial lactate > 2 times normal • Urine output < 0.5 ml/kg/hr • Capillary refill > 5 seconds • Core-to-peripheral temperature gap $> 3^\circ$ C
Respiratory	<ol style="list-style-type: none"> 1) $\text{PaO}_2/\text{FiO}_2 < 300$ in absence of congenital heart or preexisting lung disease OR 2) $\text{PaCO}_2 > 65$ torr or 20 mm Hg over baseline OR 3) Proven need for 0.5 FiO_2 to maintain saturation $\geq 92\%$ OR 4) Need for nonelective invasive or noninvasive mechanical ventilation

70 mm Hg was associated with shock, a lactate level greater than 2.5 mmol/L, and an increased risk of death in adults presenting to an ED or admitted to an intensive care unit.³⁰ Useful cutoffs for clinical decision making in children are less well defined (see Chapter 5, Monitoring in Critically Ill Children).

Trauma

Trauma can affect an isolated organ system or may cause multisystem derangements. The trauma patient is best initially assessed using an algorithmic approach with sequential or simultaneous attention to airway, breathing, and then circulation (see Chapter 12, Approach to Multisystem Trauma). A trauma patient with signs of shock may have one or more of several causes to explain the shock. Patients with obstructive shock (manifesting as decreased perfusion and hypotension or, if severe, pulseless electrical activity) can have a tension pneumothorax, massive hemothorax, or pericardial tamponade. A tension pneumothorax is identified in a patient who is in extremis with hypotension and dyspnea (or difficulty bagging) by the absence of breath sounds and hyper-

resonance to percussion on the affected side. Late and inconsistent findings include jugular venous distention and tracheal deviation. A rapid bedside ultrasound may be useful in immediately identifying cardiac tamponade and may provide clues to alternate causes for hypotension (e.g., intra-abdominal bleeding, tension pneumothorax, massive hemothorax).

In patients with trauma, tachycardia and impaired perfusion are usually due to hemorrhage. However, tachycardia is nonspecific and may be due to pain, anxiety, or fear. An altered mental status can be due to hypotension, hypoxia, or head trauma. Some have suggested using different vital sign parameters to differentiate tachycardia due to hemorrhagic shock from tachycardia due to other causes. For example, a Shock Index (heart rate/systolic blood pressure ratio) greater than 0.9 or ROPE (pulse Rate Over pulse Pressure Evaluation) greater than 3.0 are associated with the need for acute intervention and critical illness in adults, although these markers have not yet been proven useful in children.³¹ Prognosis of patients with trauma can be stratified by the initial base deficit. The more negative the base deficit, the higher the mortality and morbidity.^{5,32} Infants and children with an admission base deficit of less than -5 mEq/L have more severe injury, worse trauma scores (Glasgow Coma Scale score, Injury Severity Score, Pediatric Trauma Score), and increased mortality.⁵

Completion of the primary and secondary survey during trauma evaluation will identify possible locations of hemorrhage. Actively bleeding external wounds (e.g., open fractures, scalp lacerations, arterial bleeding), solid organ injury, and pelvis and femur fractures can lead to large volumes of blood loss. Patients with unstable vital signs despite initiation of fluid therapy, and a suspicion of surgically correctable hemorrhage (e.g., splenic laceration, large vessel disruption), should go directly to the operating room. Abdominal bleeding is usually diagnosed by computed tomography (CT) or bedside ultrasonography (FAST examination), and the physical examination is often abnormal in these patients if they have a normal mental status. Abdominal tenderness, distention, and bruising of the abdominal wall are suggestive signs. In the past, diagnostic peritoneal lavage (DPL) was frequently used to diagnose intraperitoneal injury. Now that CT and bedside ultrasound are readily available, DPL is rarely used.

Several serum markers can guide therapy and predict outcome in patients with hemorrhagic shock due to trauma. While an initial elevated lactate level is associated with mortality from trauma, a response to therapy with a normalization of lactate by 24 hours signifies a diminished probability of death.³³ Initial ED pH of ≤ 7.25 , lactate of ≥ 5 mmol/L, base excess of ≤ -7.3 mEq/L, an elevated anion gap, and a strong ion gap of ≥ 5 mEq/L all signify a higher probability of death in adults with major trauma, while patients with none of these factors have a very low probability of trauma-associated death. The strongest predictor of mortality may be an elevated strong ion gap (SIG). The SIG represents a complex calculation that measures the difference between strong anions and strong cations and is the mathematical difference between the apparent strong ion difference (SIDa) and the effective strong ion difference (SIDE).³⁴ An elevated SIG (>2 mEq/L) signifies that unmeasured strong anions are present:

$$\text{SIDa} = [\text{Na}^+ + \text{K}^+ + \text{Ca}^{+2} + \text{Mg}^{+2} - \text{Cl}^- - \text{lactate} - \text{urate}]$$

$$\text{SIDe} = [\text{albumin} \times (0.123 \times \text{pH} - 0.631)] + [\text{PO}_4 \times (0.309 \times \text{pH} - 0.469)] + \text{HCO}_3$$

$$\text{SIG} = \text{SIDa} - \text{SIDe} \text{ (abnormal SIG is } >2 \text{ mEq/L)}$$

Cardiac Disorders

Neonates and young infants with congenital disorders that obstruct the left ventricular outflow tract or with congenital obstructive left heart syndromes (COLHS) usually present early in life with shock (see Chapter 30, Congenital Heart Disease). In older infants and children, a variety of disorders cause myocardial damage and diminished pump function. These include myocarditis (e.g., viral, autoimmune), primary cardiomyopathies, and secondary cardiomyopathies due to a variety of disorders, including hyperthyroidism, metabolic defects (e.g., carnitine deficiency), neuromuscular disease (e.g., Friedreich's ataxia, muscular dystrophy), glycogen storage disease, mucopolysaccharidoses, and medication toxicity (e.g., adriamycin). Chest radiography usually shows cardiomegaly and varying degrees of congestive heart failure. Electrocardiographic (ECG) abnormalities often reflect the underlying pathology, while echocardiography is often diagnostic. Cardiac troponins and brain natriuretic peptide may be elevated. When pump function is compromised and a stressor is added (e.g., respiratory infection), the heart often cannot increase contractility to meet the excess demands and cardiogenic shock may develop. While features of the underlying disorder are often present, these patients often present with profound shock with evidence of congestive heart failure. Importantly, the myocardium may be too diseased to respond to small fluid boluses or vasopressors.

Arrhythmias (including supraventricular and ventricular tachycardia and conduction blocks with bradycardia) can also lead to diminished cardiac output and cardiogenic shock. These disorders require prompt recognition and reversal to prevent cardiac arrest.

Anaphylaxis

Anaphylaxis is a systemic allergic response at the severe end of the allergic reaction spectrum. Signs and symptoms include generalized urticaria, wheezing, respiratory distress, hypotension due to distributive shock, emesis, and GI tract inflammation. Patients with anaphylactic shock classically have food or medication sensitization and immediate immunoglobulin E-mediated hypersensitivity reactions (see Chapter 14, Anaphylaxis/Allergic Reaction).

Neonatal Shock

Neonates (birth to 28 days old) comprise an important group of patients with unique disorders causing shock (see Chapter 7, The Critically Ill Neonate). Neonatal shock is less obvious and will manifest with subtle clinical features that differ from those in older infants and cause difficulty in discriminating between disorders causing shock. Typical features include temperature instability (hypothermia and hyperthermia), lethargy, apnea, hypotension, tachycardia, respiratory distress, and poor feeding. Blood pressure does not correlate well with systemic blood flow, and the goal for mean arterial pressure is to maintain it higher than the baby's gestational age at the time of birth.³⁵ Hypotension is defined as a blood pressure that is less than the 10th percentile for

age. Normal capillary refill time for the neonate is greater than that of older infants (3 seconds), while normal capillary refill time for preterm babies can exceed 5 seconds.

Infections are an important and common cause of shock in neonates. Group B streptococcal (GBS) infections are unique, with early (48 hours postpartum) and late (2 to 90 days) presentations. Risk factors include prematurity, African American ethnicity, young maternal age (<20 years), and prior history of GBS. Meningitis manifests in one third of GBS cases, and a diffuse pneumonia with a ground-glass appearance on radiographs is common.

Several serum parameters are elevated in neonatal sepsis. An immature neutrophil-to-total neutrophil ratio greater than 0.2 is 60% to 90% sensitive and 70% to 80% specific for diagnosing neonatal sepsis, while an abnormal C-reactive protein is 75% sensitive and 86% specific for this disorder.³⁶⁻³⁸ Limited studies have found that an elevated interleukin-6 level (100 or 135 pg/ml cutoff) is 81% to 93% sensitive and 86% to 96% specific, a procalcitonin level greater than 0.5 mcg/L is 93% to 100% sensitive and 92% to 98% specific, and an elevated TNF- α level is 72% to 95% sensitive and 43% to 78% specific for diagnosing neonatal sepsis.³⁹ Other elevated serum parameters in neonatal sepsis include neutrophil CD11b, interleukin-8, interleukin-1 receptor antagonist, fibronectin, neutrophil elastase inhibitors, and TNF receptors p55 and p75.³⁹

Viral infections (especially perinatally acquired herpes simplex virus) may cause viremia and clinical sepsis. Neonates may have coexisting central nervous system (CNS) disease with seizures or disseminated disease with liver and pulmonary involvement. About 60% to 80% will have skin lesions when infected with herpes. Regardless of the responsible organism, hypovolemia, distributive mechanisms (third spacing of fluids), and cardiac dysfunction contribute to neonatal shock (see Chapter 13, Sepsis). Management is directed at each of these underlying pathologic entities in addition to the use of specific antimicrobials.

Neonates with COLHS (e.g., hypoplastic left heart, coarctation of the aorta, interrupted aortic arch, critical aortic stenosis) may present in the first 30 days of life with shock that initially appears indistinguishable from sepsis.⁴⁰ These neonates have an obstruction to cardiac outflow and present in profound shock once the ductus arteriosus closes (see Chapter 30, Congenital Heart Disease). Feeding difficulty, somnolence, cyanosis, tachycardia, delayed capillary refill time, significant upper and lower extremity blood pressures differences, and acidosis are common to both sepsis and COLHS. One study compared neonates with COLHS to those with sepsis and meningitis. Neonates with COLHS more frequently had respiratory distress (87% vs. 55%), cardiomegaly (85% vs. 5%), a murmur (53% vs. 5%), and diminished upper and lower extremity pulses (32% and 70% vs. 3% and 11%), while they less frequently had irritability (11% vs. 55%) and a fever history (0 vs. 63%).⁴⁰ Radiography shows cardiomegaly in up to 85% of cases, while ECG abnormalities are noted in 80% of cases.⁴⁰ Other cardiac disorders affecting cardiac output in neonates include arrhythmias and tamponade.

Gastrointestinal catastrophies, including necrotizing enterocolitis (in premature neonates), malrotation and midgut volvulus, and incarcerated hernias, must be considered in neonates with acute onset of vomiting (especially

bilious), abdominal distention, or GI bleeding followed by shock (see Chapter 83, Malrotation and Midgut Volvulus; and Chapter 84, Hernia). Hypovolemia (including blood loss) and sepsis contribute to shock in these neonates and require correction, with concurrent administration of antibiotics directed against gram-negative enteric organisms.

Metabolic disturbances are an important and easily overlooked cause of shock in neonates. Hypoglycemia may accompany shock due to poor glycogen reserves, decreased muscle mass, inadequate intake, and increased glucose demand in stressed states. For this reason, a rapid bedside glucose check is mandatory in all neonates with shock. Immaturity of the endocrine axis (thyroid, parathyroid) and congenital abnormalities also require consideration of thyroid and calcium replacement.

Management

Shock therapy should proceed simultaneously with a directed clinical evaluation to determine the cause of a patient's clinical syndrome. Universal management for all types of shock includes support of airway and breathing (e.g., early intubation with assisted ventilation or supplemental oxygen); continuous monitoring of cardiopulmonary status (see Chapter 5, Monitoring in Critically Ill Children) with cardiac telemetry, oximetry, and/or capnography; frequent or continuous assessment of vital signs; temperature support; and correction of underlying metabolic disorders (e.g., hypoglycemia, electrolyte disturbances). Blood pressure support and shock reversal measures are then directed at the underlying cause of shock (see Fig. 8–2).

Hypovolemia

In addition to airway management, aggressive fluid resuscitation is the most important therapy for treating hypovolemic shock. Optimally, two large-bore intravenous (IV) lines are placed, because repeated normal saline boluses of 20 ml/kg, up to a total of 60 to 80 ml/kg, may be needed to correct hypovolemia. Treatment goals include an improved mental status, capillary refill time less than 2 seconds, normal pulses, warm extremities, and a normal blood pressure. Glucose is checked as soon as IV access is obtained; ideally, blood glucose levels are maintained between 80 and 110 g/dl.⁴¹ Electrolyte abnormalities also may require correction during management. With long-standing gastroenteritis, metabolic acidosis may develop. For patients with decompensated shock and severe acidosis, treatment with bicarbonate may help to improve cardiac function.⁴² However, bicarbonate administration can worsen intracellular acidosis and cerebral acidosis and theoretically worsen shock, and cannot be routinely recommended.

For burn patients, 20-ml/kg crystalloid fluid boluses are administered in succession, with re-evaluation of hemodynamic, cardiac, and respiratory status. Lactated Ringer's solution is recommended for resuscitation in the first 24 hours after a significant burn. Lactated Ringer's solution contains physiologic concentrations of major electrolytes, and lactate serves as a buffer that lessens the risk of hyperchloremic acidosis. Large volumes of fluid are needed for burn patients since only 20% to 30% of administered isotonic fluids remain in the intravascular space. In general, potassium should not initially be added to fluids since cellular

breakdown will often lead to release of large amounts of this electrolyte. Also, albumin should not be administered in the first 24 hours after a burn since capillary leak of this colloid can markedly increase edema. Formulas used to calculate the amount of fluid required to replace losses over the first 24 hours include the Parkland formula (4 ml/kg per percent body surface area [%BSA] burned) and the Carvajal formula (5000 ml/m²/%BSA burn) (see Chapter 26, Burns). The Parkland formula may underestimate fluid losses in young children, while the Carvajal formula is ideal for use in children younger than 6 years old. Both formulas require addition of maintenance fluids, with administration of half of the total volume in the first 8 hours and the other half over the ensuing 16 hours. All fluid replacement regimens require monitoring for end points indicating adequate resuscitation, including adequate urine output (2 ml/kg/hr if <1 year old, 1.5 ml/kg if 1 to 3 years old, and 1 ml/kg if >3 years old), normal mental status, and improvement in vital signs. If these goals are not met, additional fluids above those dictated by burn formulas are indicated. Children with extensive burns may need massive quantities of fluid replacement, and the tendency to insufficiently fluid resuscitate patients with burns has been shown.⁴³

Gastrointestinal bleeding with esophageal varices may be treated with octreotide, sclerotherapy, or surgical intervention. Coagulopathy is treated with appropriate blood products. A bleeding Meckel's diverticulum that is causing hemodynamic compromise needs to be surgically removed.

Septic Shock

The Golden Hour

Primary goals in treatment of septic shock include maintenance of ventilation, oxygenation, and perfusion through normalization and optimization of circulatory hemodynamics and blood pressure (see Table 8–4 and Fig. 8–3). Infants and young children are more likely to need early intubation due to their limited pulmonary reserve. Specifically, infants and young children have a relatively reduced functional residual capacity, increased oxygen consumption, immature intercostal and diaphragmatic muscles, inefficient intercostal muscle positioning, and diaphragmatic apposition to the chest wall.⁴⁴ Intubation and mechanical ventilation can decrease oxygen requirements since the excess metabolic demand for work of breathing is removed. Moreover, aggressive fluid therapy coupled with increased capillary permeability may lead to pulmonary edema, which may require mechanical ventilation with increased peak end-expiratory pressures.⁴⁵

Inadequate early fluid resuscitation in the ED is associated with increased mortality in septic shock. One study found that children who died from septic shock only received 20 ml/kg of fluid in the first hour despite receiving more vasopressors than children who survived.¹⁰ Administration of greater than 40 ml/kg of crystalloid fluid in the first hour is associated with improved survival and does not increase the incidence of acute respiratory distress syndrome.⁴⁶

Ideally, crystalloid IV fluid should be administered in successive 20-ml/kg boluses over 5 to 10 minutes. Clinical end points of treatment include capillary refill time less than 2 seconds, normal pulses (without central-peripheral

discordance), warm extremities, urine output greater than 1 ml/kg/hr, normal mental status, and normal blood pressure.^{44,45} The patient should be monitored for the development of congestive heart failure (a gallop, rales, increased work of breathing, or hepatomegaly). Inotropic therapy should be initiated earlier in the presence of these clinical signs. If 60 ml/kg of fluid has been administered without reversal of shock, vasoactive agents should be administered. These medications can be started in a peripheral IV line, but establishment of central venous access is ideal (see Figs. 8–2 and 8–3).

Vasoactive medications are administered after fluid therapy has been maximized in septic shock. *Inotropes* are used to increase cardiac output and are particularly useful in patients with a diminished cardiac output (cardiac index <3.3 L/min/m²). Inotropes include dopamine (5–10 mcg/kg/min), dobutamine, amrinone, milrinone, and epinephrine (<0.3 mcg/kg/min or > 0.3 mcg/kg/min when combined with a vasodilator). *Vasopressors* are added to increase systemic vascular resistance (SVR) in patients with peripheral vasodilation and a depressed SVR (<800 dyne-sec/cm⁵/m²). These agents include dopamine (≥10 mcg/kg/min), norepinephrine, phenylephrine, vasopressin, and epinephrine (>0.3 mcg/kg/min). *Vasodilators* (nitroprusside, nitroglycerin, or phenolamine) are used in patients with a high SVR (>1600 dyne-sec/cm⁵/m²) to decrease the pressure head against which the heart must pump blood to the body. Clinicians must remember that specific agents may have inotropic, vasodilator, and vasopressors effects at different doses (see Fig. 8–2 and Table 8–3).

Dopamine is the drug of choice for shock unresponsive to fluids. At low doses (<5 mcg/kg/min) it increases renal and mesenteric flow, at medium doses (5 to 10 mcg/kg/min) it has inotropic activity, and at higher doses (>10 mcg/kg/min) it acts as a vasopressor. Children with septic shock often have a diminished cardiac output due to direct endotoxemic effects of bacteria as well as from acidosis- and electrolyte-induced cardiac dysfunction.⁴²

Dobutamine can be used as a first-line vasoactive agent in septic shock. Its cardiac effect on contractility improves cardiac function. In patients with increased SVR, the β₂-agonist vasodilatory effects of dobutamine may be superior to dopamine. In a study of fluid-refractory septic shock, 58% of children responded to inotropic therapy, but half of those children needed an additional vasodilator. Twenty percent of children had a high cardiac index and low SVR and responded to vasopressor therapy, with half of those children requiring an additional inotrope.⁵⁰ Twenty percent of children had both low cardiac contractility and SVR and responded to inotropes and vasopressors (see Figs. 8–2 and 8–3).

Early goal-directed therapy decreases mortality in adult patients with septic shock.^{47,48} This approach entails the use of central venous and arterial monitoring to titrate the use of fluids, vasoactive agents, airway support, and blood transfusion (if hemoglobin is <10 g/dl) to maintain normal central venous pressure (CVP), normal mean arterial pressure (MAP), and superior vena cava oxygen saturation (SVC O₂) greater than 70%.^{47,48} Mixed venous oxygen saturation (SvO₂) can substitute for SVC O₂ saturation in the absence of a central catheter in the SVC. Additional goals include decreasing arterial lactate, normalizing base deficit, optimizing cardiac function by echocardiography, maximizing perfusion pressure (MAP-CVP difference), and maintaining

cardiac index between 3.3 and 6.0 L/min/m² if a pulmonary artery catheter is placed^{1,44,45} (see Fig. 8–3).

After the initiation of dopamine, shock may persist (fluid-refractory/dopamine-resistant shock). It is necessary to differentiate between cold and warm shock at this point (see Table 8–6). For cold shock, epinephrine is added as a second agent. Norepinephrine is recommended for warm shock. Glucose and ionized calcium are measured and replaced as needed to maintain normal values (goal: glucose level of 80 to 100 g/dl and ionized calcium level of 1.14 to 1.29).⁴¹ Stress-dose hydrocortisone (1 to 2 mg/kg) is administered to children who are known to have adrenal disorders or who are on chronic steroid medication (see Fig. 8–3).

In addition to supportive treatment, the suspected infection is empirically treated with broad-spectrum antimicrobials. If time permits, blood, urine, and tissue samples from potential sites of infection should be obtained prior to antibiotic administration. However, in an unstable child, initiation of antimicrobials takes precedence over culturing all sites (see Chapter 13, Sepsis). If meningitis is a possibility, higher doses of antibiotics may be required (see Chapter 43, Central Nervous System Infections). Atypical pathogens (e.g., *Pseudomonas*, gram-negatives, fungi) should be considered in immunocompromised patients, and skin flora (e.g., *Staphylococcus aureus*) should be considered if a chronic indwelling venous catheter is present.⁴⁹

Beyond the Golden Hour

After the “golden hour” of septic shock management, goal-directed therapy is continued, aiming for an SVC or mixed venous saturation greater than 70%, and maintenance of normal perfusion using clinical examination, MAP, and perfusion pressures.

If shock persists despite fluids and catecholamine therapy, hydrocortisone should be considered. For children with catecholamine-resistant shock, baseline cortisol levels are obtained. If adrenal insufficiency is suspected (adrenal disorder, chronic steroid medication therapy, CNS disorders, or purpura that suggests meningococemia and possible Waterhouse-Friderichsen syndrome), stress-dose hydrocortisone (at least 1 to 2 mg/kg) should be administered. Debate exists as to the proper dose of steroids in suspected adrenal insufficiency-associated shock, and recommendations vary from 1 to 2 mg/kg up to 50 mg/kg.^{1,44}

After dopamine and catecholamines, several alternative vasoactive medications can be considered. For catecholamine-resistant shock with a non-hyperdynamic state (low cardiac output and high SVR), vasodilators (e.g., nitroprusside) can decrease afterload and optimize cardiac output. If blood pressure is normal and SVR is elevated, a PDE inhibitor (e.g., milrinone) may be of benefit.¹ Phosphodiesterase inhibitors in combination with catecholamines increase cardiac index and oxygen delivery⁵⁰; however, clinicians must be aware of their prolonged half-life. Catecholamine-resistant shock with a hyperdynamic state (high cardiac output and low SVR) is more common in adults than children.⁵¹ In adults, vasopressin improves hemodynamics,⁴² but studies in children are limited to case reports and its routine use in the emergency department cannot be currently recommended.^{52–54}

In refractory septic shock (see Table 8–6), extracorporeal membrane oxygenation (ECMO) should be considered.^{1,44,45} ECMO has been used in neonates with persistent pulmonary

hypertension and sepsis, and may be effective in cardiogenic shock. Further study is needed before its role in refractory septic shock is clear.^{55,56}

Other treatments under investigation for pediatric shock include activated protein C, naloxone, plasmapheresis, and immunoglobulin therapy. In adults, activated protein C is recommended in patients at high risk for death from sepsis,⁵⁷ but in children, it is not yet well studied. Case reports and a limited Phase II trial have shown improved coagulopathy parameters and safety, but no studies have demonstrated improved outcome with this agent.^{58,59}

Other treatments currently under investigation in children include plasmapheresis, IV immunoglobulins, naloxone, and recombinant bactericidal/permeability-increasing protein.⁶⁰⁻⁶³

Trauma

Patients with hemorrhagic shock require aggressive fluid resuscitation to treat hypovolemia and require blood products for hypotension that does not rapidly respond to fluids. Supplemental oxygen is an important adjunct in the setting of anemia. Dissolved oxygen will be a significant proportion of oxygen content in the anemic patient with a decreased hemoglobin. Traumatic injuries may require emergent surgery (e.g., thoracoabdominal vascular or viscous injury). These patients are identified by imaging that reveals a specific injury and hypotension that is unresponsive to blood and fluid administration, or the requirement for transfusion of more than 40 ml/kg of blood over 24 hours. Readily reversible causes of shock (e.g., cardiac tamponade, tension pneumothorax) require immediate recognition and reversal. Bedside ultrasonography may provide a rapid diagnosis.

Hypotension on ED arrival due to traumatic blood loss carries a mortality rate that may exceed 50%.⁶⁴ In hemorrhagic shock, the first-line therapy is IV crystalloid fluids. The clinician should administer 20 ml/kg of crystalloid fluid over 5 to 10 minutes using multiple large-bore IV sites, and consider administration of blood if vital signs do not improve rapidly. Colloids (e.g., albumin, blood, modified fluid gelatin, dextran, hydroxyethyl starch) are better retained in the intravascular space than crystalloids. Other than blood, colloids do not provide a mortality benefit compared to crystalloids in hemorrhagic shock.⁶⁵⁻⁶⁸

Although the generous administration of crystalloids and blood products seems logical, there is evidence to suggest that aggressive fluid management in uncontrolled hemorrhage may worsen a patient's condition by increasing blood pressure and disrupting a clot that has formed or by creating a dilutional coagulopathy that can worsen hemorrhage.⁶⁹ Several animal studies indicate that bleeding is increased with aggressive fluid resuscitation.⁷⁰ For this reason, patients with trauma-related hypotension require rapid evaluation to identify sites of bleeding and early surgical therapy to control those sites.

Although hemorrhage is the most common cause of shock in the trauma patient, hypotension in the setting of neck or back trauma, abnormal neurologic examination, or relative bradycardia may indicate distributive spinal shock. Diving, cervical flexion-extension, and back injuries should heighten the suspicion for spinal cord injury. In spinal shock, cord injury leads to abnormal neural regulation of the peripheral vasculature. This manifests as hypotension, peripheral vasodilation with warm skin, adequate peripheral pulses, and

inappropriate bradycardia or lack of expected tachycardia. Once hemorrhage has been excluded, agents with α_1 -agonist properties (e.g., phenylephrine) will counteract the underlying peripheral vasodilation. Norepinephrine and high-dose dopamine have β_1 -agonist action in addition to α_1 action and can be used if cardiac inotropy is also desired.

Cardiac Disorders

Caution is necessary when administering IV fluids to patients in shock with associated cardiac dysfunction. Depressed cardiac function may be the primary cause of shock or may coexist in patients with noncardiac shock. Patients with cardiac dysfunction require small fluid boluses if hypovolemia is a contributing factor, but aggressive fluid therapy is not used alone if cardiac dysfunction is suspected.

Myocarditis (usually from viral illness) is one of the most common causes of cardiogenic shock. Young infants and neonates may present with COLHS (e.g., hypoplastic left heart, coarctation of the aorta, an interrupted arch). In these patients, administration of prostaglandin E₁ to maintain a patent ductus arteriosus may be life saving (see Chapter 30, Congenital Heart Disease). Other important congenital heart diseases, such as left-to-right shunts (e.g., ventricular septal defect) and cyanotic heart defects (e.g., total anomalous pulmonary venous return), also may progress to congestive heart failure. Supraventricular and ventricular tachycardias and bradyarrhythmias, especially in infants, can cause cardiogenic shock due to the overreliance on heart rate as a determinant of cardiac output at this age. Pharmacologic or electrical conversion may be required for tachyarrhythmias, while chronotropic agents or a pacemaker may be required to reverse hemodynamically significant bradyarrhythmias (see Chapter 63, Dysrhythmias). Ischemic heart disease from congenital or acquired abnormalities can cause cardiogenic shock. High-output cardiac failure can result from severe anemia or shunting of blood (e.g., arteriovenous malformation).

If cardiogenic shock is suspected or known, a 5- to 10-ml/kg saline bolus should be administered if hypovolemia coexists. Inotropic therapy must be initiated early in cardiogenic shock. Dobutamine is an ideal agent for its inotropic effect on β_1 receptors in the heart and afterload reduction via β_2 peripheral vasodilation. Dopamine is also effective, although at high doses vasoconstriction predominates. In the setting of cardiogenic shock, SVR is high to maintain adequate perfusion pressure. For this reason, decreasing afterload may improve hemodynamics, making dobutamine more ideal than dopamine. Phosphodiesterase inhibitors (e.g., milrinone) can also be useful in the treatment of cardiogenic shock if SVR is high.

A small case series including infants and children demonstrated a decreased mortality with use of ECMO rescue in refractory cardiogenic shock.⁷¹ Further research is needed to study its benefit.

Anaphylaxis

Treatment for anaphylaxis includes supporting ventilation and oxygenation through treatment of bronchospasm with β_2 -agonist respiratory therapy, IV fluids, and epinephrine. Cardiovascular collapse is treated with IV fluid boluses of 20 ml/kg and simultaneous administration of epinephrine. Depending upon the degree of hypotension, 0.1 mg/kg intramuscularly or 10 mcg/kg IV should be administered over 3

to 10 minutes, following by a continuous drip of 0.1 to 1 mcg/kg/min if needed. Adjunctive therapies include H₁-receptor histamine antagonists (e.g., diphenhydramine) and corticosteroids. H₂-receptor histamine antagonists (e.g., ranitidine) are often recommended for the treatment of allergic disorders. However, these agents have only been proven to ameliorate dermatologic symptoms and may worsen bronchospasm (see Chapter 14, Anaphylaxis/Allergic Reactions).

Shock in Neonates

While typical treatment for hypovolemic shock consists of aggressive fluid management, this approach is associated with higher pulmonary, cardiac, gastrointestinal, and CNS morbidity in premature infants.^{72,73} High pulmonary vascular resistance and closure of shunts sets up a unique physiology during the transition from fetal to neonatal circulation. In the setting of shock, acidosis, and hypoxemia, increased pulmonary artery pressure may result in persistent pulmonary hypertension of the neonate (PPHN) and cardiac failure. Myocardial dysfunction frequently accompanies neonatal hypotension.⁷⁴ For this reason, neonates who receive IV fluid boluses require frequent cardiopulmonary assessment, while the use of 10-ml/kg boluses instead of 20 ml/kg is recommended in preterm neonates. Neonates with PPHN may also benefit from pulmonary vasodilation through inhaled nitric oxide therapy and metabolic alkalization.

Vasopressors do not affect the neonatal cardiac system in a manner similar to older children and adults. Only one third of a neonate's heart is composed of contractile tissue, compared to two thirds of an adult heart. For this reason, neonates cannot alter their cardiac output by increasing contractility as well as adults and older children. Myocardial norepinephrine stores are also immature and become rapidly depleted, making dopamine less effective. Changes in adrenergic receptor expression during critical illness and production of local vasodilators during shock can make neonates appear unresponsive to dopamine. Dobutamine is less effective than dopamine in raising blood pressure⁷⁵ due to dopamine's α -adrenergic vasopressor activity.

Neonates with inborn metabolic errors can present with unexplained hypoglycemia, elevated ammonia levels, or an unexplained metabolic acidosis (see Chapter 29, Inborn Errors of Metabolism). These abnormalities may be associated with seizures, hypotension, hypotonia, or feeding difficulties. Therapy is directed at reversing the metabolic problem (e.g., administering glucose and bicarbonate, managing hyperkalemia). Ammonia is reduced by hemodialysis, administration of ammonia-scavenging agents, and repletion of arginine.

Infants with congenital adrenal hyperplasia (CAH) classically present with hypotension, acidosis, hyponatremia, and hyperkalemia in the second week of life (see Chapter 108, Addisonian Crisis). However, newborn screening has reduced morbidity from CAH. Once CAH is suspected, management consists of restoring fluid homeostasis with IV fluids, correcting hypoglycemia, and administering hydrocortisone while excluding other potential causes for symptoms (e.g., sepsis).

Summary

Shock is a dynamic physiologic state that is the final end point for various disease processes. Hypovolemic, cardio-

genic, distributive, and obstructive shock are the major physiologic mechanisms by which we define shock. However, a combination of these mechanisms may play a role in individual patients with shock. If unrecognized or undertreated, shock will progress to death.

After securing an airway and maintaining adequate ventilation, the mainstay of shock treatment (excluding cardiogenic shock) is aggressive fluid resuscitation. Crystalloids should be administered in 20-ml/kg boluses up to 60 ml/kg as quickly as possible. The patient should be assessed for cardiac compromise in the form of murmurs or gallops, hepatomegaly, pulmonary rales, or jugular venous distention at the onset of treatment as well as during aggressive fluid therapy. Shock from cardiac dysfunction is treated with judicious use of fluids and the initiation of appropriate vasoactive medications.

In septic shock, after 60 ml/kg of fluid have been given, inotropes, vasopressors, or vasodilators are initiated using goal-directed parameters. Dopamine is a first-line agent that has cardiac stimulatory as well as peripheral vasoconstrictive properties. For fluid-refractory and dopamine-resistant patients, a second vasoactive agent is added. Epinephrine and norepinephrine are indicated for cold and warm shock, respectively. For catecholamine-resistant shock, relative adrenal suppression should be considered.

Mortality from shock has improved with the advent of goal-directed therapies and evidence-based guidelines. Prompt recognition with rapid and aggressive treatment will further improve outcome in children who present to the ED in shock.

Chapter 9

Cerebral Resuscitation

Genie E. Roosevelt, MD, MPH and Norman A. Paradis, MD

Key Points

Adequate basic and advanced life support are important initial determinants of outcome during cerebral resuscitation.

Clinicians must promptly identify processes that place the cerebrum at risk (e.g., asphyxia, hypotension) in order to intervene early, prevent further deterioration, and limit the need for cerebral resuscitation.

Hyperventilation is not standard therapy for increased intracranial pressure and in some instances may be detrimental.

Background and Introduction

Cerebral resuscitation is required because the primary pathophysiologic process has placed neurologic tissue at risk secondary to ischemia. In children, this generally occurs because processes such as asphyxia or trauma, with secondary edema, threaten to interfere with delivery of oxygen to neurologic tissues that are intolerant of even brief periods of severe partial anoxia. Because cerebral oxygen delivery is wholly dependent on adequate cardiac output, advanced life support comes first. Failure to promptly restore systemic hemodynamics will render all secondary efforts at cerebral resuscitation ineffective. The apparent capacity of pediatric patients to recover from neurologic injury that initially appears devastating makes cerebral resuscitation particularly important in this population.

In infants and children, the two principal mechanisms resulting in cerebral edema requiring resuscitation are traumatic brain injury (TBI) and asphyxial cardiac arrest. Other less common mechanisms include ischemia, infection, and swelling due to mass effect. Prompt identification of pathophysiologic processes that place the cerebrum at risk and early intervention to counteract their effects are crucial to limit the need for cerebral resuscitation. Many mechanisms responsible for brain injury, including the molecular, cellular, and biochemical mechanisms that underlie neurologic injury, have been elucidated over the last 30 years. However, it has been very difficult to demonstrate the clinical efficacy

of potential therapies. For this reason, pediatric cerebral resuscitation remains primarily empirical, supplemented with extrapolations from adult data. Improved understanding of the pathophysiology of cerebral ischemia, and in particular the importance of reperfusion injury, holds the promise of significantly more effective therapies in the future.

Most of the current data available focus on cerebral resuscitation after TBI, but some of these same therapies may also be applicable to cerebral resuscitation after cardiac arrest. Recent indications that hypothermia may be effective in the treatment of cerebral reperfusion injury after cardiac arrest hold particular promise, and pediatric trials are underway at the time of this writing. In 2003, guidelines for the management of pediatric severe TBI were published in both surgical and critical care journals.¹ These guidelines were an attempt to present current clinical data, combined with expert consensus, in a manner similar to adult guidelines originally developed originally in 1996 and revised in 2000.^{2,3}

The achievement of optimal clinical outcomes will require coordination between prehospital providers, emergency department staff, intensivists, and rehabilitation health care providers. Protocols necessary to achieve this coordination should generally be in place beforehand, so that timely application of multiple interventions can be achieved. Prevention of neuronal cell death often requires that therapies be given at the injury scene or shortly after the initial insult. Prevention of insults that place neuronal tissue at risk is always preferable to cerebral resuscitation, and, in reality, such prevention is optimal resuscitation. Prevention of initial hypoxia-mediated pathways and later reperfusion-mediated pathways of neurologic injury is the foundation of cerebral resuscitation.

Recognition and Approach

There are over 150,000 pediatric head injuries per year, resulting in approximately 7000 deaths and 29,000 children with new, permanent disabilities.⁴⁻⁶ Trauma is the leading cause of mortality and morbidity in children and is responsible for the majority of childhood deaths.⁷ Even with minor traumatic head injuries, there can be significant long-term sequelae.^{8,9} The most common cause of cardiac arrest in children is respiratory distress leading to respiratory failure, which accounts for the majority of admissions to pediatric

intensive care units.¹⁰ Other causes of prearrest states in children include, in descending order, cardiac failure, neurologic conditions such as seizures, and acute failure of the liver, kidney, or adrenals.¹¹

While the exact mechanisms of cerebral edema are not fully delineated, they include cellular swelling, injury to the blood-brain barrier (BBB) or vasogenic edema, osmolar swelling, and increased cerebral blood volume (CBV).¹² Cellular swelling, which is probably more important in asphyxial cardiac arrest than in TBI, is mediated by acidosis, potassium, and arachidonic acid.¹³ The swelling is predominantly in the astrocyte foot processes as the uptake of the excitatory amino acid (EAA) glutamate is coupled with sodium and water intake. The significance of BBB injury or vasogenic edema is now believed to have been overstated in the past and is probably more important in asphyxial cardiac arrest than in TBI.¹⁴ More recently, osmolar swelling in an area of contusion necrosis, defined as a cerebral contusion in which the cellular elements undergo shrinkage, disintegration, and homogenization, seems to be a much more important mechanism in TBI.¹⁵ The role of increased CBV in cerebral edema in adults has been challenged.¹⁶ However, this mechanism may be more important in pediatric TBI and requires further study.

Although TBI and asphyxial cardiac arrest are different insults, two early important mechanisms of injury for both insults appear to be excitotoxicity and hypoperfusion. Both of these mechanisms may result in early cellular damage, and appear to set in motion the triggers that lead to programmed cell death (PCD). Excitotoxicity is the process by which EAAs cause neuronal damage after hypoxia or injury. Glutamate, in particular, appears to be the predominant excitatory neurotransmitter of the brain and acts through several receptors. In both animal models and clinical studies, pathologic levels of glutamate known to cause cell death *in vitro* are seen in the cerebrospinal fluid (CSF) after both TBI and asphyxial cardiac arrest.¹⁷⁻¹⁹ EAA receptor antagonists have improved outcomes in experimental models.²⁰ The rise in glutamate occurs early, suggesting a potential role for early intervention in either field resuscitation or the emergency department. Current clinical therapies with anti-excitotoxic properties include hypothermia, barbiturates, inhaled anesthetics, calcium channel blockers, and anticonvulsants. Hypothermia reduces levels of glutamate in the cerebrospinal fluid.²¹ Induction of a barbiturate coma can reduce the amount of glutamate and lactate in the extracellular space of the brain via microdialysis.²²

Although both TBI and asphyxial cardiac arrest result in elevated EAAs, the mechanisms may differ. After TBI, excitotoxic damage is mediated by the *N*-methyl-D-aspartate (NMDA) receptor, one of the major glutamate receptors.¹⁹ One study of a competitive NMDA antagonist (selfotel) was terminated due to safety concerns as this agent had important phencyclidine-like properties and side effects that limit its use in conscious patients.²³ The dramatic excitotoxic response to TBI, particularly in children less than 4 years of age,²⁴ would suggest that therapy preventing the insult from elevated glutamate levels may be important even if there are some concerns over side effects. Elevated EAAs appear to be important enough in acute neurologic injury that additional research directed at blocking EAA effects without undue toxicity is of particular importance.

Cerebral ischemia and hypoxia play a central role in the secondary neurologic damage after cardiac arrest or TBI. Immediately after cardiac arrest or TBI, there is a period of hypoperfusion in both adults and children,^{25,26} which occurs at the same time as an increased metabolic rate termed *hyperglycolysis*.²⁷ In experimental models, cerebral hypoperfusion is seen for hours to days after global ischemia, while systemic oxygen utilization returns to normal, resulting in cerebral ischemia during reperfusion.²⁸ This suggests that increasing cerebral blood flow (CBF) after cardiac arrest may be beneficial. Experimental models suggest that L-arginine, endothelin-1 (vasoconstrictor) antagonist, and transient systemic hypertension increase CBF and may improve outcome in both TBI and cardiac arrest.²⁹⁻³¹

An exciting future direction in cerebral resuscitation is to target both cerebral hypoperfusion and EAAs simultaneously. Although the systemic effects of adenosine limit its use, an adenosine agonist has been shown to be neuroprotective in experimental animal models when given locally through a ventriculostomy catheter.³² The inhaled anesthetic isoflurane, which increases CBF while serving as a potent anti-excitotoxic agent, is associated with reduced neuronal damage after both TBI and cardiac arrest compared to fentanyl.^{33,34} Ethanol has been shown to reduce hypoperfusion, excitotoxicity, and hyperglycolysis after TBI and cardiac arrest in rats.³⁵ However, no practical, single pharmacologic agent is effective in targeting both excitotoxicity and hypoperfusion.

While some neuronal death may occur immediately after TBI and cardiac arrest, additional neuronal death may occur after the insult secondary to PCD, or apoptosis.³⁶ PCD is regulated by genes and proteins, in contrast to immediate and delayed necrotic cell death, which is not regulated by proteins and is characterized by cellular and nuclear swelling with dissolution of membranes. Upstream regulators of PCD include the Bcl-2 family of proteins, some of which promote cell survival and some of which promote cell death.³⁷ In animal models, Bcl-2 protein is seen in neurons that survive compared to neurons that do not.³⁸ In addition, elevated levels of Bcl-2 in the CSF have been associated with improved survival in children and infants after TBI.³⁹ Administration of Bcl-2 analogues is protective in animal models, suggesting a potential clinical application.⁴⁰ Other upstream regulators of PCD are the tumor necrosis factor (TNF) superfamily cell surface receptors.⁴¹ Binding of TNF or Fas ligand to their respective cell surface receptors activates the PCD cascade. Soluble Fas receptors are increased in the CSF after pediatric TBI,⁴¹ suggesting a potential means to intervene in PCD by using soluble ligands or decoy Fas or TNF receptors. Alternative, potentially effective therapies might prevent PCD by stabilizing the mitochondrial membrane with cyclosporine⁴² or antioxidants,⁴³ or might target the final pathways of the PCD cascade, particularly the caspase pathway. Several currently investigated clinical strategies, such as hypothermia and anti-excitotoxic therapies, may also work by reducing PCD.^{44,45} Since PCD is also an essential part of human development and probably maintenance of biologic function, disrupting this cascade may have disruptive effects, and methods will need to be developed to target the effect on PCD specifically to the central nervous system during the vulnerable postinsult period.

Clinical Evaluation

Since cerebral edema is associated with a significant traumatic, asphyxial, or metabolic event or derangement, such as diabetic ketoacidosis, recognition relies on the practitioner anticipating the association of the primary condition with cerebral edema. This is vitally important since early identification of the inciting event makes prevention or early resuscitation possible. Signs and symptoms associated with cerebral edema include altered mental status, pupillary changes, and posturing. Any change in a child's level of alertness or a possible focal neurologic deficit, in the context of traumatic, hypoxic, or metabolic insult, should lead to immediate counter-insult interventions. An objective assessment of the child's level of consciousness may be accomplished with the AVPU system⁴⁶ (Alert, responds to Voice, responds to Pain, Unresponsive) or the Pediatric Glasgow Coma Scale.⁴⁷ Altered mental status is the first sign, with pupillary changes and posturing presenting as late signs of cerebral edema and impending herniation.

Early intracranial pressure (ICP) monitoring allows an objective measure of cerebral edema and an assessment of the effect of therapies. ICP monitoring in TBI is accepted as effective, although data are insufficient to support a treatment standard.¹ Generally, ICP monitoring is not recommended in cardiac arrest as animal models of cardiac arrest indicate that the insult necessary to produce vegetative outcome is below the threshold that results in intracranial hypertension, implying that ICP monitoring-directed therapy is unlikely to improve outcomes.^{48,49} Recent guidelines suggest performing ICP monitoring in infants and children with severe TBI, defined as a Glasgow Coma Scale (GCS) score of 8. The presence of an open fontanelle and/or sutures does not preclude monitoring. ICP monitoring is not indicated in mild or moderate injury. Adult data support ICP monitoring in patients with severe TBI (GCS = 8 after cardiopulmonary resuscitation), and there is no evidence to suggest that this is not true in pediatrics. Monitoring is suggested in patients with severe TBI and an abnormal admission computed tomography (CT) scan demonstrating hematomas, contusions, cerebral edema, and/or compressed basal cisterns. In addition, monitoring is suggested even with a normal admission cranial CT scan if two or more of the following are present: motor posturing, systemic hypotension, or age greater than 40 years.³

Management

Cerebral resuscitation naturally falls into two broad areas: (1) therapies widely believed to be effective and that can be instituted in community emergency departments (Table 9–1, Fig. 9–1), and (2) advanced techniques that are applied only to subsets of patients and usually utilized only in tertiary centers by specialists.

Cerebral Resuscitation: Basic Techniques

As with any resuscitation, controlling and maintaining the airway, breathing, and circulation are the first priorities. In children with TBI, extreme care must be taken with respect to possible injury to the spine. There must be immediate attention to preventing additional primary insult, be it traumatic, hypoxic, or metabolic, contemporaneous with initia-

tion of cerebral resuscitation. Early therapies such as the use of sedation and osmolar agents may be initiated prior to obtaining a CT scan in cases in which cerebral edema seems likely.

Sedation and Neuromuscular Blockade

Although data are insufficient to support a treatment standard for the use of sedation and neuromuscular blockade¹ once the airway has been established, these medications may be useful in maintaining the airway, during procedures, and in the reduction of pain and stress, and have some physiologic basis for their use. Painful or stressful stimuli are associated with increases in cerebral metabolic rate,⁵⁰ and it is reasonable to conjecture that ICP will increase during Valsalva-like events that occur during poorly controlled resuscitation. Although historical concerns related to the use of depolarizing agents and their effect on ICP may not be relevant during the initial resuscitation,⁵¹ these agents are not generally used after the initial resuscitation. Suggested intravenous agents for neuromuscular blockade include rocuronium, vecuronium, and pancuronium.

There are no specific recommendations on the choice and dosing of sedation based on evidence; however, continuous propofol infusion should be avoided as it has been associated with increased mortality and morbidity (acidosis, rhabdomyolysis) when used for a prolonged period.^{52,53} Suggested intravenous agents for sedation include morphine sulfate 0.1 to 0.2 mg/kg per dose every 2 to 4 hours, with continuous infusion to run at 0.1 mg/kg/hr; lorazepam 0.05 to 0.1 mg/kg per dose, with continuous infusion to run at 0.1 mg/kg/hr, which may be titrated to effect; and midazolam 0.05 to 0.1 mg/kg per dose, with continuous infusion to run at 2 mcg/kg/min, which may be titrated to desired effect (usually within the range 0.4 to 6 mcg/kg/min).⁵⁴ Fentanyl 1 to 2 mcg/kg per dose every 1 to 2 hours, with continuous infusion to run at 1 to 3 mcg/kg per dose, is another suggested agent; however, there is limited evidence that bolus dosing may transiently increase intracranial pressure.^{55–57}

Hyperosmolar Therapy

Hyperosmolar therapies such as mannitol and hypertonic saline may be important adjuncts in cerebral resuscitation, especially in settings in which increased ICP is anticipated to be important. Data are insufficient to support a treatment standard directed at prevention of edema.¹ The absence of such data should not, however, prevent clinicians from initiating therapies intended to prevent potentially devastating increases in ICP. Consensus suggests that hyperosmolar therapy should be initiated if adequate sedation, analgesia, elevation of the head of the bed, and CSF drainage, if available, are ineffective in controlling ICP.¹

Mannitol has long been accepted as clinically efficacious without significant scientific data to support its widespread use. Mannitol is believed to reduce ICP by two mechanisms: reduction of blood viscosity^{58,59} and an osmotic effect.⁶⁰ The only scientific evidence for mannitol in pediatrics relies on two retrospective studies that involved adult patients as well.^{61,62} Effective doses of mannitol range from 0.25 g/kg to 1 g/kg, with maintenance dosing 0.25 to 0.5 g/kg every 4 to 6 hours.⁵² Serum osmolarity should be maintained below 320 mOsm/L.

In contrast, while there is limited clinical experience with hypertonic saline, recent studies suggest that it is effective

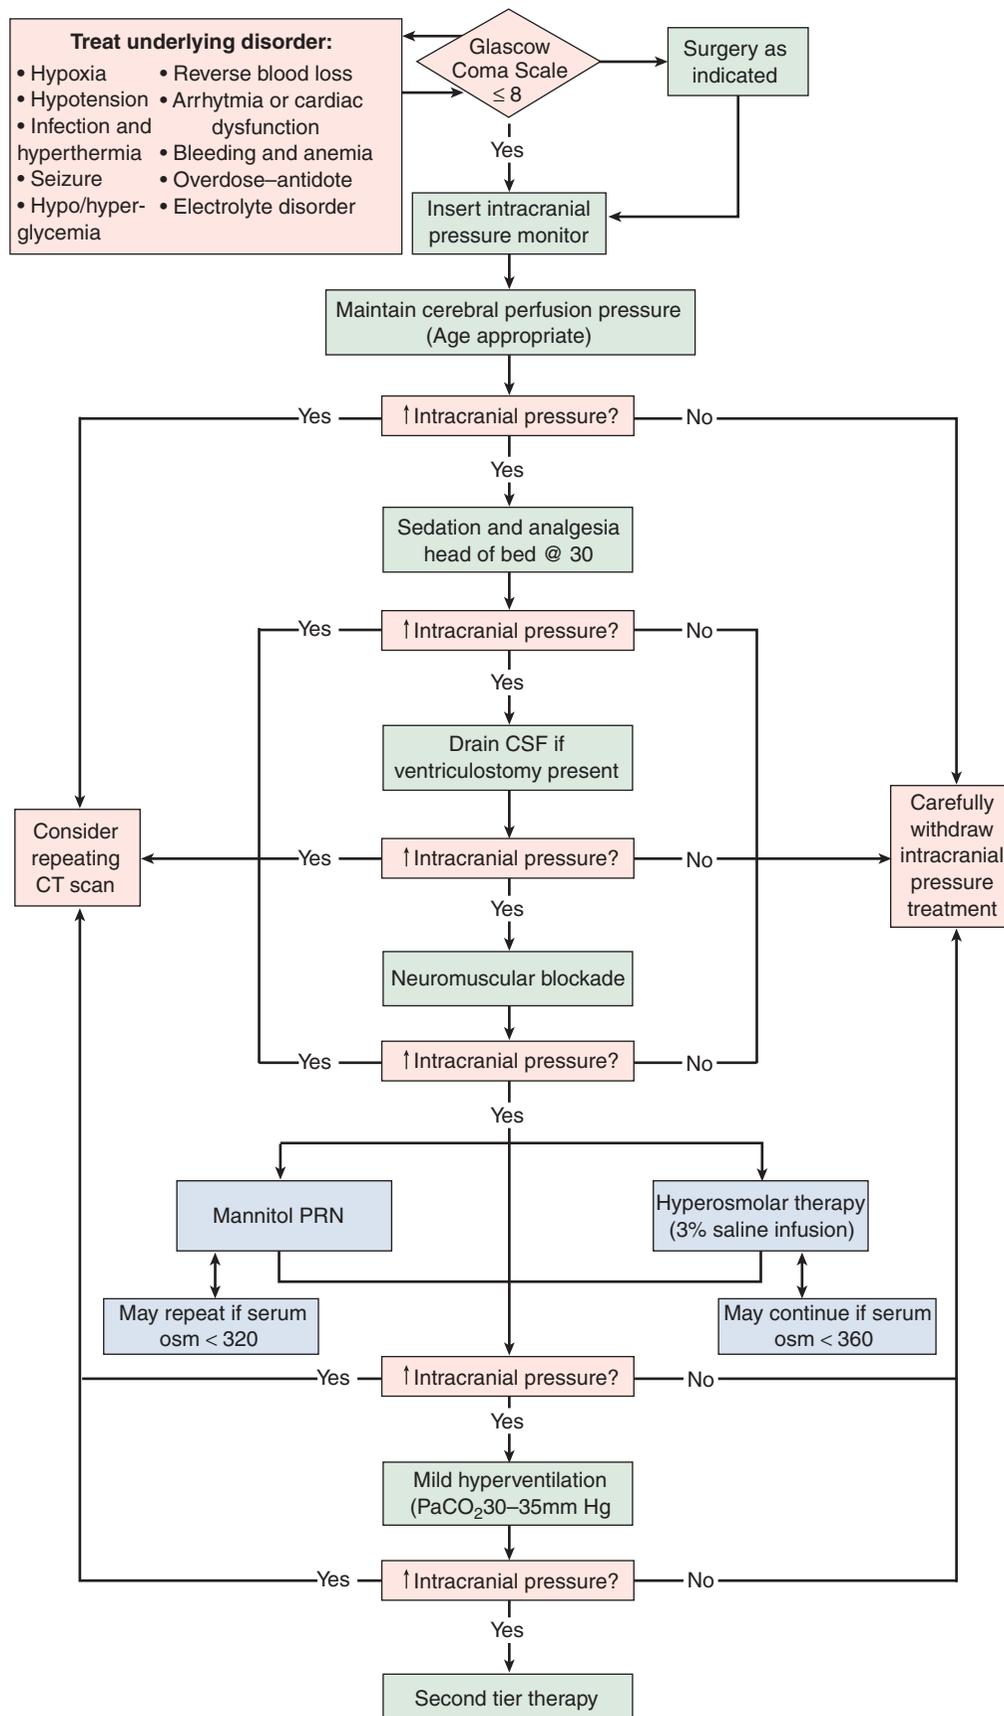

FIGURE 9-1. Algorithm for first-tier therapy. Abbreviations: CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; GCS, Glasgow Coma Scale score; HOB, head of bed; ICP, intracranial pressure; PRN, as needed. Table 9–1 Basic Cerebral Resuscitation Techniques

Treatment Category	Specific Treatment	Level of Evidence		Recommended for Prophylaxis?	Treatment Indications	Dosing Regimens
		Pediatric	Adult			
Analgesia & Sedation	Fentanyl	No evidence	No evidence	Yes	First-line therapy for treatment of painful and noxious stimuli and elevated ICP	1–2 mcg/kg/dose (inconclusive data indicate bolus dosing may ↑ intracranial pressure). Continuous infusion: 1–3 mcg/kg/hr.
	Midazolam	No evidence	No evidence	Yes	First-line therapy for treatment of painful and noxious stimuli and elevated ICP	0.05–0.1 mg/kg/dose. Continuous infusion: 2 mcg/kg/min, titrate to desired effect with range of 0.4–6 mcg/kg/min.
Paralysis (decreased muscular activity)	Rocuronium (neuromuscular blockade)	One prospective study	No evidence	Yes	First-line therapy with sedation for treatment of painful and noxious stimuli and elevated ICP	0.6–1.2 mg/kg/dose, repeat doses: 0.2 mg/kg every 20–30 min as needed. or Continuous infusion: 10–12 mcg/kg/min.
Hyperosmolar Therapy	Mannitol	Retrospective studies	Randomized, controlled trials and retrospective studies	No	If sedation, analgesia, elevation of head of bed, and CSF drainage (if available) are ineffective	0.25–1.0 g/kg bolus. Maintenance dosing: 0.25–0.5 g/kg every 4–6 hr. Serum osmolarity should be <320 mOsm/L.
	Hypertonic saline	Prospective and retrospective studies	No evidence	No	If sedation, analgesia, elevation of head of bed, and CSF drainage (if available) are ineffective	0.1–1.0 ml/kg/hr of 3% saline using minimal dose needed. Serum osmolarity should be <360 mOsm/L.
Cerebral Vasoconstriction	Hyperventilation	Prospective studies	Randomized, controlled trials and prospective studies	No	Mild HV if sedation, analgesia, elevation of head of bed, CSF, drainage (if available), and hyperosmolar therapy are ineffective. Aggressive HV may be considered as a second tier with refractory intracranial hypertension.	Mild HV: PaCO ₂ 30–35 mm Hg Aggressive HV: PaCO ₂ <30 mm Hg
Seizure Therapy & Prophylaxis	Early posttraumatic seizures	One prospective study	Prospective studies	May be considered	Seizures	First-line therapy: Fosphenytoin P.E. 15–20 mg/kg load with maintenance dosing of 4–6 mg/kg/24 hr divided 1–2 times a day. Second tier: Phenobarbital 15–20 mg/kg load with maintenance dosing of 3–5 mg/kg/24 hr divided 1–2 times a day.
	Late posttraumatic seizures	One prospective study, otherwise retrospective studies	Prospective and retrospective studies	No	Seizures	Same as early posttraumatic seizure therapy
Anti-inflammatory	Corticosteroids	Prospective and retrospective studies	Prospective and retrospective studies	No	Not recommended	Not recommended

Abbreviations: CSF, cerebrospinal fluid; HV, hyperventilation; ICP, intracerebral pressure.

in controlling increased ICP. Hypertonic saline may work through mechanisms similar to mannitol by creating an osmolar gradient, since sodium does not penetrate the BBB well. Hypertonic saline may also have specific anti-inflammatory effects.^{63,64} Effective doses of 3% saline range between 0.1 and 1.0 ml/kg/hr; clinicians should use the minimal dose needed. A higher level of serum osmolarity (360 mOsm/L) appears to be tolerated. Euvolemia must be

maintained, and a Foley catheter is recommended with all hyperosmolar therapies.

Hyperventilation

Hyperventilation has been widely used in the past to treat ICP based on the assumption that cerebral hyperemia is a major component in secondary brain insults. The intact cerebral vasculature responds to decreasing CO₂ tension by

vasoconstriction. Decreasing the volume of the intracerebral compartment can lower ICP. Hyperventilation was also thought to reduce cerebral acidosis, improve cerebral metabolism, and increase blood flow to ischemic areas of the brain. The mechanism of hyperventilation is the induction of hypocapnia, which leads to cerebral vasoconstriction and reduction in CBF. Although hypocapnia will reduce CBV, it also has the potential to induce ischemia.⁶⁵

Recent studies show that hyperemia may not be that common⁶⁶ and that hyperventilation may cause cerebral ischemia.⁶⁷ Moreover, cerebral vasculature autoregulation is lost shortly after injury, and hyperventilation becomes ineffective in lowering ICP. There are no studies comparing hyperventilation with other therapies such as hyperosmolar agents, barbiturates, and hypothermia. Therefore, data are insufficient to support a treatment standard. Recent widespread use of noninvasive means of measuring carbon dioxide, such as end-tidal carbon dioxide monitors, enable health care workers to see the immediate effects of adjustments in ventilation.⁶⁸ Consensus of expert opinion suggests the following¹:

- Prophylactic hyperventilation (arterial partial pressure of carbon dioxide [Paco₂] < 35 mm Hg) in children should be avoided.
- Mild hyperventilation (Paco₂ 30 to 35 mm Hg) may be considered for elevated ICP not responsive to sedation and analgesia, neuromuscular blockade, CSF drainage, and hyperosmolar therapy.
- Aggressive hyperventilation (Paco₂ < 30 mm Hg) may be considered as a second-tier option in the setting of refractory hypertension with monitoring to detect cerebral ischemia in place; also, aggressive hyperventilation may be necessary for brief periods of cerebral herniation or acute neurologic deterioration.

Because hyperventilation may be ineffective, and possibly deleterious, measurement of ICP should guide its application. After initial stabilization, the cervical spine should be kept in a neutral position to avoid venous outflow obstruction, which also can raise ICP.

After the initial insult, and especially during reperfusion, it is important to prevent secondary injury. In particular, it is vital that additional hypoxia and ischemia not happen. Clinicians often fail to realize that inadequate oxygen delivery can occur not only because of low delivery of oxygen, but also because of increased oxygen utilization. If oxygen delivery is limited because of shock, elevated ICP, or derangements in cerebral autoregulation, events that create any imbalance between delivery and utilization can cause a secondary injury. Examples of such events include processes that raise cerebral metabolism, such as fever or convulsion.

Seizure Therapy

Posttraumatic seizures (PTS) have been classified as early (occurring within 7 days) or late (occurring after 7 days) following injury.³ Seizures may cause secondary injury through a number of pathways, including increased cerebral metabolism, increased ICP, systemic hypoxia, increased cerebral temperature, interference with venous return, and release of excitatory neurotransmitters. Early PTS are more common in pediatric patients (20% to 39%)^{69,70} than adult patients after severe TBI. Both low GCS score and young age

(<2 years) are associated with an increased risk of early PTS.^{70,71} Consensus suggests that prophylactic antiseizure therapy may be considered as a treatment option to prevent early PTS in young children and infants at high risk for PTS.¹ Adult evidence suggests that anticonvulsants (phenytoin and carbamazepine) reduce early PTS but do not improve long-term outcomes.³ Suggested anticonvulsants include fosphenytoin and phenobarbital.⁷²

Late PTS are slightly less common in children (7% to 12%)⁷³ than adults (9% to 13%),⁷⁴ and data are insufficient to recommend prophylactic use of antiseizure medicine for children after severe TBI for preventing late PTS.

Steroids

Corticosteroids have been used in TBI with the intent of reducing cerebral swelling due to inflammation.⁷⁵ While experimental data suggests that corticosteroids reduce cerebral edema and attenuate free radical production in the setting of TBI, clinical studies have not supported their use.³ At least eight studies examined the effect of corticosteroids in pediatric patients after TBI, with some studies reporting a beneficial effect on outcome. These studies have, however, been difficult to synthesize into a standard recommendation because of heterogeneous mechanisms of injury, confounding bias, and variable complications.^{76,77} Two studies showed a marked increase in bacterial infections, including pneumonia.^{78,79} At this time, data are insufficient to support a treatment standard or guideline for the use of corticosteroids in the treatment of TBI in pediatric patients.¹

Cerebral Resuscitation: Advanced Techniques

(Table 9–2, Fig. 9–2)

ICP Monitoring

In tertiary care centers, the ability to place ICP monitoring devices allows for more precise management of increased ICP. This may be most important in TBI, as ICP monitoring is not recommended in cardiac arrest. In animal models of cardiac arrest, the insult necessary to produce a poor outcome is below the threshold needed to result in intracranial hypertension, implying that ICP monitoring–directed therapy is unlikely to improve outcomes.^{48,49} In addition to intracranial monitoring devices, adult studies suggest that monitoring cerebral extraction of oxygen via jugular bulb catheters in addition to cerebral perfusion pressure after TBI results in improved neurologic outcome.⁸⁰

Unfortunately, the decision as to when to initiate treatment of ICP in the management of TBI is made more difficult by the lack of data to support a treatment standard or guideline.¹ The posttraumatic brain is most likely sensitive to the secondary ischemia that may develop due to loss of cerebral perfusion pressure (CPP). Therefore, CPP monitoring (mean arterial pressure minus intracranial pressure) may be helpful. As ICP increases secondary to cerebral edema, it can ablate adequate perfusion. CPP estimates the ability of CBF to deliver important metabolic substrates to the cerebral tissue. As with treatment of elevated increased ICP, data are insufficient to propose a specific guideline for an appropriate range to maintain for CPP.¹ Retrospective data suggest that prolonged increased ICP greater than 20 mm Hg, and in particular ICP greater than 40 mm Hg, are associated with poor long-term neurologic outcome and mortality.^{81,82}

Table 9–2 Advanced Cerebral Resuscitation Techniques

Treatment Category	Specific Treatment	Level of Evidence		Recommended for Prophylaxis?	Treatment Indications	Dosing Regimens
		Pediatric	Adult			
Invasive Monitoring	Treatment based on ICP ICP reading	Retrospective studies	One prospective study and retrospective studies	Not applicable	ICP \geq 20 mm Hg	Not applicable
Diminished Metabolism	Barbiturates	Retrospective studies	One prospective study and retrospective studies	No	Second-tier therapy if sedation, analgesia, elevation of head of bed, CSF drainage (if available), and mild hyperventilation are ineffective	Pentobarbital 10 mg/kg load, then 5 mg/kg every hour for 3 doses with a maintenance infusion of 1 mg/kg/hr. Thiopental 10–20 mg/kg with a maintenance infusion of 3–5 mg/kg/hr. Consider reducing dose with decreased blood pressure or ICP $<$ 25 mm Hg.
	Hypothermia	Retrospective studies	Prospective studies	No	Second-tier therapy if sedation, analgesia, elevation of head of bed, CSF drainage (if available), mild hyperventilation, and barbiturates are ineffective	Core body temperature $<$ 35°C. Regimens must be established per institution.
Surgical Procedures	Ventricular drainage	Retrospective studies	2 prospective studies and retrospective studies	No	Second-tier therapy if sedation, analgesia, and elevation of head of bed are ineffective	Via ventriculostomy catheter
	Decompressive craniotomy	Retrospective studies	Retrospective studies	No	Second-tier therapy that may be considered if: diffuse cerebral swelling on CT, within 48 hr of injury, no episodes of ICP $>$ 40 mm Hg before surgery, GCS score $>$ 3 at some point after injury, secondary clinical deterioration, evolving cerebral herniation syndrome	Surgical technique left to the discretion of the surgeon

Abbreviations: CSF, cerebrospinal fluid; CT, computed tomography; GCS, Glasgow Coma Scale; ICP, intracerebral pressure.

Additionally, an inverse relationship has been seen with CPP and increased ICP, such that patients with ICP readings above 20 mm Hg are likely to have depressed CPP.⁸³ Increased mortality is associated with a mean CPP less than 40 mm Hg.⁸⁴ Therefore, treatment of increased ICP should begin at an ICP of 20 mm Hg, and CPP should be maintained in the range of 40 to 65 mm Hg in children with TBI.¹ Treatment should be supported by close physiologic monitoring, frequent clinical examinations, and cranial imaging.

Barbiturates

High-dose barbiturates reduce ICP by reduction of resting cerebral metabolic rate and altering vascular tone.^{85,86} The reduction in the metabolic rate is associated with a reduction in CBF and CBV. On a molecular level, induction of a barbiturate coma reduces the amount of glutamate and lactate (both excitotoxicity mediators that cause neuronal damage) in the extracellular space of the brain via microdialysis.²² Improvement in clinical outcomes such as long-term neuro-

logic status, however, has not been documented, and barbiturate coma has been associated with hypotension,⁸⁷ decreased jugular venous saturations, and worse outcomes.⁸⁸ Barbiturate therapy may be divided into prophylactic use for prevention of intracranial hypertension, and therapeutic use for established and refractory intracranial hypertension. There are no pediatric studies investigating the prophylactic use of barbiturates, and adult studies suggest no benefit.⁸⁹ Therefore, induction of a barbiturate coma is not indicated to prevent the development of intracranial hypertension. Studies of the efficacy of high-dose barbiturates in refractory intracranial hypertension in children have been small case series showing a reduction of ICP but no improvement in long-term neurologic outcome.^{90,91} Often therapy with barbiturates was complicated by significant hypotension requiring fluid resuscitation and the use of pressors.⁹⁰ Therefore, data are insufficient to support a treatment standard or guideline. However, expert opinion suggests that high-dose barbiturate therapy may be considered in hemodynamically stable patients with

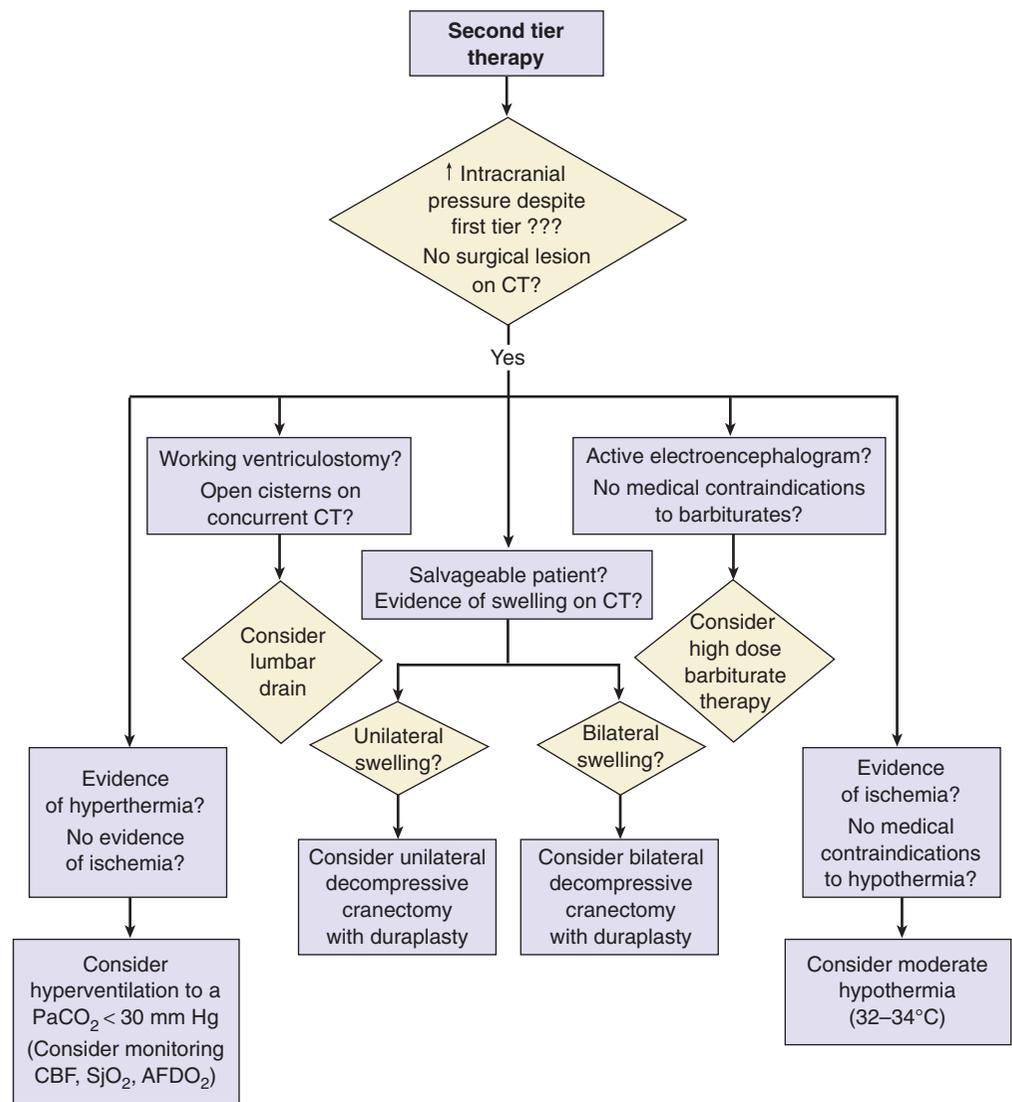

FIGURE 9–2. Algorithm for second-tier therapy. Abbreviations: A]DO₂, arterial-jugular venous difference in oxygen content; CBF, cerebral blood flow; CT, computed tomography; EEG, electroencephalogram; ICP, intracranial pressure; SjO₂, jugular venous oxygen saturation. (Adapted from Adelson PD, Bratton SL, Carney NA, et al: Guidelines for the acute medical management of severe traumatic brain injury in infants, children, and adolescents. *Pediatr Crit Care Med* 4[Suppl]:S1–S75, 2003.)

salvageable severe head injury and refractory intracranial hypertension with appropriate hemodynamic monitoring and cardiovascular support.¹ Therapeutic regimens that have been reported include pentobarbital with a loading dose of 10 mg/kg, then 5 mg/kg every hour for three doses with a maintenance drip of 1 mg/kg/hr,⁹² or thiopental with a loading dose of 10 to 20 mg/kg followed by a maintenance drip of 3 to 5 mg/kg/hr.⁹³ Barbiturates are a second-tier therapy to consider when adequate sedation, analgesia, elevation of the head of the bed, CSF drainage if available, and mild hyperventilation are ineffective in controlling ICP.¹

Therapeutic Hypothermia

Postinjury hypothermia, defined as a core body temperature less than 35° C, reduces apoptotic neuronal death in animal models.^{44,94} Hypothermia also reduces levels of glutamate in the CSF.²¹ Although two early studies showed promise in the use of hypothermia for the management of children after TBI, no additional work has been published between the 1970s and the 1990s. In the 1990s, several small adult studies showed improvements in CPP⁹⁵ and trends toward improved long-term neurologic outcome.^{95–98} However, a multicenter

trial in adults after TBI was unable to show any benefit,⁹⁹ although a trend toward improved outcome existed in patients who presented hypothermic and were less than 40 years old. No child less than 16 years old was entered. Therefore, data are insufficient to support a treatment standard or guideline for the induction or maintenance of hypothermia after TBI. An expert consensus panel concluded that hypothermia may be considered in the setting of refractory intracranial hypertension.¹ Hyperthermia has been associated with poor outcome in experimental models and adult studies¹⁰⁰ and should be avoided.

Although no current studies support the application of hypothermia in children, the outcome of patients who remain in coma after resuscitation from cardiac arrest can be so poor that the therapy should be considered based on a reasonable extrapolation of laboratory and adult clinical data. The benefit of mild hypothermia after cardiac arrest in adults is supported by European and Australian randomized clinical trials published contemporaneously in 2002.^{101,102} These studies indicated that mild hypothermia (32 to 34° C for 12 to 24 hours postarrest) is effective in preventing, or at least ameliorating, postanoxic encephalopathy in adults.

In the European Hypothermia After Cardiac Arrest (HACA) study,¹⁰² 55% of the hypothermia group met criteria for a “good outcome” as compared to 39% of the normothermia group. Overall mortality was also decreased from 55% in the normothermic group to 41% in the hypothermic group. In an Australian study,¹⁰¹ 49% of the hypothermia group achieved a “good outcome,” compared with 29% of the normothermia group. Mortality rates trended toward a decreased mortality in the hypothermia group, but these results were not statistically significant. Additional studies have subsequently appeared that also demonstrate efficacy for mild hypothermia in the setting of post-cardiac arrest neurologic injury. Taken together, the adult clinical studies are persuasive enough to have resulted in high-level recommendations for the therapy from expert consensus panels in adults suffering witnessed ventricular fibrillation. (AHA and HACA).¹⁰²

In attempting to decide if these data should be applied to children, it is important to focus on the underlying science and the overall risk-to-benefit ratio with respect to outcome. The experience in adults, limited though it is, indicates that mild hypothermia is relatively safe. Our current understanding of postanoxic encephalopathy supports the conclusion that its pathophysiology is similar in children and adults. Taken together, these assumptions support application of mild hypothermia in children who do not promptly return to their previous neurologic function after an episode of cardiac arrest. Such patients should generally be transferred to tertiary institutions.

The specific technique of mild hypothermia after cardiac arrest requires individualized institutional protocols based on the specific technology that will be utilized. Techniques range from surface cooling with ice to central circulation cooling catheters. Whatever technique is used, the patient will generally require sedation and paralysis to prevent shivering. Care must be taken to avoid temperature overshoot. This is best accomplished by measuring either central circulatory or bladder temperature and adjusting the cooling device carefully as the target temperature is approached. Some of the devices include a servo mechanism that controls temperature automatically. The most significant toxicities are infectious, so careful monitoring for early indicators of sepsis should be initiated.

Ventricular CSF Drainage and Decompression Craniotomy

Other advanced therapies applicable in tertiary centers that have been considered include ventricular CSF drainage and decompression craniotomy. Ventricular CSF drainage is used in conjunction with ICP monitoring and is thought to lower ICP by reducing intracranial volume and may remove clinically important detrimental mediators which cause neuronal death or damage. One retrospective study in children after TBI showed a reduction in ICP with CSF drainage.¹⁰³ Lumbar drainage in appropriate patients has been shown to reduce ICP in two small studies.^{104,105} All of the pediatric studies are too small to show a difference in long-term neurologic outcome. Therefore, data are insufficient to support a treatment guideline for the role of CSF drainage in the management of TBI. The expert consensus panel recommended that CSF drainage may be considered as an option.¹ In addition to ventriculostomy catheter drainage, lumbar

drainage may be considered in appropriate patients with open basal cisterns and no mass lesion or shift on radiology studies.¹

As with ventricular CSF drainage, data are insufficient to support a treatment standard or guideline for decompressive craniotomy.¹ The goal of decompressive craniotomy is to reduce ICP sufficiently to maintain CPP and prevent herniation. Several pediatric studies have documented a decrease in ICP after TBI with decompressive craniotomy, but the studies are too small to comment on long-term neurologic outcomes or the best surgical technique.¹⁰⁶⁻¹⁰⁸ The expert consensus panel suggested that decompressive craniotomy may be appropriate in patients with potentially recoverable brain injury after severe TBI and refractory intracranial hypertension who meet some or all of the following criteria: diffuse cerebral swelling on cranial CT imaging, within 48 hours of injury, no episodes of sustained ICP greater than 40 mm Hg before surgery, GCS score greater than 3 at some point subsequent to injury, secondary clinical deterioration, and/or evolving cerebral herniation syndrome. It appears less effective in patients with extensive secondary brain insults. Decompressive craniotomy should also be considered in the treatment of severe TBI in children with nonaccidental trauma and refractory intracranial hypertension.¹

Summary and Future Directions

The improved understanding of the pathophysiology involved in the secondary deterioration that occurs after TBI and asphyxial cardiac arrest indicates that future therapies that target these secondary events may improve the efficacy of pediatric cerebral resuscitation. In particular, therapies intended to mediate apoptosis hold promise in preventing additional damage secondary to reperfusion injury. Future directions in cerebral resuscitation may also involve enhancing regeneration through administration of neurotrophic factors and cell transplantation.

Recovery from TBI has been shown to be enhanced by stimulation of the catecholamine systems.¹⁰⁹ Medications with catecholamine-like effects that have been studied include D-amphetamines, amantadine, and methylphenidate.¹¹⁰⁻¹¹⁴ Increasing levels of the neurotransmitter acetylcholine attenuate memory deficits after experimental TBI.¹¹⁵ Inhibiting cholinesterase with physostigmine also results in reduced memory and attention deficits after TBI.¹¹⁶ Stimulation of the production of acetylcholine through cytidine diphosphoryl (CDP)-choline reduced postconcussion symptoms in adults after TBI when compared to placebo.¹¹⁷ Unfortunately, no studies in children with neurotransmitter replacement therapy exist, and none of these agents can be recommended clinically at this time.

Neurotrophic factors (NTFs) are a family of proteins that are responsible for the growth and survival of neurons. They stimulate damaged neurons to regrow their axonal processes. Exogenous local infusion of NTFs improved memory retention¹¹⁸ and attenuated neuronal loss in rats after TBI.¹¹⁹ The clinical application of NTFs or NTF agonists has not yet occurred. Cell transplantation of genetically altered cells or cells transfected with viral vectors may allow the delivery of neuroactive substances to focal regions of the brain. Cells modified to produce nerve growth factor do support survival of cholinergic neurons after injury in models.¹¹⁹

Although TBI and cardiac arrest are two distinctly different insults, it is likely that many therapies targeted at preventing neuronal death will be applicable to both insults. The keys to treatment after brain injury will likely focus on prevention of secondary insults. Many therapies may need to be initiated early, perhaps in the field, to be effective. As in most areas of resuscitation, there continues to be a dearth of good scientific knowledge to guide the practitioner at this time. Children who have suffered a significant cerebral injury will not, however, wait for the clear delineation of effective therapies. Clinicians must decide which children's presentations demand intervention, and apply therapies intended to prevent, to the extent possible, additional loss of neurologic function.

Chapter 10

General Approach to Poisoning

Teresa J. Coco, MD and Erica L. Liebelt, MD

Key Points

Although most unintentional ingestions in young children result in few sequelae, there are several medications and agents that are toxic or even fatal when ingested in small doses.

Identifying particular toxidromes is helpful in guiding management.

Preventing the absorption of a drug or substance with activated charcoal is the primary modality for gastrointestinal decontamination for most ingestions.

Qualitative drug screens provide minimal useful information that will change the acute management of most poisoned patients and do not always rule out a poisoning.

Most poisoned patients can be treated with supportive care alone; however, there are specific antidotes for certain drugs and toxicants that can greatly reduce the morbidity and mortality associated with the toxicity.

Introduction and Background

Childhood poisonings are among the most common presenting medical emergencies encountered in pediatrics. Fortunately, the majority of substances involved produce minimal or mild clinical toxic effects. However, certain toxic poisonings can lead to severe clinical deterioration and eventually death. Therefore, physicians and other health care providers should be knowledgeable and competent in the assessment and management of childhood ingestions.

According to the Toxic Exposure Surveillance System (TESS) of the American Association of Poison Control Centers (AAPCC), there were 2,438,644 human exposures reported to poison control centers in 2004, of which 51% occurred in children younger than 6 years of age.¹ Over 1.5 million exposure cases were reported in individuals less than 20 years of age. The most common route of exposure was by ingestion (77%), followed by dermal, inhalation, and ocular exposure. Of those cases treated in a health care facility, 10%

were less than 6 years of age, 13% were between 6 and 12 years of age, and 49% between 13 and 19 years of age. However, the majority of these cases were treated and released. There were 27 reported deaths in children younger than 6 years of age, 16 deaths in the age range 6 to 12 years, and 90 reported deaths in the age range 13 to 19 years.

Pediatric poisonings can be classified as intentional or unintentional. Unintentional ingestions occur more frequently in children less than 6 years of age. In 2004, the AAPCC reported that 61% of unintentional ingestions were in this age group.¹ Because of the inquisitive and exploratory nature of children at this developmental stage, unintentional ingestions are more common. Medication errors by caregivers have also been reported in several studies to be a frequent event in this population.²⁻⁴ The possibility of malicious intent to harm or transplacental exposure must also be recognized.

Intentional ingestion becomes more likely in school-age children over the age of 6 years. Thirty percent of intentional exposures reported to the AAPCC occurred between the ages of 6 and 19 years.¹ Older children may have more experimentation behavior that leads to the intentional ingestion. Psychosocial issues such as peer pressure can contribute to this type of ingestion. Suicidal gestures and attempts are also a frequent basis for intentional ingestions in this age group.

Since the passage of the Poison Prevention Packaging Act of 1970, which mandated child-resistant closures on household products and prescription medications, morbidity and mortality of childhood poisoning has been significantly reduced.⁵ The establishment of poison control centers in the 1950s with the assistance of the American Academy of Pediatrics has greatly improved the recognition, management, and prevention of pediatric poisonings. These poison control centers have developed into complex computerized systems with specially trained health professionals providing advice 24 hours a day. The TESS database has been instrumental in providing surveillance and identification of certain hazardous and toxic substances in pediatric poisonings, such as the 10 most common pediatric exposures (Table 10-1). Many common exposures, including personal care products, cosmetics, and cleaning substances, have a relatively low risk of causing serious systemic symptoms.⁶

Some of the most hazardous household products include hydrocarbons, pesticides, alcohols, drain and oven cleaners, and glue gun agents containing selenious acid.⁷ Pharmaceutical agents associated with the greatest potential for severe

Table 10–1 The Top 10 Pediatric Exposures in Children Less Than 6 Years of Age as Reported by the AAPCC

Cosmetics and personal care products
 Cleaning substances

 Topicals
 Foreign bodies
 Cough and cold preparations
 Plants
 Pesticides
 Vitamins
 Antihistamines

Table 10–2 Drugs and Substances That Are Toxic in Small Amounts

Drug/Substance	Toxic Effects
Benzocaine	Methemoglobinemia
β-Blockers (propranolol)	Bradycardia, hypotension, seizures, hypoglycemia
Calcium channel antagonists (verapamil)	Bradycardia, hypotension, heart block
Camphor	Seizures, CNS depression
Chloroquine	Seizures, dysrhythmias
Clonidine	Bradycardia, hypotension, CNS depression
Cyclic antidepressants	Seizures, dysrhythmias, hypotension
Diphenoxylate and atropine (Lomotil)	CNS depression, respiratory depression
Lindane	Seizures, CNS depression
Methadone	CNS depression, respiratory depression
Methyl salicylate	Seizures, metabolic acidosis, cardiovascular collapse
Phenothiazines	Seizures, CNS depression, dysrhythmias
Quinidine/quinine	Seizures, dysrhythmias
Sulfonylureas (glyburide)	Hypoglycemia

Abbreviation: CNS, central nervous system.

toxicity are iron supplements, antidepressants, cardiovascular medications, and salicylates.^{6–8} There are several agents that have been identified as extremely toxic or even fatal in children less than 2 years of age or weighing less than 10 kg when ingested in one to two swallows or one to two tablets⁹ (Table 10–2).

Recognition and Approach

Infants and children exposed to potentially toxic substances may present as an acute emergency with or without multi-system involvement. These patients may pose a diagnostic challenge for emergency physicians, depending on the substance involved and the complexity of its toxic effects. Young children with unintentional ingestions usually ingest a single known substance, making the history and evaluation more straightforward. The adolescent patient, on the other hand, usually presents with a polysubstance overdose. Caregivers may be unavailable or unwilling to provide pertinent historical information. Adolescents may withhold knowledge of ingestion in an effort to conceal substance abuse or suicidal

Table 10–3 Substances and Drugs Toxic to the Respiratory System

Respiratory System Effect	Causative Substance/Drug
Airway obstruction	Caustics (acids and alkalis), ACE inhibitors
Increased secretions	Organophosphates, nerve gases
Loss of airway reflexes	Sedative-hypnotics
CNS depression	Isoniazid, bupropion, cyclic antidepressants
Seizures	
Respiratory failure	
Pneumonitis	Hydrocarbons, inhalants
Paralysis	Botulinum toxin, tetanus
Noncardiogenic pulmonary edema/acute lung injury	Opioids, salicylates

Abbreviations: ACE, angiotensin-converting enzyme; CNS, central nervous system.

ideation.¹⁰ Clinicians must consider poisoning in any child presenting with a history or symptom complex that is atypical or confusing.¹¹

The initial phase of management in a suspected poisoning involves simultaneous assessment and stabilization according to the traditional “ABCDEs” of emergency medicine:

- Airway**
- Breathing**
- Circulation**
- Disability**
 - Mental Status—awake, lethargic or obtunded?
 - Pupils—large or small?
- Drug Therapy**
 - Oxygen—carbon monoxide poisoning
 - Naloxone—opioid poisoning
 - Glucose—insulin or sulfonylurea poisoning
- Decontamination: ocular and skin**
- Exposure: undress the patient and minimize heat loss**

Evaluation of the airway includes looking for signs of obstruction, loss of protective airway reflexes, risk of aspiration, increased secretions, or predicted rapid progression to respiratory failure. Multiple toxic substances can affect the respiratory system (Table 10–3). Elective endotracheal intubation is indicated for impending respiratory failure. Early establishment of intravenous access should be obtained for any symptomatic poisoned child.

The “D” in the mnemonic traditionally represents disability or the neurologic examination, but can also stand for life-saving drug therapy and initial decontamination. Empirical drug therapy in symptomatic patients may prove to be life saving. A potentially poisoned child who presents with altered mental status or respiratory depression should be given a trial of naloxone (0.01 mg/kg intravenously; give a subsequent dose of 0.1 mg/kg if inadequate response; use intramuscularly, subcutaneously, or endotracheal tube if intravenous is not available). Infants and young children are susceptible to drug-induced hypoglycemia due to their limited glycogen stores. Hypoglycemia is frequently reported in ingestions of ethanol, oral hypoglycemic agents, β-blockers, and salicylates (see Chapter 106, Hypoglycemia). A rapid bedside glucose test is useful in identifying hypoglycemia early. Anticonvulsants may be necessary to stabilize seizure activity. Children have a higher body surface area than adults

and are at a higher risk for toxicity in dermal exposures and for developing hypothermia. Therefore, evaluation of exposure is an important part of the initial assessment of any poisoned pediatric patient.

After the patient is stabilized, a more detailed history is needed to determine the nature of the potential poisoning. When the ingestion is not witnessed, it is difficult to predict what was ingested or available to the patient, when the ingestion occurred, and how much was ingested. However, identifying the potential severity of an ingestion will determine which therapeutic interventions will be necessary and which laboratory tests are indicated. Because children often present with an unclear history of ingestion, emergency physicians should be suspicious of ingestion when there is an acute onset of multisystem dysfunction, altered mental status, or a confusing clinical picture. If an ingestion has occurred, the clinician should assume that the child has consumed the maximum available amount of the substance that was taken. The potential milligram-per-kilogram quantity consumed is calculated based on the caregiver's description of the concentration of the type of pill or liquid. When two children have potentially co-ingested a substance, the milligram-per-kilogram quantity ingested is calculated for each child assuming that each child has ingested all the substance. The best estimation of the time of ingestion is important in determining the need for charcoal and the blood levels of specific drugs, and to estimate the length of observation needed in the emergency department. For example, a serum acetaminophen level is only predictive of hepatotoxicity if obtained at least 4 hours post-ingestion for plotting on the Rumack-Matthew nomogram or 2 hours post-ingestion for the elixir.¹² Exposures to toxins can be oral, ocular, dermal, or by inhalation. Knowing the route of exposure is important for the proper decontamination of the patient and for appropriate protection of the health care providers.

A physical examination should focus on vital signs, mental status, cardiovascular and respiratory function, pupils, skin changes, and bowel and bladder function. Specific physical findings may give the clinician clues as to the type of substance ingested. These characteristic features represent a *toxidrome*, which is a constellation of signs and symptoms that are suggestive of a certain class of toxicants/toxins. Recognition or exclusion of classic toxidromes is important when evaluating the poisoned pediatric patient (Table 10–4). Understanding the basic toxidromes can help the emergency physician determine if the patient was exposed to a drug/toxicant from one of the following classes: sympathomimetic, anticholinergic, cholinergic/anticholinesterase, sedative-hypnotic, opioid, or serotonin-like substances. However, it is important to note that exposures involving multiple substances may not develop as a classic toxidrome and that patients may not present with all of the findings associated with a single toxidrome. Therefore, in a suspected pediatric poisoning, it is essential to attempt to determine all the substances that may have been accessible at the time of ingestion. Even with an unknown ingestion, paying close attention to the presenting symptoms can direct the health care professional to the appropriate toxidrome. Patients may also present with a predominant symptom such as vomiting/diarrhea, seizures, or hyperthermia. It is helpful to go through a differential diagnosis of toxicants that can cause these predominant symptoms (Tables 10–5, 10–6, and 10–7).

Table 10–4 Toxidromes

Sympathomimetic

Vital signs	Tachycardia, hypertension, tachypnea, hyperthermia
CNS	Agitation, hallucinations, psychosis, seizures
Pupils	Mydriasis
Skin	Diaphoresis

Examples: amphetamines, methamphetamine, methylphenidate, cocaine, MDMA (Ecstasy), pseudoephedrine, caffeine, albuterol, theophylline

Anticholinergic

Vital signs	Hyperthermia, tachycardia, hypertension, tachypnea
CNS	Altered mental status, agitation, delirium, hallucinations, seizures, lethargy, coma
Pupils	Mydriasis
Skin/mucous membranes	Dry, flushed skin; dry mucous membranes
GI tract	Decreased bowel sounds
GU system	Urinary retention

Examples: atropine, antihistamines, antipsychotics, antispasmodics, cyclic antidepressants, jimsonweed

Cholinergic/Anticholinesterase

Vital signs	Bradycardia or tachycardia, tachypnea
CNS	Confusion, coma, fasciculations, seizures
Pupils	Miosis
Skin	Sweating
GI tract	Vomiting, diarrhea
Lungs	Bronchorrhea, bronchospasm
Skin/mucous membranes	Diaphoresis, lacrimation, salivation

Examples: organophosphate pesticides and nerve agents/gases (sarin, soman); carbamate insecticides; nicotine

Opioid/Clonidine

Vital signs	Bradycardia, hypotension, bradypnea/apnea, hypothermia
CNS	Euphoria, lethargy, coma
Pupils	Miosis

Examples: opiates, clonidine, other imidazolines (tetrahydrozoline eyedrops)

Serotonin Syndrome

Vital signs	Tachycardia, blood pressure fluctuation, hyperthermia
CNS	Agitation, confusion, delirium, hallucinations, mania, mutism, coma
Pupils	Mydriasis
Neuromuscular abnormalities	Hyperreflexia, myoclonus, akathisia (restlessness), seizures, rigidity

Examples: SSRIs; combinations of serotonergic agents—MAOIs, dextromethorphan, meperidine, MDMA (Ecstasy)

Sedative-Hypnotic Syndrome

Vital signs	Hypotension, bradypnea, hypothermia
CNS	Slurred speech, ataxia, depressed mental status, hyporeflexia, paradoxical excitement in very young children
Pupils	Normal to large, sluggishly reactive

Examples: barbiturates, benzodiazepines, buspirone, chloral hydrate, meprobamate, methaqualone

Abbreviations: CNS, central nervous system; GI, gastrointestinal; GU, genitourinary; MAOIs, monoamine oxidase inhibitors; SSRIs, selective serotonin reuptake inhibitors.

Table 10–5 Toxic Substances That Present with Vomiting and/or Diarrhea

Carbon monoxide
Caustic agents
Colchicine
Digoxin
Iron
Metals (arsenic, mercury, zinc)
Mushrooms
Nicotine
Organophosphate pesticides/insecticides
Salicylates
Theophylline

Ethanol withdrawal
GHB (γ-hydroxybutyrate)
Isoniazid
Lead
Lidocaine
Lindane
Lithium
Meperidine
Nerve agents (sarin, soman, tabun, VX gas, Substance 33)
Oral hypoglycemics
Organophosphates
Phencyclidine
Phenytoin
Propoxyphene
Salicylates
Sympathomimetic agents
Theophylline
Tricyclic antidepressants
Water hemlock plant

Evaluation

An understanding of laboratory assays, their indications, and their limitations is an important aspect of managing children with potential toxic exposures. Laboratory evaluation of potentially poisoned patients with systemic symptoms of an unknown ingestion should include a focused evaluation based on the clinical situation (Table 10–8). Any patient presenting with an altered mental status or the potential to develop hypoglycemia from a toxic substance or drug should have a bedside blood glucose determination. Serum electrolytes, calculation of an anion gap, and blood gas assessment can help determine if a high-anion-gap metabolic acidosis is present (Table 10–9). An elevated osmolal gap (difference between the measured and calculated serum osmolality) may be a helpful clue in determining whether a patient has ingested a toxic alcohol (isopropyl, ethylene glycol, or methanol). However, it is important to realize the limitations of this test.

Table 10–7 Drugs That Cause Hyperthermia

Amphetamines
Anticholinergics
Antihistamines
Butyrophenones (haloperidol)
Cocaine
Cyclic antidepressants
Dinotrophenol
LSD
MAOIs
Methamphetamine/Ecstasy
Phencyclidine
Phenothiazines
Pseudoephedrine
Salicylates
SSRIs
Sympathomimetic agents
Theophylline
Thyroxine
Withdrawal of ethanol, dopamine agonists, sedative-hypnotic agents

Abbreviations: LSD, lysergic acid diethylamide; MAOIs, monoamine oxidase inhibitors; SSRIs, selective serotonin reuptake inhibitors.

Serum drug levels (e.g., acetaminophen, salicylate, digoxin)
Pregnancy test
Focused toxicology laboratory testing

Table 10–9 Toxic Substances That Cause a High-Anion-Gap Metabolic Acidosis

Cyanide
Ethanol
Ethylene glycol
Iron
Isoniazid
Metformin
Methanol
Paraldehyde
Phenformin
Salicylates

Depending on the time of ingestion, little of the osmotically active parent alcohol may be present when a patient presents with signs of toxicity. The normal osmolal gap varies (–5 to 15 mOsm) depending on the equation used to determine the gap and the time the calculation was made.¹³

Acetaminophen is available in many single and multidrug over-the-counter and prescription medications. Consequently, many patients are unaware that they ingested acetaminophen. Because it is the most common co-ingestant in polydrug overdoses in the United States and there is an available antidote, all patients with intentional overdoses should

be empirically tested for acetaminophen.¹⁴ Quantitative serum concentrations of other specific drugs (digoxin, salicylate) can be important in determining the severity of the ingestion and to guide the management of interventions and specific antidotes.¹⁵ Urinalysis may reveal important diagnostic clues. Calcium oxalate crystals are considered pathognomonic for ethylene glycol poisoning, but are usually discovered late in the clinical course. A pregnancy test is recommended in female patients of childbearing age, because of the possibility that the ingestion may be prompted by a wish to abort a fetus. Certain exposures warrant counseling regarding the potential for fetal loss or malformations, including retinoids, antineoplastic agents, selected anticonvulsants (phenytoin), and coumadin.

Routine qualitative drug screens provide minimal useful information that will change the acute management of most poisoned patients.¹⁵ There is no standard definition of what constitutes a “toxicology drug screen.” It is important for the emergency physician to understand the specific testing available at his or her facility. Most laboratory toxicology screens are immunoassays capable of screening for commonly abused drugs such as marijuana, opioids, amphetamines, benzodiazepines, and cocaine in the urine. In contrast, some laboratories can perform highly specific assays for hundreds of drugs on urine and blood specimens. These more complex toxicology screens can be important when an unknown substance has been ingested or child abuse is suspected.

It is important to understand the limitations of toxicology screens. They are only qualitative tests, detecting the presence of drugs. A drug that is present may not necessarily be causing the clinical symptomatology. Also, there are several dangerous drugs and substances not routinely detected by screens (Table 10–10). False-positive results are another limiting factor of broad toxicology screens. Finally, a negative toxicology screen does not rule out a poisoning for all of the reasons mentioned earlier. The majority of toxicologic diagnostic and therapeutic decisions can be made on a clinical or historical basis for most poisoned patients.

Additional tests that may be of benefit in an unknown ingestion include a 12-lead electrocardiogram to evaluate for

a prolonged corrected QT interval, a widened QRS complex, or a dysrhythmia that may be caused by tricyclic antidepressants or other cardiotoxic agents.¹⁶ Chest radiography may demonstrate pulmonary injury caused by respiratory irritants and other gases. Some agents are radiopaque and can be detected by the use of abdominal radiographs. Examples include chloral hydrate, iron, lead, enteric-coated preparations, drug-filled condoms, and foreign bodies. Computed tomography can help to document illicit drug-induced pathology (leakage or rupture of “body packers” and “body stuffers”).¹⁷

Management

After the suspected toxin has been identified, decontamination can be directed to the particular area exposed. Ocular and dermal decontamination should be carried out immediately as the toxic substance needs to be removed promptly to prevent ongoing absorption. Ocular exposures accounted for 5.2% of exposures reported by the AAPCC in 2004.¹ Ocular toxins can produce permanent injury and blindness if not appropriately managed. Ocular injuries are considered ophthalmologic emergencies. Immediate decontamination with irrigation of the eyes with sterile water, lactated Ringer’s solution, or sterile isotonic saline solution for 15 to 30 minutes is recommended. Suspected corrosive injuries require obtaining a pH of the ocular fluid. If the pH is greater than 7, irrigation should continue until that end point is reached. Ocular injuries with persistent pain should be referred for immediate consultation with an ophthalmologist.

Dermal exposures require immediate removal of all clothing and irrigation of the affected area with water. Significant absorption through the skin can occur with certain lipophilic compounds (e.g., organophosphates). A wide range of dermal toxins can produce corrosive injuries similar to burn injuries. These injuries may be treated with the same management strategy as burns. Of particular importance is the protection of health care professionals who come in contact with the toxic substance. Protective gear should be worn for suspected dermal toxins that may contaminate the air or be contacted through dermal exposure. For example, neoprene gloves should be worn if taking care of a patient with organophosphate exposure because organophosphates can penetrate through routine latex gloves.

Any patient with a suspected inhalation exposure should be removed from the source. Appropriate protective gear must be worn by any person that may come in contact with the same exposure. All clothing should be removed from the patient. Areas of the body possibly exposed to the inhalant should be decontaminated with abundant irrigation. Supplemental oxygen should be provided to any symptomatic patient.

The decision to perform gastrointestinal decontamination should be made only after initial stabilization has been initiated. Gastrointestinal decontamination is performed to prevent absorption after a substance has been ingested. The principal components of gastrointestinal decontamination include gastric emptying and administration of an absorbent compound. The benefit of gastric emptying decreases with time and is most effective if performed within an hour of ingestion. Induction of emesis in the hospital setting has not been shown to clinically improve the outcome of poisoned

Table 10–10 Drugs and Substances Not Routinely Detected on Comprehensive Toxicology Screen Testing

- β-Agonists
- β-Blockers
- Calcium channel antagonists
- Carbon monoxide
- Clonidine
- Cyanide
- Digoxin
- Dextromethorphan
- Diphenhydramine
- Ethylene glycol
- GHB (γ-hydroxybutyrate)
- Heavy metals
- Hydrocarbons
- Iron
- Isoniazid
- Ketamine
- Methanol
- Organophosphates
- Sulfonylureas

pediatric patients and should not be performed as part of the routine management in the emergency department.¹⁸⁻²⁰ Ipecac may delay the administration or reduce the effectiveness of activated charcoal, oral antidotes, and whole-bowel irrigation.

Gastric lavage is no longer considered the standard of care for gastrointestinal decontamination and should not be routinely performed in the management of the poisoned patient. Lavage should be considered if a potentially life-threatening substance has been ingested (cyclic antidepressant, β -blocker, calcium channel antagonist) and if it can be undertaken within 1 hour of the ingestion. This change in clinical practice has evolved in the last 15 years.¹⁸ There is little evidence that gastric lavage improves outcome even if performed within an hour of ingestion.^{21,22} Gastric lavage is contraindicated in the unintubated patient with depressed consciousness, if there is potential for loss of airway protective reflexes, in cases of ingestion of a corrosive substance or hydrocarbon, and in patients at risk for hemorrhage or gastrointestinal perforation. Complications include aspiration, mechanical injury to the oropharynx, esophagus, and stomach, and electrolyte imbalances.²² Substances for which gastric lavage may be useful for improving clinical outcome include sustained-release medications, agents that delay gastric emptying (opioids, anticholinergics), and substances not absorbed by activated charcoal (iron, lithium).

One limitation of gastric lavage in children is the diameter of the tube, which may not be large enough to accommodate pill fragments. A 16- to 28-French tube should be used in a child, and at least a 36-French tube in an adolescent. Gastric lavage is almost never warranted in young children.¹⁸ In adolescents with intentional overdoses, each case should be assessed on an individual basis, but lavage should never be employed routinely.

Absorbents bind toxic substances within the gastrointestinal tract and reduce systemic absorption. Activated charcoal is extremely effective in binding a wide variety of substances ranging from pharmaceuticals to biologic agents. The absorptive capacity of activated charcoal is a function of its binding surface area, which ranges from 1000 to 2000 m²/g. The administration of activated charcoal is the most common method of gastrointestinal decontamination in poisoned children. The maximal benefit occurs when it is given within an hour of the ingestion. However, it may be given after an hour if the agent ingested delays gastric emptying. The recommended dose of charcoal is 1 g/kg in children up to the age of 1 year, 25 to 50 g in children 1 to 12 years, and 25 to 100 g in adolescents. Charcoal may be given orally or by a nasogastric tube. Activated charcoal must not be administered to patients with a depressed level of consciousness, to unintubated patients who may have loss of protective airway reflexes, in cases in which there is an increased risk of aspiration (i.e., household hydrocarbons), or in cases with suspected gastrointestinal hemorrhage or perforation. Charcoal is not indicated when the agent is nontoxic or when it is unable to bind to substances. The main adverse events associated with activated charcoal are vomiting and aspiration, which can lead to pulmonary injury and death.⁸ Activated charcoal is not effective in binding ethanol, heavy metals, iron, caustics, lithium, hydrocarbons, and potassium. Any child suspected of ingesting a potentially life-threatening substance who has the ability to protect airway reflexes

should receive a dose of activated charcoal unless there is a specific contraindication.

Cathartic agents are not recommended in the routine gastrointestinal decontamination of an infant or child. The major function of a cathartic is to rapidly move the toxin through the gastrointestinal tract, reducing the amount of time for absorption. There is no clinical evidence to support the use of cathartics as adjunctive decontamination therapy.¹⁸ Adverse effects include vomiting, electrolyte imbalances, and hypovolemia.

Whole-bowel irrigation with balanced polyethylene glycol solutions (e.g., Golytely) given in large volumes aids in the rapid elimination of the toxicant through the gastrointestinal tract. These iso-osmotic solutions can be given safely in large volumes, without electrolyte imbalances or fluid shifts, even in small children. Typical rates of administration are 0.5 L/hr for children less than 6 years of age, 1 L/hr for children ages 6 to 12 years, and 1.5 L/hr for children older than 12 years of age, either orally or by nasogastric tube. This technique is most effective in eliminating sustained-release substances and substances poorly absorbed by activated charcoal, such as iron and lithium.²³ Knowing the potential toxicity of the toxicant, the ingestion time, the chemical nature of the toxicant, and the presence of contraindications will help direct the appropriate decontamination therapy. The risks and benefits must be weighed before institution of any therapy.

Supportive care is the mainstay of treatment for most patients with overdoses. Careful attention to the basic management of airway, ventilation, and hemodynamic support is adequate for most toxic exposures. However, there are toxicants for which a specific antidote can counteract the effects of the poison. A limited number of effective pharmaceutical antidotes are available, and it is important for clinicians to understand specific indications for their administration²⁴ (Table 10–11).

Although very few toxic exposures are effectively treated by extracorporeal techniques, these modalities are essential and life saving in the treatment of selected poisoned patients. Emergency physicians must be aware of when to initiate consultations for these interventions. The extracorporeal techniques most commonly employed for the removal of toxicants are hemodialysis and charcoal hemoperfusion, although exchange transfusion and continuous ultrafiltration techniques may also be used. Implementation of these invasive techniques requires the availability of nephrologists and pediatric critical care specialists on a 24-hour basis, as well as pediatric dialysis equipment and technicians who have expertise in the care of pediatric patients. In addition, it is essential that a reference laboratory also be able to monitor the efficacy of treatment on a 24-hour basis. Indications for extracorporeal removal of drugs and toxicants are ingestion of a substance whose removal can be enhanced 30% or more in a patient with a blood level or ingested quantity that is generally associated with severe toxicity, impaired natural removal mechanisms (i.e., renal failure), a deteriorating clinical condition despite supportive care (phenobarbital), and clinical evidence of severe toxicity, such as metabolic acidosis (salicylates, methanol), dysrhythmias, or cardiac decompensation (theophylline).²⁵ A list of toxicants removed by hemodialysis is shown in Table 10–12. Continuous renal replacement therapies (e.g., continuous venovenous hemofiltration) may be more appropriate for removal of toxicants in patients who

Table 10–11 Selected Antidotes

Antidote	Indications
<i>N</i> -acetylcysteine	Acetaminophen
Atropine	Bradycardia due to cardiotoxic drugs, cholinergic poisoning (organophosphates, carbamates, nerve gas agents)
Bicarbonate, sodium and sodium chloride ^{26,27}	Cyclic antidepressants, salicylate, wide-complex dysrhythmias (cocaine, diphenhydramine, chloroquine)
Black widow spider antivenin ²⁸	Severe hypertension, muscle spasms not alleviated by analgesic and/or muscle relaxants
Calcium	Calcium channel antagonist poisoning, hydrofluoric acid burn
Crotaline antivenom ^{29,30}	Progressive and/or significant envenomation by rattlesnake, cottonmouth, copperhead snakes
Cyanide antidote kit	Cyanide poisoning
Amyl nitrite	
Sodium nitrite	
Sodium thiosulfate	
Cyproheptadine ^{31,32}	Baclofen withdrawal, serotonin syndrome
Dantrolene	Muscle rigidity, hyperthermia, metabolic acidosis due to malignant hyperthermia, neuroleptic malignant syndrome
Deferoxamine	Iron toxicity
Digoxin-specific antibody fragments (Digibind, Digifab) ³³	Digoxin, cardiac glycoside toxicity
Ethanol	Methanol or ethylene glycol poisoning when fomepizole is not available
Flumazenil	Known, pure benzodiazepine overdose in a benzodiazepine-naive patient
Fomepizole (4-MP, Antizol) ³⁴	Methanol or ethylene glycol poisoning
Glucagon ^{24,35}	β -Blocker or calcium channel antagonist overdose with bradycardia/hypotension
Hyperinsulinemia/euglycemia ^{36,37}	Calcium channel antagonist overdose with severe hypotension/symptomatic bradycardia refractory to other therapies
Methylene blue	Methemoglobinemia with symptoms of hypoxia, other systemic toxicity, or level > 25%
Naloxone (Narcan)	Opioid, imidazoline (clonidine) poisoning
Octreotide ^{38,39}	Hypoglycemia due to oral hypoglycemic agent (sulfonylurea) toxicity
Oxygen, hyperbaric	Carbon monoxide toxicity
Physostigmine ⁴⁰	Pure anticholinergic poisoning
Pralidoxime (2-PAM, Protopam)	Organophosphate, nerve agent toxicity; use in conjunction with atropine
Pyridoxine (vitamin B ₆)	Isoniazid-induced seizures, <i>Cyromitra</i> mushroom, monomethylhydrazine
Vitamin K ₁	Clinical bleeding due to coumadin, brodifacoum toxicity

Table 10–12 Common Toxicants and Drugs Removed by Hemodialysis or Charcoal Hemoperfusion

Bromide
Carbamazepine
Chloral hydrate
Ethylene glycol
Isopropanol
Lithium
Metformin
Methanol
Phenobarbital

Theophylline
Valproic acid

Table 10–13 Suggested Guidelines on When to Consider Consulting a Medical Toxicologist

Calcium channel antagonist/ β -blocker ingestion with hypotension and/or bradycardia
Cyclic antidepressant ingestion with coma, seizures, hypotension, and/or dysrhythmias
Toxic alcohol ingestion (ethylene glycol, methanol)
Organophosphates/carbamate exposure with symptoms
Acute heavy metal exposure (arsenic, mercury) with symptoms
Snake envenomation
Intractable seizures secondary to toxic substance
Critically ill patient requiring:
Special antidote—digoxin Fab, methylene blue, glucagon, antivenom
Hemodialysis
Hyperbaric oxygen

are hemodynamically unstable and avoid the problem of rebound toxicity (i.e., lithium). Consultation with a medical toxicologist and nephrologist can help decide which modality is best for the clinical situation.

There are other mechanisms that can enhance the elimination of poisons. These include urinary alkalization for salicylates and multiple doses of activated charcoal for theophylline, salicylates, and phenobarbital (see Chapter 133, *Classic Pediatric Ingestions*; and Chapter 136, *Adverse Effects of Anticonvulsants and Psychotropic Agents*).

Consider consulting a medical toxicologist for patients who are critically ill, who require specific antidotes, or who have ingested unusual or lethal toxins (Table 10–13).

Summary

Decision making regarding the disposition of a poisoned patient depends on numerous factors, including the type of exposure, the toxicant itself, the circumstances surrounding the exposure, and the child's social situation. Because most unintentional ingestions in young children result in either no or mild sequelae, these children can usually be discharged after an observation period of 4 to 6 hours. Utilization of the regional poison control center can help clinicians make these disposition decisions based on the particular exposure/ingestant. A common toll-free number

is available nationally (1-800-222-1222) so that all health care providers as well as the public have 24-hour access to their regional poison control center for poison and drug information.

“Medical clearance” of a patient who has had a potentially toxic exposure sometimes can be more problematic in the pediatric population. Any child or adolescent who presents with an intentional ingestion/overdose and does not need to be admitted for a medical reason must have a psychiatric assessment to determine whether further inpatient hospitalization is warranted. Most intentional ingestions warrant inpatient psychiatric hospitalization. If the circumstances are carefully evaluated and it is believed that the patient can be safely discharged, urgent follow-up with mental health services must be assured.

Pediatric poisonings are a common cause of presentations to emergency departments. Very few unintentional ingestions in young children require hospitalization. Yet there is a selected list of drugs and substances that can cause serious toxicity even when ingested in small amounts. Fatalities in young children due to poisonings have decreased dramatically since the 1950s due to numerous factors—product reformulations, child-resistant packaging, heightened parental awareness of product toxic effects, intervention by poison information centers, and treatment by specially trained health care professionals. The profile of intentional overdoses in adolescents is similar to that of young adults in terms of intent, nature of polysubstance ingestion, and type of substances ingested. However, the prognosis of adolescents who seek health care because of available parental oversight is excellent.

Evaluation of the potentially poisoned patient relies primarily on the history and physical examination. Recognizing specific clinical toxidromes may help the clinician to recognize particular classes of drugs, which can then help guide further evaluation and therapy. The mainstay of therapy for most poisoned patients is supportive care. There are a limited number of antidotes that can limit the toxicity of specific drugs and toxicants. In addition, there are different modalities to enhance the elimination of a limited number of drugs and toxicants that may be initiated in the emergency department. Ocular, dermal, and/or gastrointestinal decontamination may be necessary depending on the route of exposure and time since the exposure took place. Research in the last 10 years has provided evidence to support the avoidance of routine gastric emptying for all ingestions in the emergency department. Whole-bowel irrigation is a new decontamination modality for selected ingestions that are not amenable to charcoal therapy.

It is important for the emergency physician to remember other resources available—particularly the regional poison control center and the medical toxicologist, who may be at the health care facility or available through the poison control center.

Altered Mental Status/Coma

Joseph J. Zorc, MD

Key Points

The approach to a child with altered mental status requires an organized and prioritized process of stabilization, assessment, differential diagnosis, and definitive management.

In a patient with altered mental status, inability to provide a history or cooperate with assessment mandates a detailed physical examination with a particular focus on vital signs and neurologic examination.

Reversible causes of altered mental status such as hypoglycemia and opiate ingestion should be immediately identified and treated prior to further tests or interventions.

Multiple diagnostic tests may be indicated in the evaluation of a child with altered mental status. Consideration should be given to the appropriate sequence of tests based on suspicion of a focal central nervous system process versus a systemic process.

Introduction and Background

Altered mental status in a child is a particularly challenging clinical problem for an emergency physician. At initial presentation, the etiology is frequently unclear, and potential impairment of airway, breathing, and circulation requires a rapid and focused assessment. Reversible causes such as hypoglycemia and opioid ingestion need to be identified and treated prior to other procedures. History and physical examination are important and may provide key clues, but may be limited by the inability of the patient to cooperate with the evaluation. The differential diagnosis of a child with altered mental status is extensive and ranges in severity from self-limited processes requiring brief supportive care to life-threatening causes requiring aggressive intervention. Medications such as sedatives for radiographic tests or paralytics for intubation may interfere with later assessment and need to be considered carefully. For these reasons, an altered

mental status requires a structured, ordered approach to evaluation and management.

Recognition and Approach

Altered mental status occurs when the ability of a child to arouse and interact with the external environment differs from normal. Abnormality in mental status must be interpreted in the context of normal stages of childhood development as well as the baseline functioning of the specific patient being evaluated. Careful assessment and documentation of the degree of alteration is important to identify changes in mental status over time. Terms for depressed mental status are often used loosely, although specific definitions over the spectrum of abnormality have been classically described.¹ *Confusion* is a state in which cognitive abilities are slowed and impaired. *Delirium* represents an increased level of disability with disordered thinking, delusion, and often agitated behavior. *Obtundation* is a state in which the patient is less alert and disinterested in the environment. *Stupor* is a further progression in which stimulation is required to obtain arousal. *Coma* is the end point on the spectrum in which the patient does not respond to stimulation. While these terms are often used to describe infants and children with an altered mental status, it is helpful for clinicians to describe the exact nature of the abnormal behavior and to attempt to apply objective descriptors or rating scales to their behavior.

Descriptive scales that numerically rate components of consciousness, such as eye opening, verbal, and motor activity, have been developed. One such example is the Glasgow Coma Scale (GCS).² Although originally developed for use after head injury, the GCS has been applied widely as a quantitative measure of altered mental status, and adaptations are available for preverbal children (Table 11–1).^{3,4} Although useful in research and in the clinical setting to document trends in progression of symptoms over time, the reliability and validity of the GCS for use in the acute setting has been questioned.⁵ Little information exists about the use of the GCS in young children. The GCS should be used as a supplement to a more detailed assessment and descriptive documentation of alteration in mental status.

The approach to a patient with altered mental status is typically dichotomized into two broad categories of etiology: disturbances localized within the central nervous system and systemic disorders (Table 11–2). Mass lesions within the central nervous system, such as tumor or hematoma, may be

Table 11-1 Glasgow Coma Scale (GCS) with Adaptations for Preverbal Children*		
Eye Opening	Best Motor Response	Best Verbal Response
0–1 yr	0–1 yr	0–2 yr
Spontaneous (4)	Spontaneous movement (6)	Normal cry, coos, smiles (5)
To shout (3)	Localizes pain (5)	Cries (4)
To pain (2)	Flexion withdrawal (4)	Inappropriate cry, screams (3)

		No response (1)

*GCS scores ranges from 3 (worst) to 15 (best).

further subdivided into supra- and subtentorial based on the location of the lesion relative to the tentorium cerebelli, the dural fold that divides the anterior from the posterior fossa. This anatomy has clinical relevance because the midbrain at the level of the tentorium contains the reticular activating system, the network of neurons passing from spinal cord and brainstem to the cerebral cortex that plays a key role in maintaining consciousness. Mass lesions can compress this area and cause altered mental status, often accompanied by focal neurologic findings in nearby cranial nerves. In contrast, abnormalities causing altered mental status at the level of the cerebral cortex affect the brain diffusely through reduced delivery of a necessary substrate, effects of a toxin, or other widespread neuronal injury. The presence of focal findings may suggest a structural central nervous system lesion, although this is not entirely reliable as some systemic processes (e.g., hypoglycemia) may present with asymmetric findings.

Clinical Presentation

Evaluation of a child with altered mental status begins with a rapid assessment of airway, breathing, and circulation. Since unrecognized trauma is a concern, airway stabilization should be accomplished with manual stabilization of the cervical spine in the midline; a jaw thrust and other airway adjuncts such as a nasopharyngeal or oral airway may be useful depending upon the level of consciousness of the patient (see Chapter 2, Respiratory Distress and Respiratory Failure). Assessment of breathing, provision of 100% oxygen, and circulatory assessment of pulses, perfusion, and cardiac rhythm with continuous monitoring should follow.

A rapid determination of the level of consciousness should proceed while intravenous access is being obtained. A useful

Table 11-2 Differential Diagnosis of Altered Mental Status

Central Nervous System Disturbances

Trauma
 Mass lesion (epidural, subdural, intracerebral hematoma)
 Diffuse or localized cerebral edema
 Cerebral contusion
 Tumors (often with hemorrhage)
 Hydrocephalus
 Circulation disorders
 Cerebrovascular accident
 Cerebral venous thrombosis
 Infection/inflammation
 Meningitis
 Encephalitis
 Cerebral abscess
 Subdural empyema
 Cerebritis
 Seizure
 Subclinical status epilepticus
 Postictal state

Systemic Disorders

Hypoxemia
 Hypo/hyperthermia
 Hypoglycemia
 Endocrine disorders
 Diabetic ketoacidosis
 Addisonian crisis
 Thyrotoxicosis, hypothyroidism
 Electrolyte disorders: sodium, potassium, calcium, magnesium
 Hepatic encephalopathy/Reye's syndrome
 Uremic encephalopathy/hemolytic-uremic syndrome
 Inborn errors of metabolism
 Exogenous toxins
 Opiates
 Barbiturates/benzodiazepines
 Anticonvulsants: carbamazepine, phenytoin, valproic acid
 Organophosphate poisoning
 Anticholinergics: atropine, tricyclic antidepressants, phenothiazines
 Lead
 Metabolic acidosis ("MUDPILES")
 Methanol
 Uremia
 Paraldehyde
 Isoniazid, iron
 Lactic acidosis: carbon monoxide, cyanide
 Ethanol, ethylene glycol
 Salicylates
 Systemic infection
 Sepsis
 Toxin-producing (e.g., *Shigella*)
 Strangulated or herniated bowel
 Intussusception
 Volvulus

first assessment is guided by the acronym AVPU: *alert* at baseline, requires verbal stimuli to arouse, requires *painful* stimuli, or *unresponsive* to painful stimuli. More formal assessment and documentation of the level of unconsciousness by description and numerical GCS can follow.

Diagnostic evaluation begins with measurement of serum glucose using a bedside glucometer. Conservative guidelines suggest that blood glucose concentrations below 40 mg/dl should be considered abnormal at any age; blood glucose concentration between 40 and 50 mg/dl require further eval-

uation at any age, but may possibly be normal in neonates; and blood glucose concentrations below 60 mg/dl beyond early infancy should be considered borderline, with further evaluation required. Inaccuracies of bedside glucose meters should be taken into account when determining whether to undertake further evaluation and treatment for hypoglycemia. Some texts actually recommend a trial of empirical treatment with glucose in patients with unknown coma for levels as high as 80 to 100 mg/dl, but individual circumstances must be accounted for.⁶ Glucose can be given according to the “rule of 50,” whereby the product of the volume (ml/kg) and the concentration of the glucose solution should be 50 (e.g., 2 ml/kg of 25% dextrose or 5 ml/kg of 10% dextrose). Common causes of hypoglycemia that may lead to altered mental status in a child are discussed more fully elsewhere (see Chapter 106, Hypoglycemia). Ketotic (starvation) hypoglycemia, sepsis, inborn errors of metabolism, and ingestions of ethanol or oral hypoglycemic agents are among the more common causes in children.⁷

Naloxone should be administered to all patients with an altered mental status of unknown etiology or suspected opioid overdose. The clinician should not rely on the presence of pupillary constriction (miosis) to diagnose opioid overdose since meperidine, pentazocine, diphenoxylate/atropine (Lomotil), propoxyphene, and drug-induced hypoxia and co-ingestants may cause pupillary dilation (mydriasis). The empirical dose of naloxone is now recommended at 0.01 mg/kg intravenously. Give a subsequent dose of 0.1 mg/kg if there is an inadequate response. Use intramuscularly, subcutaneously or via endotracheal tube if the intravenous route is not available. Larger doses may be required for certain ingestions (e.g., diphenoxylate atropine [Lomotil], methadone, propoxyphene, pentazocine, fentanyl derivatives, and certain forms of heroin [black tar]). If a response is observed, the patient should be monitored closely with consideration for a naloxone infusion as the half-life of many ingested agents is longer than the 60- to 90-minute effect of naloxone.⁸ Unlike adults, in whom withdrawal may be a concern, trial of an empirical dose of naloxone has little potential for adverse effects in children and may also produce a partial response in other situations such as clonidine overdose or intussusception (see discussion later). Other reversal agents, such as the benzodiazepine antagonist flumazenil, should not be given empirically in unknown cases due to the risk of seizure or interaction with other potential ingestions.⁹ This agent should be reserved for situations in which an overdose of benzodiazepine alone is established, as in an iatrogenic overdose. Other agents typically administered empirically to adults, such as thiamine, are also generally not required in children.

The history should begin with a focused review of allergies, medications for the child or others in the household, and prior medical history. A thorough review of events leading up to the onset of symptoms should follow and may be best obtained by another clinician not involved in the acute stabilization. Frequently the caregiver most familiar with these events may not have accompanied the child, and reaching this person by telephone may provide key information. In particular, recent history of trauma and symptoms of infection or increased intracranial pressure should always be suspected. Many pediatric ingestions occur in new environments where the normal exploratory behavior of

young children places them in contact with unsecured toxins; this may point toward a toxicologic cause.

Physical examination should begin with obtaining vital signs. Patterns of abnormalities in vital signs accompanying other clinical findings may indicate a “toxidrome” associated with classes of toxic ingestions (see Chapter 10, General Approach to Poisoning) that may be helpful in establishing a diagnosis. Cushing’s triad is a classic pattern of bradycardia, bradypnea, and hypertension that has been described in association with elevated intracranial pressure. Patterns of abnormal respiration have also been described with various states of altered mental status. The Cheyne-Stokes variation is an alternation of deep and shallow breathing usually associated with metabolic encephalopathy. Central hyperventilation and “apneustic” inspiratory pauses have been described with various brainstem lesions.¹ The presence of fever may indicate an infection, exogenous heat exposure, and other potential diagnoses (e.g., thyrotoxicosis; ingestion of salicylate or sympathomimetic or anticholinergic agents). Hypothermia may be associated with cold exposure or metabolic abnormalities such as hyponatremia. Hypertension may also cause altered mental status in the setting of hypertensive crisis (see Chapter 65, Hypertensive Emergencies). However, hypertension may also be a compensatory response to elevated intracranial pressure, in which case treatment of the primary process is indicated as a priority to maintain cerebral perfusion pressure.¹⁰

In summary, physical findings may provide important clues to a definitive diagnosis of altered mental status in children (Table 11–3).

Neurologic Examination

A thorough neurologic examination can aid in narrowing the differential diagnosis. In particular, the cranial nerves are of importance, as the nuclei of these nerves are located close to the reticular activating system in the brainstem and may indicate dysfunction due to a focal mass lesion compressing this area. Pupillary findings also aid in identifying the cause of altered mental status. Pupils can be small or mid-sized and symmetrically reactive in metabolic coma (e.g., hypoglycemia, encephalitis, ethanol poisoning). Constricted pupils may be seen with opioid ingestion, although some reactivity usually remains on close examination. Central lesions in the pons can also cause bilaterally constricted pupils. Asymmetrically reactive pupils should raise concern for a focal mass lesion unless there is a history of eye trauma or direct exposure to a mydriatic agent (e.g., ipratropium). Horner’s syndrome occurs when there is injury to the hypothalamus or sympathetic chain nerves, resulting in a small but usually reactive pupil (miosis) associated with ptosis and anhidrosis.

Herniation syndromes are a constellation of findings that are the end result of significant elevation in intracranial pressure (see Chapter 42, Conditions Causing Increased Intracranial Pressure). The “uncal syndrome” occurs when the uncus, the medial part of the temporal lobe, herniates through the tentorium due to elevated pressure superiorly, causing compression of the oculomotor nerve and a unilateral dilated and fixed pupil, usually on the side of the mass lesion. Progression of elevated pressure on one side or symmetric elevation of intracranial pressure due to diffuse swelling or hydrocephalus can cause central herniation with bilateral pupillary and oculomotor impairment as well as decerebrate extensor

Table 11–3 Physical Clues to the Diagnosis of Infants and Children with Altered Mental Status*

Physical Finding	Diagnosis
Hypotension	<ul style="list-style-type: none"> Any disease causing hypotension can directly cause an altered mental status (e.g., bleeding, sepsis, trauma) Toxins: antihypertensive agents (e.g., β-blockers, calcium channel blockers), barbiturates, benzodiazepines, clonidine overdose (late), cyanide poisoning (late), narcotics
Hypertension	<ul style="list-style-type: none"> Intracranial bleed Intracranial mass Hypertensive encephalopathy Eclampsia Postictal state Hypoglycemia Toxins: agents causing neuroleptic malignant syndrome and serotonin syndrome, clonidine overdose (early), cyanide poisoning (early), monoamine oxidase inhibitors, phencyclidine, sympathomimetics
Hyperthermia	<ul style="list-style-type: none"> Meningitis Encephalitis Early sepsis Malignant hyperthermia or neuroleptic malignant syndrome Toxins: anticholinergics, nerve agents/gases (Sarin, Soman, Tabun, VX gas, Substance 33), organophosphates, sympathomimetics
Hypothermia	<ul style="list-style-type: none"> Adrenal insufficiency, crisis Prolonged hypoglycemia Hypothyroidism Sepsis (late) Environmental exposure to cold Toxins: barbiturates, benzodiazepines, hypoglycemic agents, or any toxin that causes patients to be immobilized and hypometabolic for prolonged periods
Tachycardia Bradycardia	<ul style="list-style-type: none"> Nonspecific and can occur with most diseases Impending brainstem herniation Respiratory failure of any etiology Cardiac disorders Toxins: β-blockers, calcium channel blockers, clonidine, cyanide, digoxin, γ-hydroxybutyrate (GHB), opioids, organophosphates
Tachypnea	<ul style="list-style-type: none"> Metabolic acidosis from any cause Toxins: isoniazid, nicotine, salicylates, theophylline, toxic alcohols
Bradypnea	<ul style="list-style-type: none"> Respiratory failure of any etiology Toxins: benzodiazepines, botulinum, GHB, narcotics, sedative-hypnotics
Diaphoresis	<ul style="list-style-type: none"> Meningitis Encephalitis Sepsis Toxins: nerve agents/gases (Sarin, Soman, Tabun, VX gas, Substance 33), organophosphates, sympathomimetics
Mydriasis (bilateral)	<ul style="list-style-type: none"> Toxins: anticholinergics, antihistamines, drug withdrawal, GHB, nerve agents/gases, organophosphates, and sympathomimetics rarely cause mydriasis when nicotinic effects exceed muscarinic effects
Miosis	<ul style="list-style-type: none"> Pontine bleed or stroke Coma from benzodiazepine, barbiturate or ethanol Toxins: anticholinesterase, clonidine, narcotics, nicotine
Abdominal pain or rectal bleeding	<ul style="list-style-type: none"> Intussusception Volvulus Strangulated or herniated bowel Toxins: iron
Seizure	<ul style="list-style-type: none"> Hypoxia Hypoglycemia from any cause Intracranial mass, bleed, or infection Toxins: all drugs causing hypoxia, anticholinergics, antidepressants, amphetamines, baclofen, β-blockers, camphor, carbamazepine, carbon monoxide, cocaine, cyanide, ethanol withdrawal, GHB, hypoglycemic agents, isoniazid, lidocaine, lindane, lithium, meperidine, propoxyphene, phencyclidine, salicylates, sympathomimetics, theophylline, water hemlock plant

*List is not all inclusive.

posturing. Compression of the brainstem leads to altered respiratory and cardiovascular status and death. Other patterns of herniation occur elsewhere in the cranium, including across the midline falx cerebri or at the level of the brainstem into the foramen magnum. The presence of an open fontanelle in a young child may provide evidence of increased intracranial pressure but does not eliminate the risk of brain herniation from one compartment to another. Evidence of herniation calls for aggressive management of intracranial pressure with mannitol and emergent neurosurgical evalua-

tion (see Chapter 9, Cerebral Resuscitation). Recent evidence suggests that 3% saline may be useful in management of intracranial hypertension.¹¹ Since intracranial pressure rises dramatically once compensatory responses in the brain have been overcome, even small interventions to reduce intracranial volume may be effective. Controlled hyperventilation can reduce intracranial pressure in emergent situations by reducing cerebral blood flow, although this may have detrimental results if used for prolonged periods beyond the goal of a partial pressure of CO₂ of 35 mm Hg.¹²

Other important findings on neurologic examination include an assessment of tone, reflexes, and motor activity to detect seizure activity. Subclinical status epilepticus can be a cause of altered mental status. Decorticate posturing with flexion of the arms and extension of the legs may accompany lesions in the cerebral hemispheres.¹ Decerebrate extensor posturing of the arms and legs usually indicates dysfunction at the level of the midbrain or cerebellum or, alternatively, severe metabolic dysfunction. Funduscopic examination should be performed to detect retinal hemorrhages associated with shaken infant syndrome; papilledema may indicate long-standing increased intracranial pressure, although it is not a reliable early finding after an acute insult. Brainstem control of eye movements can be assessed with a “doll’s-eye” maneuver of the head or cold caloric testing, although these interventions are not usually indicated during the initial assessment in the emergency department. The remainder of the physical examination involves a thorough head-to-toe secondary survey looking for subtle skin findings such as bruising or rash, abdominal mass associated with intussusception, or other abnormalities. Odors on the breath or in the urine may be indicative of diabetic ketoacidosis, ethanol ingestion, or various metabolic derangements. Psychogenic causes of coma due to conversion reaction or other causes are uncommon in children and typically can be identified on examination by the presence of voluntary responses such as resistance to movement or withdrawal from noxious stimuli.

Differential Diagnosis

The differential diagnosis of altered mental status is broad and may be organized in several ways. Categorization of physical findings into central nervous system versus systemic (see Table 11–2) is helpful from a pathophysiologic standpoint, although a mnemonic device may be most useful in the acute setting to ensure that all important diagnoses have been considered (Table 11–4). Vascular abnormalities causing altered mental status are uncommon in children and usually are associated with underlying chronic conditions such as sickle cell disease or prothrombotic states (see Chapter 44, Central Nervous System Vascular Disorders). Infection can alter mental status through direct involvement of the central nervous system from a variety of viral, bacterial, fungal, or parasitic causes (see Chapter 43, Central Nervous System Infections). Infections outside of the central nervous system can alter mental status via systemic effects or toxins produced by organisms such as the Shiga toxin from *Shigella*. Toxicologic causes of altered mental status are diverse and

are more fully discussed elsewhere (see Chapter 10, General Approach to Poisoning). Clues to presence of a toxic ingestion include the presence of clinical toxidromes such as bradycardia/bradypnea (opioid, sedative-hypnotic) or tachycardia/tachypnea (sympathomimetic, anticholinergic). Other findings such as the size of the pupils (usually small in opioid ingestions), the condition of the skin (dry in anticholinergic toxicity), or the presence of acidosis on laboratory evaluation can help to further specify the toxin involved.

Trauma can affect mental status by direct compression of the reticular activating system from an epidural or subdural hematoma with focal findings, or by intracerebral contusion, focal hemorrhage, or diffuse axonal injury (see Chapter 15, Trauma in Infants; and Chapter 17, Head Trauma). Epidural hematomas usually arise from injury to arterial vessels underlying a skull fracture; symptoms may progress rapidly to unconsciousness after an initial lucid period. Subdural hematomas are usually more indolent and may be a marker of diffuse axonal injury such as that seen in the shaken infant syndrome. These infants often appear to have a metabolic cause of altered mental status due to the nonfocal nature of the injury. If child abuse is suspected, a skeletal survey may identify occult injuries and assist with the diagnosis.

Metabolic causes of altered mental status are multiple and covered fully in Chapters 110 through 115. Young children are predisposed to hypoglycemia due to reduced glycogen stores that result in a risk for ketotic hypoglycemia with a prolonged fast. Absence of ketones in the urine in the setting of hypoglycemia should raise the concern of an inborn error of metabolism such as a fatty acid oxidation defect.¹³ Inborn errors of metabolism typically present in newborns or in young infants at the time of an illness or when new foods are introduced, when catabolic processes fail and the body is unable to appropriately break down protein, fat, or carbohydrate. Inborn errors may require consultation with an endocrinology or metabolism specialist as well as detailed laboratory testing to make a complete diagnosis. Hepatomegaly or laboratory abnormalities such as hypoglycemia, hyperammonemia, and acidosis are clues to the presence of these disorders. Metabolic causes such as electrolyte abnormalities or hepatic, renal, or endocrine disorders will usually be detected on routine chemistry screening.

Infants with strangulated or incarcerated bowel (e.g., intussusception or volvulus) can present with lethargy. This unique presentation in infants and toddlers has been described in up to half of intussusception cases in one series.¹⁴ These children are often initially considered to have systemic infections or toxic ingestions and often have significant delays in diagnosis and treatment.¹⁵ The cause of altered mental status associated with intussusception is unclear. Case reports of reversal with naloxone indicate that this process may be mediated by the release of endogenous opioid substances in the gut¹⁶ (see Chapter 74, Intussusception). Ruling out serious bowel disorders in a lethargic infant based on physical examination or plain radiographs may be difficult, and contrast or air enema, ultrasound, an upper gastrointestinal series, and/or surgical consultation may be required.¹⁷

Finally, other abnormalities in the central nervous system, such as intracranial mass lesions and hydrocephalus, should always be considered. Young infants with obstructive hydrocephalus may present with increased head circumference and

N	Neoplasm: tumor, hydrocephalus
S	Seizure: subclinical status epilepticus, postictal state

“sunsetting” of the eyes (paralysis of upward gaze) due to compression of the ocular nuclei. Various seizures may alter mental status during and following an ictal event. Generalized seizures often are accompanied by tonic-clonic activity, but subtle subclinical status epilepticus may require electroencephalography to make a definitive diagnosis. A seizure accompanied by a postictal state can be identified by the presence of an acidosis that clears rapidly. Empirical therapy with a benzodiazepine or other antiepileptic may be indicated if ongoing subclinical seizure is suspected. Absence seizures usually alter mental status for brief periods with return to baseline, as opposed to partial complex seizures, which usually are longer and may be followed by a postictal period. If a prolonged generalized tonic-clonic seizure has occurred, a postictal state may alter mental status for a period of several hours.

Management

Many potential etiologies can cause altered mental status, so an ordered process is required to organize diagnostic testing and management. If hypoglycemia and opioid ingestion have been ruled out, the next steps will be dictated by the depth of impairment and clues to the diagnosis on history and physical examination.¹⁸ Multiple etiologies may occur simultaneously; for example, a postictal state may follow a seizure due to a toxic ingestion. For this reason, it is difficult to organize management into a simple algorithm. Investigation should be individualized, with multiple potential etiologies ruled out in parallel based on clinical judgment.

Initial laboratory tests are obtained after the secondary survey so that they can be processed while other examinations are being completed. Screening tests typically include serum electrolytes, renal and liver function tests, and a complete blood count. A venous blood gas determination of acid-base status/carboxyhemoglobin level may also be appropriate. Serum ammonia level may be considered if liver disease or an inborn error of metabolism is suspected. The laboratory evaluation should also include levels of any anti-convulsant medications prescribed or potentially ingested by the patient. Toxicology screens vary by institution, so it is important to be aware of what is being ordered. Utility in the acute setting varies greatly depending upon which test is ordered. Urine drugs of abuse screens are helpful in the initial evaluation to screen for opioids, barbiturates, cannabis, cocaine, amphetamines, phencyclidine, and benzodiazepines, although other important substances may be missed (e.g., some synthetic opiates, γ -hydroxybutyrate, lysergic acid diethylamide).¹⁹ Serum toxicology screens include ethanol levels and may also include acetaminophen, salicylate, and other drugs that are appropriate for empirical testing. An electrocardiogram should be obtained if primary cardiac disease or a toxic ingestion is suspected.

Imaging of the brain is clearly indicated in altered mental status when there is a concern for an intracranial process (history of trauma, focal neurologic findings, signs of elevated intracranial pressure) or when the etiology is unknown. The usual initial study is computed tomography (CT) of the brain without contrast. Intravenous contrast can be added if tumor or an inflammatory process is suspected. CT may not identify posterior fossa masses, and further imaging may be required after the initial study.

Since imaging and other tests may require transport to another location, consideration should be given to the stability of the patient and the ability to protect the airway. The decision to control the airway should be individualized based on the patient's level of alertness, presence of airway reflexes, and expected course. If trauma is suspected, aggressive management should be considered, whereas self-limited processes such as seizure may require only monitoring and supportive care. Airway management should be performed under controlled circumstances with measures taken to avoid increases in intracranial pressure (see Chapter 3, Rapid Sequence Intubation). Short-acting sedatives and paralytics are preferred to allow for serial reassessment of mental status and neurologic examination.

For altered mental status due to suspected infection, the issue of when to obtain cerebrospinal fluid versus CT scan is controversial. Increased intracranial pressure from a mass lesion or obstruction of the ventricular system is a contraindication to lumbar puncture. Imaging is recommended prior to lumbar puncture for a patient with an undifferentiated cause of altered mental status, as clinical examination may not easily identify these contraindications.²⁰ In addition, some studies have described a temporal association between lumbar puncture and herniation in cases of severe meningitis, although the causal nature of this relationship is debated.²¹ Imaging does not reliably predict marked elevation in intracranial pressure.²² In general, when cerebrospinal fluid is obtained in a patient with altered mental status, caution is advised; close monitoring, measurement of cerebrospinal fluid pressure, and careful withdrawal of the minimal amount of fluid required with a small-bore needle are recommended. Empirical treatment with antibiotics should not be delayed for imaging or other procedures if intracranial infection is suspected.

If an etiology for altered mental status is still unclear after initial tests are completed, further tests for occult etiologies are appropriate. Since intussusception is difficult to rule out based on clinical findings, an ultrasound or barium enema may be indicated. Subclinical status epilepticus may require electroencephalographic monitoring for detection.²³ If this is not available, empirical treatment with anticonvulsant medications may be appropriate. It may not be possible to confirm encephalitis in the acute setting, and empirical treatment with intravenous acyclovir to treat herpes should be considered. In some cases no diagnosis can be made acutely, and supportive care can be provided with appropriate consultation with neurologists, toxicologists, or other consultants to further investigate other causes.

All of the above-mentioned measures can be incorporated into a general altered mental status management algorithm, although alternative management options should be tailored to the patient's presentation and the clinician's suspicion for specific disorders (Fig. 11–1).

Summary

Definitive management of a child with altered mental status will depend upon the etiology and the response to initial management. Patients with persistent symptoms or unclear etiology require hospitalization for close observation and specialty consultation. In many cases this will require admission to an intensive care unit. Prognosis of altered mental

Abbreviations: ABG, arterial blood gases; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalogram; GI, gastrointestinal; LFT, liver function test; LP, lumbar puncture; MRI, magnetic resonance imaging; UA, urinalysis; US, ultrasound; UGI, upper gastrointestinal.

status varies widely based on the etiology; mortality ranges from 3% to 84% by diagnosis in children with nontraumatic coma.²⁴ The impression that young children recover more fully from coma than adults has been questioned as more detailed studies have explored cognitive outcomes in depth.²⁵

Altered mental status in a child is a challenging clinical scenario for an emergency physician. With an organized

process for evaluation and management, the physician should be able to detect and managed most causes effectively in the emergency department. Future research in this area will likely focus on improving descriptive scales for altered mental status in children and developing more accurate diagnostic testing and treatments for the multiple potential causes of altered mental status.

Approach to Multisystem Trauma

Lance Brown, MD, MPH

Key Points

Mechanism of injury is a relatively poor predictor of injury severity.

An age-appropriate primary survey facilitates the physical examination and limits unnecessary testing.

Laboratory studies have minimal utility in the management of most traumatized children.

Computed tomographic scanning is indispensable in evaluating children at risk for multisystem trauma.

Nonoperative management of selected intra-abdominal and intracranial injuries is now common.

Introduction and Background

Using an evidence-based approach to pediatric multisystem trauma care is problematic. Due to the absence of agreed-upon definitions for “pediatric” and “multisystem,” various age thresholds for considering a subject “pediatric” exist. Development progresses at a somewhat different rate for each child. Authors of “pediatric” studies have included individuals who present to a children’s hospital without a specific age threshold identified¹⁻³ and individuals younger than 21 years of age,⁴ 19 years of age,⁵ 18 years of age,⁶⁻⁹ 16 years of age,¹⁰⁻¹² 15 years of age,^{13,14} or 11 years of age.¹⁵ The inclusion of both preverbal infants and physiologic adults in many of these studies weakens the validity of proposed conclusions regarding “pediatric” trauma.¹⁶

The term *multisystem* and synonyms such as “polytrauma” lack agreed-upon definitions. “Multisystem” most appropriately refers to multiple, serious injuries sustained by a single child following blunt trauma, or to whole-body blunt forces that place a child *at risk* for multiple internal injuries.¹⁷ This may partially explain why many studies from the pediatric trauma literature focus on injuries to a single body region.^{2,3,5-9,18-39} Unfortunately, many injuries are unlikely to be found in isolation, making uniform management recommendations difficult.

The management of children who have sustained multisystem trauma involves coordinated care among multiple specialists. These children not only require the unique skills of the emergency physician, but may also require care by an orthopedic surgeon, neurosurgeon, pediatric or general surgeon, otolaryngologist, plastic surgeon, maxillofacial surgeon, or urologist. Given the difficulties in developing an evidence-based understanding of pediatric multisystem trauma, conflicts regarding management may arise among these specialties. Although still evolving, the science of pediatric trauma care offers reasonable evidence on which physicians can base their diagnostic and management plans.

Recognition and Approach

To some extent, the unique anatomic and physiologic features of children and the mechanism of injury predispose children to specific injuries. Pedestrian motor vehicle trauma victims often have multiple injuries, including injuries to the head, thorax, and pelvis. Unrestrained motor vehicle occupants are at significant risk for head, face, and cervical injuries, while restrained passengers are at risk for cervical spine, lumbar spine, and solid and hollow organ injury. Additionally, seat belts, when used without a booster seat for children 4 to 9 years of age, increase the risk of bowel/bladder rupture or hematoma.⁴⁰ Bicyclists who are injured are at risk for head injury (especially if unhelmeted), upper extremity trauma, and handlebar injuries to the pancreas and bowel.⁴⁰ Falls from the second story of a building or higher increase the risk of head injury, with long-bone fractures increasing with falls from the third story, and thoracoabdominal injuries dramatically rising at the fifth story.⁴¹

Anatomic and physiologic developmental differences help to identify distinct injuries and responses to injury within different age groups. Head injuries are common in younger infants and children. The relatively larger size of an infant’s head dramatically increases the risk that the skull will be involved in most blunt force mechanisms. The skull is relatively soft in infants and toddlers. Forces are more easily transmitted through a weaker, immature skull to soft developing neural tissue. Unlike older children, infants with open fontanelles and sutures may actually develop hypotensive shock due to intracranial bleeding. Unlike adults, children frequently develop intracranial hyperemia following head injury, which increases cerebral blood flow, intracranial blood volume, and intracranial pressure.⁴²

Thoracoabdominal injuries are an important cause of mortality in infants and children, accounting for 10% to 20% of all trauma-related deaths.⁴³ The greater pliability of the thoracic cage in young children permits the ribs to be easily compressed without fracturing and without obvious external evidence of trauma. As a result, pulmonary contusions occur without rib fractures.⁴⁴ As the bony rib cage ossifies, fractures and obvious chest wall trauma become more common. Since the chest is relatively small compared to the head and abdomen of infants and young children, isolated thoracic trauma is uncommon. Solid abdominal organs are larger in children compared to adolescents and adults, increasing their propensity to be traumatized during blunt force injuries. Infants and young children have poorly developed abdominal muscles, a more protuberant abdomen, and less fatty insulation compared to adults, thus increasing their risk for injury during blunt trauma. The pediatric kidney retains fetal lobulations, leading to a higher risk for fracture. The spleen's capsule is relatively thicker at younger ages, allowing for an increased ability to contain traumatic splenic bleeding and improving the possibility that injuries can be managed nonoperatively. Importantly, the bladder is an abdominal organ in young children, increasing the possibility for injury following abdominal trauma.⁴⁰

A child's smaller body leads to traumatic forces that are often distributed over a smaller body mass, increasing the number of systems injured during trauma. A larger relative surface area and increased metabolic rate promote hypothermia, complicating the management of shock. Physiologic characteristics account for important cardiopulmonary responses to injury. A smaller functional residual capacity and increased oxygen consumption account for an increased risk of respiratory failure with blunt thoracic trauma and hypovolemic shock. Infants and children more readily maintain a normal blood pressure with significant bleeding, compared to adults and adolescents. As much as 25% to 30% of circulating blood volume might be lost before hypotension develops. As blood loss occurs, increases in systemic vascular resistance and peripheral vasoconstriction makes vascular access difficult. Tachycardia is a poor marker for blood loss due to the significant variability with age, pain, temperature, and stress. Capillary refill time is often cited as a useful marker for blood loss and shock in children. However, this test is an unreliable marker for hypovolemia due to high interobserver variation, large fluctuations with environmental temperatures, and variability in measurement techniques and individual responses to hypovolemia.⁴⁰

Evaluation

Injury severity occurs along a continuum from minimal injury to full traumatic arrest. At either end of the spectrum, the evaluation is typically straightforward. When a child has obviously sustained minimal injury or is uninjured, a focused history and physical examination followed by reassurance or some basic first aid (e.g., abrasion care) is all that is typically required. When confronted with a critically injured child, a protocol-driven assessment with attention to definitive airway management, prompt vascular access, and the performance of any invasive, potentially life-saving procedures is warranted. Few would question the ordering of any radiographic or laboratory test deemed potentially useful in this

extreme situation. Although emotionally and technically challenging, the decision-making processes in these cases can be formulaic. In contrast, cases with intermediate acuity or concern for subtle injuries offer a much greater challenge for the experienced emergency physician. In these cases, selective diagnostic testing is indicated and decision making is fairly complex. For emergency physicians more familiar with the resuscitation of traumatized adults, there are some important differences between children and adults that may have a substantial impact on the trauma evaluation (Table 12–1). Decision making in pediatric trauma requires knowledge of child development and proper resource utilization with regard to prehospital triage, trauma team activation, laboratory tests, and radiographic tests.

The primary survey has been considered a critical element to proper trauma care.^{45,46} Although this sequential approach of progressing through airway, breathing, circulation, disability, and exposure (the ABCDEs) is simple and has been advocated for decades, it has not been evaluated in children. Nonetheless, it has been explicitly stated that children should simply be treated the same as adults with regard to the primary survey.⁴⁵ Clinical experience suggests that applying this approach to the awake, alert, traumatized child may complicate, rather than facilitate, the evaluation and management. The typical approach involves donning masks and gowns, using loud voices, promptly applying monitoring devices, cutting clothing off, and promptly attempting intravenous line placement while keeping a child tied to a board and telling them to hold still. This can be unkind and decreases the likelihood of a meaningful physical examination. Without a meaningful physical examination, assessment of the child's mental status, abdomen, and spine are less reliable. Prolonged immobilization in a cervical collar on a hard board may lead to iatrogenic neck pain, back pain, and impaired respiratory capacity.^{47,48} This, in turn, may lead to unnecessary sedation and radiologic testing. The classically implemented primary survey is likely to be effective and appropriate for evaluating the traumatized child with grossly altered mental status, or who is critically ill or comatose. An alternative approach may be more successful in evaluating awake, alert, traumatized children (Table 12–2). Although this has not been prospectively evaluated for safety and efficacy, this approach can be considered in patients who appear to be stable and have normal mental status.

Predictors of Serious Injury

Identifying predictors of serious injury is needed for the development of decision rules for prehospital triage and trauma team activation. These two events have the greatest impact on overall trauma resource utilization. For example, a simple decision rule to determine which children are likely to require services available only at a specialty pediatric trauma center would likely reduce unnecessary transport to those centers. Similarly, for children brought to specialty trauma centers, identification of those at high risk for needing prompt surgical intervention would result in better use of surgical consultation and avoid disruption of other important patient care activities outside the emergency department.

Although there are no completely reliable predictors of the need for care at a trauma center, knowledge of trauma scores and their limitations may be useful. The Pediatric Trauma Score (PTS) was initially developed as a tool to quickly deter-

Table 12–1 Common Pediatric Characteristics That Impact Trauma Presentation, Management, and Outcome

Characteristics	Potential Impact on Trauma Care
Heart rate	<ul style="list-style-type: none"> Tachycardia is common and is not specific for bleeding or hypotension. Bradycardia is a prearrest event often signifying shock or respiratory failure.
Blood pressure	<ul style="list-style-type: none"> Up to 25–30% of blood volume may be lost before significant hypotension develops.
Head	<ul style="list-style-type: none"> Open fontanelle and sutures can lead to significant uncontrolled bleeding and cause hypotension in young infants. Hyperthermia/vasodilation is common in children with head injury, compared to vasoconstriction/ischemia in adults.
Cervical spine	<ul style="list-style-type: none"> Immature and flexible ligaments lead to false appearance of subluxation C2-3, and disparity in growth rates at C1-2 leads to false appearance of C1 burst fracture (pseudo-Jefferson's fracture). The relatively large head means that centrifugal and rotational forces more commonly lead to trauma at C1 and C2 in children under 8 years, while C5-7 injuries are more common at or above this age.
Myocardium and coronary arteries	<ul style="list-style-type: none"> Myocardium and coronary arteries are normal, with less risk for myocardial contusion.
Lungs and ribs	<ul style="list-style-type: none"> Less functional residual capacity and higher oxygen consumption (1) increase the risk for respiratory failure with chest trauma and with shock and (2) lead to quicker desaturation during rapid sequence intubation and sedation. Pliant ribs are less able to protect the liver and spleen during blunt trauma. Pliability means fewer aortic and major vascular injuries resulting from blunt trauma.
Blood vessels	
Bones	<ul style="list-style-type: none"> Immaturity results in fewer rib fractures, less obvious chest wall trauma with significant pulmonary injury, and unique growth plate injuries.
Solid abdominal organs	<ul style="list-style-type: none"> Relatively larger size, less fat insulation, and less well-developed abdominal muscles increase risk of blunt traumatic injury.
Kidneys	<ul style="list-style-type: none"> Kidneys retain fetal lobulations and are less protected by location and musculature, increasing risk of fracture.
Spleen	<ul style="list-style-type: none"> Relatively thicker capsule at younger ages may decrease risk for rupture and increase probability of successful nonoperative management.
Stomach	<ul style="list-style-type: none"> More distended and less protected within the abdomen, increasing the propensity to perforation or respiratory compromise.
Bowel	<ul style="list-style-type: none"> Small bowel is prone to injury, typically in 4- to 9-year-olds, with seat belt that encircles abdomen instead of pelvis.
Bladder	<ul style="list-style-type: none"> Abdominal structure in the very young is more likely to rupture with blunt force.

Table 12–2 Suggested Principles for a Modified Evaluation of the Awake, Alert, Traumatized Child

- Number of individuals at the bedside can be minimized (one emergency physician and one nurse is ideal).
- Quiet voices should be used at all times.
- No commands should be directed at the child.
- Attachment of monitors to the child may be delayed if deemed appropriate by the emergency physician.
- Cutting off clothes may be deferred at the discretion of the emergency physician.
- All explanations provided to the child should be age appropriate.
- Analgesia should be provided as soon as possible.
- Techniques such as distraction should be used to calm the child as needed.
- Mental status should be continually assessed by having a conversation with the child.
- Removal of the cervical collar should take place safely but expeditiously.
- Removal from the spinal board should take place as soon as possible.
- Parents and guardians should be allowed to come to the bedside as soon as possible.

Table 12–3 Pediatric Trauma Score

Patient Feature	Score		
	+2	+1	–1
Weight (kg)	>20	10–20	<10
Airway	Patent	Maintainable	Nonmaintainable
Systolic blood pressure (mm Hg)	>90	50–90	<50
Mental status	Awake	Obtunded	Comatose
Open wound	None	Minor	Major
Extremity fracture	None	Closed	Open or multiple

mine the need to transport children to a trauma center⁴⁹ (Table 12–3). Initial studies found that children with a PTS less than 0 had 100% mortality, those with a PTS of 1 to 4 had 40% mortality, those with a PTS of 5 to 8 had 7% mortality, and those with a PTS greater than 8 had virtually no mortality following trauma.^{50,51} Based on these data, a PTS

less than 8 is the recommended threshold for diverting children to a designated pediatric or adult trauma center.⁴⁹ The Revised Trauma Score (used in adults) is as accurate as the PTS for determining injury severity and is a better predictor of overall outcome in pediatric trauma^{52–54} (Table 12–4). Supporters of the RTS believe it is easier to calculate and allows for a single score to be used by prehospital personnel for all ages.^{52–54} An RTS less than 12 is the recommended threshold for diverting a child to a trauma center.⁵¹ While the RTS and the PTS can stratify the risk of deterioration following trauma, it is important to note that children with isolated abdominal injuries may manifest initial vital sign stability and relatively normal trauma scores. Up to 86% of children with isolated spleen and liver trauma have a normal heart rate, 94% have a normal systolic blood pressure, and most have a PTS above 10,⁵⁵ signifying the limitations of trauma

Table 12-4 Revised Trauma Score

Revised Trauma Score*	Glasgow Coma Scale Score	Systolic Blood Pressure (mm Hg)	Respiratory Rate (breaths/min)
4	13–15	>89	>29
3	9–12	76–89	10–29
2	6–8	50–75	6–9
1	4–5	1–49	1–5
0	3	0	0

*Add total points (0 to 4) for each category to obtain score.

scoring in identifying children who potentially require trauma center care.

There is a growing body of evidence that some of the traditionally accepted predictors of injury severity do not effectively risk-stratify traumatized children. Although frequently cited and historically relied upon, mechanism of injury tends to be a relatively poor predictor of injury severity. Still, published trauma team activation criteria include various mechanisms of injury.^{13,56-59} These mechanisms typically include falls from a height greater than 3 to 6 m (10 to 20 feet), roll-over motor vehicle accidents, pedestrian struck at greater than 16 to 32 km/hr (10 to 20 miles/hr), passenger ejection from the vehicle, death of a co-occupant of the same vehicle, and the need for a extrication from the vehicle lasting longer than 20 minutes.^{13,54,55,60-62} These mechanisms have a certain degree of intuitive appeal; however, there is building evidence that they do not accurately predict serious injuries.^{13,15,56,58,61-64} In addition, there is also a risk of false histories. It has been suggested that, if a short vertical fall is offered as the mechanism of injury and the child has sustained a serious injury, the history is most likely false^{15,61} (see Chapter 119, Physical Abuse and Child Neglect). This concept that the mechanism of injury alone fails to predict serious injury is also supported by studies of adults.^{58,65-69}

However, there is one mechanism of injury that is predictive of specific intra-abdominal injuries. A “handlebar injury” has been associated with pancreatic and bowel injuries in children in addition to liver and spleen injuries.⁷⁰⁻⁷³ In these cases, a bicycle-riding child loses control and the end of the bicycle handlebar strikes the child directly in the epigastrium during the fall. Similar injuries occur when a child is struck in the abdomen with the end of a baseball bat or kicked in the epigastrium, for example. These types of injuries result in a substantial force being applied to a relatively small area of the abdomen. In addition to the more common solid organ injuries, particular attention should be given to diagnosing pancreatic and small bowel injuries in these children.

Another frequently cited predictor of serious injury is loss of consciousness. Brief loss of consciousness, as an isolated symptom, does not predict intracranial injury.⁷⁴⁻⁷⁸ In one study, loss of consciousness had a positive predictive value of only 9%.⁷⁶ Although there is now compelling evidence to suggest that a history of brief loss of consciousness does not accurately predict intracranial injuries identifiable on computed tomography (CT) scan of the head, consensus groups persist in recommending CT scans of the head based solely on a history of loss of consciousness⁷⁹ (see Chapter 17, Head Trauma).

The use of seat belts and child safety seats, and placing children in the back seat of a vehicle, decrease the likelihood

of morbidity and mortality for children who are passengers in motor vehicle crashes.^{80,81} Properly restrained younger children are also less likely to require transport to the hospital.^{82,83}

Laboratory Testing

A small body of literature has evaluated the utility of laboratory tests in evaluating cases of pediatric multisystem trauma. In general, the diagnostic utility of laboratory tests is minimal.⁸⁴⁻⁸⁶ A substantial problem with evaluating laboratory tests is that the outcome of interest in cases of multisystem trauma is heterogeneous. The clinician desires to find all “serious injuries.” In addition, because of differences in study design, authors of different studies may arrive at incompatible conclusions. While one author examines the utility of a test as a screening tool (thereby looking for high sensitivity), another author may examine that same test, but assess its utility as a diagnostic tool (thereby looking for high specificity). Their stated conclusions may be contradictory.

Ancillary laboratory tests rarely identify unsuspected injuries in awake, alert, cooperative children without severe trauma. One author evaluated 3939 laboratory screening tests obtained in 285 consecutive children with minimal to moderate injury admitted to a pediatric trauma center, and 91 patients with proven intra-abdominal injury.⁸⁶ The abdominal examination combined with a urinalysis detected 98% of all injuries and 100% of injuries requiring surgical intervention.⁸⁶ Laboratory values often provide only confirmatory evidence that an injury is present and are not diagnostic.⁸⁷

Coagulation studies, including platelet count, prothrombin time, and partial thromboplastin time, are seldom useful in previously healthy children.⁸⁸ Children who receive multiple units of transfused blood are at risk for developing coagulopathies. Electrolyte abnormalities are uncommon in acute trauma. In children with shock due to acute blood loss, a metabolic acidosis can be expected.^{89,90} Important electrolyte abnormalities that occur primarily following massive transfusions include hyperkalemia, metabolic alkalosis, hyperphosphatemia, and hypocalcemia.

Liver function tests are elevated in most cases of blunt hepatic trauma.⁹¹ One study found that the presence of either a serum aspartate aminotransferase (AST) greater than 450 IU/L or a serum alanine aminotransferase (ALT) greater than 250 IU/L was 100% sensitive and 92% specific in detecting hepatic trauma in children with blunt abdominal trauma.⁹² AST and ALT were highest in the first 12 hours, declining to normal within 5 days of injury.⁹² A large review of adult and pediatric blunt abdominal trauma victims found that the presence of either an AST or ALT greater than 130 IU/L was 100% sensitive in detecting liver injuries.⁹³

Since CT is recommended to identify and grade suspected liver injuries, liver function tests are generally not required in managing liver injuries. Their main use might be to identify unsuspected injuries in children who do not undergo CT or who are being evaluated for other disorders.

Amylase and lipase elevations are common in patients with blunt abdominal trauma. However, these tests have poor sensitivity, with elevations reported in only 13% to 77% of CT or laparoscopically proven cases of pancreatic trauma.⁹⁴⁻¹⁰⁰ Repeat values over time may increase the sensitivity of these tests in detecting significant pancreatic injury.⁹⁸ Amylase and lipase levels cannot discriminate between pancreatic and nonpancreatic trauma. Pancreatic enzyme abnormalities are elevated in nearly half of all blunt trauma victims.⁹⁷ One study found that only 2% of patients with an elevated amylase or lipase level actually had a pancreatic injury.⁹⁷ Moreover, as few as 13% with pancreatic trauma have elevated pancreatic enzymes.¹⁰⁰ Because of the poor discriminatory ability of these tests, they should not be relied upon to diagnose or exclude pancreatic injury.

Hematuria is commonly seen in seriously injured children.¹⁰¹ Hematuria can indicate trauma anywhere within the genitourinary system. Of note, hematuria is absent in up to 50% of patients with renal pedicle injuries (associated with massive trauma) and isolated ureteral injuries (e.g., gunshot and stab wounds).¹⁰²⁻¹⁰⁴ In general, evaluation of these patients is straightforward, and all require radiologic evaluation. Importantly, most serious renal injuries occur in patients with other indications for CT of the abdomen/pelvis or gross hematuria. Debate has existed concerning the appropriate workup of patients with only minor blunt trauma, no lower genitourinary injury, minimal or no symptoms, and microscopic hematuria. In the past, radiologic evaluation was performed on all children with any degree of hematuria in the belief that minor degrees of hematuria might be the only indicator of serious renal injury or of hidden congenital renal disorders.¹⁰⁵ This approach is no longer universally accepted^{106,107} (see Chapter 21, Pelvic and Genitourinary Trauma).

Most diagnostic laboratory studies provide no useful information in previously healthy children with blunt abdominal trauma. Laboratory studies might be helpful in children with an underlying disease, hypotension, or the need for multiple units of blood, or who are at risk for developing specific complications following admission (e.g., coagulopathy, electrolyte disorders).

Imaging Studies

The utility of the traditional “C-spine, chest, pelvis” set of plain radiographs has not been adequately studied in children. Understanding the role of these radiographs in the setting of alternative imaging modalities such as CT and magnetic resonance imaging (MRI) is becoming increasingly important.

Although large, well-designed studies have provided important information on when adults do not require cervical spine imaging, studies in children are limited.¹⁰⁸⁻¹¹⁰ A large prospective series of trauma patients found that adult trauma victims did not require imaging if they met the following NEXUS criteria: a normal mental status, no midline neck tenderness, no distracting injury, no intoxication with drugs or alcohol, and no motor or sensory deficits.¹⁰⁹ This study also included 2160 patients 8 to 17 years old and 817

patients 2 to 8 years old with a total of 30 cervical spine injuries.¹¹¹ Although the criteria were 100% sensitive in detecting all cervical spine injuries at these ages, there were too few injuries to adequately assess the NEXUS criteria for use with children. Importantly, this study only included 88 patients less than 2 years old, limiting the applicability of these criteria to this age group. The total number of cervical spine injuries was small, with only 30 documented injuries (1% of cases). To verify that these criteria will be highly sensitive, they need to be done in larger studies that include more pediatric injuries.

Flexion-extension, oblique, and odontoid radiographs rarely reveal abnormalities in children.¹¹²⁻¹¹⁴ However, the number of patients in each of these studies was small. Clinical experience supports the minimal utility of these studies for evaluating traumatized children.

In cases where the cervical spine cannot be cleared clinically or with plain radiographs, maintaining spinal precautions until an MRI can be obtained is prudent.¹¹⁶ In essence, MRI is the criterion standard for evaluating the spine of the unconscious child.

Indications for obtaining a chest radiograph in pediatric trauma are not clear. In one case-control study, the presence of an abnormal respiratory rate for age, chest tenderness, or back abrasions was 100% sensitive for identifying children with abnormal chest radiographs.¹¹⁷ Clinical experience suggests that grunting respirations, hypoxia, asymmetric breath sounds, and dyspnea are indications for chest radiography. Endotracheal intubation, thoracostomy tube insertion, and central vascular access in the internal jugular or subclavian veins are also indications for chest radiography. A single study examined whether CT of the chest should replace plain radiographs.¹¹⁸ The authors concluded that plain radiographs should remain the primary imaging modality in the setting of blunt pediatric trauma.

Children are less likely to sustain pelvic fractures than adults.³⁶ This appears to be true regardless of the mechanism of injury. There is seldom the need for a rapid, bedside assessment of the pelvis using plain radiography.^{36,119} It has been shown that pelvic fractures can be readily identified on CT scanning of the abdomen and pelvis.¹²⁰ The routine ordering of pelvic radiographs may be unnecessary, particularly in situations in which a child will be undergoing CT scanning of the abdomen and pelvis based on other indications.

CT scanning has been the greatest advance in pediatric trauma management in the last few decades. CT scanning offers a painless, noninvasive, detailed set of images of the interior of the head and torso. There is ongoing work to determine the exact indications for CT scanning of the head, abdomen, and pelvis in the setting of pediatric multisystem trauma. Although there are proposed indications for head CT scanning and for abdominal and pelvic CT scanning (see Chapter 17, Head Trauma; Chapter 24, Thoracic Trauma; and Chapter 25, Abdominal Trauma), abnormal mental status is an indication for all three scans since it is impossible to confidently rule out intracranial or intra-abdominal injuries based on the clinical examination. Other indications for CT scanning of the abdomen and pelvis include gross hematuria, lap belt injury, nonaccidental trauma, handlebar injury, and abdominal tenderness.^{70-73,121} Although CT scanning of the abdomen and pelvis is very effective for evaluating injuries to solid organs such as the liver, spleen, and kidney, it is

Table 12–5 Selected General Concepts for the Emergency Department Management of Children at Risk for Multisystem Trauma

- **Whenever possible, prolonged chemical paralysis should be avoided.** Children who have sustained head injuries may develop seizures. If the child's muscle activity has been masked by medications, seizures may go unnoticed. This leaves a child at risk for unrecognized status epilepticus and severe brain injury. For the intubated child, adequate sedation should be provided rather than prolonged chemical paralysis whenever possible. (See Chapter 3, Rapid Sequence Intubation; and Chapter 40, Seizures.)
- **A negative CT scan does not rule out all intra-abdominal injuries.** Although CT scanning is excellent at identifying or ruling out most solid organ injuries, pancreatic and bowel injuries may not be apparent on initial scans.^{9,34,35,37,122-124} If a child has persistent abdominal pain or tenderness, but a negative CT scan of the abdomen and pelvis, admission for observation and repeat evaluations is typically warranted. In this way, more subtle injuries such as those to the pancreas and bowel can be identified. (See Chapter 25, Abdominal Trauma.)
- **Hemodynamic instability warrants the prompt administration of packed red blood cells.** A child who has persistent tachycardia or hypotension after the administration of two or three 20-ml/kg boluses of crystalloid (usually normal saline, although lactated Ringer's solution is acceptable) should receive at least 10 ml/kg of packed red blood cells.^{128,129} Since hemodynamic instability is often due to bleeding, the administration of packed red blood cells is also an appropriate initial treatment. (See Chapter 25, Abdominal Trauma; and Chapter 132, Utilizing Blood Bank Resources/Transfusion Reactions and Complications.)
- **Nonoperative management is becoming increasingly common.** The detailed and timely anatomic information available from CT scanning has allowed for nonoperative management of some intra-abdominal and intracranial injuries.^{5,130-139} This trend has led to infrequent laparotomies at major pediatric trauma centers.¹⁴⁰ This trend will likely continue and will increase the role of emergency physicians in the management and study of pediatric multisystem trauma. (See Chapter 25, Abdominal Trauma; and Chapter 17, Head Trauma.)

Abbreviation: CT, computed tomography.

not sensitive in ruling out pancreatic, mesenteric, or bowel injuries.^{9,34,35,37,122-124} Despite the valuable information gained, there are potential deleterious effects of radiation incurred to a child undergoing multiple CT scans in the setting of trauma. A risk:benefit analysis is indicated to minimize unnecessary CT scanning.

The utility of Focused Abdominal Sonography for Trauma (FAST), now widely used in the emergency department evaluation of adult trauma patients, is controversial in children who have sustained multisystem trauma. Ultrasound is an excellent test for identifying free fluid (i.e., blood) within the abdomen.¹²⁵ However, the presence or absence of free fluid does not necessarily impact management.^{126,127} Since the presence of free fluid in a child's abdomen does not indicate the need for immediate laparotomy except in very rare instances, ultrasound rarely impacts the clinical management of children who are at risk for multisystem trauma. In addition, there are solid organ injuries identifiable on CT scanning that are clinically important to identify, but do not lead to free fluid in the abdomen. These injuries, therefore, will be missed on ultrasound. Those individuals for whom ultrasound might be useful are almost always the same children who meet the indications for CT scanning of the abdomen and pelvis (see Chapter 179, Ultrasonography).

Management

Management is guided by the results of the initial evaluation. The combination of individual injuries that can be identified during the evaluation of a child who is at risk for multisystem trauma is nearly infinite (see Section II, Approach to the Trauma Patient). However, a few general concepts are useful for managing a child who is at risk for multisystem trauma (Table 12–5).

Summary

Our understanding of pediatric multisystem trauma is evolving. This is reflected in the currently available literature. Traditionally accepted predictors of injury severity such as mechanism of injury and brief loss of consciousness have

been shown to have limited utility in risk-stratifying traumatized children. An age-appropriate evaluation offers the clinician the greatest opportunity for obtaining a meaningful physical examination and for minimizing unnecessary testing. The traditional “C-spine, chest, pelvis” set of radiographs is no longer universally accepted due to limited utility. MRI is the criterion standard for evaluating the spine of the unconscious child. When indicated, CT scanning is the most effective means of evaluating the head, abdomen, and pelvis. Nonoperative management of some intra-abdominal and intracranial injuries has become increasingly common. This necessitates that emergency physicians have a detailed, evidence-based knowledge of the evaluation and management of children who are at risk for multisystem trauma.

Chapter 13

Sepsis

Jesus M. Arroyo, MD, James J. McCarthy, MD, and Brent R. King, MD

Key Points

The sepsis syndrome is the combination of the systemic inflammatory response syndrome (SIRS) and presence of an infection.

Key early physical findings in pediatric sepsis include age-specific hypotension, oliguria, prolonged capillary refill time (>5 seconds), core-to-peripheral temperature gap greater than 3° C, age-specific tachypnea, hypoxia, lethargy, petechiae, fever greater than 38.5° C, or hypothermia (temperature <36° C).

Early goal-directed therapy mandates aggressive intravenous fluids, appropriate antibiotics, and prompt transfer to a tertiary care center or pediatric intensive care unit.

Introduction and Background

Sepsis has long been recognized as a major cause of morbidity and mortality for both adults and children. In 1992, a consensus panel defined the clinical entity of “sepsis” for adults as a “systemic inflammatory response syndrome (SIRS) with infection”¹ This definition was reaffirmed in 2003.² In 2005 another consensus panel provided the medical community with the first pediatric-specific definitions of SIRS, infection, sepsis, severe sepsis, and septic shock³ (Tables 13–1 and 13–2). These consensus definitions provide a clear and objective basis for the diagnosis of sepsis, which provides the framework for helping clinicians communicate particularly with regard to referrals between community hospitals and tertiary care settings.

The term *sepsis syndrome* describes a complex continuum of disease, the pathophysiology of which is still not fully understood. Although the word *sepsis* implies rampant infection, the actual clinical impact of the disease process goes far beyond the presence of bacteria in the bloodstream. There is still debate as to what actually causes the clinical syndrome, but there is general agreement that the presence of the bacteria and their products is only a part of the picture. Many of the clinical findings associated with sepsis are actually the result of the host’s response to bacterial invasion. The body’s

initial and adaptive response to overwhelming infection goes awry and results in the simultaneous activation of the coagulation system and the proinflammatory network, which may progress to organ ischemia and multisystem organ failure and ultimately death.⁴ The host’s own defenses may pose a greater danger than the invading bacteria.⁵

More recently this theory has been challenged by the hypothesis that the sepsis syndrome is the result of the immune system becoming somehow compromised, leaving the patient unable to adequately respond to severe infection. Sepsis patients have features consistent with immunosuppression, such as loss of delayed hypersensitivity and a predisposition to nosocomial infection.^{6,7} The syndrome of sepsis may, therefore, actually represent a continuum that begins with an inflammatory response and progresses to immunosuppression.

While our understanding of sepsis is growing, the precise etiology of organ failure and ultimately death is still poorly understood. Myocardial depression and refractory shock clearly play a major role, but the precise details have yet to be determined. Aside from antimicrobial therapy, the mainstays of sepsis management—circulatory support, respiratory support, and vasoactive drugs—are purely supportive. Though trials of novel therapies are underway, currently the emergency physician can rely only upon a few proven treatments along with careful attention to physiologic homeostasis.

Recognition and Approach

Epidemiology

The epidemiology of severe sepsis and septic shock differs across demographic regions worldwide and is influenced by many factors. In the United States, it is estimated that annually there are three cases of sepsis for every 1000 hospitalizations, or about 750,000 cases. Of these, nearly 200,000 are presumed to be cases of severe sepsis. The incidence of severe sepsis among children has been estimated to be as high as 42,000 cases per year with over 4000 deaths.⁸

Certain patient factors play a significant role. Sepsis is more common at the extremes of age. Almost half of the annual cases of severe sepsis in children occur in patients less than 1 year old and, of these, over two thirds are neonates. By comparison, the incidence of sepsis among older children is only 0.2 cases per 1000 patients per year. Gender is a factor in neonatal sepsis, with males being affected more often than females, but this difference diminishes with increasing age

Table 13–1 Classification of Severe Pediatric Sepsis by Vital Signs According to Age

Age	Classification	Tachycardia (bpm)	Bradycardia (bpm)	Respiratory Rate (breaths/min)	SBP (mm Hg)
Birth–7 days	Newborn	>180	<100	>50	<65
1 wk–1 mo	Neonate	>180	<100	>40	<75
1 mo–1 yr	Infant	>180	<90	>34	<100
2–5 yr	Toddler	>140	NA	>22	<94
6–12 yr	School age	>130	NA	>18	<105
13–18 yr	Adolescent	>110	NA	>14	<117

*Lower values for heart rate and SPB are for the 5th percentile, and upper values for heart rate and respiratory rate and are for 95th percentile.

Abbreviations: bpm, beats per minute; NA, not applicable; SBP, systolic blood pressure.

Table 13–2 Pediatric-Specific Definitions of Sepsis and Related Terms

Term	Definition
Systemic inflammatory response syndrome (SIRS)	The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count: <ul style="list-style-type: none"> • Core temperature of > 38.5° C or < 36° C. • Tachycardia, defined as a mean heart rate > 2 SD above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hr time period OR for children < 1 yr old: bradycardia, defined as a mean heart rate < 10th percentile for age in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained persistent depression over a 0.5-hr time period. • Mean respiratory rate > 2 SD above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia. • Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or > 10% immature neutrophils.
Infection	A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen OR a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests.
Sepsis	SIRS in the presence of or as a result of suspected or proven infection.
Severe sepsis	Sepsis plus one of the following: <ul style="list-style-type: none"> • Cardiovascular organ dysfunction • Acute respiratory distress syndrome • Two or more other organ dysfunctions
Septic shock	Sepsis and cardiovascular organ dysfunction.

Modified from Goldstein B, Grier B, Randolph A, et al: International Pediatric Sepsis Consensus Conference: definitions for sepsis and organ dysfunction in pediatrics. *Pediatr Crit Care Med* 6:2–8, 2005.

Abbreviation: SD, standard deviation.

and becomes insignificant by adolescence. Among affected neonates, birth weight appears to be important. Studies of neonates who developed severe sepsis have found that 69.3% were low-birth-weight infants and, of these, fully one half were very-low-birth-weight infants.⁸ In developing countries, sepsis has been shown to be more prevalent among those with poor nutrition. Patients with compromised immunity are at greater risk than their immunocompetent peers.

Among children with severe sepsis, it is estimated that 5% to 30% will develop septic shock. In a study of over 9600 patients with severe sepsis, the mortality rate was 10.3%.⁸ This represents considerably fewer deaths than in previous studies, which reported mortality rates for septic shock exceeding 50% to 100%. Much of this difference can be attributed to the availability of newer therapies, including advanced anti-infective agents, and the use of more aggressive treatment protocols. With currently available care, mortality for severe sepsis and septic shock is thought to range from 10% to 40%, with overall mortality at 10% for pediatric patients and 40% in the elderly.⁹ As might be expected, mortality and significant complications are higher in patients

with underlying disease, in those who have undergone surgical procedures, and in immunosuppressed children (e.g., children infected with the human immunodeficiency virus [HIV] and bone marrow transplant recipients).

It has been estimated that the annual cost of treating severe sepsis is equivalent to roughly 1% of the annual gross national product. The average length of hospitalization for a child with severe sepsis is 31.2 days at a cost of approximately \$47,000. When multiplied by the number of children who are treated each year, it is estimated that this disease process is responsible for 1.3 million hospital days and \$1.97 billion in costs.

Pathophysiology

Severe sepsis is a process triggered by an infectious agent, a product produced by an infectious agent, and/or the host's response to infection. As bacterial antigens (exo- or endotoxins) enter the body and interact with cells of the immune system (macrophages, neutrophils, and dendritic cells), leukocytes release proinflammatory cytokines. These cytokines—tumor necrosis factor- α , interleukin-1 (IL-1), and

interleukin-6 (IL-6)—have two principal effects: (1) they activate transcription genes that, in turn, produce more cytokines; and (2) they recruit more leukocytes to the site of infection.^{10,11} Macrophages and dendritic cells also release interleukin-12, which activates CD4 T cells. These cells have two antagonistic functions. They can become either T helper type 1 (Th1) cells or T helper type 2 (Th2) cells. Investigations are underway to identify what determines the subtype of cell created by the CD4 T cells. Some have suggested that the subtype of cell is determined by the type of bacteria, the size of the inoculum, or the site of the infection.¹² Th1 cells release proinflammatory cytokines, which activate more macrophages and dendritic cells, creating a vicious cycle of inflammation. Previously activated neutrophils release more cytokines, which in turn activate more Th1 cells.

As the cascade progresses, inflammatory cytokines activate tissue factor in endothelial cells and monocytes. Tissue factor triggers the extrinsic coagulation pathway, activating thrombin, which has multiple physiologic effects.⁴ Inflammatory cytokines also deplete activated protein C and antithrombin III (which inhibits thrombin and many of the clotting factors in both the intrinsic and extrinsic coagulation cascades), two of the body's natural anticoagulants. The result of this process is a state of diffuse inflammation and endothelial injury and thrombosis complicated by a disordered coagulation system that cannot maintain the homeostatic balance between its procoagulant and anticoagulant properties.^{4,13,14} These processes create the final end point of sepsis pathophysiology: a state of microvascular thrombosis causing tissue ischemia and eventually cell necrosis, organ dysfunction, and, eventually, death.¹⁵ A proposed second wave in the sepsis cascade has also been described such that the immune system changes from an inflammatory cascade to an anti-inflammatory system, with progression of disease.¹³

Direct effects of bacteria and exotoxins in combination with the inflammatory mediators create a clinical state of volume depletion, peripheral vasodilation, myocardial depression, and increased metabolism. The net result is an imbalance of oxygen delivery relative to oxygen demand, resulting in profound global tissue hypoxia.¹⁶ The clinical manifestations of the processes described previously can be envisioned as follows. Bacteria enter the bloodstream, triggering an inflammatory immune response. If the process is not interrupted, the patient develops clinical evidence of diffuse systemic inflammation (SIRS) and the initial clinical manifestations of sepsis. As the process continues, the patient develops more severe symptoms that culminate in shock and multiple organ dysfunction syndrome (MODS).

Recognition of sepsis begins with a basic understanding of the physiology along with the understanding that sepsis is a disease process, rather than an isolated clinical syndrome. Patients may present for care at any point along a broad continuum of symptoms. At one end of the continuum are moribund patients with obvious systemic compromise. Many of these children even will die even with optimal management. On the other end of the continuum are those children who present so early in their course of illness that it may be impossible to distinguish them from patients with minor infections. Patients at this stage of illness will be identified by happenstance, if at all. The broad middle portion of the continuum contains those children who have some clinical

symptoms of physiologic perturbation. If these children can be identified and treated promptly, they have a reasonable chance of survival.

Evaluation

Because sepsis has multiple physiologic effects, patients may present with myriad findings, but there are a few unifying themes. Recent literature has suggested that sepsis among children be defined as the presence of SIRS (see Table 13–2) with an identified infection. Clinical findings might include symptoms identified as a part of the SIRS syndrome, such as temperature elevation or depression, tachycardia or bradycardia, tachypnea, leukocytosis, and leukopenia or a “left shift”—an increase in immature white blood cells (i.e., “bands”). Physical and/or laboratory findings consistent with a specific infectious process such as pneumonia, urinary tract infection, or cellulitis are likely to be found as well. The definition of the syndrome includes some symptoms indicative of physiologic compromise. In its mildest expression this may take the form of subtle tachycardia or tachypnea, or a narrowed pulse pressure. The adolescent or older child may actually be able to describe a feeling that “something is wrong.” As the disease process progresses, the patient will develop more extreme tachycardia and tachypnea, altered mental status, and hypotension.

It is probable that many cases of very early sepsis go unrecognized because the underlying infectious process is treated promptly and the cascade of sepsis physiology is aborted long before it becomes manifest as overt clinical symptoms. Likewise, many cases that have progressed beyond the very early stages are likely to be confused with other illnesses and nonetheless treated appropriately. An example of this latter scenario is the child with sepsis secondary to a urinary tract infection who presents to an emergency department with fever, tachycardia, and tachypnea along with a history of vomiting. The urinary tract infection is diagnosed and appropriately treated but the physiologic symptoms are attributed to dehydration rather than sepsis. However, antibiotics and intravenous fluids help to restore effective circulation and interrupt the physiologic processes that would have led to sepsis had intervention not occurred.

Subtle symptoms such as mild alteration in mental status (lethargy, irritability, unusual behavior) should prompt clinicians to consider the possibility of sepsis. Older children may demonstrate subtle cognitive deficits that can be recognized only by those who know the child well, thus parental concerns in this regard should be taken seriously. Parents of infants with early sepsis might report changes in the baby's feeding or sleeping patterns, excessive fussiness, or lethargy. Other early signs are body and joint aches, chills, rigors, and flushing. In some instances (e.g., meningococcemia), a characteristic rash will be present. As described earlier, laboratory findings are variable and might include elevated polymorphonuclear cell and/or total white blood cell counts, decreases in these counts, and a variety of electrolyte abnormalities, including hypoglycemia, hyperglycemia, and acidosis. As the disease progresses, signs of serious illness become more obvious. Respiratory compromise is manifest as tachypnea, tachycardia, grunting, or even apnea. Impaired circulation is manifest as prolonged capillary refill time, peripheral pallor, cool mottled skin, and decreased urine output. Further

evolution leads to signs of end-organ dysfunction and failure.¹⁷ The patient may develop seizures or experience a respiratory or cardiac arrest. In an otherwise healthy child with this presentation, sepsis should be the first major consideration.

Potential Pathogens

Because sepsis begins with infection, one must consider the most likely pathogens for each age group of patients as well as the ways in which such patients might present for medical care. The causative organism influences both symptoms and outcome. Patients with septic shock caused by gram-negative bacteria have a mortality of 20% to 50%, while those with gram-positive septic shock have mortality rate of only 10% to 20%.^{18,19} While gram-negative bacteria are more likely to affect the gastrointestinal system, gram-positive organisms more often affect the lungs, adrenal glands, kidneys, and heart.

In neonates, the organisms most associated with sepsis are group B streptococcus, the Enterobacteriaceae, *Listeria monocytogenes*, and *Staphylococcus aureus*, but *Streptococcus pneumoniae* and *Neisseria meningitidis* should also be considered. Agents most likely to affect infants beyond the neonatal period include *S. pneumoniae*, *N. meningitidis*, and *S. aureus*. Signs and symptoms of sepsis in neonates and infants are nonspecific and may not offer the clinician any insight into the bacterial agent responsible for an individual case. The challenge lies in identifying the infant with early sepsis who may initially present with feeding difficulties, vomiting, irritability, lethargy, fever, hypothermia, or apnea. Depending upon the source of the infection, there may be few or no signs suggestive of infection. For example, infants with pneumonia may present with tachypnea, while those with urinary tract infection may have no specific symptoms attributable to the infectious process at all. Subtle signs might be present but not immediately appreciated. For example, omphalitis or an infected scalp probe site might initially be overlooked.

The bacteria most commonly responsible for sepsis in older infants and children are *S. pneumoniae*, *N. meningitidis*, and occasionally the Enterobacteriaceae. *Haemophilus influenzae* type B, once a common cause of severe infection, has been mostly eliminated by more than a decade of immunization. Severe infection in this age group is not likely to be missed but could be confused with another process. Such patients often have, in addition to fever, tachycardia, tachypnea, lethargy, confusion, vomiting, diarrhea, and abdominal distention. The source of their symptoms can generally be identified by physical examination or with a rudimentary laboratory evaluation. The occurrence of sepsis in healthy older children and adolescents is unusual. When it occurs, the source of infection is often apparent and, when such a source cannot be identified, the physician should consider an undiagnosed immunodeficiency syndrome or intravenous drug use.

There are some populations of patients in whom both the causative agents and the presentation of sepsis might be atypical. For example, sepsis should be a consideration in the child who has undergone an invasive procedure and experiences clinical deterioration hours or days later. Also, children with immunosuppression (e.g., HIV infection, leukemia, lymphoma, or sickle cell anemia) may have more subtle presentations and have infections caused by unusual bacteria. Children receiving lipids through central venous catheters

have been shown to be at greater risk from infections caused by coagulase-negative streptococci, enterococci, and *Enterobacter cloacae*.¹⁷ Children with impaired immunity who present with fever but are otherwise well appearing can rapidly become gravely ill. For this reason, children with impaired immune systems require more careful attention and more conservative management when they present with evidence of infection. Similar consideration should be given to children with certain chronic illnesses, particularly when the patient has an indwelling central venous or urinary catheter or other medical appliance. Children with impaired mentation at baseline are also difficult to assess because of the lack of ability to communicate in an age-appropriate fashion. Additionally, they may be predisposed to problems such as decubitus ulcers that are not commonly encountered in children. Finally, there are some conditions that are actually less likely to cause sepsis but can serve to inappropriately narrow the physician's differential diagnosis. An example of this potential pitfall is the patient with a ventriculoperitoneal shunt. Except in the first few postoperative weeks, the shunt is unlikely to be the source of infection, but its presence can distract attention from the performance of an appropriate and thorough evaluation.

Clinical Assessment

Once sepsis is suspected, a multifaceted approach is warranted. This approach begins with stabilization of the patient but also includes a search for both the cause of the infection and evidence of physiologic compromise. Baseline laboratory studies should include blood cultures, with specimens drawn from at least two sites if possible, though this might be impractical in neonates and infants. If the child has an indwelling central venous catheter, culture samples should be drawn through the catheter and, if appropriate, the catheter should be removed. A complete blood count will identify neutropenia, thrombocytopenia, or anemia, any of which can contribute to a poor outcome. Because sepsis-associated microischemia can affect virtually any organ system, organ function should be assessed in a directed fashion (Table 13–3). Renal function, serum electrolytes, and calcium should be obtained along with measurements of serum glucose. Liver function studies should also be obtained to assess for sepsis-related liver injury. Serum prothrombin and partial thromboplastin times are excellent indicators of coagulation status and hepatic function. Markers of cardiac injury should be obtained in selected cases, and children at risk for thyroid dysfunction (e.g., trisomy 21, congenital heart disease) should undergo thyroid function studies, though the emergency physician can defer such testing to the inpatient setting. A urinalysis should be obtained in infants, young children, and those with impaired mental status or risk factors for urinary tract infection. Similarly, when meningitis cannot be reasonably excluded on clinical grounds, a lumbar puncture is mandatory. Children with open wounds should have wound cultures performed. In some cases, it might be possible to identify a specific causative agent early in the course of illness through the use of a rapid immune assay.

To offer the patient the best chance of survival, it is critical to identify sepsis and impending shock in its earliest stages. Prior to overt clinical findings of shock, microenvironments within the host are becoming ischemic, leading to acidosis. Therefore, any patient in whom the diagnosis of sepsis is

Table 13–3 Criteria for Defining Organ Dysfunction

Organ System	Criteria
Cardiovascular	<ul style="list-style-type: none"> • Hypotension—unresponsive to fluid challenge ≥ 60 ml/kg <i>or</i> requiring vasopressors • Cardiac arrest • Tachycardia/bradycardia <ul style="list-style-type: none"> ○ Less than 12 mo: < 50 or > 220 beats/min ○ Greater than 12 mo: < 40 or > 200 beats/min • Two of the following: <ul style="list-style-type: none"> ○ Metabolic acidosis: base deficit > 5.0 mEq/L ○ Elevated lactate $> 2 \times$ upper limit of normal ○ Oliguria ○ Capillary refill > 5 sec ○ Core-to-peripheral temperature gap $> 3^\circ$ C

being seriously considered should undergo measurement of serum acid-base status and serum lactate determination. Some authors have suggested that mixed venous oxygen saturation be measured initially and later to gauge response to therapy. Since some children have risk factors for reduced cortisol levels and an impaired response to physiologic stress, many investigators have recommended that cortisol levels be drawn, and supplemental steroids be administered empirically to such children. Others have suggested that an adrenocorticotropic hormone (ACTH) stimulation test be conducted before administration of steroids.²⁰ C-reactive protein plays a role in the sepsis cascade and is easily measured, but its utility as a marker of severity of illness or a guide to further therapy is unclear. Other more esoteric laboratory studies of mediators involved in the evolution of SIRS, sepsis, septic shock, and/or MODS (e.g., procalcitonin, IL-1, IL-6, nitric oxide metabolites) have been described in the literature, but currently these are utilized most often in research settings.

Imaging studies should be ordered as indicated by the clinical scenario, for example, obtaining a chest radiograph when pneumonia is suspected. Computed tomography may help to identify clinically occult abscesses and to delineate the extent to which a particular organ is involved. As described later, bedside ultrasonography can be used to

evaluate cardiac function as myocardial depression is a well-recognized complication of sepsis.²¹ More formal echocardiography might also be used to identify possible endocarditis.

Differential Diagnosis

Because the symptoms of sepsis are nonspecific, the differential diagnosis is necessarily broad. Many conditions that cause severe illness and shock can mimic sepsis, and some of these are, in fact, closely related conditions. Toxic shock syndrome must be considered in the infant or child presenting with a clinical picture consistent with septic shock. In certain infants, necrotizing enterocolitis might be confused with sepsis; meningitis or encephalitis might also resemble sepsis.

Because sepsis may ultimately cause shock, septic shock can be confused with other types of shock. While hemorrhagic and neurogenic shock are in the differential diagnosis, cardiogenic shock from congenital heart disease or viral myocarditis is most likely to be confused with sepsis. The child with cardiogenic shock is more likely to present with congestive heart failure. It has recently been demonstrated that emergency physicians using bedside ultrasonography can identify impaired cardiac wall motion and decreased ejection fraction with reasonable accuracy.²² As this technology becomes more widely used, it may be possible to identify those patients whose symptoms are at least partially caused by cardiac dysfunction. Hemorrhagic and neurogenic shock generally follow significant trauma. Without such a history, with the exception of the adolescent female with a ruptured ectopic pregnancy, the clinician must consider inflicted injury.

Children who have impaired production of cortisol, and are less able to tolerate physiologic stress, may present with shock or a sepsis-like picture. Included are children with congenital adrenal hyperplasia and those with severe pituitary or adrenal dysfunction. It is important to note that a similar picture can be created by the chronic administration of steroid hormones. Any severe illness can mimic sepsis, but most such illnesses are rare in the pediatric age group and most present with clues that direct the clinician toward the specific etiology. Consider the possibility of rare conditions such as pulmonary embolus, acute renal failure, myocardial infarction, or aortic dissection when the clinical picture indicates such consideration or is confusing.

Management

The foundations of sepsis management are establishment and maintenance of a patent airway, effective ventilation and oxygenation, circulatory support, treatment of infection, and exclusion of alternative diagnoses. Adherence to rigorous treatment protocols, and awareness of the concept of early goal-directed therapy (EGDT) have resulted in a 92% decrease in sepsis-related mortality over the last 4 decades.^{22a} It is critical to recognize that most of the recommendations noted in this section are derived from studies of adult patients. Few, if any, similar studies involving infants and children are available; therefore, these recommendations must be approached with caution. However, many have proven themselves in the clinical arena, and they represent the best therapy available for a potentially devastating disease process.

A 9-year retrospective review of infants transported a tertiary care center with sepsis and septic shock demonstrated that better survival was associated with aggressive resuscitation by the referring physicians.²³ Early aggressive treatment in the community was clearly beneficial, but many septic patients were frequently underresuscitated in community emergency departments.²³ When the diagnosis of sepsis is being considered, treatment must be instituted immediately. Circulatory and respiratory support are vitally important. Antimicrobial therapy plays an important role but is in and of itself insufficient. The progression of sepsis in children is different from that seen in adults. Whereas an adult patient might experience a gradual deterioration, children often appear stable for an extended period only to experience a precipitous decline in vital function.

Antimicrobial therapy is a key component of treatment and should be started as soon as possible. Treatment should include one or more antimicrobial agents with activity against the most likely pathogens, taking into account community- and facility-specific patterns of bacterial resistance, and mitigating host factors. Unless rapid testing has identified a specific agent, prudence dictates the selection of broad-spectrum agents until specific pathogens have been identified (Table 13–4). Patients who are immune deficient or who are at risk for particularly virulent bacteria (e.g., *Pseudomonas*) should be treated with several antibiotics appropriately, but broadly directed at the suspected pathogens. Additionally, in some cases, a potential source of infection can be eliminated. Abscesses can be drained, necrotic tissue can be incised, and indwelling catheters can be removed.

Circulatory support is critical and should be initiated before hypotension and other signs of shock have developed. Effectiveness of therapy should be monitored by evaluation of several parameters, including heart rate, urine output, mental status, respiratory rate, serum acid-base status, and serum lactate, in addition to blood pressure and pulse pressure. Some authors have advocated continuous measurement

of central venous pressure and arterial pressure rather than blood pressure.

Aggressive early volume resuscitation is the cornerstone of initial therapy. While physicians often do an excellent job in the management of sepsis, they frequently do not administer enough volume when resuscitating septic patients and fail to follow the current advanced life support guidelines.²³ They should first administer 20 ml/kg of crystalloid and give subsequent boluses based upon patient response. Some authors advocate the administration of colloid after several boluses of crystalloid because it can provide similar clinical effects with a smaller volume of administration. However, no studies have demonstrated a definite benefit of one fluid type over another. The risk of overhydration is overstated. Aggressive fluid resuscitation in excess of 40 ml/kg in the first hour of treatment is associated with increased survival with no increased risk of acute respiratory distress syndrome (ARDS) or cardiogenic pulmonary edema.²⁴

Evaluation of EGDT for severe sepsis and septic shock in a major adult sepsis clinical trial¹⁶ suggested that initial therapy should be dictated by mixed venous oxygen saturation, hematocrit, and central venous pressure. The goal of volume expansion should be a central venous pressure of 8 to 12 mm Hg except in the case of mechanically ventilated patients, who require higher central venous pressure of 12 to 15 mm Hg due to elevated intrathoracic pressures. Volume expansion might help to restore systemic circulation and reverse the sepsis cascade, but alone may not be sufficient. Mixed venous oxygen saturation, measured by a Swan-Ganz catheter or other special measurement device, should be maintained above 70%. During the first 6 hours of treatment, if fluid therapy has achieved a central venous pressure of 8 to 12 mm Hg (12 to 15 mm Hg in mechanically ventilated patients) and the patient's mixed venous oxygen saturation remains below 70%, further therapy is guided by the hematocrit. For a hematocrit below 30%, blood is transfused. If the hematocrit is normal or if transfusion fails to achieve a mixed venous oxygen saturation of 70%, dobutamine is administered until this goal has been achieved or to a maximum dose of 20 mcg/kg/min (see Chapter 8, Circulatory Emergencies: Shock).

In the absence of mixed venous oxygen saturation, the treating physician should aim for a central venous pressure of 8 to 12 mm Hg (12 to 15 mm Hg if mechanically ventilated) and a hematocrit no less than 30%. Once these goals have been met, signs of poor perfusion should be treated with dobutamine as described. Dobutamine is recommended because it is assumed that, given adequate left ventricular filling pressures and red blood cell volume, the most likely source of impaired perfusion is depressed cardiac output. As described earlier, bedside ultrasound may allow the clinician to determine the effectiveness of cardiac activity and help guide therapy.

EGDT has been demonstrated to improve the mortality from sepsis in adults. These guidelines have not been tested in children, but several investigators have found that, in conjunction with goal-directed therapy, implementation of the American College of Critical Care Medicine Pediatric Advanced Life Support guidelines results in improved clinical outcomes.²⁵ Published guidelines for the treatment of pediatric and neonatal sepsis have incorporated these elements (Fig. 13–1).

Table 13–4 Age-Specific Recommendations for Initial Empiric Antibiotic Selection in Sepsis

Age	Antibiotics
Neonates < 1 wk old	Ampicillin 25 mg/kg q8h <i>and</i> Cefotaxime 50 mg/kg q8h
Neonates 1–4 wk	Ampicillin 25 mg/kg q8h <i>and</i> Cefotaxime 50 mg/kg q8h <i>or</i> ceftriaxone 75 mg/kg q24h
Children	Cefotaxime 50 mg/kg q8h <i>or</i> Ceftriaxone 100 mg/kg q24h
Adolescents/young adults	Cefepime 50 mg/kg q8h <i>or</i> Imipenem 25 mg/kg q6h <i>or</i> Meropenem 60 mg/kg q8h
Special considerations	Suspected MRSA—add vancomycin Suspected VRE—add linezolid Abdominal processes—add anaerobic coverage Urinary pathogen—add aminoglycoside Suspected pulmonary infection—add macrolide

*Selections should be tailored to suspected sources, local resistance patterns, and patient allergies.
Abbreviations: MRSA, methicillin-resistant *Staphylococcus aureus*; VRE, vancomycin-resistant enterococcus.

Recognize SIRS/Sepsis

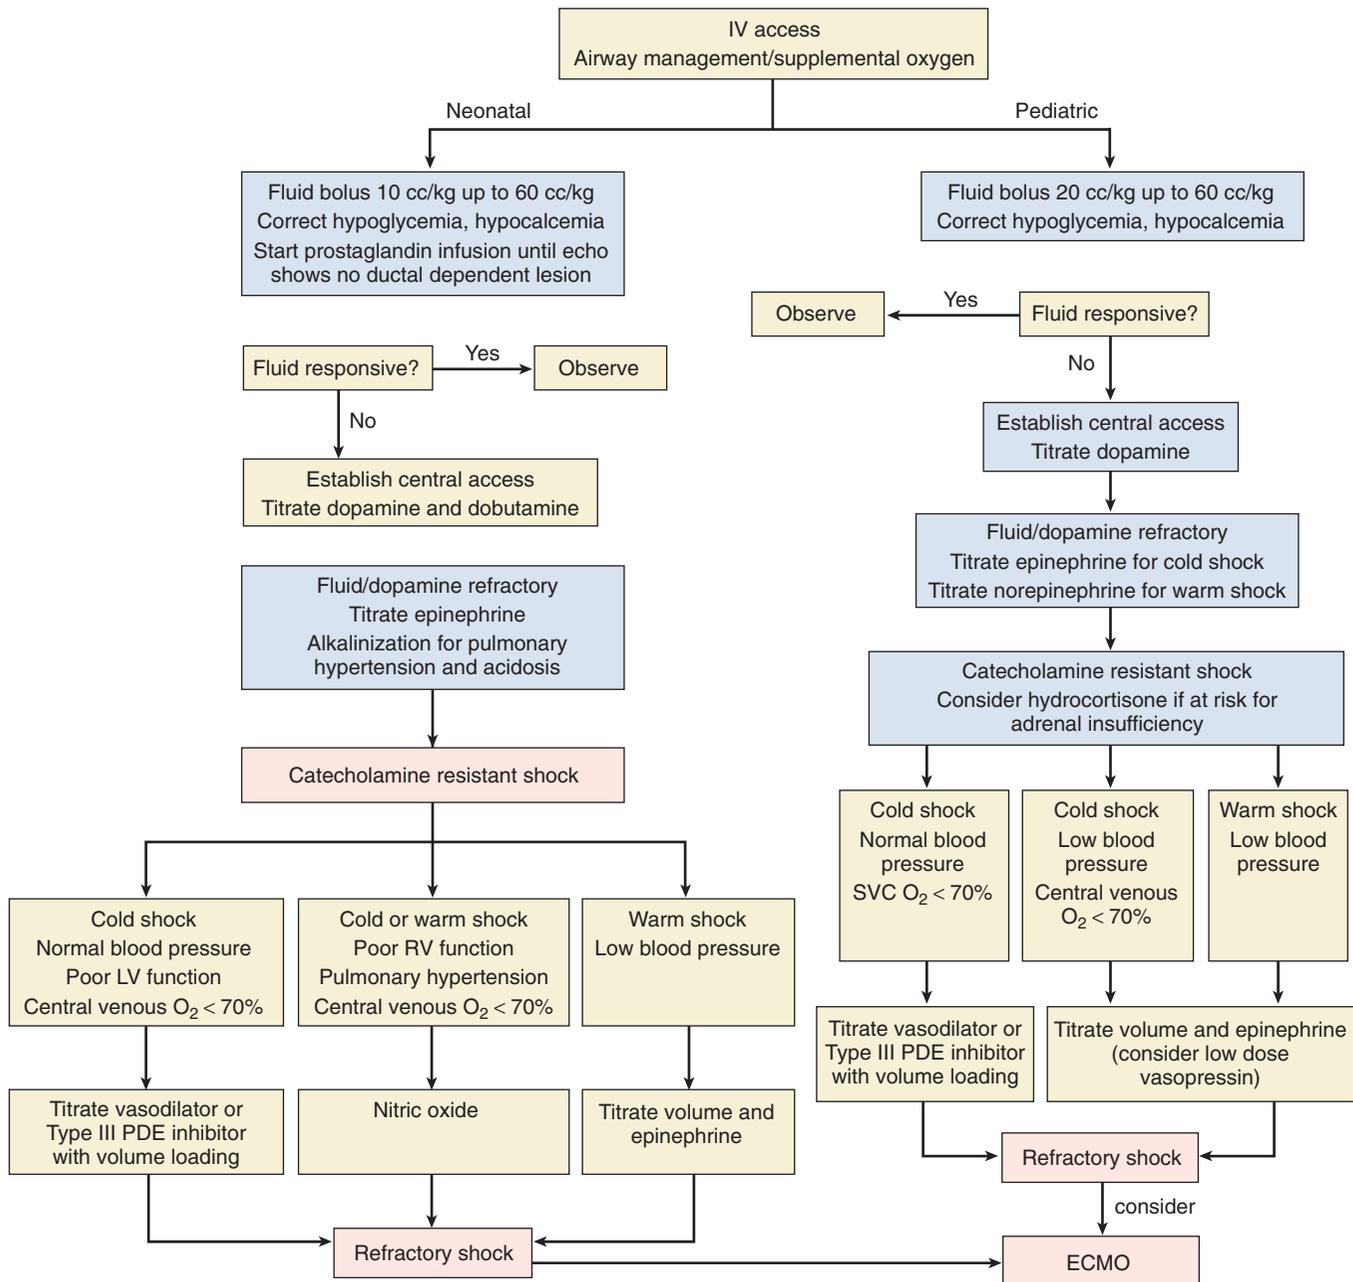

FIGURE 13-1. Algorithm for treatment of pediatric and neonatal sepsis. (Adapted from Carcillo JA, Fields AI; American College of Critical Care Medicine Task Force Committee Members: Clinical practice parameters for hemodynamic support of pediatric and neonatal patients in septic shock. *Crit Care Med* 30:1365–1378, 2002.)

Other vasopressors can be added to achieve specific desired effects. If cardiac output cannot be determined or is adequate after volume resuscitation, the physician should consider dopamine or norepinephrine. One of these drugs can be added to dobutamine for persistent hypotension despite correction of cardiac output. These agents are preferred over epinephrine because they cause less profound tachycardia and less vasoconstriction of the splanchnic bed. However, there is evidence of an age-dependent resistance to dopamine,²⁶ and failure to respond should prompt the clinician to employ another agent. Phenylephrine causes vasoconstriction

without tachycardia and could be chosen when vasodilatory shock is strongly suspected. Ideally, the administration of vasopressors should be guided by continuous arterial pressure monitoring. Such monitoring is not universally available in the emergency department. In its absence, the clinician should rely upon measurement of peripheral blood pressure, urine output, mental status, and systemic acid-base status until the patient can be transferred to an intensive care unit.

One should consider adding a short-acting, titratable vasodilator such as nitroprusside or nitroglycerine for patients

with strong evidence of elevated peripheral vascular resistance and depressed cardiac output unresponsive to the previously discussed therapies. If these agents fail to improve cardiac output and peripheral perfusion, then milrinone or amrinone should be considered. Abnormally low cardiac output in pediatric patients is associated with increased mortality, so every effort should be made to ensure that it is normal.

Children with cortisol deficiency may be resistant to vasopressor therapy. At least one trial has demonstrated improved outcome when such children are identified and treated promptly.²⁵ Adrenal insufficiency can be the result of sepsis itself (e.g., Waterhouse-Friederichsen syndrome), but is more likely to be the result of a congenital or acquired endocrinopathy or chronic steroid use. Experts recommend administration of stress doses of corticosteroids (e.g., hydrocortisone 1 to 2 mg/m²/hr) for children with potential adrenal insufficiency and higher doses (25 to 50 mg/m² loading dose followed by 1 to 2 mg/m²/hr) for shock states associated with Waterhouse-Friederichsen syndrome. However, two adult studies have demonstrated worse outcomes in patients receiving high-dose corticosteroids (e.g., more than 300 mg/day), so excessively high doses are not recommended.²⁷⁻²⁹

When uncertainty exists regarding the state of the patient's pituitary-adrenal axis, a cortisol stimulation test can be obtained. Patients who have an adequate response to ACTH do not need exogenous steroids. This test is impractical in many emergency departments; dexamethasone (0.6 to 1 mg/kg) will not interfere with the stimulation test and can be safely given if this test is deemed necessary at a later point. Corticosteroids have not been demonstrated to be beneficial to patients who have normal cortisol production and should not be administered in this situation.

Priority should be given to the patient's electrolyte balance and glucose levels. Maintenance of serum glucose at levels between 80 and 150 mg/dl has been associated with improved survival.^{29a} Hypoglycemia should be avoided and hyperglycemia should be treated with regular insulin, administered intravenously. Glucose levels should be monitored frequently. Calcium can be depleted during septic shock but should only be replaced if indicated by a low serum ionized calcium level.

Several immune-modulating agents that theoretically decrease the exogenous immune response and improve tissue ischemia have been investigated as potential therapies in pediatric sepsis. Thus far, only recombinant human activated protein C has shown minimal benefit, and only in adult patients.³⁰ Activated protein C decreases serum levels of activated factors V and VIII, thus decreasing thrombin formation and increasing fibrinolysis. Both tissue pathway factor inhibitor and interferon gamma have produced some promising early results in clinical trials. Studies of plasma filtration have demonstrated that this therapy can reduce amounts of circulating acute-phase reactants, but has thus far not been shown to improve outcomes.^{30a}

Many children with sepsis will require mechanical ventilation. Recent literature suggests that ventilator-associated lung injury contributes to ARDS both by direct barotrauma and by increased pulmonary cytokine production. Experts now recommend ventilation with low tidal volumes (e.g., 6 ml/kg), low end-expiratory pressures, and, if necessary, permissive hypercapnia.³¹⁻³³ Because many of these patients

will be intubated in the emergency department, emergency physicians must understand these issues and adhere to these principles during both manual and mechanical ventilation.

Neonates with advanced sepsis present some unique challenges. The acidosis associated with sepsis can lead to persistent patency of the ductus arteriosus and, in some cases, to persistent pulmonary hypertension. This disease state can create a vicious cycle of hypoxemia and worsening acidosis and can ultimately cause right ventricular failure. Inhaled nitric oxide is currently used in neonatal units and by many neonatal transport teams to avert this complication. In most emergency departments, treatment would primarily include supplemental oxygen and correction of acidosis.

Summary

Recognition and management of sepsis in the pediatric population requires early diagnosis and aggressive, goal-directed therapy. Emergency physicians must be very familiar with the specific criteria for SIRS, stay attuned to possible subtle presentations of infection in infancy and childhood, and be highly suspicious for the diagnosis of sepsis in infants and immunocompromised children. Effective initial stabilization can be performed in a variety of settings. However, with rare exceptions, all septic pediatric patients require prompt transfer to tertiary care centers, preferably those with pediatric-specific critical care units.

Isotonic intravenous fluids, blood product transfusions, ventilatory support, early appropriate antibiotics, and early surgical intervention for abscesses and acute abdominal processes are the mainstays of therapy. Initial therapeutic efforts should be focused on aggressive restoration of volume and, if necessary, ion-tropic support. Treatment decisions should be based on a balance between potential benefits and potential harms. Because septic children and adults have differing mortality rates, treatment-related morbidity may not always favor intervention.

Research in sepsis is particularly challenging, and is more so in children. The new consensus definition of sepsis helps to provide a framework to generate multicenter trials. As our knowledge and understanding of the pathophysiology of sepsis continue to grow, our ability to intervene will move beyond antibiotics and supportive therapy. Areas of promise and current trials include serum markers for sepsis, "designer antibiotics," and coagulation- and inflammatory-pathway specific therapies.

Anaphylaxis

Suzanne M. Beno, MD

Key Points

Survival is dependent upon immediate recognition and intervention.

Rapid administration of intramuscular epinephrine is first-line therapy for anaphylaxis.

Children with asthma are at increased risk for delayed and more severe reactions.

Introduction and Background

Anaphylaxis has long been recognized as a severe, life-threatening reaction that involves multiple target organs, including skin, respiratory, gastrointestinal, cardiovascular, and neurologic systems.¹ Consensus regarding its exact definition currently does not exist and there is considerable disagreement about its prevalence, diagnosis, and management. A recent practice parameter addresses these issues and attempts to provide an evidence-based approach to the definition of this condition.² Anaphylaxis is considered to be highly likely when any one of the following three criteria is present:

1. Acute onset of an illness (minutes to hours) involving skin/mucosa and either respiratory compromise or hypotension (associated symptoms)
2. Two or more of the following that occur rapidly after exposure (minutes to hours) to a *likely* allergen for that patient: skin/mucosal involvement, respiratory compromise, hypotension and associated symptoms, and persistent gastrointestinal symptoms
3. Hypotension after exposure to *known* allergen for that patient (minutes to hours)

The term *anaphylaxis* encompasses both immunoglobulin E (IgE)-mediated reactions and non-IgE-mediated mechanisms (*anaphylactoid* reactions); the difference impacts allergen counseling but is of little consequence in the immediate management of the patient.²

Recognition and Approach

Epidemiology data in the general population are sparse and affected by variable definitions, coding, and misclassification

errors. Population data from the 1980s estimated an annual occurrence rate of 30 per 100,000 person-years, while more recent literature suggests occurrence rates as high as 590 per 100,000 person-years.³ The actual incidence, especially in children, remains uncertain as very few population-based studies exist. A prevalence study using rates of injectable epinephrine dispensing data in Manitoba supports various retrospective reviews suggesting a 1% prevalence in the community. This study specifically noted a peak in anaphylaxis from all triggers in early childhood with a gradual decline toward adolescence.⁴

Anaphylaxis is generally considered to be at the severe end of the generalized hypersensitivity spectrum, with respiratory and/or cardiovascular involvement denoting severity. Different grading systems have been explored, and are based upon the current proposed definition for anaphylaxis.² A systematic compilation of the frequency of signs and symptoms in anaphylaxis is shown in Table 14–1.

Evaluation

Anaphylaxis is an immediate uniphasic reaction invoking various end-organ responses in the skin, respiratory tract, and cardiovascular and gastrointestinal systems. Other patterns of anaphylaxis exist, and include delayed onset (>30 minutes postexposure), protracted or persistent reactions (can last up to 32 hours), and biphasic reactions in which recurrence of symptoms follows a symptom-free period (8 to 12 hours). The resultant reaction in a biphasic response is usually more severe and less amenable to treatment.^{6,7}

The majority of anaphylaxis will present with some degree of cutaneous involvement, such as flushing, pruritus, urticaria, and angioedema, but these symptoms may be either overlooked or missed after epinephrine administration.⁸ Other classic features include signs of upper and lower airway obstruction, gastrointestinal symptoms, syncope, hypotension, and dizziness. In its severe form, anaphylaxis can result in cardiovascular collapse and death.

The most common etiologies of anaphylactic reactions include reactions to food, medications, *Hymenoptera* stings, and latex.² Certain groups of children are more prone to anaphylaxis. Children with neural tube defects and/or genitourinary abnormalities requiring self-catheterization are at increased risk for latex allergy. Children with asthma, particularly if poorly controlled, have an increased incidence of fatal anaphylaxis.^{6,9,10}

Table 14–1 Signs and Symptoms: Frequency of Occurrence in Anaphylaxis (%)

	Lieberman et al. ⁵ (mostly adults)	Lee and Greenes ³⁵ (children): N = 106	Dibs and Baker ³⁶ (children): N = 55
Cutaneous	>90	92	93
Urticaria/angioedema	85–90		
Flushing	45–55		
Pruritis w/o rash	<5		
Respiratory	40–60		93
Upper airway	50–60	78	
Dyspnea, wheeze	45–50	58	
Rhinitis	15–20

Neurologic			
Seizure/HA	5–8	27	26
Seizure alone	1–2		
Miscellaneous			
Substernal chest pain	4–6		

Adapted from references 5, 35, 36.

Food-Induced Anaphylaxis

This is the single most common cause of anaphylaxis treated in emergency departments in the United States, particularly in children, and these reactions are mainly attributable to peanuts, tree nuts, fish, shellfish, milk, and eggs.¹¹ The prevalence of these reactions is rising and estimated to now affect 0.8% to 2.0% of the population.^{12,13} Reactions tend to worsen in severity with age and the development of asthma. Food-associated exercise-induced anaphylaxis can occur when exercise takes place within 2 to 4 hours after ingestion of a specific food, but its pathogenesis and true incidence are unknown.¹⁴

Drug-Induced Anaphylaxis

A careful history is key to establishing the correct diagnosis, including when the exposure occurred, the interval to reaction, previous medications, and response to therapy. The development of drug-specific IgE antibodies during previous sensitization accounts for these reactions. Penicillin is the most common cause of drug-induced anaphylaxis, followed by aspirin and nonsteroidal anti-inflammatory medications. Validated tests for IgE-mediated reactions are available for penicillin and insulin, but largely unavailable for most drugs and biologic agents.² There is a 5% to 10% cross reactivity of penicillin with first-generation cephalosporins and less than 1% cross reactivity with third-generation cephalosporins. Some drugs cause anaphylactoid reactions, and do not require a preceding sensitization. Radiographic contrast material (RCM) is such an agent, and moderate reactions requiring treatment occur in about 1% of patients receiving RCM, while life-threatening reactions occur less than 0.1% of the time.⁵ Pretreatment regimens in emergency situations include some combination of corticosteroids and H₁-receptor antagonists and possibly H₂-receptor antagonists (antihistamines).

Insect Sting-Induced Anaphylaxis

Self-administered epinephrine is critically important in this situation. Onset of anaphylaxis after an insect sting is rapid, with 96% of fatal reactions beginning within 30 minutes of

the insect sting.¹⁵ Unfortunately, most fatal reactions occur with the first sting reaction and thus are not preventable. Diagnostic skin testing for screening purposes lacks specificity as 25% of adults are positive, and its utility in children has not been established.¹⁶ Immunotherapy is available for prevention of subsequent anaphylactic reactions, and individuals should be referred for this purpose.¹⁷

Latex-Induced Anaphylaxis

Latex-induced anaphylaxis is an IgE mast cell-mediated reaction. Its incidence has reached a plateau after a steady increase over the last 20 years; 6.5% in the general population are affected. Up to 17% of cases of intraoperative anaphylaxis are latex induced, and approximately 75% of the spina bifida population are sensitized.⁵ The plateau and hopeful decline are likely secondary to the creation of latex-safe environments through increased awareness, decreased use of latex products, and Food and Drug Administration labeling warnings about the presence of latex in medical products.¹⁸

Idiopathic Anaphylaxis

This is a diagnosis of exclusion encompassing approximately 20% of cases of anaphylaxis, and is more common in adults than in children. It lacks distinguishing features, may be fatal, and is sometimes treated with prophylactic corticosteroid and antihistamine therapy.¹⁹ Systemic mastocytosis should be ruled out in these patients.

Angioedema

Angioedema is a hypersensitivity disorder that manifests as an acute onset of noninflammatory edema in the subcutaneous tissues or mucosa, most often in the upper respiratory or gastrointestinal tracts. Children can present with life-threatening airway obstruction or with symptoms mimicking an acute abdomen. Urticaria is not typically seen. Both hereditary and acquired forms are clinically similar. Hereditary angioedema is an autosomal dominant disease characterized by an inherited defect in C₁ esterase inhibitor activity that disrupts regulation of the allergic cascade, and usually

manifests in late childhood. Although standard anaphylaxis therapy is often not very helpful for this condition, antihistamines, corticosteroids, and epinephrine may be beneficial.²⁰ The treatment of choice is an intravenous concentrate of C_1 inhibitor.²¹ Fresh frozen plasma contains C_1 inhibitor and can be helpful but occasionally paradoxically worsens angioedema.²² Antifibrinolytic agents such as ϵ -aminocaproic acid are used in children in place of attenuated androgens, which increase complement levels and are standard treatment in adults.²⁰

Anaphylaxis remains a clinical diagnosis, and laboratory tests are of little value. Two mediators that are currently available as serum levels are tryptase and histamine, both of which have unreliable diagnostic accuracy and poor predictive value. Additional biomarkers that are easily and rapidly measured may be of benefit in the future.⁵

The two major pitfalls in the management of an anaphylactic reaction are (1) failure to recognize anaphylaxis and (2) failure to administer epinephrine early in suspected anaphylaxis. Recognition failure can be the result of physician-related factors, such as failing to diagnose anaphylaxis in the absence of shock with subsequent failure to prescribe epinephrine for future reactions. Patient-related factors include not appreciating the significance of mild to moderate symptoms that often spontaneously resolve, and thus never seeking evaluation or treatment. Reported rates are thus believed to be an underestimate of the true prevalence of this condition mainly for these reasons.⁴

Table 14–2 illustrates many of the conditions that can be misinterpreted as anaphylaxis. One condition in particular, acute asphyxial asthma, may confound the diagnosis of anaphylaxis. Acute asphyxial asthma has recently been recognized as a subset of sudden and severe asthma exacerbations.²³ There exists concern that children presenting with typical symptoms of this disorder, particularly those with urticaria, hypotension, or a poor response to bronchodilators, may actually be experiencing anaphylaxis. This finding is supported by postmortem histologic examination. There may be a role for prescribing self-administered epinephrine devices, Medic Alert bracelets, and allergen counseling for survivors of this condition.²⁴

Table 14–2 Conditions Mimicking Acute Anaphylaxis

Vasodepressor (vasovagal) reactions
Flushing episodes (vancomycin-induced “red man” syndrome, alcohol intoxication or withdrawal, malignancy, autonomic epilepsy)
Postprandial syndromes (monosodium glutamate [MSG], sulfites, scombroid)
Asthma (acute asphyxial asthma)
Vocal cord dysfunction
Acute anxiety (panic attacks, hyperventilation)
Myocardial dysfunction
Pulmonary embolus
Shock (hemorrhagic, cardiogenic)
Systemic mast cell disorders
Foreign-body aspiration
Acute poisoning
Hypoglycemia
Erythema multiforme major

Management

Immediate management in the emergency department includes ensuring a patent airway and adequate oxygenation, establishment of intravenous (IV) access for circulatory support, and early administration of epinephrine (Box 14–1). A multicenter emergency department–based study showed wide variability in treatment of allergic reactions and found that treatment was largely symptom based, with use of some combination of antihistamines, steroids, and epinephrine.²⁵

Epinephrine is considered the drug of choice for anaphylaxis, and it should be given immediately. The recommended dose is 0.01 mg/kg (1:1000 solution) intramuscularly, with a minimum of 0.1 mg/dose and a maximum of 0.3 mg/dose. The dose can be repeated every 10 to 20 minutes if symptoms persist or worsen.⁵ The lateral aspect of the thigh is considered the optimal location for administration in adults, and intramuscular injections are preferred to subcutaneous administration in both children and adults based on mean plasma concentrations in asymptomatic individuals.^{26,27} Current outpatient formulations include (1) EpiPen (0.3 mg) and EpiPen Jr (0.15 mg) for children weighing less than 25 kg, and (2) Twinject (0.3 mg and 0.15 mg) which recently came on the market and offers two doses of epinephrine in one device. Considerable discussion among experts regarding appropriate childhood dosing for injectable epinephrine has taken place and will hopefully result in availability of additional fixed-dose pens.^{11,28} Alternative delivery methods of epinephrine include sublingual and inhaled administration. Inhaled epinephrine was recently studied prospectively in a small number of asymptomatic children who were unable to inhale sufficient quantities to significantly increase their plasma epinephrine concentration. Therefore, it may be beneficial for reversal of laryngeal edema or persistent

Box 14–1 Therapeutics

- Cardiac monitor, continuous pulse oximetry
- Supplemental oxygen
- Airway management
- IM epinephrine (0.01 mg/kg of 1:1000; max 0.3 mg per dose, min 0.1 mg per dose)
- IV epinephrine (0.01 mg/kg of 1:10,000 over 2–5 min) for patients in extremis or refractory shock
- IV fluid expansion (20 ml/kg NS or LR; repeat as needed)
- Consider Trendelenburg positioning
- Nebulized albuterol (0.5–1 ml 5% soln), ipratropium (125–500 mcg), or racemic epinephrine (0.25–0.5 ml 2.25% soln)
- H_1 antagonist (diphenhydramine 1 mg/kg up to 50 mg)
- H_2 antagonist (ranitidine 1–2 mg/kg); use with caution in children with bronchospasm
- Corticosteroids (1–2 mg/kg prednisone or methylprednisolone)
- Glucagon (20–30 mcg/kg up to 1 mg)

Abbreviations: IM, intramuscular; IV, intravenous; LR, lactated Ringer’s solution; NS, normal saline; soln, solution.

bronchospasm but is not an equivalent substitute for injected epinephrine.²⁹ Intravenous epinephrine is reserved for patients in extremis, persistent hypotension, or shock. Although epinephrine injected early is more likely to reverse the reaction, as many as 10% of cases may not be reversible.¹⁰ Epinephrine has no absolute contraindications in anaphylaxis; it is *relatively* contraindicated with concomitant cocaine use because of its sensitization of the myocardium. The dose *may* need to be halved for patients taking β -blocker agents, tricyclic antidepressants, and monoamine oxidase inhibitors because of the risk of unopposed α -adrenergic receptor activity and cardiac arrhythmias.¹

Patients with anaphylaxis should be placed in a supine position. A recent practice parameter also suggests elevation of the lower extremities to prevent orthostasis and to shunt effective circulation to the head, heart, and kidneys, but the Trendelenburg position has also been shown to worsen pulmonary hemodynamics.^{5,30} A review of 214 cases of anaphylaxis noted a link in patients who, after assuming an upright posture, had immediate cardiovascular collapse.³¹ Changes in vascular permeability in anaphylaxis can result in potential loss of 50% of an individual's intravascular fluid within 10 minutes.³² Patients with persistent hypotension despite epinephrine need volume expansion, typically in the form of crystalloid solutions such as 0.9% saline or lactated Ringer's solution. Children require at least 20 ml/kg within the first hour of therapy.

Secondary therapeutic interventions include the use of histamine receptor antagonists, corticosteroids, β_2 -agonists and glucagon therapy. Antihistamines are a useful adjunct in the management of anaphylaxis, specifically targeting urticaria-angioedema and pruritus. Diphenhydramine at 1 mg/kg (up to 50 mg) administered intravenously, intramuscularly, or orally has traditionally been used to block H₁ receptors. Second-generation agents such as loratadine and cetirizine are equally effective and have less sedating effects than first-generation antihistamines in urticaria, but their role in anaphylaxis has yet to be explored. The role of H₂ antagonists has yielded inconsistent results in the literature; however, recently an emergency department-based study of almost 100 adults demonstrated combining diphenhydramine with ranitidine resulted in superior resolution of cutaneous symptoms and tachycardia.³³

Currently there is no evidence for use of H₂ antagonists in children experiencing anaphylaxis. If administered to children, ranitidine at 1 to 2 mg/kg per dose IV over 10 to 15 minutes is the agent of choice.⁵ It can be repeated up to twice a day or to a maximum of 300 mg/day. H₁ and H₂ blockers have competing effects in the lungs, thus H₂ blockers can theoretically lead to bronchoconstriction. While H₂ blockers have been proven useful in cutaneous manifestations of anaphylaxis, they have not been proven to ameliorate other manifestations.

Corticosteroids, though commonly used in anaphylaxis, have never been evaluated in placebo-controlled trials. The effects of corticosteroids are believed to occur within 4 to 6 hours, potentially prevent protracted or biphasic anaphylaxis, and provide additional benefit for children with asthma. Methylprednisolone at 1 to 2 mg/kg/day administered intravenously every 6 hours or 1 to 2 mg/kg of oral prednisone for milder attacks are commonly used regimens.⁵ Inhaled β_2 -agonists, such as albuterol 0.5 to 1 ml of a 0.5% solution or

racemic epinephrine 0.25 to 0.05 ml of 2.25% solution, should be administered for bronchospasm; ipratropium may also reverse bronchospasm. Children taking β -blockers are more likely to experience profound bradycardia, hypotension, and bronchospasm that is unresponsive, or only partially responsive, to epinephrine. These children and those whose hypotension is refractory require aggressive volume expansion and glucagon therapy (20 to 30 mcg/kg up to 1 mg in children) administered intramuscularly, intravenously, or subcutaneously followed by an infusion.

It is vital to immediately discontinue exposure to the suspected causal agent, such as avoiding all latex products in the treatment of latex-induced anaphylaxis. This problem is now easily obviated by the replacement of latex products in many emergency departments or the availability of latex-free treatment areas and emergency equipment carts. Bee sting-induced anaphylaxis can also benefit from local application of ice and removal of the stinger if feasible. Other therapeutic complications include improperly injected epinephrine resulting in ineffective drug delivery or tissue ischemia if inadvertently injected into a digit.

Summary

The prognosis of anaphylaxis is variable, ranging from immediate recovery to irreversible cardiovascular collapse. Children with asthma experience more severe and often delayed reactions, placing them at increased risk of death. Other predictors of severity include older age, insect venom, and iatrogenic causes; as well, some studies suggest the use of angiotensin-converting enzyme inhibitors and β -blockers as independent risk factors.³⁴

Transportation to a facility with appropriate resources is mandatory for all prehospital-treated patients. Biphasic reactions with resultant death after premature discharge from the emergency department have been reported to occur between 1.3 and 28 hours after the first symptoms subside. Therefore, patients should be observed for at least 8 hours after the initial symptoms subside, or admitted for 24 hours based on severity, etiology, and underlying disease.³⁵ A history of a previous severe reaction or a patient's inability to return promptly if symptoms relapse mandates an admission to hospital for observation.¹¹ Treatment upon discharge should be continued for at least 48 hours. Standard treatment includes scheduled antihistamines and corticosteroids, although supportive evidence for the latter does not currently exist. Debate exists regarding prescription of injectable epinephrine or an anaphylaxis kit; however, any child having experienced an anaphylactic reaction secondary to food or insect venom *must* receive at least one on discharge with adequate instruction in its use. All children with anaphylaxis should be referred to an allergist for further counseling, diagnostic testing, or immunotherapy as applicable. Ideally children with a known allergen should wear a Medic Alert bracelet that will help identify their disease on presentation to the emergency department.

Currently there is no consensus regarding the definition and classification of anaphylaxis. Future research will explore the pathophysiology of why individuals have such variable responses and presentations, as well as identification of laboratory markers with high predictive values that identify both anaphylactic reactions and individuals at risk for them. Pro-

spective evaluation of diagnostic and management algorithms, along with increased public and provider education, is greatly needed.

Trauma in Infants

Gail M. Stewart, DO and Ameer P. Mody, MD, MPH

Key Points

Although infant trauma is common, it is rarely associated with severe injury.

Infants are not “little children.” Unique anatomic and physiologic variations result in distinct injury patterns.

Decision rules for management of infant trauma have not been developed.

Car seats have had a profound impact on decreasing the frequency and severity of infant injuries sustained during traffic collisions.

Introduction and Background

Evaluating and managing a screaming, wiggling 6-month-old who presents to the emergency department (ED) taped and strapped to her car seat following a traffic collision can be a challenge. Infants with traumatic injuries are in a special subset of pediatric patients. Their inability to cooperate or communicate makes it difficult to assess the severity of injury based on history or physical examination. Their preverbal and relatively immobile state makes them susceptible to nonaccidental trauma. Unique anatomic variations include a disproportionately large head, weak neck muscles, lack of complete skeletal ossification, relatively large body surface area, and immature central nervous system.

Generally, infants are defined as children younger than 12 months of age. There are some predictable patterns of injuries in this age group and a relatively low frequency of comorbid medical conditions. Regrettably, few papers have been published addressing how to manage traumatized infants. Most management principles are extrapolated from adult or pediatric literature that includes older children. This chapter focuses on accidental trauma in infants (see Chapter 119, Physical Abuse and Child Neglect). An overarching theme to this chapter is that “infants are not just little children.”

Recognition and Approach

Infant trauma is a common occurrence. Ten percent of infant visits to EDs are for nonfatal injuries.¹ The most common mechanisms of injury are falls (50% to 60%), burns (5%), being struck by a falling object (5%), ingestions (5%), and traffic collisions (5%).²⁻⁴ Hospitalization is uncommonly needed, occurring in approximately 5% of infants evaluated in an ED.^{4,5} The infant mortality rate due to accidental injury is low, approximately 3%.² Epidemiologic studies of infant injuries suggest a bimodal distribution predominantly comprising minor injuries and severe, life-threatening injuries. Cases of intermediate acuity are less common than either of these two extremes.

The advent of the rear-facing infant car seat has significantly altered the mechanism and frequency of infant injury in traffic collisions.^{6,7} The rear-facing position provides better support to the infant’s head, neck, and back, and spreads the crash force more evenly over the entire body. Current guidelines recommend infants remain in the rear-facing position until reaching 1 year of age, or a minimum of 20 pounds (approximately 10 kg).⁸ Car seat use has resulted in a 71% reduction in the number of serious injuries and deaths sustained by infants involved in motor vehicle accidents.⁸

Head trauma is the most frequently reported injury in infants. Up to 97% of falls result in injury to the head, which is disproportionately large compared to the body, and supported by weak neck muscles.^{5,9} Distinctive features of the infant skull include a soft, thin, bone, unfused sutures and open fontanelles.⁴ The infant skull fractures easily, even following relatively minor trauma.^{10,11} Forces applied to the deformable skull are easily transmitted to the underlying brain, causing direct tissue damage.¹² Infants with a skull fracture are at an increased risk for having an associated intracranial bleed.¹³ In the vast majority of infants, there will be soft tissue swelling overlying the site of the fracture.¹⁰ It is important to document the presence of even seemingly clinically insignificant skull fractures because a leptomeningeal cyst (i.e., a “growing fracture”) may develop later.¹⁴ The infant scalp can develop significant extracranial hematomas following impact. Infantile extracranial hematomas may arise in one of two different anatomic locations resulting in either a subgaleal hematoma or a cephalohematoma. Subgaleal hematomas are composed of a collection of blood between the galea aponeurotica and the periosteum of the skull. These hematomas can become quite large, are not generally

associated with skull fractures, and cross suture lines. Cephalohematomas form underneath the periosteum. These hematomas do not cross suture lines and have an association with underlying skull fractures.^{15,16} Both subgaleal hematomas and cephalohematomas may cause clinically significant anemia.

The infant brain differs from that of older children in that myelination is incomplete, cerebral autoregulation is underdeveloped, and cerebrospinal fluid spaces are larger.⁹ With impact, the brain has more motion within the calvarium, causing the dural veins to stretch and tear. Subdural hematomas in infants are common following high-velocity impact injury, and are typically associated with contusion, cerebral edema, or diffuse axonal injury.^{9,15} Infants who sustain severe traumatic brain injury have a poor prognosis for recovery.¹⁴

Cervical spine injuries in infants are rare. In a study of 3065 pediatric patients who underwent imaging for a suspected neck injury, less than 1% had a cervical injury, and of these, none was less than 2 years of age.¹⁷ Spinal cord injuries in infants most often result from abusive shaking, motor vehicle accidents, or falls from a height. Younger children tend to have upper cervical spine involvement compared to older children and adults.¹⁸ Anatomic differences in the pediatric cervical spine include anterior wedging of the vertebral bodies, horizontal facet orientation, and absence of uncinat processes on the vertebral bodies. The net result is that infants have relatively more ligamentous injuries than bony injuries.¹⁹ Infants are susceptible to hyperextension and flexion injuries, which can cause momentary dislocation followed by spontaneous reduction of the vertebrae.¹⁹

The bony and ligamentous spinal column of infants is quite elastic and can stretch up to a total of 50 mm vertically. However, the spinal cord can only tolerate about 5 mm of stretch without substantial disruption occurring.¹⁸ Therefore, spinal cord injuries may occur without demonstrable bony injury. In 1982, Pang and Wilberger coined the term *spinal cord injury without radiographic abnormality* (SCIWORA) to describe this phenomenon.²⁰ With the advent of magnetic resonance imaging (MRI), which can allow for the visualization of ligamentous injuries and injuries to the spinal cord itself, the term SCIWORA is probably no longer clinically meaningful (see Chapter 23, Spinal Trauma).

Infant thoracic trauma usually results from a blunt force applied to the chest wall, resulting in pulmonary contusion, pneumothorax, or hemothorax. Injury to the heart, tracheobronchial tree, aorta, esophagus, or diaphragm is rare.²¹ Pulmonary contusion is the most common, serious thoracic injury identified in infants, occurring when the anterior ribs are compressed against the posterior ribs.²² Because infants' ribs are so pliable, internal thoracic injury often occurs without fracture.^{23,24} Presence of rib fractures in infants indicates significant energy transfer, and should alert the physician to the possibility of child abuse and multisystem injuries^{21,25} (see Chapter 12, Approach to Multisystem Trauma; Chapter 24, Thoracic Trauma; and Chapter 119, Physical Abuse and Child Neglect).

Management of an infant with a potential abdominal injury generally follows the same principles as those applicable to older children (see Chapter 25, Abdominal Trauma). In infants, the abdominal organs are proportionately larger and closer together. They are less protected due to weaker abdominal wall musculature and the higher position of the

rib cage. The spleen and liver are the most frequently injured abdominal organs in infants. Up to 90% of abdominal organ injuries are managed nonoperatively.²⁶ Infants have a smaller total circulating blood volume, and therefore any particular volume loss is relatively larger for an infant than for older children.

Evaluation

In approaching the injured infant, an effort should be made to establish eye contact and calm the baby before assessing mental status. To the extent possible, the parent or caregiver should be allowed to be within eye and physical contact of the infant, and analgesia and sedation should not be withheld.

In recent years, some Emergency Medical Services providers have adopted a protocol that allows for an injured infant to be immobilized and transported in his or her car seat from the scene of an accident to the ED (Fig. 15–1). Once in the ED, if the infant appears stable, parts of the initial evaluation can be done with the infant remaining in the car seat. If significant injury is suspected, a two-person technique is used

FIGURE 15–1. Typical car seat cervical spine immobilization of a young infant.

to carefully remove the baby from the car seat while maintaining spinal immobilization.

Just as in the evaluation of older children, the evaluation of an injured infant can be organized around primary and secondary surveys. The primary survey assesses and treats problems with the airway, breathing, and circulation. During the primary survey, a brief neurologic examination is performed and the infant is undressed. In the secondary survey, a complete head-to-toe assessment is undertaken. The physician should take advantage of the “windows of opportunity” that the infant offers. For example, the mouth can be examined when the baby is crying and the fontanelle can be assessed when the infant is quiet.

Physical Examination

The infant skull should be carefully palpated for swelling or bony step-offs. Hematomas should be identified because they can cause significant bleeding. Soft tissue swelling of the scalp may overlie a skull fracture. A bulging fontanelle in a quiet infant is associated with increased intracranial pressure and in the setting of trauma suggests intracranial hemorrhage. Small infants are sensitive to bright lights. It may be helpful to dim the lights before attempting to examine the pupillary response.

The cervical spine should be evaluated by palpation, assessing for tenderness, swelling, crepitus, or bony anomalies. A thorough neurologic examination should be done in conjunction with the neck examination. If the neck seems tender, or any focal neurologic anomalies are present, cervical immobilization should be maintained pending imaging studies. Unfortunately, the NEXUS criteria used to predict cervical spine injuries in adults cannot be applied to infants.²⁷

The infant trachea is narrow, short, and compressible. Small changes in airway diameter can cause rapid respiratory embarrassment.²² Frequent suctioning may be necessary. Because breath sounds are shallow and easily transmitted, the lung fields may sound equal on auscultation despite the presence of a pulmonary contusion or pneumothorax. Infants with respiratory distress from pulmonary contusions may

demonstrate “abdominal” breathing, increased work of breathing, and grunting. The examination of the infant abdomen is not substantially different than the examination of older children. However, infants tend to cry more and can present with a distended abdomen secondary to aerophagia (i.e., excessive air in the stomach).²⁶ Extremities should be examined looking for bony deformities, swelling, or tenderness.

An initial neurologic examination of the infant should evaluate the infant’s mental status, pupillary response, motor function, and deep tendon reflexes. A more detailed neurologic examination should be completed following stabilization.

Laboratory Testing

There is no routine “trauma panel” recommended for the injured infant. Laboratory tests should be tailored to individual circumstances (see Chapter 12, Approach to Multisystem Trauma).

Imaging Studies

Imaging studies may help elucidate anomalies detected on the primary or secondary survey. In the infant with major head trauma, an emergent computed tomography (CT) scan should be expediently obtained. The role for imaging studies in children with minor head trauma is controversial (see Chapter 17, Head Trauma). Some believe that skull radiographs are only indicated to confirm a depressed fracture, to evaluate a penetrating injury, or to help evaluate for nonaccidental trauma.²⁸ Guidelines published by the American Academy of Pediatrics for managing minor head injury in children only apply to those over 2 years of age.²⁹

In a review by an expert panel, infants younger than 2 years with apparently minor head injury were designated as having a high, intermediate, or low risk for presence of intracranial injury based on history, mechanism of injury, and clinical parameters. Imaging recommendations were based on risk level (Table 15–1). Since the incidence of intracranial injury following minor head trauma is 3% to 6% in infants, a low threshold for head imaging is probably reasonable.

Table 15–1 Proposed Guidelines for Imaging Children <2 Years of Age with Apparently Minor Head Trauma

High Risk: CT Scan	Intermediate Risk		Low Risk: Observation
	Subgroup 1*: Consider CT or Observation 4–6 hr	Subgroup 2†: Consider CT, Skull Radiograph, or Observation	
Depressed mental status Focal neurologic findings	Vomiting 3–4 times Transient LOC	Higher force mechanism Falls onto hard surface	Low-energy mechanism No signs or symptoms ≥2 hr after injury
Signs of depressed/basilar fracture Skull fracture by radiograph Irritability	History of lethargy or irritability Behavior not at baseline Nonacute skull fracture (>24 hr old)	Scalp hematomas Unwitnessed trauma Vague or absent history of trauma	>3–6 mo of age
Bulging fontanelle Seizure Progressive vomiting LOC >1 min			

*Children with clinical indicators of possible brain injury.

†Children with concerning or unknown mechanism.

Abbreviation: LOC, loss of consciousness.

Table adapted from Schutzman et al.³⁰

Presence of a scalp hematoma is a predictor of a skull fracture and, if relatively large, predictive of intracranial hemorrhage.³⁰

Cervical spine injuries in children are uncommon, occurring in about 1% of all pediatric trauma victims.^{27,31} The incidence is undoubtedly lower in infants. Two proposed explanations for the low incidence are that (1) infants may not be exposed to the dangerous mechanisms that cause these injuries, or (2) infants with injuries to the upper cervical spine have lethal injuries that are never specifically identified, at least not in the ED.²⁷ There are few studies addressing infants with cervical spine injuries. Infants involved in a high-risk mechanism of injury should undergo a careful physical examination. Diagnostic imaging of the cervical spine should be obtained in the presence of cervical spine tenderness, crepitus or bony step-off, or altered mental status, or in patients with focal motor deficit or paralysis of an extremity. The assessment of tenderness is often impossible in infants. The choice of imaging study is controversial. Initially, a radiograph with anterior-posterior and lateral views is generally recommended. These radiographs will generally allow adequate visualization of the entire cervical spine.¹⁸ The utility of the odontoid view radiograph in the presence of a normal lateral view is questionable and can be technically challenging in infants. A study of pediatric radiologists' practice in using the open-mouth odontoid view in young children found significant variability in its perceived utility.³² If the plain radiographs are negative, an infant suspected of having a cervical spine injury should undergo MRI of the spine. MRI is sensitive for detecting ligament disruptions, and can define the extent of the any clinically significant spinal cord injury. MRI is also useful in the obtunded, intubated infant.³³ A CT scan of the cervical spine can be used to delineate and clarify anomalies detected on the plain film; however, CT scanning does not allow for imaging of the spinal cord. Clinical experience suggests that the traumatized infant who is awake, moving all extremities, easily consoled, and without neck pain or other major injury may be clinically cleared from cervical spine immobilization.

Indications for imaging the chest and extremities of the traumatized infant are similar to those for older children (see Chapter 12, Approach to Multisystem Trauma; Chapter 19, Upper Extremity Trauma; Chapter 20, Lower Extremity Trauma; and Chapter 24, Thoracic Trauma).

Infants who present to the emergency department with suspected abdominal trauma might have external bruising, abdominal distention, or tenderness on palpation. In the past, the hemodynamically unstable infant with abdominal trauma was taken directly to surgery, whereas the hemodynamically stable patient underwent laboratory evaluation and CT scan. The introduction of the "focused abdominal sonography for trauma" (FAST) scan to emergency medicine has altered how adults with blunt abdominal trauma are approached and managed. Using a portable ultrasound machine, the FAST scan quickly detects fluid in the abdomen, pelvis, or pericardium. It is gaining worldwide acceptance as an efficient screening tool. A positive scan in a hemodynamically unstable adult indicates the need for a laparotomy. The role of the FAST scan in pediatrics is currently being investigated.³⁴ The advantages to FAST scanning are the availability at the bedside, speed, low cost, and avoidance of exposure to ionizing radiation. CT scanning, in contrast, can be time consuming and expensive, may require sedation, and exposes

the infant to ionizing radiation.³³ An advantage of the CT scan, however, is that it provides an accurate diagnosis of parenchymal and retroperitoneal injuries, whereas sonography is poor at identifying organ-specific injuries or injuries that do not produce free fluid (i.e., blood) in the abdominal cavity. Since most cases of pediatric abdominal organ injury are now managed nonoperatively, this may be a serious limitation to the use of FAST scanning in the evaluation of traumatized infants.²⁶

Management

The management of traumatized infants should proceed efficiently. The bimodal distribution of injury severity should be kept in mind, necessitating early and aggressive treatment for clearly injured patients and a conservative approach to those who appear well. Because infants have a small blood volume and limited pulmonary reserve, they can progress rapidly to uncompensated shock and death (see Chapter 8, Circulatory Emergencies: Shock).

Securing the airway is the principal goal in the management of traumatized infants. Indications for intubation include unstable vital signs, respiratory distress, shock, and signs of significant head injury. In the obtunded infant with significant injury, head trauma should be presumed and rapid sequence intubation performed (see Chapter 3, Rapid Sequence Intubation). The use of lidocaine to decrease the risk of elevating the intracranial pressure during intubation^{35,36} and atropine to avoid bradycardia³⁷ are both controversial. Due to the shortened length of the infant trachea, it is easy for the endotracheal tube to enter the right mainstem bronchus. If a postintubation chest radiograph shows a whiteout of the left hemithorax in the setting of a right mainstem intubation, the first consideration should be a right mainstem intubation and not massive hemothorax. A trial of pulling the endotracheal tube back into an appropriate position may resolve the radiographic whiteout and minimize iatrogenic trauma.

Fluid resuscitation requirements are based on the physical examination findings. The presence of poor perfusion and tachycardia indicates the need for fluid resuscitation. An intravenous or intraosseous bolus of 20 ml/kg crystalloid (e.g., normal saline) is the most readily available and appropriate initial management option. Re-evaluation after the initial fluid bolus can guide further management decisions. In the hemodynamically unstable patient, the need for colloid or blood products should be anticipated early to allow the blood bank adequate preparation time. Vascular access in the volume-depleted infant can be very challenging. Oftentimes an intraosseous needle is the most practical and efficient early option (see Chapter 161, Vascular Access).

Infants are prone to becoming hypothermic due to their relatively large body surface area. Replacing wet linens with warm blankets will assist in stabilization and assessment. Use of warming lights and warmed intravenous fluids may also be beneficial. Oftentimes a cold, crying, tachycardic infant with poor capillary refill will improve with these basic interventions. Infants also have relatively small glycogen stores and are prone to develop hypoglycemia when stressed and kept *nil per os* (NPO) (see Chapter 106, Hypoglycemia). Blood sugars should be frequently monitored and hypoglycemia should be treated promptly.

The pliable chest wall in infants makes rib fractures less common than pulmonary contusion, and also makes signs of external trauma unreliable in predicting deeper injury. On chest radiograph, pulmonary contusions can appear as scattered patchy infiltrates or a complete whiteout of the involved lung. Management requires early endotracheal intubation and application of sufficient positive end-expiratory pressure to open the alveoli. A pulmonary contusion that appears as a whiteout of one side of the chest must be differentiated from a hemothorax. However, pulmonary contusions are much more common than hemothoraces. Yet, when complete unilateral whiteout is seen, tube thoracostomy may be indicated (see Chapter 168, Thoracostomy Tube). A gentle approach, to avoid placing the thoracostomy tube directly into the injured lung parenchyma, is prudent.

Summary

Accidental injuries in infants most often result from falls, scald burns, falling objects, or motor vehicle accidents. Fortunately, these injuries are seldom severe. Primary preventative interventions have had a positive influence on the epidemiology of accidental infant trauma as evidenced by a decrease in the frequency and severity of injuries. Research into preventative measures has been successful in the past (e.g., car seats) and offers an excellent opportunity for the improvement in the health of infants.

The pronounced physiologic differences between adults and infants alter how injuries are managed in the ED. Trauma guidelines and protocols developed for management of adult trauma (i.e., the Advanced Trauma Life Support course) may not be applicable to the care of the injured infant. Research directed toward development of a tailored approach to the injured infant should include recognition of injuries, stabilization, appropriate diagnostic testing and treatment, and techniques for proper sedation and analgesia. Infants with major injuries will benefit from admission or transfer to a pediatric intensive care unit.

Chapter 16

Oral, Ocular, and Maxillofacial Trauma

Ran D. Goldman, MD and Steven G. Rothrock, MD

Key Points

Nasal bone and mandibular fractures are the most common facial fractures in children, while midface and Le Fort fractures are uncommon.

Head and face injuries occur in most infants and children who are abused.

Computed tomography scanning is the radiologic test of choice for most facial injuries in children.

Facial fractures that do not result in functional (e.g., limited eye movements, visual changes, malocclusion) or cosmetic problems are seldom serious.

Introduction and Background

The etiology of facial injury depends mostly on a child's age. In a large series from Austria, the main causes of facial trauma in children less than 15 years old were play (58%) and sports (32%). Half of all children had soft tissue injuries, and three quarters had dentoalveolar injuries.¹ Facial fractures only occur in a minority of children with facial injury and are most commonly due to motor vehicle accidents.²⁻⁴ Other important fracture causes include falls, sports injuries, bicycle/motorcycle accidents, and assaults.²⁻⁴ One easily overlooked mechanism is abuse, with facial bruising or abrasions occurring in the majority of abused infants and children.⁵ Boys have a 1.5- to 3-fold greater risk of facial injury compared to girls.^{1,3,4,6,7} In addition, the risk of facial fracture occurring with facial trauma rises with increasing age. While 5% to 15% of all facial fractures occur in children less than 16 years old, fewer than 1% occur in those less than 5 years old.⁸⁻¹²

While nasal bone fractures are the most common pediatric facial fracture, the most frequent fracture site in admitted patients is the mandible (Fig. 16-1), followed by the zygomatic arch and alveolar ridge.^{3,4} Less common fracture sites

include the orbital floor, the hard palate, and rarely the midface (Le Fort fractures). Importantly, Le Fort fractures almost never occur in children under 10 years old. Associated injuries occur in most children with facial trauma, including intracranial, spine, eye, dental, and nerve injuries. For those children with serious injury mechanisms, thoracoabdominal and orthopedic injuries must be excluded.

Recognition and Approach

While children under 7 years old are at risk for soft tissue injury, fractures are uncommon at this age.¹³ Eighty percent of cranial growth occurs during the first years of life. After age 2, the face begins to grow faster than the skull. In a newborn infant, the ratio of cranial volume to facial volume is 8 : 1, while in adults this ratio is 2 : 1.¹³ Therefore, trauma is more likely to impact the skull and forehead and less likely to injure midfacial structures in young children. This disproportionate growth results in more frequent orbital roof (cranial floor) fractures in infants and more frequent associated neurologic trauma. In contrast, lower orbital fractures generally occur after age 7, have less associated intracranial injury, and more often require surgical reconstruction.¹³ Other protective features of a young child's face include underdeveloped paranasal sinuses, increased number of facial fat pads, unerupted dentition that strengthens the maxilla and mandible, and relatively flexible bone. In contrast to young children, adolescents have higher rates of facial trauma due to a mature facial skeleton and more adult activity profile.

Clinicians must be able to recognize the location of important structures when confronted with children with facial trauma (Fig. 16-2). The major portions of the facial nerve are posterior to a vertical line perpendicular to the lateral canthus.¹⁴ Facial nerve injuries anterior to this line only require repair if they involve solitary terminal branches (i.e., marginal mandibular branch, frontal branch).¹⁴ The parotid gland lies anterior to the sternomastoid and external auditory meatus and inferior to the posterior two thirds of the zygomatic arch. Stensen's duct exits the parotid and traverses along the middle third of a line drawn from the tragus to the midportion of the upper lip. This duct opens into the mouth opposite the secondary maxillary molar. The buccal branch

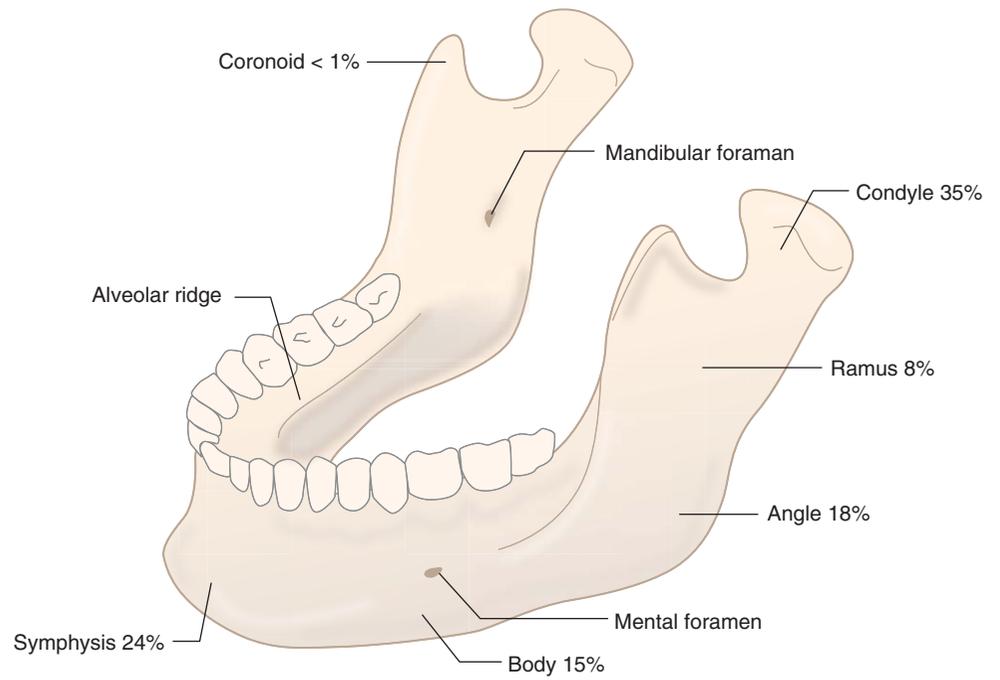

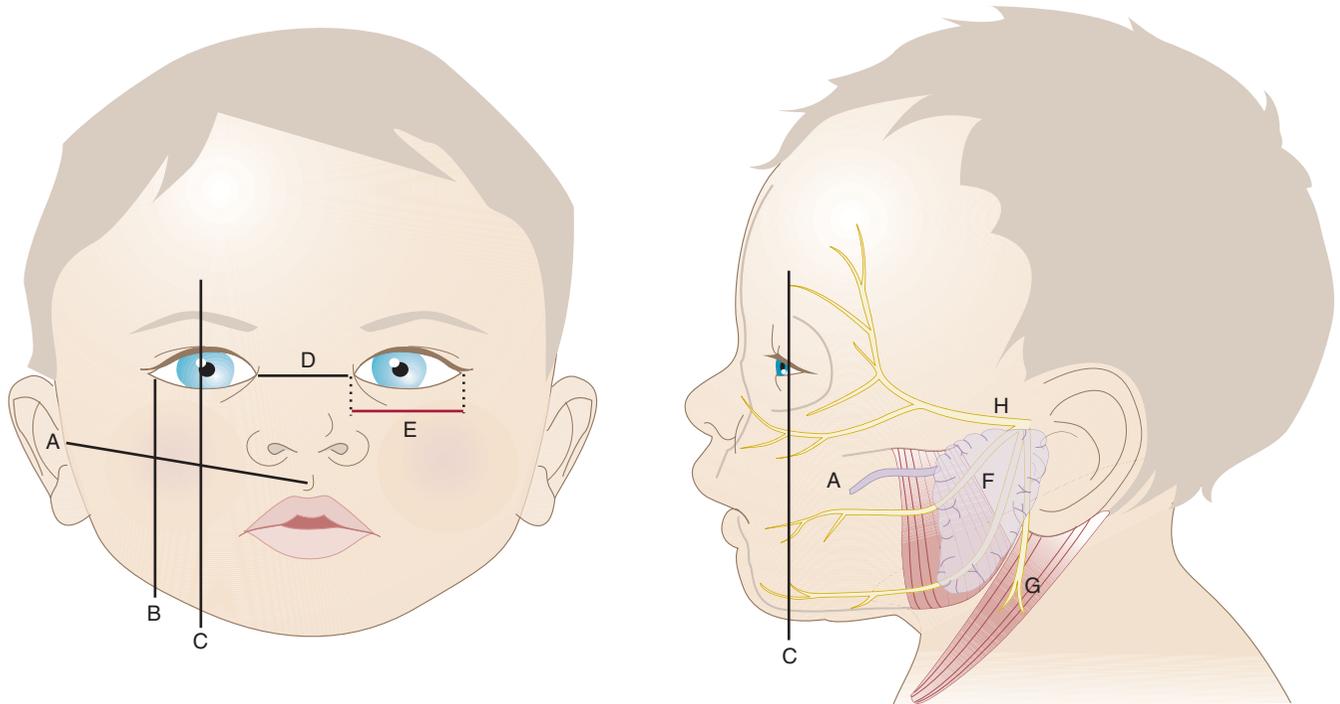

FIGURE 16-1. Most common location of mandibular fractures in children.

A

B

FIGURE 16-2. The parotid duct (A) traverses the middle third of a line connecting the tragus to the middle of the upper lip. Repair of facial nerve branches beyond a vertical line (B) originating at the lateral canthus is usually not required. Trigeminal nerve branches exit the face at foramina located along this line (C) (vertical line through pupil), including the supraorbital branch of the ophthalmic nerve (V1), the infraorbital branch of the maxillary nerve (V2), and the mental nerve (branches of the trigeminal nerve) (V3). The distance between the medial canthi of each eye (D) should be no greater than the size of the palpebral fissure (red line) (E). The parotid gland (F) lies below the zygomatic arch and anterior to the sternomastoid muscle (G). Major branches of the facial nerve (H) run through the parotid gland.

of the facial nerve traverses the midportion of Stensen's duct, and injuries of the duct and nerve often coexist.

Evaluation

History

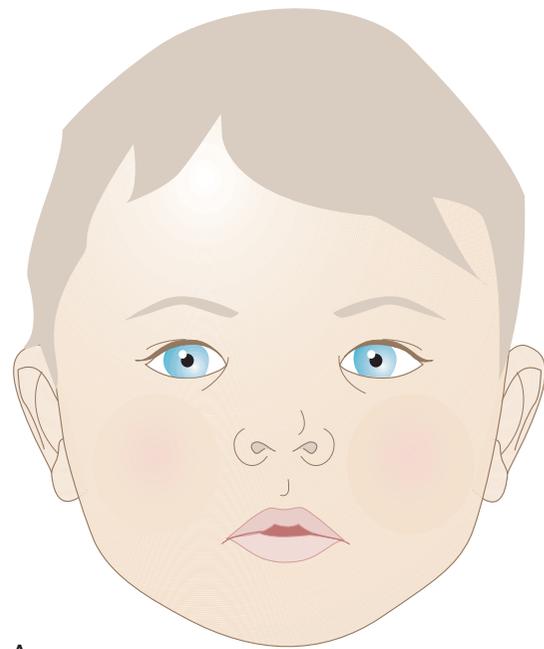

Initially, the clinician should exclude life-threatening injury (e.g., inadequate airway, blood loss), immobilize the cervical spine, provide suctioning, and administer oxygen if needed. Patients should be asked if they are having difficulty breathing, or if they have bleeding into the mouth or pharynx. When time permits, the mechanism and forces that caused the injury should be determined. Patients should be asked if they have vision loss, monocular diplopia, or eye pain, which may suggest ocular or orbital trauma. Binocular diplopia suggests orbital trauma or extraocular muscle or nerve injury. Facial numbness may occur with trauma to the branches of the trigeminal nerve, fractures, or swelling and trauma near their respective foramina. Hearing loss may be due to temporal bone fracture or direct ear trauma. Malocclusion and difficulty opening or closing the mouth can occur with mandibular or zygomatic trauma.

Physical Examination

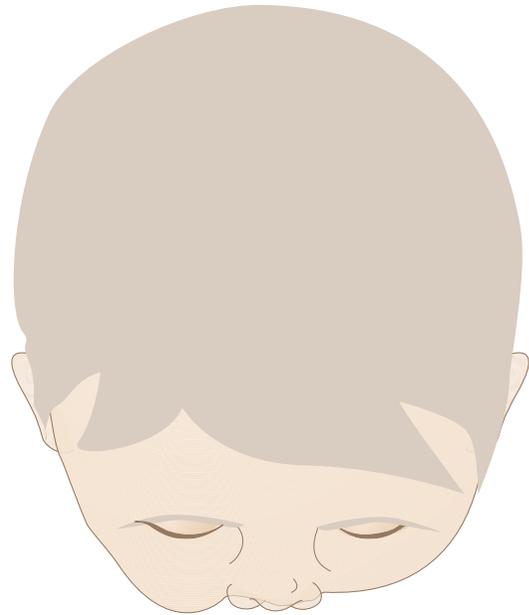

Prior to examination, the clinician should ensure that appropriate lighting and tools are present, including a headlamp or mirror, tongue blades, a suction device, a nasal speculum, an otoscope, and an ophthalmoscope. The examination should begin with a visual inspection of the face and skull from all angles, paying attention to sites of asymmetry, bruising, and swelling. Lacerations or blunt trauma that involves specific landmarks may indicate damage to the lacrimal duct, parotid duct, or cranial nerves (see Fig. 16–2). A bird's-eye view (looking down from above) may reveal asymmetric malar eminences with zygomatic fractures, or enophthalmos or exophthalmos with orbital trauma (Fig. 16–3). The inside of the nose is examined for septal hematomas, and the inside of the mouth for bleeding, deformity, or hematoma suggesting fracture. If there is bleeding around a tooth near a mandible fracture, it must be assumed that the fracture is open. A sublingual hematoma is common with mandibular fractures. The insides of the ears are examined for bleeding, fluid leak, lacerations, or a purplish tympanic membrane consistent with temporal bone or basilar skull fracture.

The face and cranium are palpated to detect areas of tenderness, bony irregularities, or crepitus. Mobility of the midface may be tested by grasping the anterior alveolar arch and pulling forward. Malocclusion or trismus can be assessed by having the patient open and close the mouth while palpating the mandibular condyles by placing a finger within or just below the external auditory canal. Cooperative patients can be asked to bite down on a tongue blade. In adolescents and adults, the inability to break the blade when it is twisted is 95% sensitive for mandibular fractures.¹⁵ The patient should be asked to smile, frown, raise the eyebrows, and open and close the eyes tightly to assess facial nerve integrity. Sensation to terminal trigeminal nerve branches should be tested (see Fig. 16–2).

A thorough eye examination is required in all infants and children with facial trauma. The eyelids should be inspected

A

B

FIGURE 16–3. A, Normal appearance to facial contour looking anteriorly at face. B, Bird's-eye view of the face demonstrating swelling of the right malar eminence.

for lacerations that involve the tarsal plate, either the canthus or potentially the lacrimal duct. If the distance between the medial canthi is greater than the horizontal width of an orbit (or 35 to 40 mm in a child > 5 years old), *telecanthus* is present and a midfacial fracture is likely. Extraocular muscles are tested for entrapment (e.g., limited upward gaze with orbital blowout fracture). Visual acuities should be obtained in older, cooperative children. The clinician should assess pupil size, test direct and indirect pupillary reaction to light,

and directly examine the cornea. Fluorescein administration and slit-lamp examination may be required.

Lack of cooperation, anxiety, pain, and limited communication skills can interfere with proper evaluation of infants and children with facial injuries. Appropriate analgesia and sedation should be administered depending upon the patient's airway, associated injuries, and medical condition (see Chapter 159, Procedural Sedation and Analgesia).

An integral part of evaluating infants and children with facial trauma includes a head-to-toe examination for nonfacial injuries.¹⁶ Associated injuries are present in up to 87% of children facial fractures.³ In addition, early photographs may be helpful in preoperative planning and patient counseling, as well as for prospective medicolegal matters.

Radiology

With the exception of a Panorex view, plain radiography usually provides limited diagnostic information to the clinical examination and limited information regarding facial fractures in children.³ Nearly half of all significant facial fractures in children are missed by plain radiography.³ For this reason, children with suspected facial bone injury usually require a computed tomography (CT) scan of the face. Typically, facial CT consists of 3-mm slices taken in the axial plane with both axial and coronal reconstruction.^{10,17} Three-dimensional reconstruction can provide even more detail regarding fractures. One quick clue to the presence of a midface fracture is the presence of fluid within the paranasal sinuses. In adults, nearly 100% of all midface fractures (excluding nasal, and zygomatic fractures) have associated paranasal sinus fluid.¹⁸ A panoramic view (*Panorex*) of the mandible can display upper and lower teeth and the mandibular condyles; however, full cooperation of the injured child is needed and an upright posture must be maintained. Supplemental oblique mandible views (*mandible series*) can be used to evaluate the mandibular condyles and rami. A *Towne's view* (anterior-posterior view 35 degrees caudad) can be helpful for zygoma and mandibular rami fractures. Other views, including the *Waters'* (occipitomental), *submentoverte*x (jug-handle), and *Caldwell's* (posterior-anterior) views, have largely been supplanted by facial CT due to its superior accuracy at identifying facial fractures.

Clinical features suggestive of the need for facial CT have been identified in adults and can be recognized by the mnemonic LIPS-N, which stand for lip laceration, intraoral laceration, periorbital contusion, subconjunctival bleeding, and nasal laceration.¹⁹ Others have identified the following features in 96% of all orbital fractures and 98% of all orbital fractures requiring surgery: blepharohematoma, subcutaneous emphysema, a palpable deformity or gap, infraorbital anesthesia, enophthalmos, exophthalmos, abnormal ocular motility, diplopia, abnormal papillary reaction, or vision problems.²⁰ It is uncertain if the mnemonic LIPS-N or other identified features in adults are equally sensitive in identifying fractures in children. Children who require head CT are another population who are at high risk for facial fractures. Ten percent to 12% of patients requiring a head CT will have a facial fracture.^{4,19,21} In the subset of patients with severe head injury (i.e., those who are intubated), up to 29% will have facial fractures; many of which are unsuspected.²²

Management

Initial Management

Management of any child with facial injury initially begins with assessment of airway patency. Accompanying head injury may lead to apnea and decreased airway tone with obstruction. Contrary to popular belief, airway obstruction in patients with an altered mental status is more likely due to hypotonia with collapse of the hypopharynx, soft palate, and epiglottis and not obstruction by the tongue.²³⁻²⁵ For this reason, airway maneuvers that move the tongue anteriorly (e.g., chin lift, jaw thrust) are not always successful at opening an obstructed airway. For the same reason, use of an oral airway in obstructed patients may be unsuccessful and oral intubation may be required at an early stage. Clinicians must realize that sedation and paralysis may be extremely difficult in patients with significant mandible or maxillary fractures. Blood and secretions should be gently suctioned from the mouth, and foreign bodies such as teeth or bone fragments identified and removed. Intubation in cases of distorted anatomy might be necessary as a preventive measure and should not be delayed. Before intubation, a team experienced in difficult airway management and all the necessary equipment must be at the bedside (see Chapter 3, Rapid Sequence Intubation; and Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts). Warning signs such as stridor, drooling, active bleeding, or hematoma on the face or neck indicate immediate or impending airway compromise and mandate intubation.

Cervical spine stabilization is crucial for children with facial injury, in order to prevent further damage to cervical structures affected by the trauma. A head-to-toe evaluation is required to exclude other life-threatening injuries (see Chapter 12, Approach to Multisystem Trauma).

Maxillofacial Fractures

Mandibular Fractures

Mandibular fractures are the most common facial fractures found in hospitalized children.²⁶ The mandible includes the condyle, ramus, body, angle, and arch (symphysis and parasymphysis) (see Fig. 16-1). Fractures of the mandible are relatively common compared to other bones in the face, mostly due to transferred force through the overlying fat tissue. Condylar fractures, in particular, are common since the condyles are heavily vascularized and thin in children.²⁶

Most mandibular fractures with normal occlusion and movement are usually treated with a soft diet and movement exercise. Most condylar, body, and angle fractures fall within this category and are treated conservatively. If malocclusion or movement limitations are present or an open fracture is present, immobilization is required via surgery, or splinting.

Midface and Maxillary Fractures

Maxillary fractures are infrequent in young children and occur primarily in children ≥ 10 years old.^{1,4} The Le Fort classification used to classify maxillary fractures in adolescents and adults is based on the horizontal level of the fracture. Le Fort I fractures result in separation of the maxilla from the palate. These fractures may result from a force on the maxillary alveolar rim in a descending direction. Le Fort

II fractures result in separation of the cranium from the midface. Le Fort III is the most severe fracture and results in complete separation of the facial bones from the cranium. Displaced midface fractures require open reduction and rigid internal fixation.²⁶

Nasoethmoid Fractures

Nasoethmoid fractures occur when there is disruption at the nasofrontal suture, nasal bones, medial orbital rim, and infraorbital rim. If all four sides are involved, a central fragment may exist. Surgery will be required if telecanthus is present, or there is disruption of bony or soft tissue support for the eye.^{13,26}

Nasal fractures are the most common facial bone injury in children. The younger the child, the lower the risk of nasal fracture since the cartilaginous part of the nose is larger and more elastic. Clinical interpretation of a nasal fracture is usually difficult in the emergency department (ED) due to swelling and hematoma in the area as a result of the injury. It may be necessary to wait a few days to determine if a fracture actually occurred.

Nasal radiographs are usually not necessary in the ED unless ordered for parental reassurance.²⁷ Radiographs are nonspecific, and even if a fracture is suspected, they do not alter subsequent management.

High vascularity of the nose cause significant bleeding even after minor soft tissue injury. Septal hematoma is one of the known complications after such bleeding, and is an indication for immediate evacuation. Unilateral nasal obstruction is common in septal hematoma, and rhinoscopy will show a bulging mass (usually purple) in one nostril. Evacuation of septal hematoma will relieve pain due to pressure in the area, and will also prevent septal deformity. Infection in the area is also possible. Once the hematoma is drained, oral antibiotics should be administered.

Zygomaxillary Complex Fractures

Zygomaxillary complex fractures are uncommon under the age of 5 years, before the maxillary sinus becomes aerated. Low-impact injuries often result in greenstick fractures, which are usually nondisplaced and often require no treatment. Open reduction and internal fixation is required for displaced, comminuted, or unstable fractures. Functional deficits (e.g., diplopia, or infraorbital sensory loss) also often require surgery.²⁶

Frontal Bone/Sinus Fractures

The frontal sinus becomes developed by age 6 to 8 years. Before this age, frontal sinus fractures are uncommon. Anterior sinus table fractures that are not displaced can be observed, with most experts administering antibiotics since the fracture connects to a sinus. Because displaced anterior fractures are associated with mucocele formation, nasofrontal duct obstruction, and cosmetic deformity, surgical repair is generally required. Posterior wall fractures should be treated as an open skull fracture with the potential for associated cerebrospinal fluid leak. Neurosurgical consultation is required.

Orbital Trauma

Childhood is the most common period for serious eye injuries throughout life,^{28,29} with the majority of injuries occur-

ring in boys. Ocular trauma is the leading cause of noncongenital unilateral blindness in children under 20 years old and the foremost cause for enucleation of the eye in children, especially in boys.³⁰ Most major eye trauma in children occurs during sports activities because proportionally more children and adolescents participate in high-risk activities. Basketball, baseball, racquet sports, martial arts, wrestling, and archery are the most frequent cause of injury. BB and pellet guns also present an extreme hazard to children.

Understanding the mechanism of injury is important for planning management better. Clinicians must determine if there is blunt or sharp object injury, if a foreign body is present in the eye, and if protected devices were used. As assessment of pain, photophobia, eye movements (diplopia), and visual acuity will aid in determining the nature of the injury. Visual acuity examination is the most important part of the physical examination and should be separately performed for each eye. Finger counting, the “E” chart, and a numeric chart can be used for examination of the injured child. If needed, a topical anesthetic (such as tetracaine or proparacaine) should be administered to ensure adequate examination.

During examination of the eyes and orbit, the emergency physician should examine the integrity of the orbital rims, orbital floor, vision, extraocular motion, position of the globe, and intercanthal distance. A complaint of diplopia or limited extraocular movements on examination is usually the result of entrapment and dysfunction of extraocular muscles with associated orbital floor blowout fractures. Cranial nerve palsy from associated head injury can also result in headache and diplopia. With globe or scleral rupture, severe external disruption of the eye is not always evident. With rupture, the iris or choroids will extend toward the wound, resulting in a dark (blue or black) spot on the sclera (Fig. 16-4). The pupil may take a dysmorphic or teardrop shape.

Pupils are usually examined as part of the neurologic evaluation in the primary survey. However, they should be examined carefully in any suspected injury. The clinician should assess size, shape, and direct plus indirect reaction to light.

While anisocoria could be a normal phenomenon in a small percentage of the population, this finding may indicate

FIGURE 16-4. Scleral rupture with extruded uvea, which appears brown-black.

a possible injury to the third cranial nerve or increased intraocular pressure (IOP). A combination of ptosis, miosis, and anhidrosis, known as Horner's syndrome, suggests a lesion of the sympathetic pathway.

In the ED, direct ophthalmoscopy and slit-lamp examination may be required to evaluate the cornea, anterior and posterior chambers, and retina. Measurement of IOP is contraindicated in suspected globe rupture, but may help to identify retrobulbar hemorrhage causing increased IOP. Except for cases of large radiopaque foreign bodies, plain radiography of the ocular system is usually unhelpful. For sites with expertise, ultrasonography can be used to identify ocular foreign bodies, retinal detachment, vitreous hemorrhage, and globe rupture.³¹ For most other sites, CT with thin slices (1 to 1.5 mm) in the canthal-meatal plane, with sagittal and coronal reconstruction, is used for identification of potential intraocular injuries.³² Orbital CT is 75% sensitive and 93% specific for identifying globe rupture.³³ CT is also accurate at identifying ocular foreign bodies.³² Helical CT can detect all steel and copper foreign bodies larger than 1 mm³ and most glass foreign bodies larger than 2 mm³.³⁴ Wood and plastic can be difficult to visualize using typical bone and soft tissue CT windows since wood may be isodense with air and fat. To identify wooden foreign bodies, the CT window should be adjusted to allow visualization of soft tissue contrast and show an attenuation difference between the wood and surrounding tissue, or the alternating density pattern of the grain of the wood. Alternately, magnetic resonance imaging can be used to identify wood or plastic foreign bodies once metallic foreign bodies have been excluded.

Orbital Fractures

Following blunt compressive eye trauma, the eyeball may be pushed posteriorly and induce pressure that causes “blowout” of one or more bones of the orbital wall. Unlike adults, children are particularly susceptible to pure orbital fractures, usually of the “trapdoor” type.³⁵ Most of the orbital floor is immature in childhood, and this elasticity makes the orbital bones more susceptible to fractures when pushed against external force. The fracture is usually linear along the obliquely situated infraorbital canal, resulting in trapping of muscles. These fractures occur when a circular segment of the bony orbit fractures and becomes displaced, but remains attached on one side. Afterward, orbital contents can herniate through the fractured site, with entrapment of the herniated contents.³⁶

Blowout fractures of the orbital wall are usually diagnosed clinically after observation of asymmetric and restricted eyeball movement. Trapping of the intraocular muscle prevents movement of the eye away from the fracture site. While orbital hemorrhage is a differential diagnosis in this clinical scenario, lack of normal range of motion should raise a high suspicion of orbital fracture in an injured child. Due to the disrupted wall, the eyeball might fall back into the fracture, and the eye will also look sunken.

Orbital roof fracture occurs mostly in children under 5 years, because of a proportionally larger cranium and the lack of frontal sinus pneumatization, while orbital floor fractures occur later in childhood, after facial growth and the pneumatization of the paranasal sinuses. *Orbital roof* fractures are particularly hazardous because of the possible communication between the orbit and the intracranial cavity.

Pulsating proptosis could serve as a clue to the presence of such a fracture. A history of a blow to the brow in conjunction with late periorbital ecchymosis may be an important clue to the injury. *Orbital floor* fractures are less common but could cause partial or complete injury to the infraorbital nerve, causing ipsilateral numbness of the malar region. This is usually a transient phenomenon. Periorbital ecchymosis, lid edema, subconjunctival hemorrhage, and diplopia are the most common presenting signs. Most patients have a severe limitation of ocular movement caused by direct entrapment of the inferior rectus muscle into the fracture site, and many patients, especially those with muscle entrapment, will suffer extreme pain with eye movements and will present with nausea and vomiting.³⁷

Ophthalmologic consultation is important in cases of suspected orbital wall fracture since in some cases an intraorbital injury is accompanied by other skeletal fractures. CT scan is the radiologic test of choice for children with suspected orbital bony injury, and both axial and coronal views are necessary.³⁸

The emergency physician should always consider the possibility of child abuse³⁰ in cases of orbital fracture in young children. The ED staff also has a role in teaching the young patient and the family how to effectively protect the eye from trauma, especially due to foreign bodies. The use of protective eyewear during activities associated with ocular trauma, such as sports, is of great importance.

Ruptured Globe

A rupture of the globe is rare and can occur after significant laceration of the cornea or sclera due to sharp objects or blunt trauma. The limbus (beneath the insertions of the rectus muscle) and the equator of the globe are the weakest areas of the sclera and most prone to rupture following blunt trauma. Visual loss, bloody chemosis (especially localized), a soft globe, and an abnormally deep anterior chamber are seen with rupture. The uvea may appear as a dark mass prolapsing through the ruptured site (see Fig. 16–4). Associated hyphema, lens dislocation, and vitreous hemorrhage also may occur.

When a rupture is suspected, a protective shield should be placed over the eye. Broad-spectrum intravenous antibiotics effective against skin flora (*Streptococcus* and *Staphylococcus aureus/epidermidis*) and tetanus prophylaxis should be administered, as well as analgesics and sedatives if needed. Antiemetics may be required to diminish increased IOP from vomiting. For children requiring intubation, debate exists as to the appropriate use of muscle relaxants. Succinylcholine can increase IOP by an average of 9 mm Hg following administration. However, these effects can be blunted by multiple medications (see Chapter 3, Rapid Sequence Intubation). Moreover, rare ocular injury following use of succinylcholine has primarily been reported in patients receiving light or inadequate sedation.³⁹ For this reason, some experts still recommend use of succinylcholine for patients at risk for a difficult airway due to its fast onset and short duration, as long as efforts are made to attenuate its IOP effects.³⁹ For all other patients, non-depolarizing muscle relaxants are recommended.³⁹ Following patient stabilization, immediate pediatric ophthalmologist consultation is required if scleral rupture is suspected since damage to the posterior segment of the eye can cause permanent visual loss.

Retrobulbar Hemorrhage

Retrobulbar hemorrhage can lead to rapid compression of the optic nerve and irreversible vision loss. Patients usually have severe blunt trauma, proptosis, vision loss with afferent pupillary defect, chemosis, and increased IOP. CT is often diagnostic. Treatment consists of a lateral canthotomy with lysis of the inferior lateral canthal tendon. Depending upon the availability of backup, severity of vision loss, and IOP, this procedure may need to be performed in the ED. This allows the orbital contents to move forward, releasing pressure on the optic nerve.

Optic Nerve Injury

The optic nerve is divided into a small intraocular portion and a long mobile intraorbital portion, and intracanalicular (within the bony canal) and intracranial segments. Fractures within the bony canal may occur with severe head or midface injury, with transection of the optic nerve. Alternately, shearing, compression, or tearing of arterioles along the course of the nerve from blunt trauma may disrupt the arterial supply. Depending upon the cause of trauma, the eye may have a normal appearance. Visual loss may be severe or complete, and an afferent pupillary defect may be present. Funduscopic examination may be normal, with eventual development of pallor. Orbital CT can identify the site of trauma. Surgical decompression may be necessary with disruption of the intracanalicular optic nerve, while the use of high-dose steroids is controversial for these injuries.

Posterior Eye Injuries (Vitreous and Retinal Trauma)

While the posterior segments of the eye are not involved in eye trauma as often as anterior structures, these injuries are more likely to result in permanent visual loss. The retina or vitreous is involved in half of all severe open and closed globe injuries.⁴⁰

Retinal detachment can occur from blunt trauma deforming the eye with peripheral tears, while penetrating trauma can result in direct localized tears or rupture. While retinal detachments do not cause pain, associated ocular trauma may be painful. Symptoms of detachment include floaters due to bleeding, flashing lights, and variably decreased visual acuity depending upon the location of the detachment and amount of bleeding. Patients may complain of a curtain coming down, up, or across their visual field. The anterior segment is usually normal, while the red reflex may be absent with a hazy or gray appearance to the retina, on funduscopic examination. Importantly, direct ophthalmoscopy may not reveal the site of detachment. If an optic nerve injury or significant retinal detachment is present, an afferent pupillary defect may be present.⁴⁰

Isolated vitreous hemorrhage or detachment can produce symptoms similar to retinal detachment. However, an afferent pupillary defect will not be present. Ophthalmologic consultation is required to exclude or treat associated retinal and optic nerve trauma.⁴⁰

Iris and Ciliary Trauma

Traumatic iridocyclitis can occur from blunt trauma with contusion, causing inflammation of the iris and ciliary body with resulting ciliary spasm. Children complain of photo-

phobia, redness, and pain with onset often delayed until 1 to 3 days after the injury. The pupil is usually constricted (*traumatic miosis*). However, if the sphincter is torn or injured, *traumatic mydriasis* or an irregular or scalloped pupil margin may be present. In iritis, slit-lamp examination will reveal flare and cells. Initially, the IOP may be low or normal. Treatment consists of a cycloplegic to relax the iris and ciliary body (e.g., homatropine) and pain medications.

If the iris root is separated from the ciliary body, *iridodiolysis* is present. This results in the iris bowing toward the pupil. A coexisting hyphema is often present. Patients may complain of glare, photophobia, and monocular diplopia. A double-pupil appearance to the pupil may be present on examination. Initially, treatment is directed at managing the hyphema. Late surgical repair may be required for double vision, persistent glare, or cosmesis. While initial IOPs are often depressed, glaucoma often occurs in the ensuing 3 months.

Damage to the structures of the anterior chamber may impede drainage of aqueous humor from the eye and lead to *acute glaucoma*. Patients who present with eye pain following blunt trauma require measurement of IOP once rupture and cornea trauma have been excluded.

Lens Injury

Blunt lens trauma can lead to *cataract* formation. If the lens capsule is torn, swelling and opacification of the lens can occur.

Blunt injury to the lens also can disrupt the lens zonules that encircle the lens and anchor it to the ciliary body. The lens can fall partially (*subluxation*) or completely (*dislocation*) away. The edge of the lens may be at the pupillary border, or the entire lens may be dislocated into the anterior or posterior chamber. Patients may complain of visual blurring or monocular diplopia. *Iridodonesis* or trembling of the iris may be seen following rapid eye movements if the lens is dislocated. If the lens is trapped within the pupil or touching the cornea (anterior dislocation), acute glaucoma may occur and emergency surgery is required. Isolated posterior dislocations do not require emergency surgery.

Hyphema

A hyphema refers to accumulation of blood in the anterior chamber of the eye. The blood may be layered inferiorly or may be spread diffusely throughout the anterior chamber. Blood is normally caused by a tear in the iris root and bleeding from arterioles supplying the iris. Complications occur from obstruction of the outflow of the anterior chamber, with resulting inflammation and increased IOP. Patients with sickle cell disease or trait, those with thalassemia, or those taking anticoagulants are at risk for central retinal artery and optic nerve damage from less than severe elevations in IOP. Patients are at risk for rebleeding 3 to 5 days after the initial injury due to clot lysis and retraction.

Management should be coordinated with an ophthalmologist. Initial treatment consists of supportive care, with initial bed rest and elevation of the head of the bed 30 degrees and application of a protective barrier. Patients with large hyphemas (i.e., > 50% of the anterior chamber) may benefit from admission. Patients should avoid aspirin and nonsteroidal anti-inflammatory medications. Topical anticholinergics are

administered to stabilize the blood-aqueous barrier and improve symptoms from associated iritis. Topical steroids are also administered. Patients at high risk for rebleeding are treated with oral steroids. Oral aminocaproic acid is administered to enhance clot lysis. Initially, IOP elevations may be treated with topical β -blockers, α -agonists, or carbonic anhydrase inhibitors. Surgery is indicated for persistent elevation of IOP, corneal blood staining, or select patients with sickle cell disease or trait.⁴¹

Corneal Injuries

Corneal injuries are one of the most common reasons for pediatric visits to the emergency department with ophthalmologic complaints. Self-inflicted injuries from fingers, chemicals, or contact lenses are common, as are injuries inflicted by foreign bodies in the eye. Pain is a prominent complaint in patients with corneal injury. Corneal injury should be part of the assessment of the crying infant since irritability is a common presenting symptom in this age group. Excessive tearing, photophobia, and complaints of a foreign body sensation are common.

While changes in visual acuity are hard to assess due to pain, tearing and frequent blinking are easily noticed on examination. Visual acuity is part of the eye physical examination in children with suspected injury. However, normal visual acuity does not rule out corneal trauma. Examination with fluorescein should follow. The first step should be administration of a topical anesthetic such as tetracaine or proparacaine, followed by a drop of fluorescein from a wet sterile paper strip in the inferior fornix. Foreign body or abrasion can easily be seen under cobalt blue light as corneal lesions will fluoresce brightly.

Corneal Abrasion

Corneal abrasions are the most common eye injury in all ages and are especially common among older children who wear contact lenses. Although found in about 10% of visits with a chief complaint related to eye problem in EDs, the actual estimated incidence of corneal abrasions in children is not known.

Current management of corneal abrasion in children is based on treatment established in adults. Recommended therapy consists of eye patching, cycloplegic drops, and antibiotics. Cycloplegic drops prevent discomfort from ciliary spasm, and antibiotics are administered to prevent infection.⁴² In the past, patching was thought to facilitate healing and to relieve pain due to decreased shearing forces over the defect.⁴³ However, routine use of a patch has been questioned because it impairs binocular vision; obscures half of the visual field; may carry a risk for anaerobic infections, particularly in children using contact lenses; and does not improve the rate of healing.^{44,45} Although no clear evidence exists, many ophthalmologists prescribe a topical antibiotic (e.g., fluoroquinolone) for infection prophylaxis after corneal abrasion in children.

All children except those with a very mild corneal abrasion should have a slit-lamp examination. In all significant corneal injuries, examination by an ophthalmologist is desirable for management and further follow-up after discharge from the ED. Close follow-up care of children with corneal abrasions is necessary because of a possible progression of the abrasion to an ulcer.

Soft Tissue Injuries

Eyelid Lacerations

Eyelid lacerations are common in children with blunt and penetrating facial trauma. While relatively easy to detect externally, an underlying eye injury should always be suspected and skilled evaluation of the eye should take place before correction of the laceration. Ocular injury is assumed to be present in any full-thickness penetration of the eyelid. Importantly, visualization of fat from an eyelid injury indicates full-thickness injury with septal trauma and possible levator injury. The lids should be everted and the conjunctival surface examined in all eyelid injuries. If there is any suspicion that ocular penetration has occurred from penetrating trauma (e.g., pellets or BBs), an orbital CT should be obtained. Hyphema, orbital fractures, orbital penetration, and other ocular adnexal trauma often occurs with lid trauma. To test levator function, the position of the brow is fixed and the patient is asked to look up and down. If the canthal angles are rounded, medial or lateral canthus trauma is likely. With eyelid margin lacerations, there is often retraction of tissue due to orbicularis contraction, and the eyelid appears avulsed.⁴⁶ However, this tissue often stretches out to its normal size. Lacerations of the nasolacrimal duct puncta or medial to this site require probing of the canaliculus for possible injury. Sensation above the orbital rim should be tested to exclude supraorbital nerve injury.

Depending upon the child's age, anxiety level, and complexity of repair, eyelid lacerations may require moderate to deep sedation (see Chapter 159, Procedural Sedation and Analgesia). Simple partial-thickness lacerations may be repaired using 6-0 or 7-0 nylon sutures. However, plastic surgery or ophthalmology repair is required for full-thickness lacerations or those with a high potential for cosmetic deformity, canthal ligament involvement, lid margin involvement, lacrimal damage (e.g., medial lower eyelid), tissue avulsion, or levator involvement.

Ear Trauma

Blunt trauma to the external ear canal may result in hematoma, laceration to the auricle, cartilage trauma, and fractures of adjacent skull or facial bones. A subperichondrial hematoma may result from blunt trauma to the pinna. Failure to recognize and treat this condition early usually leads to a visual deformity. The pinna becomes a shapeless, reddish purple mass when blood collects between the perichondrium and the cartilage. Because the perichondrium carries the blood supply to the cartilage, avascular necrosis of the cartilage may occur. Organized, calcified hematoma may result in "cauliflower ear." Collection of blood or serous fluid between the perichondrium and cartilage may be successfully treated by needle aspiration under sterile conditions, followed by the application of a pressure dressing. If a hematoma recurs within 48 hours, formal incision and drainage are then required.

For lacerations of the pinna that penetrate the cartilage and skin on both sides, treatment is aimed at covering the exposed cartilage and minimizing deformity. Cartilage is avascular with a high risk of infection and minimal healing ability. Prior to any repair, devitalized tissue is removed. The cartilage is approximated with overlying perichondrium using 4-0 or 5-0 absorbable sutures. Next, the posterior skin

surface is closed with 5-0 nonabsorbable sutures. Then the anterior surface is closed with 5-0 or 6-0 nonabsorbable sutures with attention to joining landmarks and everting wound edges along the rim of the ear so that notching does not occur. Following repair, a compression dressing is applied to ensure a hematoma does not develop. Antibiotics should be administered to patients with devitalized or contaminated wounds. If there is not enough skin to cover cartilage (i.e., indicating a need for a skin flap) or if there is a high potential for deformity, plastic surgical consultation should be obtained.⁴⁷

Forceful blows to the mandible may be transmitted to the anterior wall of the ear canal (posterior wall of the glenoid fossa). Displaced fragments from a fractured anterior wall may cause stenosis of the canal and must be reduced or removed using a general anesthetic.

Abrasions and lacerations of the external auditory canal are common and may be caused either by the patient or iatrogenically while trying to remove wax. Eardrops containing antibiotics are usually effective in preventing an external otitis resulting from secondary infection. Aminoglycoside drops should be avoided in the presence of a tympanic membrane perforation.

Oral and Tongue Lacerations

Most inner lip and tongue lacerations do not require suturing. Importantly, lacerations that penetrate the oral mucosa require close inspection to exclude a tooth fragment or other foreign body. Patients with lacerations involving the gingiva also require evaluation to ensure that no associated fracture is present. Lacerations with large flaps and those with uncontrolled bleeding, that gape and are likely to collect food, or that involve an extensive amount of the tongue edge and may cause functional impairment require repair in the ED. The maxillary frenulum has no function and does not require repair unless trauma is extensive and extends into the surrounding mucosa. In contrast, the lingual frenulum is highly vascular and more likely to require repair to prevent continued bleeding. Lacerations that cause a degloving injury to the gum margin also require repair, usually by an oral surgeon.

For intraoral repair, absorbable sutures are used in all cases. For through-and-through tongue lacerations, the muscle layer is closed separately. Moderate sedation is often required for children who need tongue laceration repair (see Chapter 159, Procedural Sedation and Analgesia).

Other Structures

NASOLACRIMAL SYSTEM

Tears drain from the eye via puncta into the upper and lower canaliculi at the medial aspect of the eye. These puncta are directed posteriorly toward the globe and usually cannot be visualized unless the lids are everted. The upper and lower canaliculi merge to form a common canaliculus that drains into the lacrimal sac, which then drains into the nasolacrimal duct, which courses inferiorly and posteriorly through the maxilla, draining inferiorly to the inferior turbinate. Children with upper or lower eyelid trauma that is medial to the pupil require examination to exclude trauma to these structures. Moreover, if medial canthal disruption is present (e.g., rounded medial canthus), nasolacrimal trauma is also

possible. In either instance, ophthalmology consultation is required.

NERVES

Five branches of the facial nerve supply motor innervation to facial muscles: the temporal, zygomatic, buccal, mandibular, and cervical branches. Paralysis of the facial nerve can affect the forehead, eyebrow, eye, nose, mouth, lips, or platysma, depending on the branches of the facial nerve affected. If hearing or taste is affected or decreased tear production is present in the ipsilateral eye, then facial nerve injury is localized to its intratemporal course (e.g., temporal bone fracture) where it give off branches involved in hearing and taste. The trigeminal nerve innervates the muscles of mastication (temporalis and masseter) and sensation to the face (see Fig. 16–2). In general, nerve injury due to penetrating trauma requires acute repair. Blunt traumatic injuries with associated fractures (e.g., temporal bone) may require decompression or may be managed conservatively depending upon the presence of associated facial injuries. In some instances, surgeons may base their decision to operate on the extent of injury noted during electrodiagnostic testing.

PAROTID DUCT

The parotid gland occupies a key location within the face, with important facial nerve branches and the parotid duct contained within its structure (see Fig. 16–2). It lies anterior to the sternomastoid muscle and inferior to the zygoma. Importantly, the buccal branch of the facial nerve, which supplies the buccinator, closely approximates the position of the parotid duct. Injury to the parotid duct or buccal branch of the facial nerve requires exploration for corresponding injury to the adjacent structure. In general, parotid duct injuries require exploration and repair by a plastic surgeon.

Summary

Oral, facial, and ocular injuries are common injuries that are easily overlooked. Clinical evaluation requires knowledge of important anatomic landmarks. While the clinical evaluation of infants and children with facial fractures can be difficult, CT is the ideal imaging study for evaluating children with potential fractures. Play, sports, and motor vehicle accidents are common causes of facial trauma in children. However, clinicians must consider and exclude the diagnosis of abuse in all cases. Importantly, patients with closed injuries and no functional deficit (e.g., visual loss, sensory/motor loss, malocclusion) usually require no acute intervention. Unless they are open, most facial fractures that are displaced or comminuted or that result in a functional deformity may wait until swelling subsides (2 to 4 days) before undergoing surgery.

Chapter 17

Head Trauma

Vincent J. Grant, MD

Key Points

Head trauma is common and a significant source of pediatric morbidity and mortality.

Injury prevention is the only intervention that can minimize primary traumatic brain injury.

The main goals of the emergency department management of head-injured children are to identify serious intracranial injuries and minimize secondary traumatic brain injury.

Signs and symptoms of head injury do not correlate well with the risk of intracranial injuries.

In the evaluation of most head-injured children, the greatest challenge is deciding when it is safe to evaluate these children without performing computed tomographic scanning of the head.

Introduction and Background

Emergency physicians treat children with head injuries every day.^{1,2} These injuries range from trivial to fatal. Along this severity spectrum, many management issues and controversies arise. Familiarity with these issues and controversies allows emergency physicians to make rational and reasoned decisions in the face of conflicting or absent evidence.

One approach to categorizing head injuries is to group them according to the patient's Glasgow Coma Scale score³ (Table 17-1). According to this scheme, children with mild injuries have Glasgow Coma Scale scores of 13, 14, and 15; those with moderate injuries have scores from 9 to 12; and those with severe injuries have a score of 8 or less.⁴ Although relatively simple in concept, there are several problems with this approach. The Glasgow Coma Scale score seems to have only modest interrater reliability.⁵ This calls into question the reproducibility of studies based on this categorization scheme. In addition, Glasgow Coma Scale scores do not adequately correlate with intracranial injuries identified on computed tomographic (CT) scanning of the head.⁶ This suggests that this categorization scheme is not a valid surrogate for brain injuries. The Glasgow Coma Scale was intended for use

in the era before the widespread availability of CT scanning. To consider a patient with a completely normal evaluation (Glasgow Coma Scale score 15) and a patient who is confused and localizes pain (Glasgow Coma Scale score 13) to both have the same category of head injury is counterintuitive. Nonetheless, this categorization scheme is commonly used. There have been modifications to the Glasgow Coma Scale to make it more applicable to children.^{7,8} These modified scoring systems have the same problems as the original.

Recognition and Approach

Traumatic brain injury is the leading cause of death and disability in pediatric trauma.⁹⁻¹¹ In the United States, traumatic brain injury accounts for approximately 3000 deaths, 50,000 hospitalizations and 650,000 emergency department visits annually.^{12,13} Most children have a greater propensity for head injuries than most adults. Children tend to have proportionately larger heads, relatively weaker neck musculature, and less refined coordination than adults. In addition, they participate in different daily activities, are less inclined to understand and use safety equipment, have underdeveloped judgment, and may lack the required supervision to keep them safe. Infants, in particular, are at risk for nonaccidental trauma and have relatively thin skulls (see Chapter 119, Physical Abuse and Child Neglect).

The mechanisms of injury for pediatric head injuries are age dependent. The majority of accidental head injuries in younger children are due to falls and motor vehicle accidents. Adolescents are more likely to have injuries related to sporting or recreational activities, although motor vehicle accidents are also a frequent cause of head injuries in this age group. Penetrating head injuries are relatively rare in children and uncommon in most populations of adolescents. Gang activities in some adolescents increases the risk of penetrating head injuries (see Chapter 157, Interpersonal and Intimate Partner Violence).

One conceptually simple approach to traumatic brain injuries categorizes them as either primary or secondary. Primary brain injury occurs at the time of the injury. At the time of impact, cellular and structural damage occurs. We currently have no effective treatments for primary brain injuries. The only effective intervention yet to be identified is injury prevention.¹⁴ Effective interventions include laws mandating the use of seat belts, car seats, and bicycle helmets.^{15,16} Although emergency physicians can play an important role in promoting injury prevention, this does not

help the child who presents having already sustained a head injury. Secondary brain injury occurs after the time of the initial impact. The major causes of secondary brain injury include hypoxia, hypotension, and intracranial hypertension.¹⁷ Examples of secondary brain injury include anoxic brain injury from hypoxia that occurs after an injury or brain herniation due to an expanding intracranial hemorrhage or brain swelling. Left untreated, secondary brain injury can lead to progressive neurologic deterioration and death. Prehospital and emergency department care is directed at minimizing secondary brain injury.

Evaluation

Several intuitively appealing signs and symptoms that potentially predict the presence of a clinically significant head injury have been studied. These include abnormal mental status, loss of consciousness, amnesia to the event, a Glasgow Coma Scale score less than 15, skull fracture, scalp hematoma, a focal neurologic examination, irritability, a bulging fontanelle, vomiting, seizure, and headache.^{18–22} One meta-analysis found that loss of consciousness, skull fracture, focal neurologic signs, and a Glasgow Coma Scale score less than 15 are strong risk factors for intracranial injuries.²³ Another group found that loss of consciousness, amnesia to the event, or both did not correlate with traumatic brain injuries on CT scanning.²⁴ The NEXUS II investigators took another approach.^{22,25} This group suggested that, if the following seven criteria were not present, the risk of clinically significant intracranial injury was very low: (1) evidence of significant skull fracture, (2) altered level of alertness, (3) neurologic deficit, (4) persistent vomiting, (5) presence of scalp hematoma, (6) abnormal behavior, and (7) coagulopathy.²² The implication, of course, is that if these seven criteria are not present, CT scanning is not needed. Although the authors note that their decision criteria worked well in children younger than 3 years of age, the number of these young children in this study was small. After reviewing the available literature, one group proposing

a practice guideline for infants and young children determined that loss of consciousness and vomiting did not correlate with clinically significant findings on CT scanning.²⁶ Strangely, this group acknowledged this and yet still recommended CT scanning for children who lost consciousness for greater than 1 minute or who vomited five or more times.²⁶ One group suggested that infants could present in an “occult” manner without appreciable signs or symptoms of head injury.²⁷ Another group disputed the existence of “occult” head injuries.²¹ The reasons for the variability in the findings of these studies are not entirely clear. It is conceivable that the heterogeneity of the injury types, the ages and development of the children in the study populations, and the outcomes of interest led to conflicting and confusing results.

The greatest advances in evaluating children with head injuries are in imaging. CT scanning has had the greatest impact. The decision about when to obtain a CT scan, however, is not always clear. The greatest controversy exists for those children at the less severe end of the injury spectrum. It is clear that a traumatized, comatose child requires CT scanning of the head. At the other end of the severity spectrum, the decision on when to perform CT scanning is controversial. It is probably reasonable to perform CT scanning on children who have abnormal mental status and infants with relatively large scalp hematomas.^{23,24,28–31} Isolated, brief loss of consciousness is probably not an indication for CT scanning.²⁰ Beyond that, it is difficult to universally define when CT scanning is indicated. There is no role for skull radiographs in the identification of intracranial injuries as the intracranial contents are not seen on plain radiographs. Since intracranial injuries occur in the absence of skull fractures, skull radiographs poorly risk-stratify children for the presence of intracranial injuries. Magnetic resonance imaging is currently too time consuming for the evaluation of acutely injured children in the emergency department.³²

Management

Management of head-injured children is directed at specific findings on physical examination and CT scanning results. The management of head-injured children needs to take into account the possibility of multisystem trauma and follow general principles of resuscitating children (see Chapter 1, Approach to Resuscitation and Advanced Life Support for Infants and Children; Chapter 3, Rapid Sequence Intubation; and Chapter 12, Approach to Multisystem Trauma). There has been some interest in using controlled hypothermia to treat severe brain injuries. Laboratory studies have shown that moderate hypothermia decreases neuronal loss, decreases excessive neurotransmitter release, and prevents disruption of the blood-brain barrier.³³ Hypothermia has not been adequately studied to recommend it at this time. More detailed basic and advanced cerebral resuscitation techniques are described in detail elsewhere (see Chapter 9, Cerebral Resuscitation).

Impending Herniation

In severely head injured children there is the possibility of impending brain herniation. This is usually evident on physical examination by the presence of a bulging fontanelle, unequal or fixed and dilated pupils, and posturing or coma. If the child is hemodynamically stable enough to undergo CT

scanning, the scan may reveal intracranial bleeding or diffuse axonal injury. Diffuse axonal injury is the proposed mechanism for patients who suffer severe closed head injury without the presence of obvious macroscopic intracranial injuries, such as contusion, hematoma, or cerebral edema on CT scanning.³⁴ A few interventions have been recommended for decreasing intracranial hypertension. One is elevation of the head of the bed 30 degrees.³⁵ This has been recommended for children, but has not been studied in children. Although generally recommended several years ago, hyperventilation is to be avoided as it is now thought to lead to intracranial blood vessel constriction and brain ischemia.^{36,37} Instead of the traditional mannitol used to treat adults, the use of 3% hypertonic saline (which can be given as a bolus of 3 ml/kg intravenously) is gaining acceptance as a means of treating and preventing intracranial hypertension^{38,39} (see Chapter 9, Cerebral Resuscitation).

Scalp Injuries

Although it is a highly vascular structure that bleeds profusely when injured, the scalp is underestimated in its contribution to head injury morbidity. In young infants, scalp injuries, with or without an opening in the skin, can cause deterioration from hemorrhagic shock.^{19,40} In particular, a subgaleal hematoma in an infant may be a significant source of hypovolemia from scalp hemorrhage without any signs of external bleeding.

Skull Fractures

There are four main types of skull fractures: linear, depressed, diastatic, and basilar. Linear skull fractures are the most common type of fracture seen in pediatrics, comprising approximately 75% to 90% of all fractures.¹⁹ A depressed skull fracture includes any skull fracture in which the bone fragment is depressed below the inner table of the skull. A depressed skull fracture typically requires operative elevation if it is depressed to a depth greater than the thickness of the skull.¹⁹ Diastatic fractures involve sutures. One common complication of both depressed and diastatic fractures is the leptomeningeal cyst or “growing” fracture. This complication arises when a tear in the dura allows the arachnoid membrane to penetrate the fracture, leading to demineralization of the bone fragments at the fracture site and penetration of cerebrospinal fluid into the subarachnoid space.⁴¹ Healing is impaired, and therefore necessitates careful follow-up, with surgical repair being occasionally required if the fracture continues to “grow” 2 to 3 months following the injury. Basilar skull fractures account for up to 20% of all skull fractures, and classically have distinctive clinical features, including periorbital ecchymosis (“raccoon eyes”), postauricular mastoid ecchymosis (Battle’s sign), hemotympanum, and cerebrospinal fluid rhinorrhea or otorrhea. In these cases, ecchymosis is not typically present on presentation to the emergency department. Complications of basal skull fractures include facial nerve palsy, cerebrospinal fluid fistulas, and meningitis. Antibiotic prophylaxis for basilar skull fractures is not recommended as this may lead to subsequent meningitis with resistant bacteria.¹⁹

Intracranial Hemorrhages

Intracranial hemorrhages represent the most common life-threatening complications of head injuries. As a group, these

injuries occur in up to 12% of patients with mild head injuries alone.⁴¹ Early diagnosis of intracranial hemorrhage is essential to allow identification of the subgroup that requires prompt neurosurgical management. Intracranial hemorrhages can be divided into four main types: parenchymal contusions, epidural hematomas, subdural hematomas, and subarachnoid hemorrhages.

Parenchymal contusions develop as a result of direct impact between the brain and the overlying skull, causing a focal area of bruising, hemorrhage, and edema. Contusions are either caused by abrupt acceleration of the head, causing a “coup” injury on the same side as impact, or by abrupt deceleration of the head, causing a “contrecoup” injury on the opposite side from impact. Immediate surgical intervention is not usually indicated for parenchymal contusions.

Epidural hematomas are collections of blood between the skull and the dura of the brain. Because the dura is tightly adhered to the skull in certain areas, the collection of hemorrhage grows in a characteristic lens-shaped pattern. The vessel injury in question can be either arterial or venous, but the most significant injuries are from arterial injury, typically the middle meningeal artery. There may be an associated skull fracture. The clinical presentation may lead to false reassurance, because the typical presentation usually includes a lucid interval of time between the initial injury and rapid neurologic deterioration associated with rapid expansion of the hematoma. Small epidural hematomas have been shown to occur after minor head trauma in alert children with no focal neurologic signs.⁴² Larger epidural hematomas usually require urgent neurosurgical intervention.³¹ Prognosis is excellent with early treatment.³¹

Subdural hematomas are collections of blood between the dura and the arachnoid membrane. This hemorrhage is most commonly a result of torn bridging veins in the subdural space, that present as crescent-shaped lesions on CT. Typically, these lesions are not associated with skull fractures, and occur most often as a result of rapid acceleration/deceleration.⁴³ Compared to epidural hematomas, subdural hematomas are less amenable to neurosurgical intervention, and outcomes may be poor, with up to 50% of patients developing profound disabilities regardless of the treatment provided.⁴³

Subarachnoid hemorrhage occurs as a result of damage to superficial vessels running along the surface of the brain, underneath the arachnoid membranes. The blood is irritating to the meninges, sometimes causing nuchal rigidity and severe headache. These lesions can result in vasospasm and further ischemic injury, but rarely require acute intervention.

Posttraumatic Seizures

Posttraumatic seizures occur in as many as 5% to 10% of all head-injured children. The timing of the seizures is classified as immediate, early, and late. Immediate posttraumatic seizures occur at the time of injury, and are thought to be due to instant depolarization of the cortex in response to the injury. This type of seizure generally does not recur. These “impact seizures” are not predictive of clinically significant intracranial injuries, nor do they require any specific treatment or imaging. In contrast, early seizures occur after the impact, but within 24 hours of the injury. Early seizures are more likely to be a manifestation of an intracranial injury and therefore warrant imaging. Late seizures occur greater than 1 week after injury and are a result of scarring and

mechanical irritation of the brain.⁴¹ The routine use of prophylactic antiepileptic medications after minor head injuries is not necessary.^{41,44} Children with repeated seizures or those in status epilepticus require prompt management of their seizures (see Chapter 40, Seizures).

Transient Cortical Blindness and Trauma-Triggered Migraine

Since the mid-1960s, with Bodian's original description of six children who had transient loss of vision for a few hours following trauma, transient cortical blindness has been recognized as a complication of head trauma.⁴⁵⁻⁴⁹ Traumatic cortical blindness is typically seen in children and young adults who have sustained minor head injury, brief or no loss of consciousness, blindness occurring within hours of the head injury, normal pupils and fundi, and a normal CT scan of the head.⁵⁰ Particularly in the young child with limited language skills, assessing blindness may be exceedingly difficult and the patient may simply exhibit anxiety and agitation.⁵¹ There appears to be some overlap with transient cortical blindness and what has been called "trauma-triggered migraine."^{52,53} In these cases, a child sustains a blow to the head and then has a clinical presentation like that of a classic or complicated migraine (see Chapter 41, Headaches). Visual disturbances include scintillating scotoma, homonymous hemianopia, blurred vision, tunnel vision, or transient blindness. These symptoms usually resolve and are then replaced by headache, nausea, and vomiting. The patient may exhibit confusion or incoherence, paresthesias, dysphasia, and hemiparesis. Children may become agitated and combative.⁵² The etiology of transient cortical blindness and trauma-triggered migraine is unknown. Theories to explain these events have centered on vasospasm and localized cerebral edema.⁵⁴ Although β -blocker therapy has been considered a treatment for posttraumatic migraines, there is currently no standard treatment.⁵³

Summary

The disposition and prognosis for head-injured children is dependent on the type and degree of injury. Most children who have negative CT scans and have resolution of their symptoms in the emergency department can be safely discharged home. There is no need for awakening the child throughout the night as the likelihood of a missed clinically significant intracranial injury is very low. Exceptions to this include hemophiliacs and children on warfarin, in whom the risk of a delayed bleed is much greater. Children who are awake and have small intracranial bleeds may be admitted or transferred to a facility with a pediatric neurosurgeon and a monitored intensive care area. Severely injured children will require admission or transfer to a pediatric intensive care unit for pediatric neurosurgical evaluation.

An area of some controversy is the management of child diagnosed with a concussion who has a normal CT scan of the head. A concussion is a transient alteration in mental status following a blow to the head. The main controversy surrounds the decision as to when a child may return to sporting activities. There are no evidence-based guidelines; however, there are some consensus-based recommendations.⁵⁵ For children who experience transient confusion with resolution of symptoms within 15 minutes and without

loss of consciousness, the recommendation is to have the child be immediately removed from play and return to play if his or her mental status is normal after 15 minutes on the sidelines. For children who experience transient confusion for longer than 15 minutes without loss of consciousness, the recommendation is to have the child sit out for the rest of the day and return to play in 1 week if the neurologic examination is normal at that point. For children who experience any loss of consciousness, the recommendation is for removal from play for 1 week if the loss of consciousness lasts for a few seconds or 2 weeks if the loss of consciousness lasts longer than that. For these children, the child needs to be asymptomatic at rest and with exertion to return to play after sitting out for a week or two.

Survivors of traumatic brain injury are at increased risk for long-term neuropsychological deficits in the areas of verbal reasoning, learning and recall, attention, executive functions, and constructional skills. If these functions recover, the recovery period may last years.⁵⁶ Children with traumatic brain injuries are also at risk of psychiatric disturbances, such as major depression and anxiety disorders, attention-deficit/hyperactivity disorder, and organic personality disorder.^{57,58}

Neck Trauma

Jan M. Shoenberger, MD and William K. Mallon, MD

Key Points

Early definitive airway management with rapid sequence intubation can be lifesaving in blunt and penetrating neck trauma.

Identifying the zone of injury (I, II, and III) is important for determining the appropriate management plan.

Penetrating facial trauma below the horizon of the pupils may result in zone III neck injuries.

Neurologic deficits, even if transient, suggest a vascular or spinal cord injury.

Introduction and Background

The mechanisms of injury for cases of pediatric neck trauma are numerous and heterogeneous. The most common cause of both penetrating and blunt neck injuries is motor vehicle accidents. Penetrating injuries occur most frequently in adolescents, including accidental injuries and injuries received when they are victims of violent crime.^{1,2} Penetrating neck wounds from impalement, dog and human bites, and fireworks are also reported.³⁻⁵ Mechanisms of injury causing blunt neck trauma include bicycle injuries, sports injuries, falls, near-hangings, and scooter and in-line skating injuries.⁶⁻¹⁴ Trampoline use is associated with both neck injuries and cervical spine injuries^{15,16} (see Chapter 23, Spinal Trauma).

Recognition and Approach

Neck anatomy is complex, with many vital structures contained within a relatively small, flexible space. To describe neck injuries, a commonly accepted approach is to divide the neck into three anatomic zones designated I, II, and III (Fig. 18-1). The numbering is somewhat counterintuitive, with zone III being the most cephalad. Zone I extends inferiorly from the cricoid cartilage to the clavicles. Injuries in this region carry a higher mortality because they can involve major vessels, lung apices, and the esophagus, trachea, thyroid structures, and thoracic duct. Zone I is difficult to access

surgically. Zone II consists of the area between the cricoid cartilage and the angle of the mandible. Zone II is where the majority of neck wounds occur. The major structures in zone II include the trachea, esophagus, larynx, spinal cord, jugular veins, and carotid arteries. Injuries in zone II carry a lower mortality. The assessment and surgical management of zone II neck injuries is easier than that in the other two zones due to the absence of bony obstruction. Zone III comprises the area between the angle of the mandible and the base of the skull. The major structures in zone III include the pharynx, jugular veins, and vertebral and carotid arteries. Penetrating facial trauma as high as the horizon of the pupils may result in zone III neck injuries. Injuries to the spinal cord may occur in conjunction with injuries to any zone. Zone II injuries account for about 50% of neck injuries, with zones I and III accounting for about 25% each.^{17,18}

The neck can also be divided into anterior and posterior triangles. Wounds in the anterior and lateral aspects of the neck pose the greatest threat to a patient's airway because of their proximity to the trachea, larynx, laryngeal nerves, and vessels of the neck.¹⁹ Trauma involving the area posterior to the trapezius ridge is the least likely to involve vital structures. The neck is a three-dimensional structure, and the apparent depth of wounds contributes to the overall assessment and management plan. For example, for anterior penetrating wounds, if the platysma muscle has been violated, the management approach is much more aggressive than if it has not been violated.

The anatomic relationships in the pediatric neck differ from those seen in adults (Table 18-1). Because the pediatric neck is much shorter, the zones of the neck are less distinct; thus the surgeon will have less operative exposure. The vascular structures are proportionately larger and have less muscle and soft tissue protection than seen in most adults. Compared with adults, hematomas may expand and extend more rapidly in children due to greater tissue pliability. The larynx is in a more anterior position and the trachea is shorter.²⁰ A smaller mandible and chin result in children being less likely to "take it on the chin." The pediatric airway is more flexible and has bulkier adjacent soft tissues, increasing the potential for early obstruction.²¹

Evaluation

The prehospital care phase should include consideration of cervical immobilization. Clinical experience suggests that

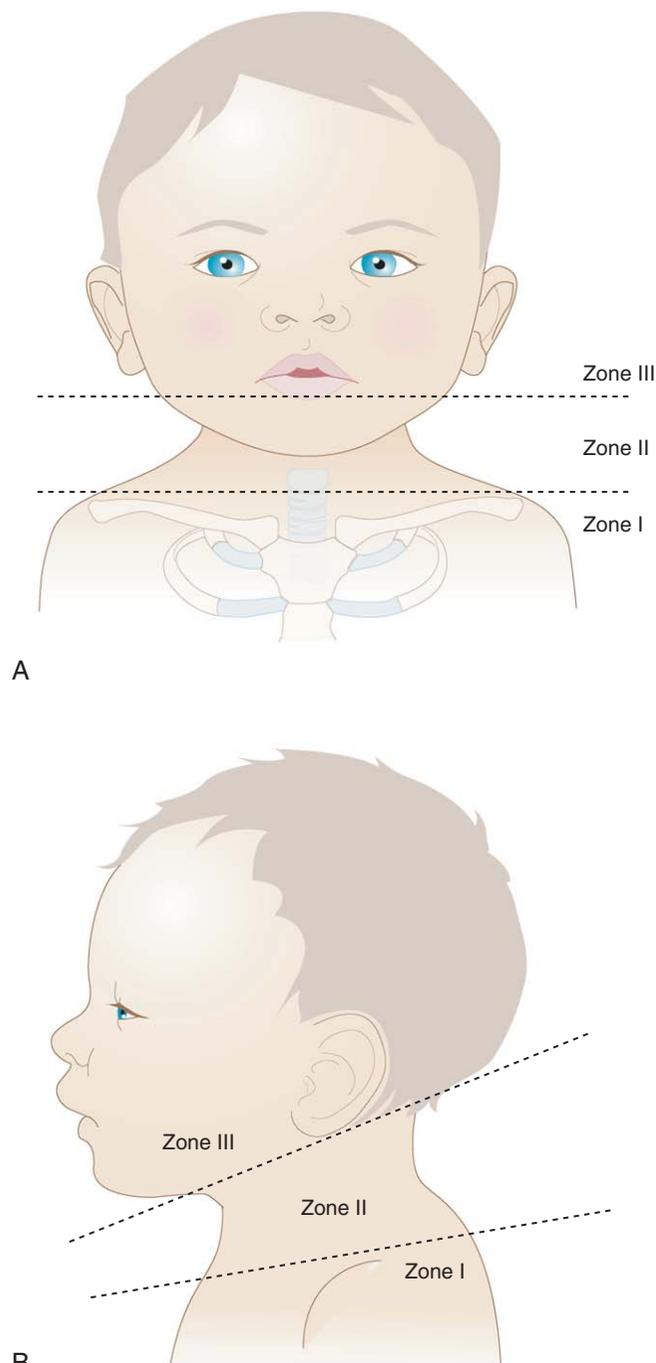

FIGURE 18-1. Zones of the neck. **A,** Anterior view. **B,** Lateral view.

some prehospital care providers place all traumatized individuals in cervical spine precautions. This global approach has been challenged, particularly with regard to penetrating injuries.²² The utility of cervical spine immobilization in most cases of neck injuries is probably very low. In addition, cervical collars make it difficult to visualize important life-threatening signs and hinder access to sites of bleeding.

In the emergency department, the assessment and management of the airway is the highest initial priority²¹ (see Chapter 2, Respiratory Distress and Respiratory Failure). Patients with penetrating neck injuries may have an internal

Table 18-1 Characteristics of the Pediatric Neck

Relatively small chin
Short neck
Small cricothyroid membrane
Small muscle mass

derangement of the airway structures developing in a dynamic fashion. False reassurance may develop because the skin overlying the neck may be relatively normal in appearance even in cases of substantial internal injury. An airway injury is suspected if the child exhibits stridor, hoarseness, subcutaneous emphysema, or air bubbling from any wound. Other signs of serious neck injuries include a vascular bruit, a pulse deficit, a neurologic deficit, hemoptysis, hematemesis, and crepitation.²³ In general, it is unwise to probe neck wounds. Probing blindly can disrupt hematomas, can cause new injuries, and is uncomfortable. Probing also can be misleading due to mobile tissue planes.

The major decision node for neck injuries relates to the airway and hemodynamic stability of the patient. Unstable patients generally require prompt surgical exploration. Previously, “all” zone II penetrating neck injuries underwent surgical exploration. This historical approach is increasingly uncommon.²⁴ For stable children, computed tomographic (CT) angiography is currently the imaging modality of choice for assessing vascular injuries.²⁵ Ultrasound with color flow Doppler technique is another valuable imaging tool, but has not been studied as extensively as CT angiography.^{26,27} For serious, stable, penetrating injuries, CT angiography is often combined with esophagoscopy, laryngoscopy, and bronchoscopy to fully evaluate vital structures.¹⁷

Management

The primary tasks for emergency physicians in the setting of serious neck injuries are airway and hemorrhage control. Orotracheal intubation is the preferred route for definitive airway control. This can best be achieved with rapid sequence intubation²⁸ (see Chapter 3, Rapid Sequence Intubation). The decision on when to intubate is not always clear. In general, anticipating deterioration and airway occlusion is prudent. However, this must be balanced with the risk of performing an unnecessary intubation and causing airway trauma. If airway compromise is imminent and intubation is not successful, needle jet ventilation may be a reasonable temporizing measure pending definitive airway control. Similar to other body regions, active bleeding can usually be controlled with direct pressure. Obviously, applying excessive pressure to the structures of the neck can have deleterious effects. The balance between applying sufficient pressure to control hemorrhage and avoiding excessive pressure can be difficult. Acute anemia from hemorrhage may require the transfusion of packed red blood cells. Consultation with trauma surgeons and ear, nose, and throat surgeons is indicated in many cases of serious neck injuries. Consultation with a neurosurgeon for suspected spinal cord injuries is also indicated.

Summary

Specific risk criteria that differentiate “minor” from “major” neck injuries have not been identified. Nonetheless, most blunt neck injuries in children require no imaging, require no testing, and have few complications. After a “brief” period of observation, these children can be discharged home with close follow-up. For moderate blunt injuries, there are no definitive pediatric studies. The utility of relatively prolonged observation or imaging is unclear. More severe blunt neck injuries and all but the obviously superficial penetrating injuries require multidisciplinary evaluation and management. Disposition depends on the results of imaging studies and visualization of structures with endoscopy. Given the heterogeneity of neck injuries, the prognosis of these children varies greatly.

Chapter 19

Upper Extremity Trauma

Michael D. Burg, MD and Sieuwert-Jan C. ten Napel, MD

Key Points

Pediatric upper extremity trauma is extremely common and therefore a major source of morbidity.

Determining the need for radiographs in an acutely injured child is often difficult.

Radiographs comparing the injured arm to the uninjured arm are not routinely indicated.

Injuries may be produced by a single major trauma or accident, repeated minor trauma, nonaccidental trauma, or physiologic stress on a pathologic site.

Recognizing activity-injury patterns and the ages at which these injuries tend to occur may allow for the identification of subtle fractures and fracture-dislocations.

Selected Diagnoses

Shoulder Injuries

- Clavicular Fractures
- Acromioclavicular Separation
- Shoulder Dislocation
- Shoulder Injuries in the Child Athlete
- Upper Arm and Elbow Injuries
- Humeral Fractures
- Radial Head Subluxation
- Elbow Fractures
- Elbow Dislocation
- Elbow Injuries in the Child Athlete

Forearm Injuries

- Forearm Fractures
- Monteggia Fracture-Dislocation
- Galeazzi Fracture-Dislocation
- Greenstick Fractures

Wrist and Hand Injuries

- Wrist Fractures
- Hand Fractures
- Nail Bed Injuries

Discussion of Individual Diagnoses

Shoulder Injuries

Clavicular Fractures

In children, the clavicle is the most commonly broken bone in the shoulder region, accounting for 8% to 15% of all fractures in this population.^{1,2} The clavicle may be injured during delivery (0.4% to 1.5% of all newborns), and accounts for nearly 90% of all obstetric fractures. Clavicle fractures in newborns are associated with shoulder dystocia, increased birth weight, and increased gestational age.^{3,4} Clavicular fractures are classified by anatomic location: medial third, middle third, and distal third.⁵ The middle third is the most frequently fractured, accounting for 80% of all clavicular fractures; most of them are nondisplaced.² Distal third fractures range from 15% in incidence.^{2,6} Medial third fractures are relatively uncommon, accounting for 5% of all clavicle fractures in children and adolescents.² A fall on the shoulder is the most common injury mechanism. Others include a direct blow to the clavicle and a fall on an outstretched hand, the latter being a relatively uncommon cause.⁷ Clavicle fractures also occur in multitrauma patients, in whom the injury is often a minor problem.⁸

A child with a broken clavicle will characteristically present supporting the elbow on the affected side with the contralateral hand. Often the head will be turned toward the fracture in order to relax the sternocleidomastoid muscle. Spasm of the sternocleidomastoid or trapezius muscle may lift the proximal fragment superiorly.^{9,10} A visible and palpable deformity can be found along with variable degrees of tenderness. The skin overlying the fracture may be tented, and limited shoulder motion may be seen.¹⁰ Assessment of distal neurovascular status is an important part of the evaluation. Plain radiographs are usually sufficient for diagnosis and management.¹⁰ Ultrasound can be used to detect clavicle fractures in newborns.¹¹

Most clavicular fractures are treated conservatively. A sling to support the elbow and forearm and pain medication are generally all that is required. A randomized controlled trial found that slings caused less discomfort and possibly fewer complications than treatment with a figure-of-eight bandage. The functional and cosmetic results were identical.¹² No statistically significant difference was found in the speed of recovery between these two conservative therapies.¹³ The sling should be used during waking hours for at least 2

weeks, and longer in children older than 12 years. Parents should be advised about callus formation and resultant deformity, which can be visible for up to a year.¹⁰ Clavicle fractures in children seldom require operative management. A study of 939 clavicular fractures reported a 1.6% operative rate. Operative indications included open fractures, soft tissue impingement, skin perforation potential, severe shortening of the shoulder girdle with or without displaced intermediate fragments, and displaced fractures with potential risk to the neurovascular bundle or mediastinal structures.¹⁴ In another study, 2 of 26 children with distal clavicle fractures underwent operation; all others were treated conservatively with good results.⁶ Excellent results were found in all of 25 children with conservative treatment of lateral clavicle fractures.¹⁵

Acromioclavicular Separation

True acromioclavicular separations in young children are rare. A fall on the point of the shoulder usually results in an acromioclavicular separation in the adult or older adolescent, but in children results in fractures through the physis or metaphysis.¹⁰ Because distal clavicular epiphyseal ossification does not occur until the age of 18 or 19 years, fractures in this area appear as acromioclavicular dislocations or pseudodislocations.^{16,17} Superior displacement of the lateral clavicle occurs due to a tear in the thick periosteal tube surrounding the distal clavicle. The lateral clavicular epiphysis, along with the acromioclavicular and coracoclavicular ligaments, usually remains intact.^{10,17} Injury mechanisms include birth trauma, child abuse, falls, and motor vehicle crashes. Children will present with pain or tenderness over the acromioclavicular region.¹⁷ Nondisplaced to moderately displaced fractures require symptomatic treatment with a sling. Operative stabilization is required in injuries with marked displacement of the fracture fragments.^{10,16-18}

Shoulder Dislocation

Limited recent literature exists concerning the incidence and presentation of shoulder dislocations in children. Optimal reduction techniques are also not well studied, so standard adult techniques are generally used. A 5-year survey study found a 4.2% incidence of primary anterior dislocation in children ages 12 to 17 years.¹⁹ Anterior dislocations in children less than 10 years of age are uncommon.²⁰ Recent literature does address the incidence of re-dislocation after a primary dislocation in adolescents. The recurrence rates after primary dislocation range from 72% to 86% for teens.^{19,21} Fewer re-dislocations were found in younger patients in two studies,^{19,21} and it was hypothesized that this may be due to greater shoulder capsule elasticity in younger patients.¹⁹ This finding contradicts that of a study reporting a 100% recurrence rate in 21 children with open physes.²² Another study found that the type and duration of immobilization technique had no effect on re-dislocation rate.²³ The high incidence of re-dislocation or shoulder instability makes orthopedic follow-up after treatment in the emergency department prudent.

Shoulder Injuries in the Child Athlete

An ever-increasing number of children participate in organized sports and recreational programs. Over one third of young athletes will sustain injuries requiring medical

attention.²⁴ Acute shoulder injuries are commonly seen in football, bicycling, snowboarding, skiing, wrestling, and baseball.¹⁰ Injuries can also occur due to repetitive stress and are common in swimmers, gymnasts, cheerleaders, and baseball players (see Chapter 98, Overuse Syndromes and Inflammatory Conditions).²⁵

One overuse injury in children is “little leaguer’s shoulder.” It represents a stress fracture of the proximal humerus growth plate.²⁵ The patient with this injury will complain of pain during throwing localized to the proximal humerus. On physical examination, tenderness to palpation over the proximal or lateral aspect of the humerus is found.²⁶ This condition is mostly seen between 11 and 13 years of age and can be treated with rest.¹⁰ Ninety-one percent of those with little leaguer’s shoulder were asymptomatic while playing baseball after a 3-month rest period.²⁶

Upper Arm and Elbow Injuries

Humeral Fractures

PROXIMAL HUMERAL FRACTURES

Proximal humeral epiphyseal fractures are rare and occur more in adolescents than younger children.²⁷ If they occur, therapy is primarily conservative.^{28,29} Patients present with shoulder swelling and pain, especially when moving the shoulder joint. A neurovascular examination is an important part of the evaluation, as are anteroposterior and lateral radiographs.^{20,30,31} Nonoperative treatment is appropriate in almost all cases, even with severely displaced fractures, and consists of a hanging cast or simple sling.²⁷ The magnitude of displacement alone does not justify operative management.³² Proximal humeral fractures have excellent remodeling capacity.^{32,33} Open fractures, those causing neurovascular compromise, pathologic fractures in juvenile bone cysts, and displaced fractures of the articular surface are operative indications.^{28,31,33}

HUMERAL SHAFT FRACTURES

Humeral shaft fractures comprise a small percentage of all fractures in children, with an increased incidence in adolescence.³⁴ Therapy is mainly conservative, and generally only angulations greater than 10 degrees need surgical stabilization, the preferred method being elastic-stable intramedullary nailing.²⁸ Humeral fractures can cause radial nerve palsy. Most have a good prognosis, and expectant management is advocated.^{35,36} Impaired brachioradialis muscle functioning, wrist extension, and finger and thumb extension are seen with radial nerve injury.³⁵ Of 222 diaphyseal fractures in children, 8 patients had radial nerve palsy and 1 patient had ulnar nerve palsy; all were transitory.³⁶ The clinician must be alert to the possibility of child abuse in toddlers with humeral shaft fractures. Midshaft or metaphyseal humeral fractures were found to be a marker for abuse in those under 3 years of age.³⁷ A study in a similar population classified 18% of humeral shaft fractures as probably due to abuse but cautioned that neither fracture pattern nor age is diagnostic of abuse.³⁸

SUPRACONDYLAR FRACTURES

The supracondylar humerus fracture is the most common elbow fracture in children, accounting for more than half of all pediatric elbow fractures^{39,40} and 3% to 18% of all

fractures seen in children.^{1,34} Diagnosis of these fractures can be challenging, and, if missed or improperly treated, vascular, neurologic, and structural complications can occur. A fall on an outstretched hand with elbow extension is the main cause (70% to 90%) of these fractures.^{41,42} The majority of supracondylar fractures occur in the first decade of life, with a peak incidence between ages 4 and 7 years.^{34,39,42} The non-dominant arm is more often injured than the dominant arm.^{34,39,40,42} In children, ligamentous strength exceeds bone strength. When falling with the hand outstretched and the elbow extended, the collateral ligaments of the elbow prevent hyperextension at the joint space and the olecranon transmits the longitudinal force to the supracondylar region, which fractures.⁴¹ These extension-type injuries account for almost all supracondylar fractures.⁴³ Extension-type supracondylar fractures are divided into three types based on displacement: type I, minimal or none; type II, partially intact posterior cortex with angulation but without complete displacement; and type III, completely displaced.⁴⁴ Flexion-type fractures are caused by a direct fall on the elbow with impact on the olecranon, resulting in a posterior cortical disruption and anterior displacement or angulation.^{41,43}

Children with supracondylar fractures will complain of arm or elbow pain. They often hold the injured arm in an extended, pronated position. The elbow will be swollen and resistant to movement. The distal humerus will be focally tender.⁴¹ Assessment and documentation of distal neurovascular status is critically important. The reported incidence of specific nerve injury varies widely.^{41,45} The median nerve is most commonly injured (28% to 60%), with the anterior interosseous branch most commonly involved (80%). The radial nerve is involved in 26% to 61% of cases and the ulnar nerve in 11% to 15%.⁴⁵⁻⁴⁷ Anterior interosseous nerve impairment results in mild weakness of forearm supination, of the flexor digitorum profundus to the index finger, and of the flexor pollicis longus. Nerve function is assessed by asking the patient to make an “OK” sign and testing this for strength.⁴¹ Complete radial, median, and ulnar nerve functional testing are important, although this may be difficult in a child in pain. Type III fractures are those most often associated with neurovascular damage.^{40,45-48} Vascular status is assessed by checking capillary refill, color, distal pulses, and skin temperature. The uninjured arm may serve as a control. A Doppler ultrasound device is used if the pulses are faint or nonpalpable. Vascular compromise is most often due to a brachial artery injury,⁴⁹ and immediate orthopedic consultation is warranted. If neurovascular compromise exists, the initial treatment is immediate reduction. If an orthopedist is not readily available, the emergency physician should perform the reduction.⁴¹ If the radial pulse is not palpable while the hand stays well perfused, no consensus exists on optimal treatment. A strategy of closed reduction and internal fixation followed by close observation and neurovascular checks is advocated by some.^{49,50} Others recommend a more aggressive approach: immediate surgical exploration.⁵¹⁻⁵³

Radiographs of the elbow are obtained to confirm the diagnosis and estimate the degree of distraction and angulation. On a properly obtained, normal lateral radiograph, a line drawn down the anterior cortical margin of the humerus should intersect the middle third of the capitellum (Fig. 19–1). With extension-type fractures, the anterior humeral line will pass anterior to this area, and with flexion-type injuries

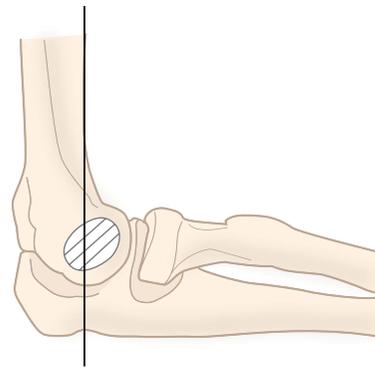

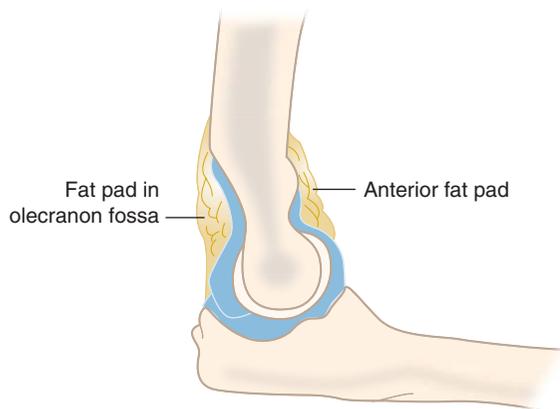

FIGURE 19–1. Radiographic line that is demonstrated on a lateral radiograph of the elbow. The anterior humeral line is drawn down the outer edge of the anterior cortex of the distal end of the humerus. As the line is drawn distally through the capitellum, it should pass through the middle of the capitellum. (From Green NE, Swiontkowski MF [eds]: *Skeletal Trauma in Children*, 3rd ed. Philadelphia: WB Saunders, 2003.)

the line will pass posteriorly. A line drawn along the midshaft of the proximal radius should intersect the capitellum in all radiographic views.⁴¹ The significance of a positive posterior “fat pad sign” is uncertain. Only 9 of 54 children with joint effusions and no identifiable fracture immediately after elbow trauma ultimately had evidence of a healing fracture.⁵⁴ In a prospective study limited to children, the presence of a posterior fat pad was predictive of fracture in 76% of patients.⁵⁵ It seems prudent to continue to treat children with elbow trauma and posterior fat pad signs as though they have occult supracondylar fractures (Fig. 19–2). A comparison of radiography of traumatized elbows with magnetic resonance imaging (MRI) concluded that a less severe spectrum of injury occurred in children with normal findings on radiographs versus those with an effusion.⁵⁶ Studies show that comparison views of the uninjured elbow in children with a spectrum of injuries do not improve diagnostic accuracy and are unnecessary.^{57,58}

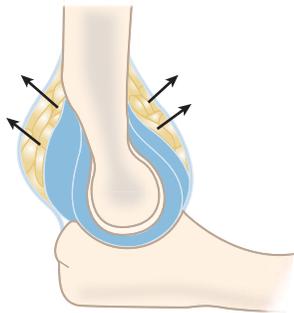

Type I fractures are typically treated with a long arm posterior splint for 3 weeks with the elbow flexed to 90 degrees and the forearm in a neutral position. The most likely pitfall associated with type I fractures is missing the diagnosis.⁴¹ Treatment of type II and III fractures depends on the degree of displacement and fracture stability. Definitive therapy includes closed reduction and internal fixation.⁴⁸ The distal neurovascular status of patients with supracondylar fractures must be reassessed in a timely fashion. For type I fractures this can be done on an outpatient basis, but for type II and III fractures, hospitalization is recommended.⁴¹ Most nerve injuries due to supracondylar fractures are neurapraxias. Motor deficits typically resolve over 7 to 12 weeks; sensory recovery can take as long as 6 months.^{46,59} A feared complication described after vascular injury is compartment syndrome (see Chapter 22, Compartment Syndrome). Untreated compartment syndrome may lead to Volkmann’s ischemic contracture which is characterized by fixed elbow flexion, forearm pronation, wrist flexion, metacarpophalangeal joint extension, and interphalangeal joint flexion.⁴⁸ Immobilizing the elbow in a position more flexed than 90 degrees can lead to increased pressure in the antecubital region and increase the risk of compartment syndrome.⁶⁰ Inadequately reduced or stabilized fractures may heal with a varus deformity.^{48,61}

C, An effusion displaces both fat pads. This posterior fat pad is now visible. (From Marx JA, Hockberger RS, Walls RM, et al [eds]: *Rosen’s Emergency Medicine: Concepts and Clinical Practice*, 5th ed. St. Louis: Mosby, 2002.)

Radial Head Subluxation

Radial head subluxation is also known as pulled elbow or nursemaid’s elbow. Most radial head subluxations occur in children 1 to 3 years of age. The presumed pathophysiology of this injury is entrapment of the immature radial head

distal to the annular ligament that occurs during longitudinal traction on the arm.^{62,63} This often happens when a child sinks toward the ground while being held at the wrist. However, in approximately 50% of cases, a “pull” mechanism of injury is not elucidated.⁶⁴ Parents or other caregivers are occasionally unable or unwilling to provide an accurate history either because they did not witness the injury or because they are afraid of being considered abusive. Simple observation will generally reveal a nondistressed child with the affected arm held immobile at the side, in minimal flexion at the elbow and pronation at the wrist. No deformity will be seen. The child will generally cry out if the elbow is moved or if pressure is placed on the radial head. Local swelling is uncommon. The remainder of the physical examination will be unremarkable. When the history and physical examination findings are consistent with radial head subluxation, radiographs are not required to confirm the diagnosis.⁶⁵ However, many physicians do order radiographs in children with arm injuries when the history is unclear or when the physical examination suggests an alternative diagnosis.⁶⁶

Classically, reduction of a radial head subluxation is performed by supinating the patient’s wrist and flexing the elbow while palpating the radial head.⁶⁷ A click over the radial head generally signifies successful reduction. Children less than 2 years of age may have a slower return to normal functioning.⁶⁸ Two relatively recent papers describe a hyperpronation method of reduction for radial head subluxations.^{63,69} In this method, hyperpronation of the forearm is followed by elbow flexion. Both studies found hyperpronation to be superior to supination, with success rates of 80% versus 69% in one study⁶⁹ and 95% versus 77%⁶³ on first attempts. A trend toward less pain with the hyperpronation technique was reported in one study.⁶⁹ After a reduction attempt, the child is expected to begin using the injured arm, generally within 15 minutes. If this does not occur, there are three main possibilities: unsuccessful reduction, alternative diagnosis (fracture), or slow resolution. Second and even third attempts at reduction are completely acceptable. Fractures about the elbow and at more distant sites (especially the clavicle) should be considered as well. Children under the age of 2 years may take longer to begin using their injured arm even after successful reduction.⁶⁸ Immobilization with a collar and cuff or sling is a classic, non-evidence-based recommendation, but is impractical given the ages of children affected by this process and its benign course. No immobilization is needed. Parents should be cautioned not to pull on the child’s arms. Analgesics are infrequently needed after reduction.

Elbow Fractures

The elbow consists of a complex series of three unions, the radiocapitellar and radioulnar articulations and the articulation of the distal humerus with the olecranon fossa of the ulna.^{70,71} A large variety of elbow fractures have been described. Three of the more common periarticular elbow fractures are described in this section. Complicating the evaluation of the child with an elbow fracture is the fact that six ossification centers exist around the joint (Fig. 19-3). Knowing the location of the ossification centers and the age at which each appears is important when evaluating children with elbow trauma. The mnemonic CRMTOL (Come Read My Tale Of Love), standing for capitellum, radial head, medial

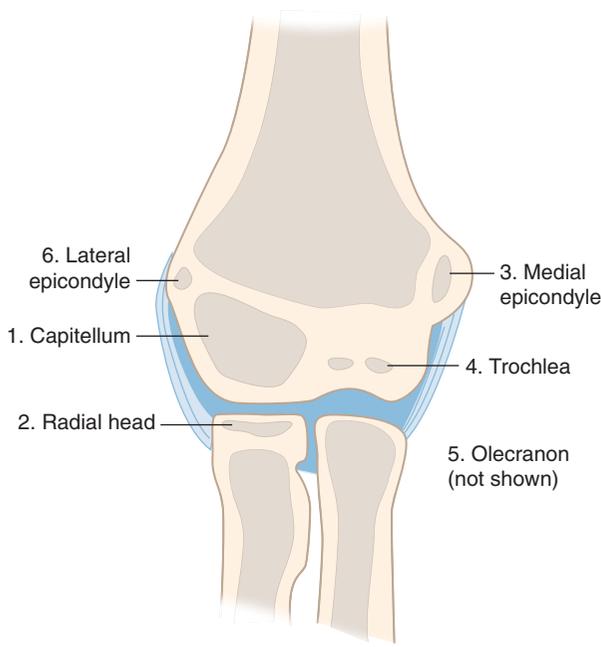

FIGURE 19–3. The six ossification centers of the elbow: 1, capitellum; 2, radial head; 3, medial epicondyle; 4, trochlea; 5, olecranon (not shown); and 6, lateral epicondyle. (From Connolly JF [ed]: DePalma's The Management of Fractures and Dislocations: An Atlas. Philadelphia: WB Saunders, 1981.)

epicondyle, trochlea, olecranon, and lateral epicondyle, can be used to recall the names of the ossification centers. The age in years at which each appears is variably quoted as: capitellum, 1 to 2; radial head, 4 to 5; medial epicondyle, 4 to 7; trochlea, 8 to 10; olecranon, 8 to 10; and lateral epicondyle, 10 to 11.^{70–73} Ossification of these centers in boys tends to lag that in girls by about 1 year.⁷⁰

The literature does not support the routine use of comparison radiographs of the contralateral, uninjured elbow to improve diagnostic accuracy.^{57,58} However, in selected cases, comparison views may be helpful. In the case of a diagnostic dilemma, additional radiographs or alternate imaging techniques (computed tomography, MRI, bone scan, others) may be helpful. At least one study of children with elbow trauma demonstrated that MRI detected a wide spectrum of injuries not apparent on plain radiographs. However, this same study found that the additional sensitivity of MRI did little to alter treatment.⁵⁶ For the child with a worrisome mechanism of injury and physical examination, but with normal radiographs, a reasonable plan is to immobilize the elbow in a splint, prescribe analgesia, and arrange follow-up with an orthopedist.⁷⁴

RADIAL HEAD AND NECK FRACTURES

These injuries constitute approximately 5% to 15% of all pediatric elbow fractures, and their optimal treatment is an area of active controversy.^{75,76} Generally these fractures occur due to a fall on an outstretched hand.⁷⁵ Nine and one-half years is the mean age for radial neck fractures; 13 years is the mean age for radial head fractures.^{75,76} Boys and girls are at equal risk.⁷⁵ The child with this injury usually holds the elbow slightly flexed. Flexion-extension, pronation-supination, and radial head palpation cause pain. There is no consensus among orthopedists regarding classification of

these injuries. Even the terms *radial head* and *radial neck* are often used interchangeably in the literature. Additionally, identifying which injuries should be treated with closed reduction versus percutaneous versus open reduction is murky. Finally, definitive studies assessing functional outcomes, range of motion, and complications among the treatment options are lacking. Minimally displaced fractures can be treated with long arm immobilization with the elbow flexed to 90 degrees.⁷⁵ Orthopedic consultation is required for all other fractures involving the radial head and neck. Up to half of these patients will have other associated elbow fractures; elbow or radial head dislocation may accompany these injuries as well.⁷⁵

FRACTURES OF THE LATERAL EPICONDYLE

This injury is difficult to diagnose and is fraught with a variety of complications including nonunion, malunion, late stiffness, late ulnar nerve palsy, avascular necrosis of the lateral condyle, and deformity.^{71,72,77,78} The usual mechanism for a lateral condyle fracture is a fall on an outstretched hand with the elbow extended and the forearm supinated. Varus stress acts to avulse the lateral condyle.^{71,72,77} This is the second most common pediatric elbow fracture.⁷² Swelling and tenderness are usually found only over the lateral portion of the elbow, and acute neurovascular compromise is unusual.⁷² Radiographs should include anteroposterior, lateral, and oblique views. The oblique view is most likely to show the injury and true degree of fracture displacement.^{71,72} Nondisplaced or minimally displaced fractures (0 to 2 mm) are treated with a long arm cast.^{71,72} Close follow-up is important since up to 10% of these fractures may displace while immobilized.^{77,78} Fractures displaced more than 2 mm require orthopedic consultation. Some advocate open reduction and internal fixation for all these injuries, while some perform closed reduction and pinning for fractures displaced 2 to 4 mm and open procedures for more widely displaced fractures.^{71,72,79}

FRACTURES OF THE MEDIAL EPICONDYLE

Medial epicondyle avulsion fractures, which occur at the growth plate, can occur due to acute or chronic valgus stress on the elbow. Throwers (e.g., baseball pitchers) are prone to this type of injury.⁸⁰ Medial epicondyle fractures are also commonly seen along with pediatric elbow dislocations.⁸¹ Children with fractures of the medial epicondyle typically present with localized pain, swelling, and tenderness directly over the medial epicondyle.^{70,80} If the injury is due to chronic overuse in a thrower, there may be a history of decreased throwing effectiveness or distance. Nondisplaced fractures are treated with a short period of immobilization and pain relief.⁸⁰ Those children with displaced fractures should be referred to an orthopedist for consideration of operative repair.^{70,80,82} Controversy exists over operative indications in isolated, displaced medial humeral epicondyle fractures. One retrospective study found similar functional outcomes in nonsurgical versus surgical management of this injury.⁸³ Fracture fragments within the joint space require emergent extrication and fixation.^{80,84}

Elbow Dislocation

This is an uncommon injury in children, with the peak incidence during the early teen years.^{10,86} Contact sports and falls

account for most of these injuries. Most dislocations are posterior and closed, but a wide spectrum of dislocation patterns has been described^{10,81} (Fig. 19–4). A variety of associated fractures are seen with elbow dislocations.^{81,85} Injuries to the median, ulnar, and radial nerves have been described, as well as vascular injuries. Nerve entrapment or a fracture fragment within the ulnohumeral joint mandates immediate surgery.⁸⁶ If elbow reduction attempts are unsuccessful, an entrapped fracture fragment or interposed soft tissue should be suspected.¹⁰

Elbow Injuries in the Child Athlete

Over 30 million children in the United States participate in organized sports. The incidence of upper extremity injury is second only to ankle and knee injuries in the child athlete.⁸⁷ Although a wide variety of acute elbow injuries can be sustained by the child athlete, one chronic overuse injury seen by emergency physicians is “little leaguer’s elbow.” The repetitive valgus stress induced by throwing or similar motions produces osseous damage of the elbow. While little leaguer’s elbow was originally described in baseball pitchers, it is also seen in nonpitching baseball players, racquet sport players, football players, and others.¹⁰ Most with this condition will complain of medial elbow pain. When questioned, the athlete with little leaguer’s elbow will also report decreased throwing effectiveness or distance.^{10,88} Radiographs may reveal hypertrophy or separation of the medial humeral condyle.⁸⁹ The optimal “treatment” is prevention, through a combination of rest, proper throwing mechanics, and avoidance of overexertion. Once little leaguer’s elbow develops, rest—until there is complete resolution of pain—is important. When activity resumes, proper throwing mechanics are key to preventing recurrence.⁹⁰

Forearm Injuries

Forearm Fractures

Distal forearm fractures occur most commonly at the time of the pubertal growth spurt in early adolescence. This is

FIGURE 19–4. Posterior dislocation of the elbow. **A**, Lateral radiograph of the elbow. The ulna and radius are displaced posteriorly. **B**, Anteroposterior radiograph of the posterior dislocation of the elbow. (From Green NE, Swiontkowski MF [eds]: *Skeletal Trauma in Children*, 3rd ed. Philadelphia: WB Saunders, 2003.)

likely due to increased physical activity that occurs at this time of life and decreased bone strength due to enhanced bone turnover.⁹¹ Most of these fractures occur due to a fall on an outstretched hand, although direct local trauma can produce them as well.⁹² Acceptable pronation, supination, and cosmesis are the main treatment outcomes of interest.⁹² Outcomes are largely dependent on fracture angulation at the time of fracture healing. Fracture angulation, in turn, depends on the quality and maintenance of the initial reduction.⁹³ Most pediatric forearm fractures can be successfully treated with a combination of reduction and immobilization. There is controversy regarding the treatment of completely displaced metaphyseal fractures of the distal radius. Since up to 21% of distal radius fractures displace after successful reduction,⁹⁴ some have suggested the use of percutaneous Kirschner wires to maintain reduction.⁹⁵

For diaphyseal forearm fractures, failure of closed reduction is the most common surgical indication. Adolescents with these injuries are generally treated with internal fixation and early mobilization like adults with these injuries.⁹⁶ During the physical examination of these children, particular attention paid to the wrist and elbow will make missing a Monteggia or Galeazzi fracture-dislocation less likely.⁹² Most nerve injuries resulting from forearm fractures are neuropraxias that typically resolve within several weeks without specific intervention.

Monteggia Fracture-Dislocation

Isolated ulna fractures in children are uncommon.⁹⁷ A Monteggia fracture-dislocation is an ulnar fracture in association with a radial head dislocation.⁹⁸ Four primary Monteggia-type injuries have been described, with the type dependent upon the fracture location and the direction of ulnar dislocation.⁹⁹ It is well established that Monteggia fracture-dislocations are misdiagnosed by both emergency physicians and radiologists.⁹⁹ The injury generally results from a fall on an outstretched hand. Boys more commonly sustain this injury, and the average age is approximately 7 years with a wide range.¹⁰⁰ The wrist and elbow must be carefully examined for fractures and dislocations. Patients with an isolated ulna fracture and radial head tenderness may have spontaneously reduced their dislocation. Neurologic deficits may be found in up to 17% of patients. They are generally neuropraxias and resolve over weeks to months.¹⁰⁰ If a Monteggia fracture-dislocation is suspected, radiographs of the wrist and elbow (in addition to the forearm) are indicated. To avoid missing this injury, it is essential to recognize that in normal radiographs, the midshaft of the proximal radius points at the capitellum in all views.¹⁰⁰ Closed reduction of both components of the fracture-dislocation and immobilization are used to treat most of these injuries. Open reduction may be required in the case of an otherwise irreducible radial head or an unstable ulna fracture.⁹⁹

Galeazzi Fracture-Dislocation

The Galeazzi fracture-dislocation is an uncommon but important injury in children.¹⁰¹ The Galeazzi fracture-dislocation is a radial shaft fracture in association with a distal radioulnar joint dislocation.¹⁰¹ The injury is usually caused by a fall on an outstretched hand with the forearm in pronation. Careful examination of the wrist is helpful in avoiding missing this injury.¹⁰¹ Children with a Galeazzi

fracture dislocation will not be able to fully promote and supinate their forearms. Treatment involves closed reduction and immobilization.¹⁰¹⁻¹⁰³

Greenstick Fractures

This fracture type involves a break in one bony cortex and compression of the bony cortex opposite the fracture site. In one large series of over 3300 pediatric patients with upper extremity fractures, greenstick fractures occurred in just over 5% of patients.¹⁰⁴ However, another large study found a nearly 52% incidence of greenstick fractures.¹⁰⁵ Subject selection for these studies likely explains this discrepancy. The decision to reduce these fractures generally depends on the amount of angulation present. If reduction is required, the angulation is overcorrected toward the cortical break, in essence completing the fracture so as to prevent persistent angulation and resultant deformity. A splint is then applied.

Wrist and Hand Injuries

Wrist Fractures

DISTAL RADIUS FRACTURES

These injuries are common in children and generally result from a fall onto an outstretched hand.¹⁰⁵ The most common type of distal radius fracture is the buckle fracture (also known as a torus fracture).¹⁰⁶⁻¹⁰⁹ These minor fractures tend to do very well with a removable splint that can be worn for three to four weeks.¹⁰⁶⁻¹⁰⁸ These fractures seldom have complications and can be managed by either primary care physicians or orthopedists. In more severe injuries, there may be a distal “both bones” fracture involving both the radius and ulna. Local tenderness and swelling are invariably present, but may be somewhat subtle. If angulated or displaced, these fractures typically require closed reduction that can be performed by the emergency physician or an orthopedist. There is no universally accepted degree of residual angulation after reduction and local standards tend to guide the acceptance of a reduction attempt. Younger children have greater degrees of acceptable residual angulation.¹¹⁰ This is due to a greater capacity for remodeling in younger children. For very distal injuries that may involve the growth plate, orthopedic follow-up is prudent.¹¹¹ In general, children with distal radius fractures do well. Resultant traumatic arthritis is rare.¹¹²

CARPAL INJURIES

Pediatric carpal fractures are uncommon. This may be because the carpus is largely unossified throughout much of early childhood. Adolescents, whose carpal bones are nearly completely ossified, have adult-type injury patterns.¹¹³ The scaphoid is the most commonly fractured carpal bone in children, as it is in adults, although the patterns of injury are different.¹¹³ More are located distally, they more often involve a single cortex, and they are more often nondisplaced.¹¹⁴ The peak incidence of scaphoid fractures occurs at age 12 years.¹¹³ Radiographs done in the emergency department may easily miss scaphoid fractures. MRI is far more sensitive for fracture detection in this region.¹¹⁵ However, no study has examined the benefit of early detection of scaphoid injuries, so long as they are suspected, immobilized in a thumb spica splint, and referred for follow-up. Scaphoid fractures have

been reported in association with distal radius fractures.¹¹⁶ Tenderness in the anatomic snuffbox or scaphoid compression pain should cause the treating physician to consider a scaphoid fracture and treat for same. A wide variety of carpal fractures and dislocations have been described in children, all in small case series. Care is therefore individualized.

Hand Fractures

Hand injuries are common in children of all ages, and fractures make up 15% to 19% of all hand injuries.¹¹⁷⁻¹¹⁹ Fracture incidence has a bimodal distribution, with distal phalanx injuries predominating at age 1 year and other phalangeal and metacarpal injuries peaking at age 12 years.^{120,121} Most pediatric hand fractures heal uneventfully.¹²² Open fractures, those involving articular surfaces, comminuted fractures, and markedly displaced and angulated fractures mandate the timely involvement of a hand surgeon or orthopedist experienced in caring for hand injuries.

METACARPAL FRACTURES

The shaft is the most commonly fractured metacarpal region in children; however, articular and periarticular fractures do occur.^{120,122} A volar angulated fracture involving the neck of the fourth or fifth metacarpal (i.e., a boxer's fracture) often occurs when a hard surface is punched. Evidence to guide the optimal treatment of these injuries is scant. Depending on community standards and degree of angulation, these fractures can be reduced¹²⁰ or left in place and the digit either buddy taped or placed in an ulnar gutter splint. Rotational deformity of the affected digit needs to be identified since healing and regrowth will not correct this abnormality. To check for rotational deformity, the patient should be asked to fully flex all the digits. In full flexion, all digit tips should point evenly at the thenar eminence. Overlap, indicating rotation, should prompt consultation with a hand surgeon. Similarly, fractures at the base of the thumb metacarpal require hand surgeon consultation.^{120,123}

PROXIMAL PHALANX FRACTURES

Many of these fractures in children are articular or periarticular.^{120,123} Radiographs including posteroanterior, lateral, and oblique views are helpful to avoid missing subtle injuries.¹²⁰ A common injury pattern is the Salter type II fracture at the phalangeal base¹²³ (see Fig. 20–2). If it involves the little finger, the digit is usually abducted and extended. Reduction is performed by using a pencil in the fourth web space to lever the fracture back into place. Reduction is maintained by buddy taping.^{120,123} Fractures at the base of the thumb's proximal phalanx are often Salter type III fractures and can be considered the childhood equivalent of ulnar collateral ligament rupture (i.e., gamekeeper's or skier's thumb). Although experts are not in perfect agreement on treatment, in general, minimally displaced fractures can be immobilized without reduction. Displaced fractures require reduction and internal fixation.^{120,123}

Distal periarticular or articular fractures can be easily overlooked. The mechanism of injury may be a tip-off. One paper suggests this fracture type occurs when a child's digit is closed in a car door and forcibly extracted. It further states that the fracture fragment may be purely cartilaginous, making radiographic visualization of it difficult.¹²⁰ Another suggests that oblique radiographs may be particularly helpful

in diagnosing these injuries.¹²³ In any event, displaced distal fractures involving the articular surface must be reduced and internally fixed.^{120,123}

MIDDLE PHALANX FRACTURES

Many of these fractures are similar to those seen in the proximal phalanges 2 through 5.¹²⁰ Nondisplaced articular fractures are treated with buddy taping. Fractures displaced more than 2 mm require reduction and internal fixation.^{120,123}

DISTAL PHALANX FRACTURES

Many of these involve crush injury to the fingertip, nail, and nail bed and vary widely in severity.^{120,123-125} As one would expect, outcome and degree of initial injury are correlated.¹²⁴ Traditionally, open crush injuries are treated with antibiotics to reduce the risk of osteomyelitis,¹²⁰ although this is not an evidence-based recommendation. A prescription for oral antibiotics is probably adequate. Mallet finger-type fractures are generally treated with closed reduction and immobilization in slight hyperextension.¹²³

Nail Bed Injuries

For subungual hematomas larger than 25%, nail removal and nail bed repair is often advocated. However, a 1999 study has called this recommendation into question.¹²⁵ It found that, in children with an intact nail and nail margin and a subungual hematoma, trephination versus nail bed repair produced similarly excellent results (see Chapter 173, Management of Digit Injuries and Infections).

Chapter 20

Lower Extremity Trauma

Besh Barcega, MD, MBA and Lilit Minasyan, MD

Key Points

A delayed diagnosis of slipped capital femoral epiphysis has a high likelihood of leading to avascular necrosis of the femoral head.

A saline arthrogram is useful for identifying knee lacerations that penetrate the joint space.

Tibia and fibula fractures place the child at risk for a compartment syndrome of the leg.

Selected Diagnoses

- Traumatic hip dislocation
- Slipped capital femoral epiphysis
- Femur fractures
- Knee injuries
- Osgood-Schlatter disease
- Tibia and fibula fractures
- Ankle injuries
- Foot injuries
- Toe injuries
- Approach to the special needs child

Discussion of Individual Diagnoses

Traumatic Hip Dislocation

Traumatic hip dislocations are relatively rare in children.¹ The mechanisms of injury involve high-energy events such as falls from substantial heights and motor vehicle accidents. Children generally present with groin and thigh pain, flexion and external rotation of the involved hip, and apparent shortening of the lower extremity. A small percentage of children with hip dislocations will also have associated acetabular fractures.¹ Posterior dislocations are the most common. Pain control and neurovascular assessment are important factors in the initial emergency department evaluation of these children. An anterior-posterior pelvis radiograph will usually confirm the diagnosis (Fig. 20–1). Closed reduction by the emergency physician is indicated. The use of procedure-related sedation for this procedure is prudent. Once success-

ful reduction has occurred, keeping the hips in abduction with a pillow or blankets between the thighs minimizes the risk of re-dislocation. Postreduction radiographs are indicated. Patients with traumatic hip dislocations are usually admitted to the hospital for spica casting or traction followed by early mobilization. Emergent orthopedic consultation is needed if initial reduction attempts are unsuccessful. A delay in diagnosis or successful reduction increases the risk of avascular necrosis of the femoral head. With prompt treatment, most children with traumatic hip dislocations do well and have minimal or no long-term sequelae.¹

Slipped Capital Femoral Epiphysis

A slipped capital femoral epiphysis (SCFE, usually pronounced “skiffy”) results from shearing forces through the proximal femoral physis. This is a type of Salter-Harris type I fracture (Fig. 20–2). SCFE is in the differential diagnosis of any child with a limp and no other constitutional symptoms.^{2–4} The most commonly affected age group includes older school-age children and younger adolescents. Bone age is probably more important than chronological age.⁵ There may be a history of relatively minor trauma. The onset may be sudden and rather obvious or indolent and subtle. The child may complain of groin, hip, or knee pain. In particular, an older school-age child who has seen multiple physicians for knee pain, has undergone multiple normal radiographs of the knee, and has a normal knee examination is a classic example of an indolent case of SCFE. More than 20% of children with SCFE will have bilateral disease at presentation or will develop SCFE on the contralateral side at some point in childhood.⁶ Obese children are at higher risk for bilateral disease.⁶

When SCFE is suspected, anterior-posterior and frog-leg lateral hip radiographs and an anterior-posterior pelvis radiograph are indicated. The key finding on radiographs is an abnormal position of the proximal femoral epiphysis in relation to the metaphysis. This has been referred to as “the ice cream falling off the cone.” When slippage is not obvious, evaluation of Klein’s line is useful.⁷ Klein’s line is drawn along the superior aspect of the femoral neck and should intersect the femoral epiphysis. Failure of Klein’s line to intersect the femoral epiphysis is supportive of the diagnosis of SCFE. Once SCFE is identified, orthopedic consultation is indicated. Operative stabilization is usually undertaken. The timing of this is controversial and is at the discretion of the orthopedist.⁸ If radiographs are normal yet the diagnosis of

SCFE remains likely, one reasonable plan is to discharge the patient home with crutches and instructions for non-weight bearing on the involved extremity. Arrangements can then be made for an outpatient magnetic resonance imaging (MRI) study of the hip within 1 to 2 weeks.⁹ Complications of SCFE include avascular necrosis of the femoral head and

osteoarthritis of the hip. A delayed diagnosis increases the risk of complications. Even with appropriate management, avascular necrosis occurs in as many as 14% of children diagnosed with SCFE.¹⁰

Femur Fractures

Femur fractures are the most common traumatic orthopedic injuries requiring hospitalization.¹¹ Most femur fractures result from a high-impact mechanism, and the patients present with obvious swelling, deformity, pain, and tenderness in the affected thigh. Shortening of the involved extremity will be evident on physical examination. Infants and nonverbal children with femur fractures may present with a history of refusing to crawl, excessive crying, and swelling over the thigh or tenderness over the fracture site. Although femur fractures in nonambulatory infants and children are suggestive of nonaccidental trauma, they are not pathognomonic for child abuse¹² (see Chapter 119, Physical Abuse and Child Neglect).

Emergency department management of femur fractures generally involves splinting, analgesia, and monitoring the neurovascular status of the involved extremity. Radiographs of femur fractures are seldom subtle. Unlike adults, isolated, closed femur fractures have not been found to be a significant cause of hypotension in children.^{13,14} If a child with a closed femur fracture is experiencing hemodynamic instability, alternative causes should be investigated. Orthopedic consultation in the emergency department is indicated for most

FIGURE 20-1. Radiograph of a traumatic hip dislocation.

Salter-Harris Classification of Growth Plate Fractures

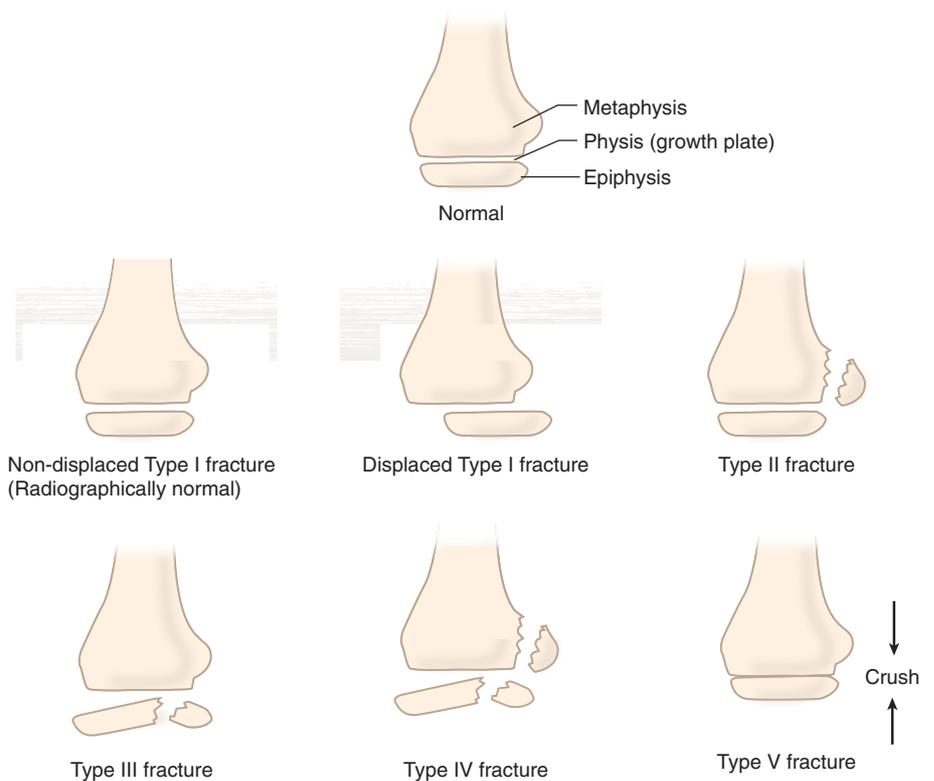

FIGURE 20-2. Salter-Harris classification of growth plate fractures. (Adapted from Salter RB, Harris WR: Injuries involving the epiphyseal plate. *J Bone Joint Surg [Am]* 45:587-622, 1963.)

femur fractures as most infants and children under age 6 are treated with spica casting and those over 6 years are typically treated with open reduction and internal fixation.¹¹ In certain circumstances, children with femur fractures can be discharged home from the emergency department without orthopedic consultation. Examples of these fractures include a child with a torus fracture of the femoral metaphysis without significant displacement or angulation and an adolescent with an avulsion fracture of the lesser trochanter.¹⁵

Knee Injuries

Urgent orthopedic consultation is seldom needed for knee injuries seen in the pediatric emergency department. Specific conditions managed by the emergency physician include patellar dislocations and injuries to the menisci and ligaments. In most patellar dislocations, the patella is displaced laterally. Reduction is straightforward and is accomplished by extending the knee. This reduction is somewhat painful, but mercifully brief and simple to perform. Procedural sedation is seldom needed. Prompt pain relief is expected. Discharge to home in a knee immobilizer is the usual disposition. Orthopedic or primary care follow-up for a gradual return to normal activities is appropriate.

Meniscal and ligamentous injuries are frequently due to a forced twisting motion of the knee. Frequently, the patient will have joint swelling due to hemarthrosis. Joint line tenderness is expected in most of these injuries. Injuries to the ligaments will result in a degree of joint laxity in the direction supported by the injured ligament. However, if the knee is excessively tender and swollen, testing for joint laxity will not be feasible. Radiographs typically will not reveal a fracture unless ligamentous disruption has resulted in a small avulsion fracture. Discharge to home in a knee immobilizer with or without crutches is the usual disposition. Orthopedic follow-up with the expectation of an outpatient MRI is a reasonable plan under most circumstances.^{16,17} There has recently been some interest in using bedside ultrasound to evaluate ligamentous and meniscal injuries.¹⁸ The role for ultrasound for this purpose is unclear at this point.

Traditionally, nearly all patients with injured knees underwent radiographs. Although obviously indicated in severe injuries, the utility of these radiographs on the less acute end of the continuum of injuries was frequently questionable at best. In an attempt to limit unnecessary knee radiographs, the Ottawa knee rules were developed¹⁹⁻²¹ (Table 20-1). Recent studies have validated the Ottawa knee rules for children.¹⁹⁻²¹ Unfortunately, relatively few young children were

included in these studies, thus limiting the applicability of the rules to younger children. Applying the Ottawa knee rules to older school-age children and adolescents is probably reasonable.

Several conditions involving the knee require urgent orthopedic consultation. These include open fractures, displaced fractures involving the growth plate, penetrating injuries involving the joint space, significantly avulsed tibial spine fractures, and foreign bodies within the joint space.²² Another injury pattern requiring prompt orthopedic consultation is the “floating knee,” which results from ipsilateral femoral and tibial fractures. This fracture combination is relatively rare in children, arising in the setting of high-energy trauma such as occurs when pediatric pedestrians are struck by automobiles (i.e., “auto vs. pedestrian”). Children with floating knees present with pain, swelling, and obvious deformity over the fracture sites. There is substantial instability of the entire middle of the lower extremity. Bedside portable radiographs are usually sufficient to make the diagnosis. Emergent angiography, including assessment of the popliteal vessels, is indicated. The initial emergency department management of these injuries involves providing adequate analgesia, applying a posterior long-leg splint, and obtaining prompt orthopedic consultation. The definitive treatment is open reduction and internal fixation.^{23,24}

The knee is the most common joint to sustain a penetrating injury. Treatment of children is similar to that of adults. Plain radiographs can be obtained to evaluate for associated fracture, air in the joint space indicating a violation of the joint, and the presence of a radiopaque foreign body. In addition, vascular trauma must be diagnosed in a timely manner to assure appropriate treatment. Bynoe et al. found duplex ultrasonography to accurately locate vascular injuries.²⁵ In appropriate hands, duplex ultrasonography may serve as a noninvasive alternative to arteriography. Deep lacerations in close proximity to the joint should raise suspicion for an open joint wound. This can be confirmed by performing an arthrogram of the joint. An arthrogram is performed by preparing a sterile field on a site distant from the laceration and inserting a relatively large-bore needle (e.g., 18 gauge) into the joint space. By infusing injectable, sterile normal saline (from a bag of normal saline used for intravenous infusion, not the saline used for wound irrigation) into the joint space until there is swelling, the emergency physician observes for fluid leakage from the wound. Fluid leakage suggests an open joint injury. This should prompt urgent orthopedic consultation for operative washout and repair.

Osgood-Schlatter Disease

Osgood-Schlatter disease refers to osteochondrosis of the anterior tuberosity of the tibia.²⁶ Osteochondrosis is a “disease of ossification centers in children that begins as a degeneration or necrosis followed by regeneration or recalcification.”²⁶ Osgood-Schlatter disease is a relatively common condition in adolescents and is more common in boys.²⁷ As many as 25% to 50% of cases are bilateral.²⁷ There is some debate as to whether this disease is a form of tendonitis or a Salter-Harris type I fracture of the tibial tubercle²⁸ (see Fig. 20-1). These patients often present with knee pain that is worse with activity and relieved with rest. The physical examination is generally diagnostic, with tenderness and a bony bulge at the site of the tibial tuberosity. Radiographs are seldom needed for

Table 20-1 Ottawa Knee Rules

Obtain knee radiographs if there is a history of acute knee injury and at least one of the following:

- Inability to walk 4 steps immediately after the injury and in the emergency department (regardless of limp)
- Tenderness over the patella
- Tenderness of the head of the fibula
- Inability to flex the knee to 90 degrees
- Age greater than 55 yr

Data from Khine H, Dorfman DH, Avner JR: Applicability of Ottawa knee rule for knee injury in children. *Pediatr Emerg Care* 17:401-404, 2001.

the diagnosis or management of suspected Osgood-Schlatter disease. The usual treatment is conservative and consists of rest, anti-inflammatory/analgesic medications (e.g., ibuprofen), and follow-up with a primary care physician. For serious athletes, follow-up with a sports medicine physician is ideal to allow for maximum participation balanced with sufficient rest to minimize pain.

Tibia and Fibula Fractures

Most fractures of the fibula occur in association with tibia fractures. Isolated fibula fractures are rare in children. The location of the injury is usually clear from the physical examination, in which crepitus, a palpable step-off, bruising, and tenderness are expected at the fracture site. Radiographs of the entire tibia and fibula tend to offer adequate visualization of clinically important fractures. The identification of a fracture of both the tibia and fibula is straightforward. Emergency department management with a posterior molded splint is also straightforward. However, because of the relatively “tight” compartments of the leg, compartment syndrome may develop due to swelling at the fracture site (see Chapter 22, Compartment Syndrome). Prolonged periods of elevation are indicated during the first day or two after the injury. Admission to an observation unit or to the hospital overnight after reduction and splinting is suggested. Selected patients likely to be very compliant with the elevation requirement are the best candidates for discharge home from the emergency department.

A tibial fracture seen only in young children is the toddler’s fracture. Toddler’s fractures are oblique or spiral fractures in the middle or distal third of the tibia. These fractures are due to a twisting force. Classically, these fractures have no displacement and no angulation. The classic story is of a toddler limping or refusing to walk after getting the foot caught in something and falling while twisting about to release the foot. The child may present without a clear mechanism of injury, however. The physical examination findings may be subtle. If the child is able to tolerate the examination, pain may be elicited at the fracture site. There is typically little, if any swelling. The overlying skin usually appears normal. Toddler’s fractures are notoriously difficult to diagnose on plain radiographs: the fracture may appear to be a “nutrient vessel” with a dark, oblique line running through the tibial shaft without apparent violation of the cortex, or it may appear on only one view. The fracture may not be evident at all on initial radiographs, only appearing when repeat radiographs are obtained 7 to 10 days after the injury as callus formation becomes radiographically evident.²⁹ Treatment for toddler’s fractures, both those clearly diagnosed and those merely suspected, is with a long-leg splint and close follow-up with a primary care physician or orthopedist in 7 to 10 days.³⁰⁻³³

Ankle Injuries

Ankle injuries are common. The ankle is a flexible, multidirectional, narrow joint that must support the body’s entire weight while moving and changing direction over uneven surfaces. Ankle injuries can range from minor strains of the supporting ligaments to serious fractures requiring operative intervention.

At the more serious end of the injury spectrum are the Tillaux fracture and the Maisonneuve fracture. The Tillaux

fracture is a Salter-Harris type III fracture of the lateral, distal tibia. This fracture appears to be unique to adolescents. The fracture pattern is thought to result from asymmetric closing of the growth plate with the medial aspect closing earlier than the lateral aspect. This fracture may be difficult to appreciate on plain radiographs. Computed tomographic (CT) scanning may be required to make the diagnosis.³⁴ Open reduction and internal fixation are usually required.³⁵ The Maisonneuve fracture is actually two fractures. The first is a medial malleolar fracture (of the distal tibia). The second is an oblique fracture of the proximal fibula. If the physical examination and plain radiographs focus exclusively on the ankle, this proximal fibula fracture might be missed. With most Maisonneuve fractures there is disruption of the interosseous membrane between the tibia and fibula. When this occurs, the ankle joint is unstable and subsequent diastasis of the joint is likely. Maisonneuve fractures typically require open reduction and internal fixation.³⁶

Along the more minor end of the spectrum of ankle injuries are ankle sprains and “occult” distal fibula fractures. Classic teaching has suggested that the ligaments of pediatric ankles are stronger than the growth plate of the distal fibula. If true, nondisplaced Salter-Harris type I fractures of the distal fibula would be expected to be more common than ankle sprains in children. For children who have sustained inversion injuries to the ankle and have normal radiographs, the treatment recommendations have typically focused on immobilization with a posterior molded splint and avoidance of weight bearing. The recommended follow-up plan is then to have a primary care physician or orthopedist reevaluate the child in about 10 days with the expectation of repeat radiographs to look for callus formation. Preliminary work with ultrasound suggests that it may be able to differentiate ankle sprains from occult distal fibula fractures.³⁷ Further study is required before ultrasound can be recommended for this purpose.

One area of controversy is the use of the Ottawa ankle rules for evaluating children with ankle injuries (Table 20–2). The Ottawa ankle rules were developed to minimize the use of unnecessary radiographs in the evaluation of relatively minor ankle injuries.³⁸ A few studies have supported the use of the Ottawa ankle rules in children,³⁹⁻⁴¹ and one study found the

Table 20–2 Ottawa Foot and Ankle Rules

<p>Obtain ankle radiographs if there is acute ankle injury and at least one of the following:</p> <ul style="list-style-type: none"> • Inability to bear weight (4 steps) immediately after the injury and in the emergency department regardless of limp • Tenderness to palpation over the posterior edge or tip of the lateral malleolus • Tenderness to palpation over the posterior edge or tip of the medial malleolus <p>Obtain foot radiographs if there is a history of acute foot injury and at least one of the following:</p> <ul style="list-style-type: none"> • Inability to bear weight immediately after the injury and in the emergency department • Tenderness to palpation over the base of the 5th metatarsal • Tenderness to palpation over the navicular bone
--

Data from Stiell IG, McKnight RD, Greenberg GH, et al: Implementation of the Ottawa Ankle Rules. *JAMA* 271:827–832, 1994.

Ottawa ankle rules inappropriate for children.⁴² Other decision rules have also been suggested for evaluating pediatric ankle injuries.^{43,44} The clinical application of any of these decision rules is dependent on the emergency physician's tolerance for failing to identify a clinically insignificant ankle fracture. The use of radiograph-minimizing decision rules for children remains controversial. What is clear, however, is that skeletally mature adolescents with ankle injuries can be treated like adults with similar injuries.³⁸

Foot Injuries

Pediatric midfoot and hindfoot fractures are relatively common. In younger children, these fractures often present with a chief complaint of limp and may be mistakenly diagnosed as a toddler's fracture or foot sprain as the initial radiographs may be normal at the time of the emergency department visit. In cases of subtle midfoot and hindfoot injuries, plain radiographs obtained 2 to 4 weeks after the initial visit will typically reveal sclerotic changes at the fracture sites.^{45,46} The most commonly seen of these fractures involve the calcaneus or cuboid. Because of the difficulty in diagnosing subtle midfoot and hindfoot fractures, bone scans have been advocated for the early evaluation of these fractures.⁴⁵⁻⁴⁷ However, the clinical outcomes of these injuries is generally excellent without any particular intervention suggesting that bone scans may only be indicated for serious athletes or other special groups. Displaced fractures of the calcaneus and the midfoot sustained under a high-impact mechanism require orthopedic consultation in the emergency department. Avascular necrosis is a serious complication of these fractures. Lisfranc-type injuries (tarsometatarsal joint injuries after a midfoot plantar-flexion injury) rarely occur in young children. Unlike adults and adolescents who require urgent orthopedic consultation in the emergency department, younger children with these injuries can be successfully managed with a short-leg walking cast for 3 to 7 weeks.⁴⁸ One complication of Lisfranc-type injuries is compartment syndrome. Therefore, elevation of the injured foot and monitoring for the development of compartment syndrome are indicated for these injuries.

Common foot injuries in all age groups are proximal fifth metatarsal fractures. These fractures arise from inversion injuries of the foot and may be missed if the physical examination and evaluation of the radiographs focuses exclusively on the ankle. This is reflected in the inclusion of these fractures in the Ottawa ankle rules (see Table 20-2). The location of the fracture determines the management and prognosis. The most proximal fractures are usually avulsion fractures and are often referred to as dancer's fractures. These fractures can usually be treated in a hard-soled shoe for a few weeks and seldom lead to complications. Follow-up with a primary care physician is reasonable for these common fractures. More distal fractures are usually referred to as Jones fractures. There is not a well-defined distinction between dancer's fractures and Jones fractures. In adults, dancer's fractures are thought to occur within 1.5 cm from the proximal tip of the fifth metatarsal, while Jones fractures occur more distally. Jones fractures do not heal as well as dancer's fractures and may require open reduction and internal fixation if closed treatment fails. A short-leg, posterior molded splint and the avoidance of weight bearing are usually indicated for Jones fractures. Alternatively, a walking boot may

be used. Follow-up with an orthopedist is indicated for Jones fractures.

The approach to the patient with a puncture wound to the plantar surface of the foot depends on the mechanism of injury, the timing of the injury, and the possibility of a retained foreign body (see Chapter 160, Wound Management). Plain radiographs can aid in documenting the presence of radiopaque foreign bodies such as glass and metal. For wooden foreign bodies, ultrasound, CT scanning, and MRI may be reasonable imaging studies depending on the individual circumstances.⁴⁹⁻⁵² Lawnmower and bicycle spoke injuries can result in extensive bony and soft tissue damage and loss. Urgent orthopedic consultation is indicated.

Toe Injuries

Nondisplaced fractures of the toes are seldom serious and are generally treated with "buddy taping" the injured toe to the adjacent toe. For displaced fractures, closed reduction and buddy taping by the emergency physician is usually adequate. This is particularly important for fifth toe fractures. If reduction is not accomplished, the fifth toe will protrude laterally from the foot. This leads to the patient "catching" the toe on objects when walking barefoot at any point in the future. Orthopedic consultation in 1 to 2 weeks may be obtained on an outpatient basis for unstable fractures. Great toe injuries with bleeding around the nail bed are probably best treated as open fractures with irrigation and prophylactic antibiotics to minimize the risk of osteomyelitis.⁵³ Cephalexin (25 mg/kg per dose three times per day for 7 days) is a reasonable antibiotic choice.

Approach to the Special Needs Child

Technology-dependent children and those who are not ambulatory frequently have osteopenia that places them at high risk for fractures. Certain conditions are well known to predispose children to fractures. Examples include osteogenesis imperfecta and Ehlers-Danlos syndrome. Fracture of the lower extremity is included in the differential diagnosis for the fussy special needs child, especially if the examination reveals redness, swelling, or possible tenderness to palpation of the lower extremity. There may be a recent history of physical therapy or pain during patient transfer (such as in and out of a specialized wheelchair), but no history of any significant trauma, such as a fall. Plain radiographs of the involved extremity from the hip to the toes may be needed to locate the injury. Fractures in the nonambulating special needs child generally can be treated with splinting and pain control. Closed reduction of significantly displaced fractures is prudent. Procedural sedation may be required to accomplish these reductions (see Chapter 159, Procedural Sedation and Analgesia).

Chapter 21

Pelvic and Genitourinary Trauma

Peter S. Auerbach, MD

Key Points

In children, mortality directly related to pelvic fractures is very low.

“Routine” pelvic radiographs are no longer advocated.

Approximately 10% of children with pelvic fractures also have injuries to the genitourinary system.

The utility of a microscopic urinalysis is unclear.

Blood seen at the penile meatus is a contraindication to blindly placing a Foley catheter.

Introduction and Background

Pelvic fractures are relatively uncommon in children, occurring in 3% to 5% of children versus 6% to 10% of adult blunt trauma patients.^{1,2} When fractures of the pelvis do occur in children, they are usually associated with a severe mechanism and multiple associated injuries. Mortality from pelvic fractures is lower in children than in adults due to differences in the types of fractures sustained and the inherent fracture resistance of the bony and ligamentous structures of the pediatric pelvis.

Although rarely life threatening, injuries to the genitourinary system often occur in children with pelvic trauma and are sometimes overlooked during the initial assessment due to the high incidence of higher priority, associated injuries. Lower genitourinary injuries (i.e., injuries to the bladder, urethra, and genitals) are seen in fewer than 5% of children with pelvic fractures.³ Urethral injuries are difficult to diagnose. Serious renal injuries are seldom missed because of the high frequency with which abdominal and pelvic computed tomographic (CT) scanning are performed on traumatized children.

Recognition and Approach

The most common mechanism of injury resulting in pediatric pelvic fractures is a pedestrian struck by a motor vehicle.⁴⁻⁷ In contrast, adults who sustain pelvic fractures are more

likely to be the driver or passenger in a motor vehicle collision.^{1,2} The most common significant injury associated with pelvic fractures in children is a head injury. Intra-abdominal solid organ injuries are also commonly associated with pelvic fractures.

The classification of pediatric pelvic fractures has not been standardized, which makes a direct comparison of published studies difficult. Of the classification systems used, the most widely accepted classifies pelvic fractures into three types based on structural integrity⁸ (Fig. 21–1). Type A fractures spare the posterior pelvic arch and are therefore mechanically stable. Commonly seen type A fractures include those of the pubic rami. Type B fractures involve incomplete disruption of the posterior arch, making the pelvic ring horizontally unstable but vertically stable. Type B pelvic fractures are frequently the result of anterior-posterior compression. Type C fractures involve complete disruption of the posterior arch, often through the sacroiliac joint, rendering the pelvic ring both horizontally and vertically unstable. Type C pelvic fractures are frequently the result of vertical forces resulting from a fall. Type B and C fractures are relatively rare in children.^{4,5}

The pediatric genitourinary system differs from that of adults in several important ways. The kidneys are more easily injured in children because they are relatively larger in size and less well protected by the ribs. Children tend to have less perirenal fat, weaker abdominal muscles, and a flexible rib cage. In addition, pediatric kidneys are more likely to contain persistent fetal lobulations, which may predispose to parenchymal disruption during blunt trauma.⁹ The pediatric bladder is more susceptible to injury because it extends superiorly into the abdomen and is less well protected by the pelvic ring. The bladder wall musculature is weakest at the superior pole, where it lies in contact with the peritoneum, making intraperitoneal bladder rupture more likely. In boys, the urethra may also be more susceptible to injury because it is less elastic and less well protected by the prostate.¹⁰

Injuries may involve any portion of the genitourinary system. The kidney is the most commonly injured portion of the genitourinary system. The most widely accepted scoring system for kidney injuries is incorporated into the comprehensive Organ Injury Scoring and Scaling System¹¹ (Table 21–1). Most pediatric kidney injuries identified are grade I. The bladder is the second most frequently injured component of the genitourinary system. There is some utility in

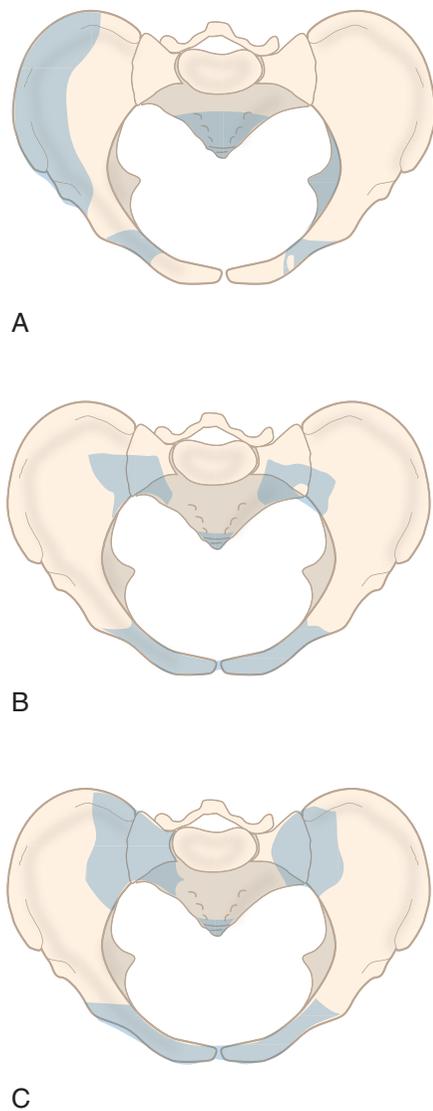

FIGURE 21-1. Classification of pelvic fractures. **Type A**, Lesions sparing (or with no displacement of) the posterior pelvic arch. **Type B**, Incomplete disruption of the posterior arch (partially stable). **Type C**, Complete disruption of the posterior arch (unstable). (Images courtesy of the Orthopedic Trauma Association.)

separating bladder injuries into three general categories: bladder contusions, extraperitoneal bladder rupture, and intraperitoneal bladder rupture. Contusions are partial tears of the bladder mucosa. Extraperitoneal bladder rupture usually occurs as a result of a displaced pelvic fracture lacerating the bladder. Intraperitoneal bladder rupture usually results from significant blunt trauma to a full bladder. Intraperitoneal bladder rupture is the most serious type of bladder injury and is the most likely type of bladder injury to require operative repair. Bladder injuries almost always present with gross hematuria, difficulty with urination, or significant abdominal pain.³ The male urethra is susceptible to injury during pelvic and perineal trauma. The male urethra is anatomically divided into posterior and anterior segments by the urogenital diaphragm between the pubic rami. The posterior segment is proximal and the anterior segment is distal. The two segments of the male urethra have different patterns of

Table 21-1 Kidney Injury Scoring

Grade	Description of Injury
I	Contusion <i>or</i> Subcapsular hematoma
II	Nonexpanding perirenal hematoma confined to the retroperitoneum <i>or</i> <1.0-cm renal parenchymal laceration without urinary extravasation
III	>1.0-cm renal parenchymal laceration without urinary extravasation <i>or</i> Collecting system involvement
IV	Laceration extending into the collecting system <i>or</i> Renal artery or vein injury with contained hemorrhage
V	Shattered kidney <i>or</i> Avulsion of renal hilum, which devascularizes kidney

injury. Posterior urethral injuries result from high-energy blunt trauma and are often associated with pelvic fractures and bladder injuries (Fig. 21-2). In contrast, anterior urethral trauma usually results from straddle injuries. Anterior urethral injuries are associated with external genital injuries. Both types of urethral injuries almost always present with blood at the penile meatus. Accidental injuries to the female urethra are extremely rare and are almost always accompanied by pelvic fractures.¹²

Blunt trauma to the pelvis and perineum can also result in injury to the external genitalia. In males, the most common genital injuries occur to the testicles. Injuries to the testicle include testicular rupture, traumatic torsion, dislocation, hematomas, and hematoceles (see Chapter 87, Testicular Torsion). In females, the most common accidental injuries to the external genitalia involve minor vulvar lacerations from straddle injuries.

Evaluation

The initial approach to a child with possible pelvic or genitourinary trauma should begin with an accurate description of the mechanism of injury. A history of significant deceleration is associated with renal injuries even in the absence of abnormal physical findings or gross hematuria.¹³⁻¹⁵ Physical examination findings associated with pelvic fractures include pelvic tenderness, instability on gentle compression, and ecchymoses or abrasions directly overlying the bony pelvis. In most children with serious pelvic injuries, CT scanning of the abdomen and pelvis is ostensibly performed for other indications (see Chapter 25, Abdominal Trauma). When CT scanning is performed, these images of the bony pelvis preclude the need for plain radiographs. If CT scanning is not planned, a single anterior-posterior pelvis radiograph may be obtained if indicated by the physical examination. Routine pelvis radiographs as part of a traditional “C-spine/chest/pelvis” set of radiographs are no longer advocated. Several recent pediatric studies of blunt trauma patients have

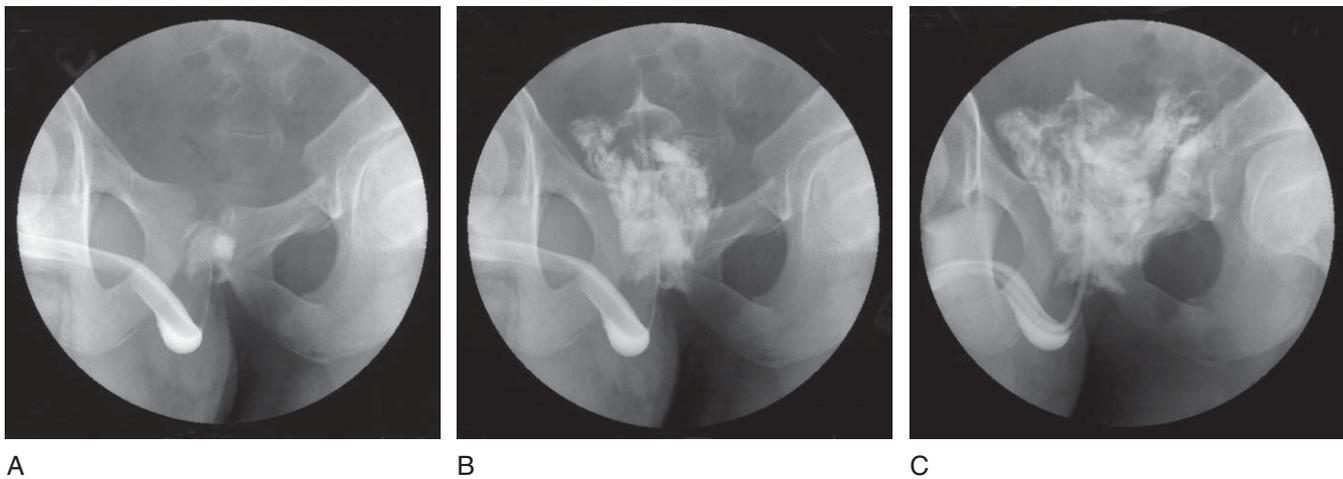

FIGURE 21-2. Retrograde urethrogram demonstrating posterior urethral tear in a 16-year-old boy. **A**, Immediate extravasation of contrast at the level of the prostatic urethra. **B** and **C**, Further retrograde dye injection demonstrates extravasation of nearly all contrast medium with no significant filling of the bladder.

demonstrated that the “routine” pelvis radiograph has extremely low yield and may be safely omitted in many patients. In particular, this is true for children with normal mental status, a normal physical examination of the pelvis, and no distracting injuries.¹⁶⁻¹⁸

Open pelvic fractures are rare in children but have a mortality rate of 20% or higher.¹⁹ Open pelvic fractures must therefore be excluded through a detailed examination of the overlying skin. Any laceration near a fracture site, as well as on the buttocks, perineum, or genital area, is suspicious for an open fracture. Although rectal examinations are seldom indicated otherwise,^{20,21} a careful rectal examination should be performed in patients with displaced pelvic fractures to exclude internal lacerations. Care must be taken by the examiner to avoid sustaining a finger laceration. These examinations may require procedural sedation or general anesthesia to be performed safely. Girls with displaced pelvic fractures should have a cautious manual vaginal examination. For prepubertal girls who are not comatose, it is prudent to perform these examinations with procedural sedation or under general anesthesia.

The physical examination may suggest particular genitourinary injuries. Physical findings suggestive of renal injury include flank or lateral abdominal tenderness, ecchymosis, hematomas, or a palpable mass. In the absence of such findings, gross hematuria alone is a highly sensitive sign of a serious renal injury and should prompt radiographic imaging. Patients with bladder or urethral injuries may complain of lower abdominal pain, urinary urgency, or the inability to void. Physical findings associated with lower genitourinary injuries include gross hematuria, blood at the penile meatus, suprapubic tenderness, and a palpable, tender bladder. Gross hematuria is seen in nearly all cases of lower genitourinary injuries, and its absence is enough to exclude significant bladder or urethral injury unless abnormal physical examination findings or multiple associated injuries are present.^{3,22} The finding of blood at the penile meatus is highly sensitive for urethral injury and is a contraindication to blind urethral catheterization, even if a patient is able to spontaneously void. If catheterization is inappropriately attempted, the

urinary catheter could convert a partial urethral tear into a complete tear.

Historically, various degrees of microscopic hematuria have been used to screen for the presence of renal injury.²³⁻²⁹ There continues to be debate in the literature over how many red blood cells on microscopic urinalysis should be considered significant enough to prompt genitourinary imaging in the absence of other indications. The quest for this “magic number” of red blood cells has not led to a definitive result. Data from multiple recent pediatric studies suggest that isolated microscopic hematuria has a very low yield when used as the sole indication for genitourinary imaging.^{13-15,30-32} It is conceivable that the test characteristics of microscopic urinalysis for identifying genitourinary injuries are not good enough to advocate using microscopic hematuria for this kind of decision making.

Contemporary options for imaging children at risk for genitourinary injuries include CT scanning, ultrasound, cystograms, and urethrograms. The studies selected reflect the anatomic area of concern and, to some extent, the overall hemodynamic stability of the patients. Historically, the intravenous pyelogram was used to image the kidneys and ureters,^{23,24} but CT scanning is now the imaging modality of choice. CT scanning leads to faster results, is more sensitive for identifying renal injuries, and can be used to identify injuries to other intra-abdominal and pelvic structures.^{13,33} Ultrasound has a sensitivity for renal injury of only 70%, but can be performed rapidly at the bedside and does not require the use of intravenous contrast or radiation.³⁴ Ultrasound may have the greatest utility in pregnant girls and any child too hemodynamically unstable to tolerate CT scanning. Ultrasound is useful for follow-up imaging in patients with known injuries (Fig. 21-3). Ultrasound, particularly when Doppler flow is assessed, is also useful for evaluating testicular injuries. Bladder injuries can best be identified by performing a cystogram. Cystograms involve the retrograde injection of contrast material through the urethra into the bladder. Cystograms may be performed with plain radiographs or with CT scanning. Bladder rupture is diagnosed by observing extravasation of the contrast material. Urethral

FIGURE 21-3. Renal laceration and perinephric hematoma in a 17-year-old boy. **A**, Computed tomography shows acute laceration of the left kidney with a large perinephric hematoma. **B**, Ultrasound image of same patient 3 weeks later shows resolving hematoma but does not reveal a laceration. **C**, Comparison view of right (normal) kidney ultrasound.

injuries are diagnosed in a similar manner by retrograde urethrogram. A urethrogram is performed by gently injecting a small amount of contrast material (usually 10 to 30 ml depending upon the size of the child) into the distal urethra under fluoroscopy or while obtaining a plain film radiograph. If a complete urethral tear is present, extravasation of contrast material will be seen without filling of the urethra or bladder proximal to the injury (see Fig. 21-2). If the bladder fills but extravasation is present, the likely diagnosis is a partial tear of the urethra. If no extravasation occurs and the bladder fills, then the examination is negative for urethral disruption.

Management

In general, the identification of pelvic fractures and genitourinary injuries takes place in the context of an evaluation for multisystem trauma (see Chapter 11, Approach to Multisystem Trauma). Treatments for specific pelvic and genitourinary injuries need to be incorporated into the overall management of the traumatized child.

Pelvic Fractures

If a pelvic fracture is closed and nondisplaced, and the pelvic ring is stable, then no immediate management of the fracture is indicated. In this circumstance, the priorities are analgesia and identification of associated injuries. Children rarely become hypotensive as a direct result of pelvic fractures, so children in shock should be presumed to have another source of bleeding. In the rare event that a severe pelvic fracture contributes to ongoing blood loss, immediate measures can be taken in the emergency department (ED) to stabilize the pelvis by reapproximating the fracture surfaces. This is most often necessary for “open book” pelvic fractures. The simplest means to reapproximate such fractures and control hemorrhage is to tighten a sheet around the pelvis. Commercial devices designed for this purpose may be inappropriately sized for most children. Urgent orthopedic consultation for internal or external fixation is then needed. Embolization performed by an interventional radiologist may also be indicated. This may require transfer of the patient to a pediatric trauma center.

Obvious or suspected open pelvic fractures require the prompt administration of intravenous antibiotics. Open pelvic fractures, particularly in children, are sufficiently rare

that no evidence-based recommendations on antibiotic selection can be made. In this context, the selection of antibiotics may be based on the degree of soft tissue injury and the likelihood of bowel perforation.^{35,36} Relatively clean, open fractures of the iliac wing, for example, may do well with intravenous cefazolin. Open pelvic fractures with more extensive soft tissue damage may do well with intravenous cefazolin and gentamicin. Injuries likely to involve bowel perforation may do best with traditional “triple antibiotics” (i.e., cefazolin, gentamicin, and metronidazole).

Given that many pelvic fractures are associated with other internal injuries, most children with pelvic fractures will require hospitalization. Over 90% of pelvic fractures in children are treated nonoperatively.^{4-6,37} Children with minor pelvic fractures and no other injuries may be candidates for discharge from the ED with close outpatient follow-up.

Renal and Ureteral Injuries

Almost 90% of blunt renal injuries, including severe ones, can be managed nonoperatively by hospitalization with close observation of hemodynamics, urine output, and hematocrit.^{38,39} This may also be true for some penetrating renal injuries.⁴⁰ Immediate complications associated with renal injury include infection, urinary obstruction, persistent bleeding, and urinary extravasation. Ureteral injuries are generally managed surgically, either by reanastomosis or stent placement. When a delay in the diagnosis of a ureteral injury occurs, urinary diversion with delayed repair is usually necessary.

Bladder Injuries

The management of bladder injuries depends on the type and severity of the injury. Children with simple bladder contusions can be discharged with outpatient urologic follow-up if they can spontaneously void and have no other indications for admission. Extraperitoneal bladder rupture generally requires external urinary drainage. This can be accomplished by placement of a Foley or suprapubic catheter. If a displaced fragment of bone from the pelvis remains in the bladder wall, however, surgical removal and repair may be necessary. Intraperitoneal bladder rupture requires surgical repair. These injuries require suprapubic urinary diversion. Complications of bladder rupture include infection, vesicular fistula formation, and poor healing with the need for delayed surgical repair.

Urethral Injuries

Damage to the urethra may be managed in a number of ways depending upon the location and severity of injury. Posterior urethral injuries are typically treated with endoscopic catheterization using a guidewire. The urethra is then allowed to heal over the catheter. Severe posterior injuries require urinary diversion (e.g., suprapubic cystostomy) with delayed surgical reanastomosis. Anterior urethral injuries are treated by either long-term catheter placement, which allows healing of the urethra over the catheter, or reanastomosis. If urologic consultation is not immediately available and a patient with a urethral injury cannot void, then a suprapubic urinary catheter can be placed by the emergency physician to empty the bladder. This is most easily accomplished using a kit designed for this purpose, which usually includes a guidewire, dilator, and introducer sheath. Young children may require a smaller catheter size than is provided in standard kits. Procedural sedation may be needed to facilitate this procedure. Complications of urethral injury include stricture formation, infection, and impotence.

Testicular Injuries

Testicular rupture and traumatic torsion both require immediate operative intervention (see Chapter 87, Testicular Torsion). Testicular salvage rates decrease with time. If dislocation is suspected, the missing testis will likely be palpable superior to the scrotum. Manual reduction is typically indicated. Intravenous analgesia or procedural sedation is prudent for this procedure. Urologic consultation is required if attempts at reduction by the ED physician are unsuccessful. Large testicular hematomas and hematoceles may require surgical treatment. Children who have small scrotal hematomas, skin ecchymosis, or superficial lacerations without evidence of injury to the testicle can be discharged home with outpatient follow-up and oral analgesia as needed. More significant scrotal injuries, and any injury involving the testes, typically require urologic consultation.

Summary

Pelvic fractures are uncommon in children. Genitourinary injuries are more common, but seldom life threatening. Children with pelvic fractures and associated genitourinary injuries are usually also at risk for multisystem trauma. The prognosis of children with isolated pelvic fractures is generally excellent. Injuries to other anatomic systems usually dictate overall management and contribute strongly to the ultimate outcome.

Chapter 22

Compartment Syndrome

Christian Vaillancourt, MD, MSc and Ian Shrier, MD, PhD

Key Points

Acute compartment syndrome is a limb-threatening condition.

This condition should be recognized early, before pulses are lost.

Significant necrosis can occur within 3 to 4 hours of the injury.

Compartment pressure should be measured when the diagnosis is clinically equivocal.

Definitive therapy is surgical fasciotomy.

Introduction and Background

Acute compartment syndrome is a limb-threatening condition in which increased pressure within closed tissue spaces compromises the nutrient blood flow to muscles and nerves such that necrosis will invariably occur if decompression is not performed.¹⁻⁴ This is in contrast to chronic (or recurrent) compartment syndrome, in which the mechanism of injury is usually exertional, symptoms most often subside at rest, and the condition is managed conservatively initially and by elective surgery when warranted.⁵⁻⁸ Acute compartment syndrome was first described in 1881 by a German physician named Dr. Richard von Volkmann.⁹ He reported on many cases of clawhand resulting from elbow injuries in children, which initially became known as “Volkmann’s contracture.”

A compartment is a functional unit usually containing muscles, nerves, veins, and arteries. Each compartment is surrounded by a thick fascia that lacks the ability to stretch. A limb can contain more than one compartment; the four leg compartments are depicted in Figure 22–1. Acute compartment syndrome is not limited to the extremities; for example, it has been reported in the orbit¹⁰ as well as in the abdominal cavity.¹¹

When pressure increases inside a closed compartment, it compresses both arterioles and venules. The increased venous

resistance results in increased venular pressure, and presumably increased capillary pressure.¹² This may explain why one observes more serious injuries in acute compartment syndrome–induced ischemia compared to that produced by tourniquet-induced ischemia alone, a condition associated with decreased venular pressure.¹³

Recognition and Approach

As suggested by Matsen,¹⁴ the numerous acute compartment syndrome etiologies can be classified within two categories: increased compartmental content and decreased compartmental volume (Table 22–1). Acute compartment syndrome is a well-recognized complication of revascularization surgery,^{15,16} as well as pelvic surgery in the lithotomy position.^{17,18} It has been described in a variety of other conditions, such as steroid use,¹⁹ human immunodeficiency virus–induced myositis,²⁰ post–diagnostic electromyography,²¹ and self-induced hand suction in children.²² Because such a variety of circumstances can lead to acute compartment syndrome, it is important to maintain a high level of suspicion and inquire about the mechanism of injury. Most patients will be young males, will be involved in a traumatic incident, and will often have an associated fracture.^{23,24}

The leg compartments are most often involved in the adult population²⁵ (Fig. 22–2). Perhaps because of their smaller stature or a different mechanism of injury, there seems to be a more equal distribution between upper and lower extremities in children.^{23,24}

Evaluation

The presence of a tight compartment on palpation should alert emergency physicians to the possibility of acute compartment syndrome.² The hallmark presentation is that of pain out of proportion to the apparent injury (Table 22–2). Nerve structures are particularly sensitive to ischemia, leading to early paresthesia or paralysis. Particular attention should be given to agitated/uncooperative young patients,²³ those requiring increasing amounts of analgesia,^{23,26} or those receiving continuous epidural analgesia.²⁷ The loss of peripheral pulses is a late and ominous sign; acute compartment syndrome should be diagnosed before pulses are lost.

It is often clinically easier to exclude the diagnosis of acute compartment syndrome than it is to confirm it.²⁸ While

Fascial Compartments of Leg

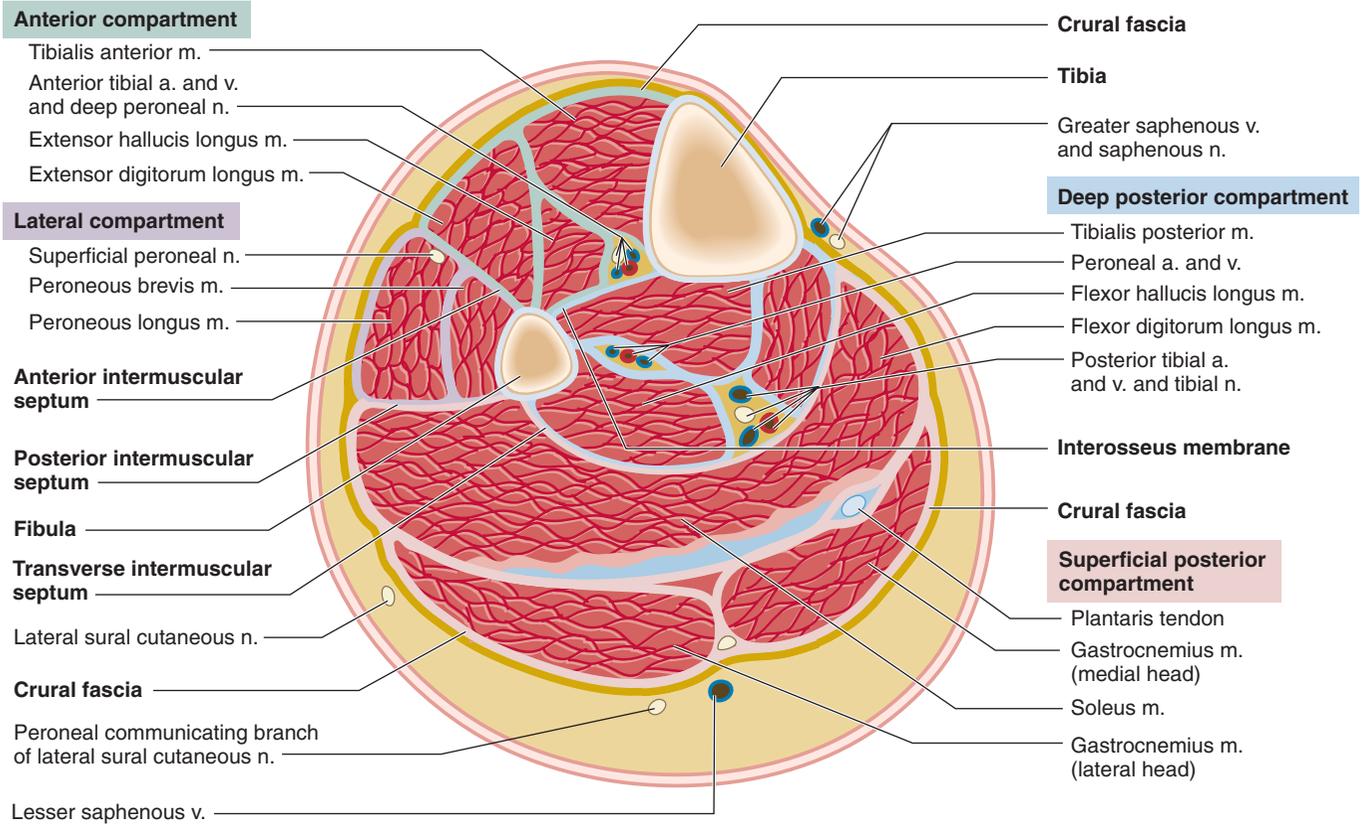

FIGURE 22-1. Cross-section of a leg illustrating its four compartments and their respective contents.

Table 22-1 Classification of Acute Compartment Syndrome Etiologies	
Increased Content	Decreased Volume
Bleeding	Tight dressing or cast
Major vascular injuries	Military antishock trousers (MAST)
Bleeding disorder or anticoagulants	Burn eschars
Increased capillary permeability	Lying on a limb or localized external pressure
Postischemic swelling	Closure of fascial defects
Muscle contraction (exercise, seizure, tetany)	
Burns	
Intra-arterial drugs	
Envenomation	
Infiltrated infusion	
Nephrotic syndrome	

Table 22-2 Clinical Findings in Conscious Patients	
Common Clinical Findings*	
Pain	95%
Neurologic abnormalities	53%
Pain on passive stretch	49%

*Pallor and pulselessness are late and ominous signs. Acute compartment syndrome should be diagnosed before they occur.

clinically obvious cases should be referred to an orthopedic surgeon without further delay,^{29,30} up to 50% of cases will remain equivocal despite a thorough clinical evaluation.^{25,31} Measurement of intracompartmental pressure can be achieved using one of three methods: the Stryker instrument, the manometric Intervenous Alarm Control (IVAC) pump, or the Whitesides method. The Stryker instrument is accurate and easy to use³² (Fig. 22-3). If this instrument is not available, the pressure can just as accurately be measured using a method described by Uppal et al.³³: (1) set up the

IVAC pump to manometric mode, (2) zero the IVAC pump with the pump placed at the same height as the limb compartment that is to be measured to ensure that there is no hydrostatic pressure gradient, (3) insert the 18-gauge needle into the compartment, (4) infuse 0.3 ml of normal saline, and (5) read the pressure measurement. The Whitesides method requires a complicated procedure that includes a mercury manometer and is not as reliable.³⁴ When measuring the pressure, the needle should be inserted within 5 cm of a suspected fracture, and measurements may have to be repeated if clinical suspicion is high.³⁵

While it is accepted that normal compartment pressure should be less than 10 mm Hg, the pressure threshold for diagnosis of acute compartment syndrome is more controversial. Many surgeons make the diagnosis when an absolute pressure measurement of 30 to 40 mm Hg is reached.³¹

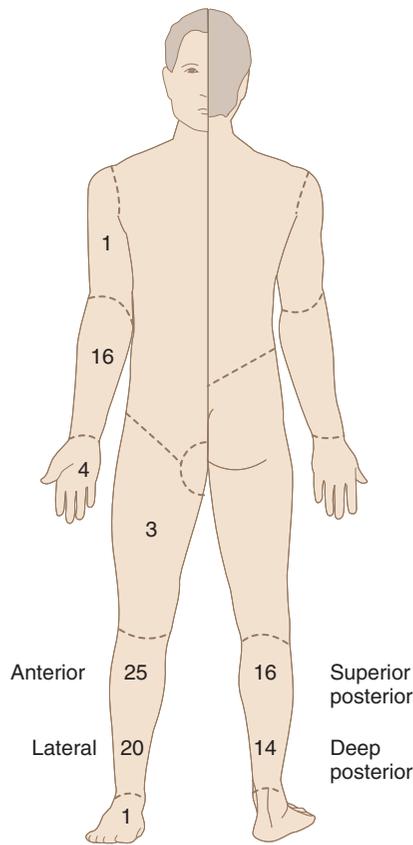

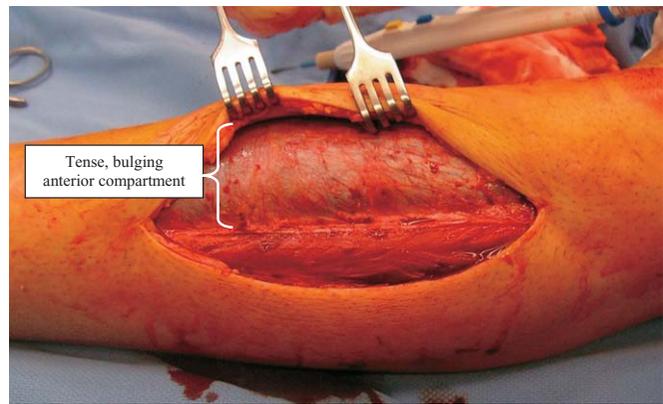

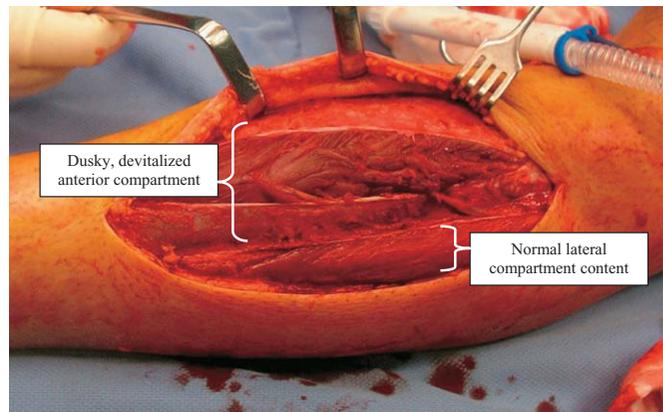

FIGURE 22-2. Distribution of involved compartments in patients with acute compartment syndrome confirmed at time of surgery ($n = 76$, age range 1 to 80 years). Some patients had more than one compartment involved. Numbers represent the percentage of of the total number of involved compartments ($n = 140$). Most injuries occurred in the lower extremities. (From Vaillancourt C, Shrier I, Vandal A, et al: Acute compartment syndrome: how long before muscle necrosis occurs? *Can J Emerg Med* 6:147–154, 2004.)

FIGURE 22-3. Using the Stryker instrument to measure the intracompartmental pressure: (1) assemble the needle, the diaphragm chamber, and the prefilled syringe on the pressure monitor as shown; (2) zero the Stryker instrument; (3) insert the needle in the compartment to be measured; (4) inject 0.3 ml of normal saline; and (5) read the pressure measurement. (Photo courtesy of the Stryker Corporation.)

A

B

FIGURE 22-4. Acute compartment syndrome (**A**) immediately after anterolateral incision, anterior compartment is bulging and hard; and (**B**) after fasciotomy release of the anterior and lateral compartments, the lateral compartment content is normal and viable but the anterior compartment content is dusky and devitalized. (Images reproduced with permission from Dr. Steven Papp, Assistant Professor, Orthopedic Trauma, The Ottawa Hospital, University of Ottawa, Canada.)

Original work from McQueen and Court-Brown has shown that many unnecessary surgeries would result from using this absolute pressure measurement criterion, and that a differential pressure of 30 mm Hg (i.e., diastolic pressure—compartment pressure is < 30 mm Hg) is more appropriate and would have missed no case of acute compartment syndrome.³⁶

Management

The only accepted therapy for acute compartment syndrome is urgent fasciotomy^{2-4,29}; this should only be second to adequate narcotic pain control. Delays in diagnosis and compartment decompression can result in tissue necrosis, disability, or loss of limb^{25,37-40} (Fig. 22-4). While basic science has determined that muscle can tolerate up to 3 hours of tourniquet-induced ischemia before necrosis occurs,⁴¹ laboratory and clinical data on acute compartment syndrome have shown that muscle necrosis can occur well within that presumably safe 3-hour period.^{13,25} In a recent review of 76 acute compartment syndrome cases, almost half suffered some level of muscle necrosis, 30% of those lost more than 25% of the muscle belly, and it is estimated that necrosis

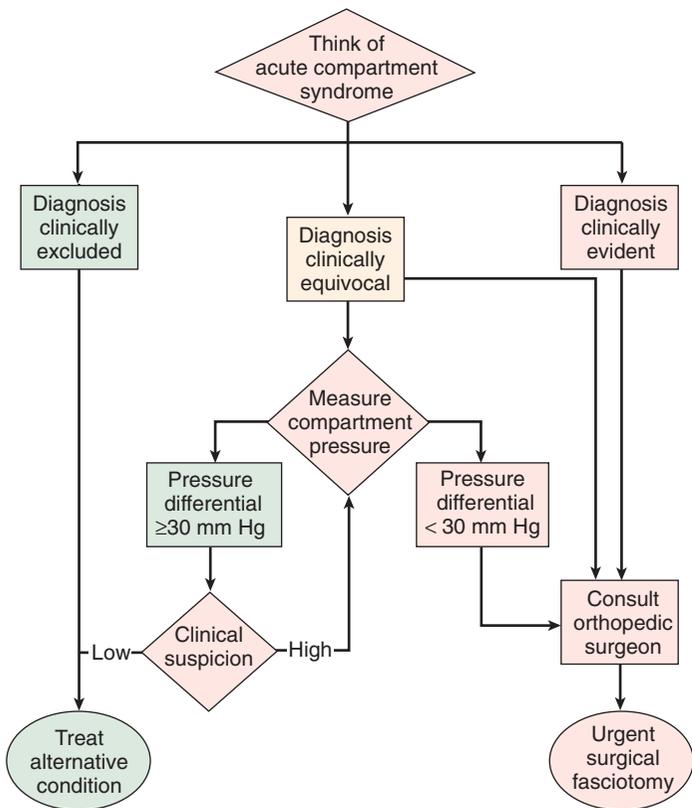

FIGURE 22-5. Diagnostic and therapeutic algorithm for acute compartment syndrome.

occurred within 3 hours of the initial injury in 37% of cases.²⁵

Repeated or continuous monitoring of compartment pressure^{36,42} should occur in suspected cases if the initial pressure measurement was normal, if the child's ability to communicate is limited due to age or other injuries, or if the child is receiving frequent or continuous narcotic analgesia. In the meantime, it is controversial whether the limb should be elevated or not; in acute compartment syndrome, limb elevation could lead to decreased perfusion pressure and more tissue damage.

A number of adjunct therapeutic modalities have been suggested. These include mannitol,^{2,43} octreotide,⁴⁴ melatonin,⁴⁵ and hyperbaric oxygen.⁴⁶ Unfortunately, none of these measures can alleviate the need for a rapid surgical fasciotomy.

Summary

Acute compartment syndrome is a limb-threatening disease that can rapidly lead to permanent disability or lost of limb. A high level of suspicion for acute compartment syndrome should be maintained in appropriate cases. When in doubt, emergency physicians can easily confirm the diagnosis using needle pressure measurements (Fig. 22-5). Repeated or continuous pressure measurements should be performed in cases where suspicion for acute compartment syndrome remains high. Orthopedic surgeons should be consulted early, and urgent fasciotomy should take place when the diagnosis is confirmed.

Spinal Trauma

Andrew Wackett, MD and Peter Viccellio, MD

Key Points

The management of a child with a potential spinal injury begins with the assessment of airway, breathing, and circulation while maintaining spinal immobilization.

Children are more susceptible to upper cervical spine injuries, which bring a greater risk for airway compromise.

Spinal cord injury without radiologic abnormality (SCIWORA) presentation ranges from subtle to obvious and may be delayed.

Neurogenic shock is characterized by hypotension and bradycardia, but it is a diagnosis that should be entertained only after hemorrhagic shock has been excluded.

Although controversial, steroid use in spinal cord injuries has become a standard of care in the United States.

Introduction and Background

The National Head and Spinal Cord Injury Survey indicates that there are approximately 11,200 new cases of acute spinal cord injury in the United States each year. Children account for 1065 (10%) of these cases. The mortality among spine-injured children is estimated at 25% to 32%. Costs of medical treatment for all spinal cord injury are estimated to be in excess of \$380 million/year. Motor vehicle collisions are the most common etiology. They account for 36% to 54% of cases. Falls, diving injuries, sports-related injuries, birth injuries, penetrating injuries (knife and gunshot wounds), and child abuse account for the remaining precipitants.¹

Recognition and Approach

There are several vertebral injury patterns that present in children. These patterns are best understood by three unifying

concepts: the unique pediatric anatomy, Denis' three-column system, and Daffner's "fingerprints" of vertebral trauma.¹⁻³

Pediatric Spinal Anatomy

Pediatric vertebral and spinal injuries have unique characteristics. Specifically, the type and distribution of vertebral injuries in young children, up to 8 to 12 years of age, are different from those of adolescents and adults. The fulcrum of cervical motion occurs at the C5-6 level in adolescents and adults, and it occurs at the C2-3 level in children, due to the relatively larger mass of the head. Thus the majority of spinal injuries in children involve the upper cervical spine and the cranio-vertebral junction, and the associated mortality is higher in children.¹

Compared to adults, children have much more laxity in their spinal ligaments, weaker musculature, and more horizontally angled facet joints. Children can have significant spinal cord injuries without spinal fractures. This injury is referred to as a spinal cord injury without radiologic abnormality (SCIWORA). The reported incidence of SCIWORA is 16% to 19% in children compared to 0.2% in adults.⁴

During assessment of infants and children, including radiographic examination, clinicians must be aware of anatomic variation and age-related normal development (Tables 23-1 and 23-2).

Vertebral Functional Columns

The vertebrae can be divided into three distinct functional columns. The anterior column extends from the anterior longitudinal ligament to a line drawn vertically through the center of the vertebral body. The middle column begins at this line and extends to the posterior longitudinal ligament. The posterior column extends from the posterior longitudinal ligament to the supraspinous ligament (Fig. 23-1). All the major support structures for the vertebrae are contained within the middle and posterior columns. Thus any disruption extending through all three columns will produce an unstable injury.³

Mechanisms of Spine Injury

Spine injury mechanisms include flexion, extension, shearing, and rotational injuries.²

Flexion Injuries

Flexion injuries can be further divided into simple, burst, distraction, and dislocation patterns (Fig. 23-2). Simple

flexion injuries demonstrate anterior compression of the superior aspect of the vertebral body. These injuries occur due to an anterior flexion force. There may or may not be narrowing of the disk space above the level of injury; however, the posterior vertebral body line and posterior ligamentous structures must remain intact. With up to 50% compression, the posterior and middle elements are not involved, thus leaving the injury both mechanically and neurologically stable. Greater than 50% compression should raise suspicion for posterior injury.

Burst injuries show a vertebra comminuted by compressive forces with retropulsion of fragments. The mechanism of injury involves an axial load. These fractures involve both the anterior and middle columns and are therefore usually unstable, especially when the middle column is retropulsed into the spinal canal.

Distraction injuries demonstrate widening of the interspinous and interfacet distance. Seat belt fractures, also known as Chance fractures, are examples of these injuries. These

fractures involve failure of the middle and posterior columns and are thus unstable.

Finally, dislocation injuries display a complete loss of bone continuity at the articular surfaces. Since there is failure of all three columns, these fractures are always unstable.

Extension Injuries

The radiographic findings of extension injuries include compression, fragmentation, burst vertebral bodies, teardrop fragments, wide interspinous spaces, anterolisthesis, locked facets, and narrow disk spaces. Extension injuries result when the child hyperextends the vertebral column over a solid object. Like flexion injuries, they are also subdivided into simple, distraction, and dislocation injuries. The simple subtype leaves the posterior and middle columns intact and as such is a stable injury. Distraction and dislocation exten-

Age	Feature
<6 mo	C1 ring invisible and all synchondroses are open, vertebrae are normally wedged anteriorly, and there is often no lordosis to the uninjured spine
1 yr	Body of C1 becomes visible radiographically
3 yr	Posteriorly located spinous process synchondroses fuse
3-6 yr	Dens becomes ossified (visible radiographically) Neurocentral (body) and C2-odontoid synchondroses fuse
	Summit ossification center appears at the apex (top) of the odontoid
	Anterior wedging of the vertebral bodies resolves (wedging is not normal if seen now)
8 yr	Pseudosubluxation and predental widening resolve, lordosis is normal now
12-14 yr	Secondary ossification centers appear at spinous process tips (mistaken for fractures), summit ossification center of odontoid fuses (if it does not, os odontoideum is present), superior/inferior epiphyseal rings appear on body
25 yr	Secondary ossification centers at tips of spinous processes fuse Superior/inferior epiphyseal rings fuse to vertebral body

Table 23-2 Infant/Child Versus Adult Cervical Spine

- More horizontal facets allowing for increased mobility and spine injury
- Differential growth of C1 compared to C2 gives false appearance of burst fracture (pseudo-Jefferson's fracture)
- Increased predental space (up to 5 mm) compared to adults
- Normal lordosis to cervical spine is absent in 14% of children
- Normal posterior angulation of odontoid can be seen
- Majority of injuries occur at C1-2 in children ≤ 8 yr old and in lower cervical spine in those > 8 yr old
- Os odontoideum—congenital anomaly in which odontoid does not fuse with C2*
- Ossiculum terminale—a secondary center of ossification for odontoid tip; appears by age 3 yr (in 26% of children) and fuses with odontoid by age 12 yr (may never fuse)
- Prevertebral space at C3 is $\leq 1/2-1/3$ that of C3 vertebral body width or $\leq 5-7$ mm[†]
- Prevertebral space at C5 is $\leq 5/4$ of (C5 or C6) vertebral body width or ≤ 14 mm[†]
- Predental space up to 5 mm in children ≤ 8 yr old (up to 3 mm in children > 8 yr old)
- Pseudo-Jefferson's fracture—C1 lateral masses grow faster than those of C2, so C1 overlaps C2 (usually < 6 mm); present in 90% of children age 1-2 yr, 18% of children age 7 yr
- Pseudosubluxation of C2/C3 or C3/C4 in 40% (normal variant in which anterior aspect of C2 spinolaminar line is ≤ 2 mm anterior or posterior to posterior cervical line)

*Injury can occur with minor trauma.

[†]These values can be unreliable in children.

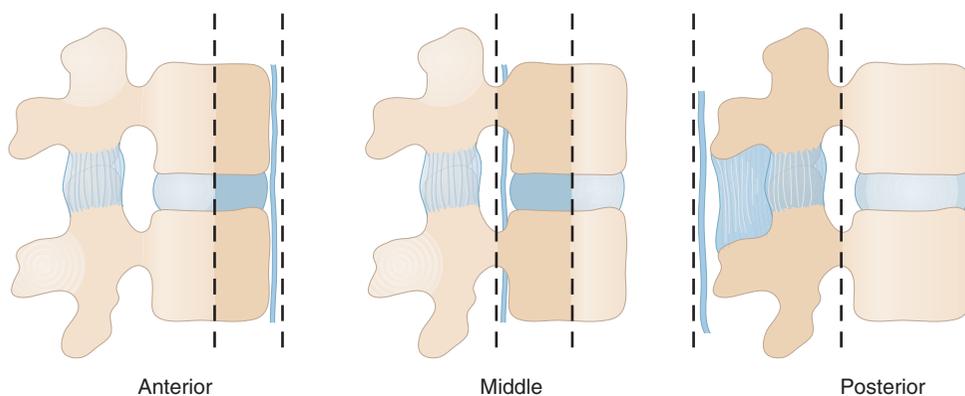

FIGURE 23-1. The three-column model of Denis is shown with anterior, middle, and posterior columns. (From Garfin S, et al: Thoracic and upper lumbar spine injuries. In Browner BD, et al [eds]: Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries, 2nd ed. Philadelphia: WB Saunders, 1998.)

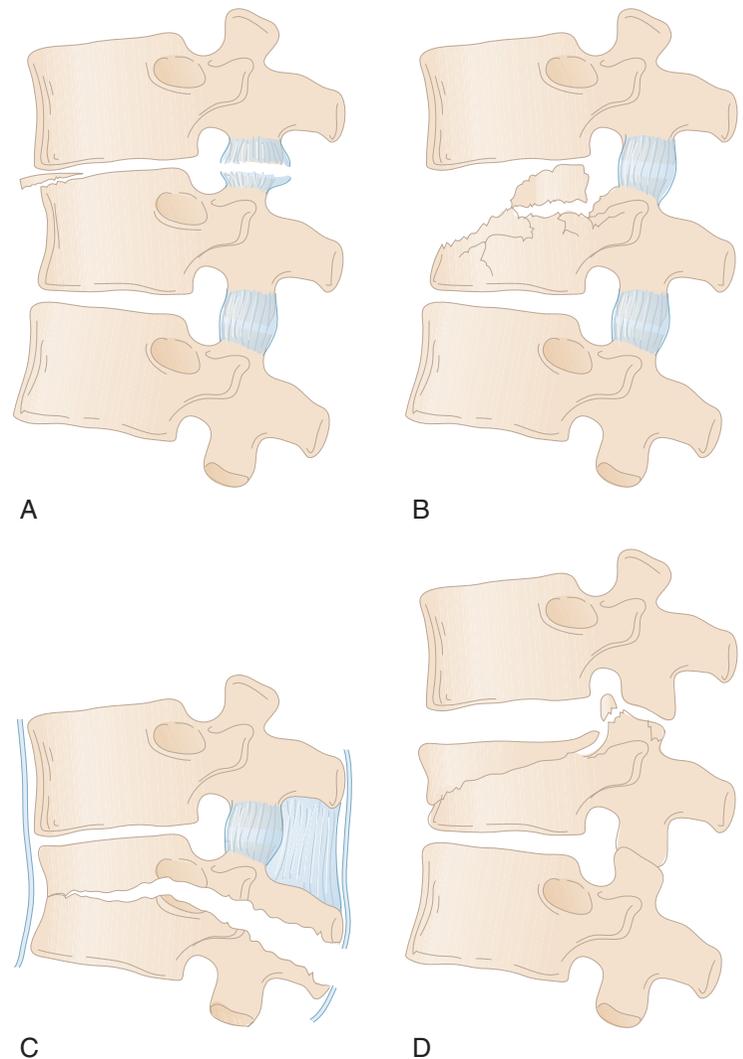

FIGURE 23-2. Daffner's flexion injuries can be further divided into simple (A), burst (B), distraction (C), and dislocation (D) patterns. (From Garfin S, et al: Thoracic and upper lumbar spine injuries. In Browner BD, et al [eds]: *Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries*, 2nd ed. Philadelphia: WB Saunders, 1998.)

sion injuries disrupt two or more columns and are unstable (Fig. 23-3). The radiographic findings of extension injuries include wide disk space, triangular avulsion fracture, retrolisthesis, neural arch fracture, and anterolisthesis with normal interspinous space and spinolaminar line.

Shearing Injuries

Shearing injuries result from forces horizontally or obliquely directed upon the vertebral column with the lower body fixed. These injuries typically disrupt all three columns and are therefore unstable (Fig. 23-4). The radiographic findings demonstrate lateral distraction, lateral dislocation, and transverse process fractures.

Rotational Injuries

Rotational injuries result from a rotary or torsional force applied about the long axis of the vertebral column. An example is a heavy blow to the upper torso that compresses the vertebral column and flexes the torso laterally with the lower portion of the body in a fixed position. These injuries typically disrupt all three columns and are unstable (Fig. 23-5). The radiographic findings include rotation, dislocation, and facet/pillar fractures.

Spine Injuries Typically Seen in Children

Several specific injuries are seen in children. They include atlanto-occipital dislocation, atlas fractures, atlantoaxial subluxation, odontoid fractures, axis fractures, middle to lower cervical spine injuries, and thoracolumbar injuries.⁵

Atlanto-occipital dislocation is rarely seen as it is usually associated with brainstem injury and cardiorespiratory arrest. The atlanto-occipital articulation is less stable in children due to the relatively large head, small occipital condyles, and horizontal orientation of the joint. Therefore, the cranium moves with respect to the spine.

Fractures of the atlas are uncommon in young children, but are seen in teenagers after axial compression injuries such as those sustained while diving. Jefferson's or burst fracture involves fractures through the anterior and posterior arches.

Atlantoaxial subluxation occurs due to traumatic disruption of the transverse ligament. It is quite rare in children as an odontoid fracture is more likely to occur. The exception occurs in children with Down syndrome and connective tissue disorders.

Odontoid fractures occur uniquely in children. A cartilaginous synchondrosis between the odontoid and body

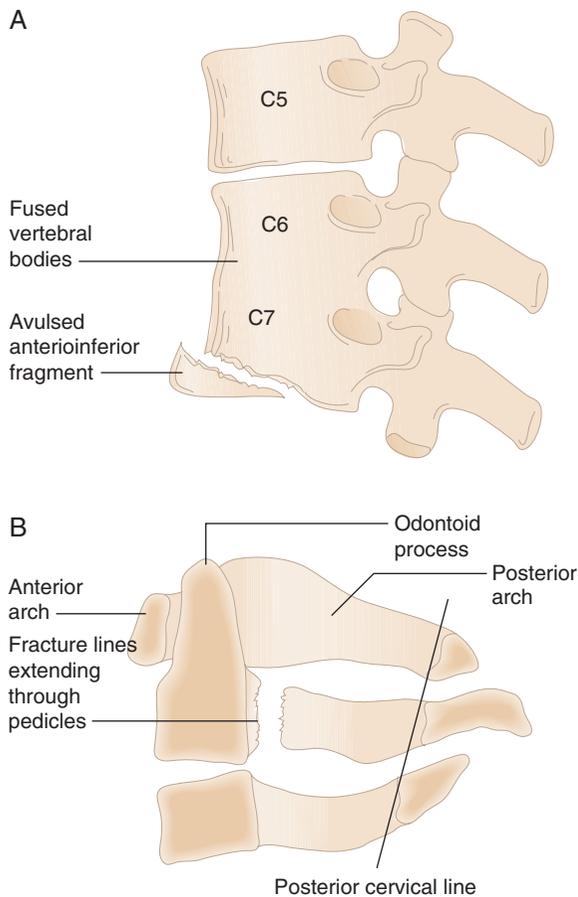

FIGURE 23-3. Extension injuries are stable if the posterior and middle columns remain intact. A small extension teardrop fracture is stable as it interrupts the anterior column only. This larger extension teardrop fracture (**A**) interrupts the anterior and middle column. The hangman's fracture (**B** and **C**) interrupts the middle column. Both are unstable. (**A** and **B** from Marx JA, Hockberger RS, Walls RM, et al [eds]: *Rosen's Emergency Medicine: Concepts and Clinical Practice*, 5th ed. St. Louis: Mosby, 2002; **C** courtesy of Stony Brook University Medical Center.)

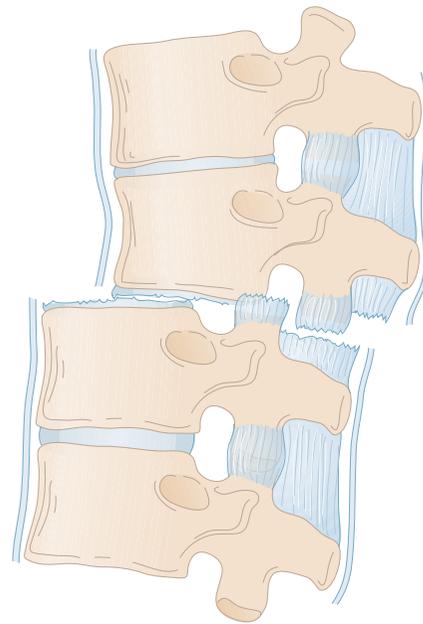

FIGURE 23-4. Shearing injuries disrupt all three columns and are unstable. (From Garfin S, et al: *Thoracic and upper lumbar spine injuries*. In Browner BD, et al [eds]: *Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries*, 2nd ed. Philadelphia: WB Saunders, 1998.)

exists until 5 to 7 years of age. Thus fractures occur through this growth plate until 7 years of age. They occur at the base of the odontoid in older children.⁵

The hangman's fracture is the typical axis fracture. It includes bilateral fracture of the pars interarticularis and anterior subluxation of C2 on C3.

Injuries to the middle and lower cervical spine are less common. They include facet disruption, compression fractures, and end plate injuries, of which injury of the inferior end plate is more common.

Vertebral injuries below the cervical spine are less common. Thoracic injuries predominately consist of compression fractures with anterior wedging. Lumbar injuries consist of anterior compression, burst fractures, isolated neural arch and transverse process fractures, Chance fractures, and Smith's fractures. Chance fractures were referred to earlier. They are horizontal fractures through the spinous process, pedicles, and posterior vertebral body. Smith's fractures are horizontal fractures through the spinous process, pedicles, and posterior spinal ligaments.

SCIWORA

Infants and children are prone to spinal cord injuries without radiologic abnormality (SCIWORA), meaning spinal cord injury without evidence of vertebral fracture or malalignment on plain radiographs or computed tomography (CT). The incidence is typically 16% to 19%, but has been reported as high as 65%.⁴ It is predominately seen in children under 8 years.⁴ SCIWORA likely occurs due to one of four mechanisms: longitudinal distraction, hyperflexion, hyperextension, or ischemic spinal cord injury.⁴

1. Longitudinal distraction causes SCIWORA by the following mechanism. The infantile bony spinal column is quite elastic and stretches approximately 5 cm prior

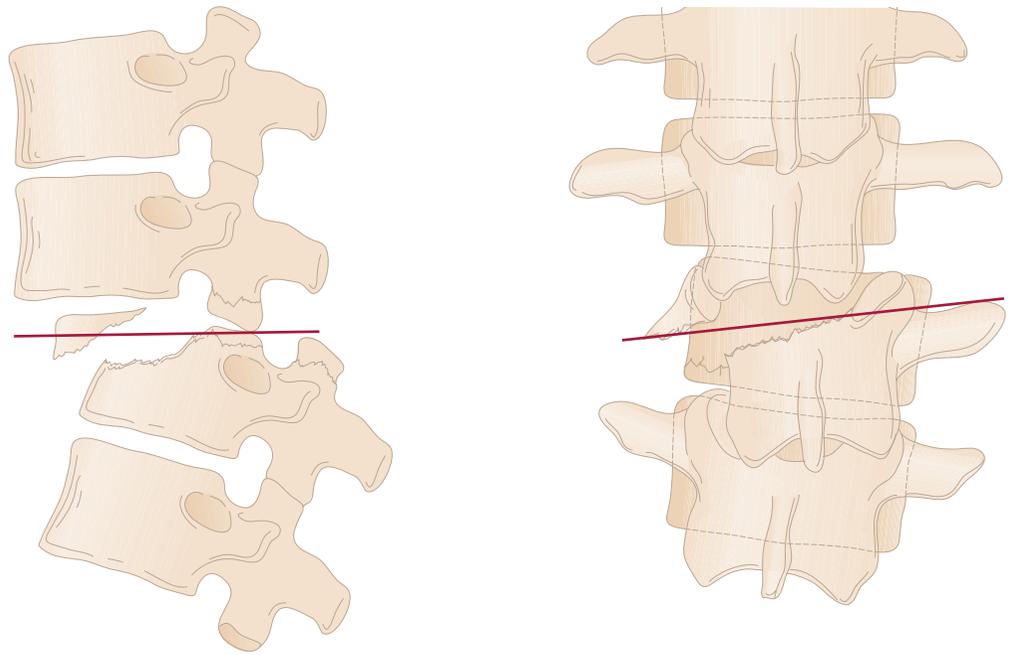

FIGURE 23-5. Rotational injuries disrupt all three columns and are unstable. (From Garfin S, et al: Thoracic and upper lumbar spine injuries. In Browner BD, et al [eds]: *Skeletal Trauma: Fractures, Dislocations, Ligamentous Injuries*, 2nd ed. Philadelphia: WB Saunders, 1998.)

to disruption. The spinal cord is less pliable and is disrupted with as little as 5 mm of traction.

2. Hyperflexion can also contribute to SCIWORA. The combination of horizontally oriented facet joints and physiologic anterior wedging of the vertebral bodies allows for excessive forward flexion of the vertebrae, thus stretching the cord without disrupting the vertebral column.
3. Hyperextension of the cervical spine causes forward bulging of the interlaminar ligaments, which compress the cord without bony vertebral damage.
4. Direct vessel injury from compression, hypotension, and hypoperfusion can contribute to spinal cord infarction. Thus spinal cord injury can become apparent without bony trauma.

Injury to the spinal cord has the highest morbidity and mortality of vertebral trauma. The effect on the spinal cord includes both the direct trauma and the events that proceed the trauma. Spinal cord edema, decreased blood flow to the spinal cord, cell membrane disruption, ion and calcium fluxes, lipid peroxidation due to free radicals, and impaired prostaglandin synthesis produce secondary injury to the cord.^{6,7} Appropriate evaluation and management are targeted toward reducing these secondary effects.

Evaluation

The evaluation of the patient with suspected vertebral or spinal cord injury begins during the initial stabilization. The child, guardian, and out-of-hospital providers should be questioned as to the mechanism of the injury, any neck or back pain, and any numbness or weakness, including transient symptoms. The complaint of transient pins and needles–like sensations to the extremities may represent SCIWORA.

The physical examination should include both a careful neck and neurologic evaluation. This examination should test for sensory and motor function (Fig. 23–6). By convention, a spinal cord injury is identified using the lowest functional level. Neurologic examination also includes a rectal examination, and evaluation for priapism and presence of the bulbocavernosus reflex. Absence of the bulbocavernosus reflex associated with hypotonia and areflexia indicates presence of spinal shock. Assessment of an injury level is unreliable until resolution of spinal shock, which may take up to 72 hours.⁸

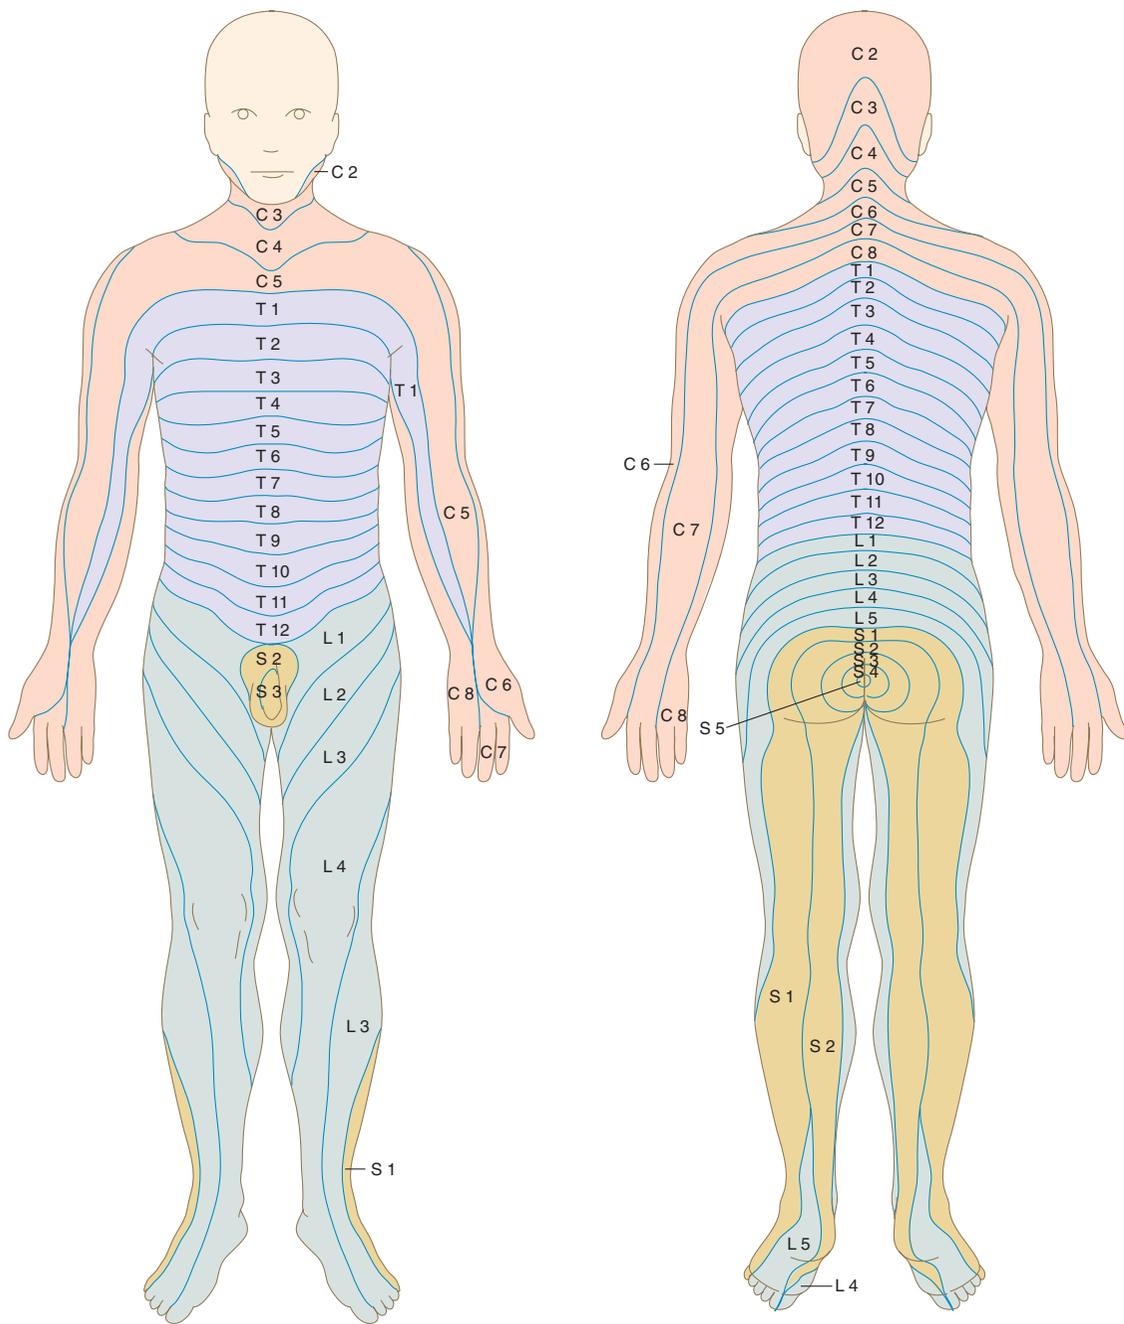

Respiratory compromise is common after cervical spinal cord injuries and must be monitored. Normal breathing utilizes the diaphragm, intercostals, and abdominal muscles. When necessary, the accessory muscles can be recruited. With high cervical injuries, the accessory muscles operate alone, causing paradoxical abdominal breathing. The accessory muscles expand the thorax on inspiration, causing passive upward movement of the diaphragms and inversion of the abdomen. The reverse occurs with expiration. Paradoxical abdominal breathing is an ominous sign.⁸

Spinal cord injury may involve disruption in the descending sympathetic pathways. Hypotension can result from reduced vasomotor constrictor tone and bradycardia can result from unchecked vagal stimulation to the heart. Hypovolemic shock is another cause for hemodynamic instability.

Spinal Cord Injury Syndromes

There are five specific spinal cord injury syndromes: central cord syndrome, Brown-Séquard's syndrome, anterior spinal cord syndrome, complete spinal cord injury syndrome, and partial spinal cord injury syndrome.

In central cord syndrome, the damage involves the central part of the cervical spinal cord, thus interrupting the more medially placed fibers of the cervical roots. In this case the

A

Cord Level	Muscles
C5	Elbow flexors (biceps, brachialis)
C6	Wrist extensors (extensor carpi radialis longus and brevis)
C7	Elbow extensors (triceps)
C8	Finger flexors to the middle finger (flexor digitorum profundus)
T1	Small finger abductors (abductor digiti minimi)
L2	Hip flexors (iliopsoas)
L3	Knee extensors (quadriceps)
L4	Ankle dorsiflexors (tibialis anterior)
L5	Long toe extensors (extensor hallucis longus)
S1	Ankle plantarflexors (gastrocnemius soleus)

B

FIGURE 23-6. The physical examination should test for sensory and motor function. **A**, Dermatomes of each spinal segment. **B**, Key muscles for testing motor function. (From Ferrera PC, et al [eds]: Trauma Management: An Emergency Medicine Approach. St. Louis: Mosby, 2001.)

upper limbs, especially the hands, are weaker than the lower limbs, which are often normal.

Brown-Séguard's syndrome is a situation in which damage produces a hemisection of the cord. There is motor loss on the ipsilateral side of the lesion and pain and temperature loss beginning one or two levels below the lesion on the opposite side.

If trauma produces disruption to the anterior spinal artery, there is an anterior spinal cord syndrome with only the dorsal columns being spared. These children may have complete paralysis and loss of pain and temperature sensation from that level down. Vibration, proprioception, and light touch are spared.

Complete spinal cord injury syndrome is the loss of function (motor, sensation, reflexes, rectal tone, and bowel/bladder function) below the injured level. Complete spinal cord injury is the most common spinal cord injury pattern in children. The reason for this is not completely clear, but it may be related to the immature spinal cord microvasculature in children.¹ Partial spinal cord injury syndrome includes a combination of symptoms that do not fit into any of the other syndromes.

Imaging Studies

The criteria for radiologic evaluation, as defined by the National Emergency X-Radiography Utilization Study (NEXUS) criteria,⁹ include the presence of posterior midline tenderness, altered mental status due to either brain injury or intoxication, neurologic deficits, and distracting injuries.¹⁰ This study, which evaluated presenting features of adults following trauma, also included 2160 patients 8 to 17 years old and 817 patients 2 to 8 years old with a total of 30 cervical spine injuries.⁹ The criteria were 100% sensitive in detecting all cervical spine injuries at these ages. Importantly, only 88 patients less than 2 years old were included, limiting the applicability of these criteria to this age. For all infants and children, the total number of cervical spine injuries was small, with only 30 document injuries (1% of cases). To confirm that these criteria are highly sensitive, they need to be verified in large studies that include more injuries and a more diverse population.

To adequately evaluate the cervical spine, at least three views are required. The lateral view yields a sensitivity of 79% to 85% in children. The addition of the anteroposterior (AP) and open-mouth views increases sensitivity to 94%.⁹ Thoracic and lumbar imaging includes AP and lateral views. If spinal injury is identified at one level, the entire spine should be imaged, as multilevel injury occurs in 16% of cases.¹

CT should be employed in two situations: if additional detail of an injury is required for the management of the patient or to detect injuries that are highly suspect, but apparently absent on plain radiographs. The occiput through the second cervical level and the cervicothoracic junction are the anatomic areas where plain radiographs are not always reliable.¹¹

Finally, children with neurologic deficits need the addition of magnetic resonance imaging. T1-weighting images emphasize the skeletal anatomy and demonstrate vertebral alignment and bony relationships to the spinal cord. T2-weighting images are useful for evaluating the interface of the cerebrospinal fluid and the extradural space, especially for patients with extradural compression from bone fragments.¹²

Evaluation of Spine Radiographs

Evaluation of spine radiographs should proceed in a systematic fashion. A useful system is the ABC'S^{13,14}: adequacy and abnormalities of alignment, abnormalities of bony integrity, abnormalities of cartilage or joint space, and abnormalities of soft tissues. First, the spine series must be adequate. On the lateral cervical view, all seven cervical vertebrae and the cervicothoracic junction should be visualized. If this is not the case, a swimmer's view or CT scan should be added.

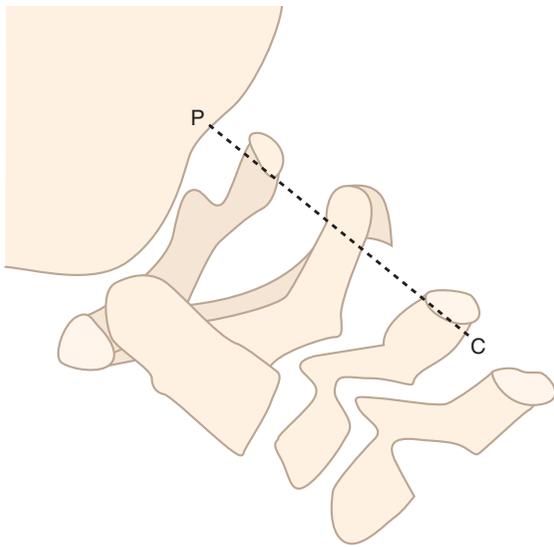

Cervical spine radiographs are also inspected for alignment. On the lateral view, the anterior spinal line, the posterior spinal line, and the spinolaminar line should form smooth arcs. The spinolaminar line does not always intersect the base of the C2 spinous process, a normal variant called pseudosubluxation. Pseudosubluxation, an anterior displacement of C2 on C3 or of C3 on C4 of up to 4 mm, occurs in 40% of children up to age 7. The posterior cervical line (or line of Swischuk) helps differentiate pseudosubluxation from pathologic subluxation. A line drawn between the anterior cortices of the spinous processes of C1 and C3 should intersect or be less than 2 mm from the anterior cortex of the spinous process of C2; otherwise pathologic subluxation should be considered (Fig. 23-7).

Additionally, there should be no widening between spinous processes, the distance from the anterior arch of C1 to the odontoid should be no more than 5 mm, and the distance from the base of the clivus to the superior continuation of the line drawn from the posterior cortex of the body of C2 should be no more than 12 mm. On the AP projection, the spinous processes and facets should be in straight alignment and evenly spaced. Spinous process distance should vary by no more than 50% and should form a straight line. The open-mouth view is inspected for alignment of the lateral masses of C1 to the odontoid process and to the lateral margins of the articular surface of C2. The lateral masses may extend beyond these margins slightly, termed *pseudospread*, but should be less than 6 mm. Pseudospread is common up to 4 to 7 years of age.⁸

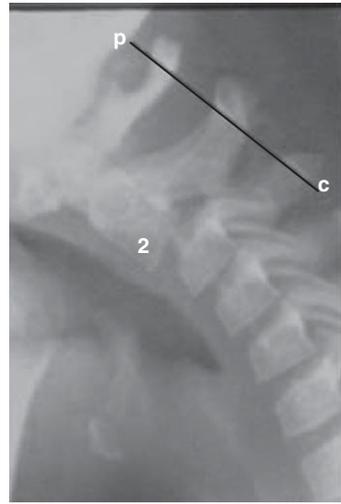

The lateral and AP views of the thoracic and lumbar spine are inspected for alignment. On the lateral view, the anterior, posterior, and spinolaminar lines should show parallel alignment. On the AP view, the lateral margins of the vertebral bodies, the position of the transverse processes, and the interspinous distance should be aligned.

Next, the bones are individually inspected. On the lateral projection of the cervical spine, the bones are inspected for superior or inferior end plate fractures. Also, the anterior vertebral body height should be no more than 3 mm less than the posterior height. Anterior wedging up to 3 mm may occur normally. In the lumbar and thoracic spines, abnormalities of bony integrity are usually obvious. The width of the interpediculate distance on the AP view and the posterior vertebral body line on the lateral view should be reviewed for any abnormalities. A difference of more than 3 mm between anterior and posterior vertebral body height is considered abnormal.

Cartilage and joint space abnormalities are considered next. The cervical, thoracic, and lumbar radiographs should be reviewed for widening or narrowing of the intervertebral disk space, widening of the facet joint, or widening of the interspinous distance on both AP and lateral views.

FIGURE 23–7. Spinolaminar line. **A**, Diagram of spinolaminar line. **B**, Radiograph demonstrating pseudosubluxation of C2 on C3. Note the the anterior cortex of the spinous process for C2 is less than 2 mm from the posterior cervical line (the line connecting the anterior cortex of the first and third cervical spinous processes). **C**, Odontoid fracture; note the abnormal spinolaminar line and the irregular suspicious line through the body of C2 (arrow). (A and C courtesy of Stony Brook University Medical Center; B from Grainger RG, Allison DJ, Dixon AK [eds]: Grainger & Allison’s Diagnostic Radiology: A Textbook of Medical Imaging, 4th ed. New York: Churchill Livingstone, 2001, p 2139. Copyright © 2001 Churchill Livingstone, Inc; from the MD Consult website.)

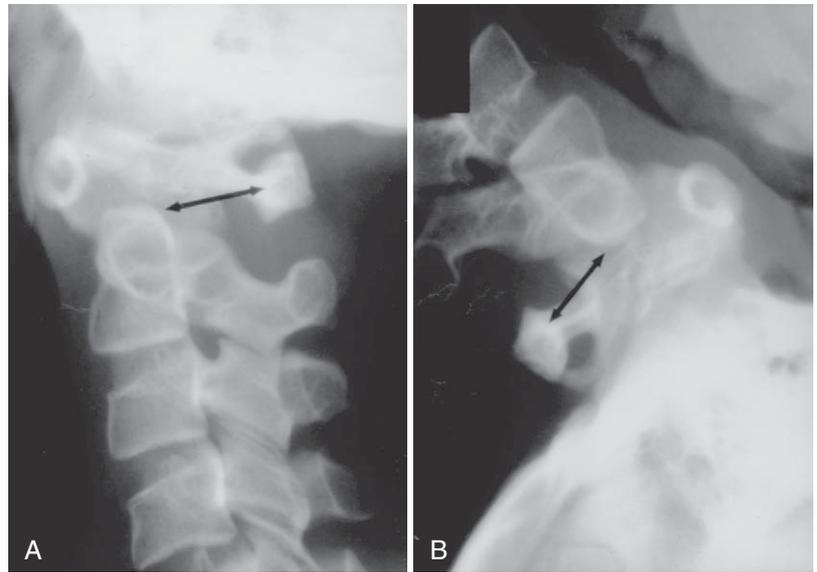

FIGURE 23–8. Extension (A) and flexion (B) lateral cervical radiographs of an adolescent boy with an os odontoideum and a progressive decrease in exercise tolerance. Note decrease in the space available for the spinal cord (arrow). Because the ossicle of the odontoid moves with the ring of C1, it is not possible to measure the atlantodental interval. (From Herman MJ, Pizzutillo PD: Cervical spine disorders in children. *Orthop Clin North Am* 30:460, 1999.)

Finally, the radiographs should be inspected for soft tissue abnormalities. The cervicocranial prevertebral soft tissue contour should follow the contour of the anterior cortex of the atlas and axis. The width of the soft tissues at C2 is no more than 7 mm, although this is influenced by neck posture or crying, and that at C6 should be no more than 14 mm. Thoracic and lumbar radiographs can demonstrate a paraspinal soft tissue mass or loss of the psoas stripe on the AP views.

Evidence of Spine Injuries Typically Seen in Children

Radiographic evidence of those injuries typically seen in children (atlanto-occipital dislocation, atlas fractures, atlantoaxial subluxation, odontoid fractures, axis fractures, middle to lower cervical spine injuries, and thoracolumbar injuries) is as follows.

Atlanto-occipital dislocation includes widening of the gap between the occipital condyles and the condylar surface of the atlas to more than 5 mm or a distance of greater than 12 mm between the tip of the clivus and a line drawn along the posterior cortex of the body of the axis.

Jefferson's or burst fractures show bilateral offset of the lateral masses with respect to the odontoid.

Atlantoaxial subluxation demonstrates greater than 5 mm of distance between the anterior arch of the atlas and the odontoid on the lateral view.

Odontoid fractures show prevertebral soft tissue swelling on the lateral radiograph and subtle lucency through the base of the odontoid on open-mouth view. The hangman's fracture is a fracture through the pedicle of C2 and is best seen on the lateral radiograph. Os odontoideum is a condition in which the dens is separated from the axis body. This disorder once was thought to be a congenital failure of fusion of the dens to the axis. Now, it is believed to be due to a prior fracture of the odontoid synchondrosis before its closure at age 5 to 6 years. Os odontoideum appears as an ossicle that is separated from the axis by a large gap (Fig. 23–8). The border of the ossicle does not directly match up with the axis body.

Impingement of the upper cervical cord or vertebral artery can occur due to hypermobility at C1-2. In contrast, ossiculum terminale is due to failure of the secondary ossification center of the dens to fuse with the base of the odontoid. Persistent ossiculum terminale is differentiated from os odontoideum by its ossicle, which is much smaller and is at the tip of the dens. Ossiculum terminale, unlike os odontoideum, is not associated with significant instability.

Compression fractures of the middle and lower cervical spine are seen on the lateral radiograph. Although underossification of growth plates can be misleading, greater than 50% of anterior wedging is pathologic. Vertebral end plate injuries are also obvious on lateral radiographs but should not be confused with secondary centers of ossification, which appear between 10 and 12 years of age.

Anterior wedge fractures are observed on the lateral thoracic spine radiograph when the difference in height between the anterior and posterior cortices is greater than 3 mm. Anterior wedge fractures are similarly observed on the lateral lumbar spine radiographs, and can be distinguished from burst fractures as the latter show disruption of the posterior cortex of the vertebral body, as well as widening of the interpedicular distance on the AP view.

Associated Injuries

Children with spinal injuries should also be evaluated for associated injuries. Children with spinal injuries have associated head injuries in 25% to 50% of cases, extremity fractures in 30% of cases, and chest and abdominal injuries in 21% of cases.⁵ Abdominal injuries of the small bowel are associated with seat belt fractures of the thoracolumbar spine. Children who fall or jump from a height and land on their feet should be examined for calcaneal, ankle, and thoracolumbar spine injuries.⁵ Finally, a high index of suspicion should be held for nonaccidental trauma in the setting of vertebral injuries. Both vertebral body fractures and subluxation have moderate specificity for child abuse. They are highly specific when the history of trauma is absent or inconsistent.¹⁵

Management

The management of vertebral trauma is multifaceted. It begins in the field. Airway management and breathing are the first clinical priorities. Adequate airway management also helps prevent secondary injury to the spinal cord from hypoxia.

During airway interventions, manipulation of the spine should be minimized. Basic airway techniques include chin lift, jaw thrust, and placement of oropharyngeal and nasopharyngeal airways. Placement of an oropharyngeal airway should be avoided in a patient with an intact gag reflex as movement during gagging and vomiting could worsen spinal cord injury. Initially, supplemental oxygen should be delivered by non-rebreather mask; if ventilations are not adequate, they should be assisted by a bag-valve mask. There is some degree of controversy as to which method of intubation is best in the patient with spinal cord injury. However, most authorities agree that the technique with which one is most familiar should be used.¹⁶ This typically involves orotracheal intubation facilitated by rapid sequence induction. Manual in-line stabilization must be maintained by a second team member during any airway intervention.^{16,17}

Circulation should also be attended to early in the management. Bleeding must be controlled, and volume replaced with crystalloid fluids initially and then blood, if indicated, to maintain hemodynamic stability.

Before transport, patients with suspected vertebral trauma should be properly immobilized. Immobilization includes a rigid cervical collar, short and long backboards, and cervical blocks. Ideally, if time allows and the child is without immediate life-threatening injuries, the cervical collar is placed and the short board immobilizer is used to maintain vertebral alignment during extrication. The child is then transferred to the long board, cervical blocks are placed, and straps are engaged. In children up to 6 years of age, the occiput is large relative to the torso and therefore a pad is placed behind the child's shoulders to prevent flexion of the spine.¹⁸ Thus criteria for immobilizing the child's cervical spine should be evidence based, such as the criteria introduced by the NEXUS study.^{10,18-20}

In the emergency department, airway, breathing, and circulation, with maintenance of spine stabilization, should again be evaluated. Hemodynamic instability can also occur after spinal cord trauma. Neurogenic shock is one possible etiology. Hypovolemic shock may be another cause for hemodynamic instability and should be ruled out systematically. The child should be placed on continuous cardiac monitoring, and either an indwelling arterial catheter or a noninvasive blood pressure cuff recording pressures every 5 minutes should be instituted. If neurogenic shock is considered and hemorrhagic shock has been excluded, bradycardia should be treated with atropine 0.02 mg/kg and hypotension managed initially with fluids and then α -agonists (e.g., phenylephrine).²¹

Neurologic deterioration occurs rostrally and may be due to spinal cord edema, hemorrhage, or mechanical and/or physiologic secondary insults. If deterioration is apparent, magnetic resonance imaging should be obtained to evaluate for disk herniation, epidural hematoma, or vascular injury to the vertebral arteries. Surgical intervention should be expedited in these circumstances.^{12,22}

Next, the patient should be removed from the uncushioned backboard at the earliest convenience. Insensate skin of the child with spinal cord injury is rapidly susceptible to pressure sores.⁸

Finally, the pharmacologic therapy for spinal cord injury should be addressed. While pharmacology at this point can do little to reverse the primary injury to the spinal cord, it can be used to reduce secondary damage from spinal cord edema, cell membrane damage, lipid peroxidation, and prostaglandin synthesis. The second National Acute Spinal Cord Injury Study (NASCIS II) compared high-dose methylprednisolone with naloxone and placebo. The results demonstrated a statistically significant improvement in motor abilities after long-term follow-up. However, positive results were only found after post hoc subset analysis.⁶ Recent studies have been less supportive of the benefits of steroids. They have shown no benefit from steroids and have shown an increased risk of pneumonia, sepsis, myopathy, myelopathy (nerve degeneration), decreased spinal blood flow, increased hospital length of stay, and increased cost. Moreover, no patients under 13 years old were included in these studies.

The treatment guidelines for spinal cord injuries should be multidisciplinary and institutionally supported.²³⁻²⁵ Currently, several specialty societies state that steroid treatment is experimental and not the standard of care, including the American Academy of Emergency Medicine, the California Association of Emergency Physicians, the Canadian Association of Emergency Physicians, the Canadian Spine Society, and the Canadian Neurosurgical Society. Seventy-five percent of British and most European spine centers do not use steroids for acute spinal cord injury.²⁶ Due to the controversy surrounding the use of steroids, each institution should reach a consensus with its trauma and neurosurgical experts regarding their use. For those sites using steroids, ASCISS III further defined the duration of treatment based upon time of onset. Within 3 hours of injury, the child with spinal cord injury should receive 30 mg/kg of methylprednisolone over 15 minutes, followed in 45 minutes by a 23-hour infusion of 5.4 mg/kg/hr. If the patient is between 3 and 8 hours postinjury, a 48-hour course is given.⁷

The operative management of vertebral and spinal cord injuries is at the discretion of the spine surgeon or neurosurgeon. Nonoperative treatment is usually recommended for stable injuries such as compression fractures with less than 50% loss of body height or SCIWORA injuries with complete neurologic deficits. Unstable fractures and those with worsening neurologic deficits require surgical management.²⁷ The timing of the surgery depends on the overall condition of the patient and occurs after open fractures and head, thoracic, abdominal, tibia, femur, and pelvis injuries have been stabilized.⁸

Summary

Patterns of injury with vertebral and spinal cord injuries in children vary from those of adults. Knowledge of the anatomic differences in children helps in understanding these differences and predicting findings. Evaluation involves meticulous gathering of history and physical examination combined with radiologic imaging when indicated. Management should focus on airway, breathing, and circulation;

preventing and reducing secondary injuries; and identifying other threatening injuries.

The most effective strategy is prevention. As motor vehicle accidents are frequently responsible, attention has been paid to this mechanism. Proper child restraint mechanisms offer the greatest potential for reducing needless injuries. The appropriate restraint mechanism varies in infants, toddlers, school-age children, and adolescents as the center of gravity migrates from head to pelvis. Infants and toddlers (ages birth to 3 years) should be placed in a child safety seat. At this age, the proportionately larger head produces a high center of gravity. School-age children (ages 4 to 9 years) should be placed in a booster seat. The center of gravity moves toward the umbilicus at this age. Also, the iliac crests are not developed enough to hold the lap belt, and so it slides up over the abdomen if the child is placed in the standard seat. Adolescents (ages 10 years and up) can be restrained as would be an adult. Their center of gravity is lower and their iliac crests are adequately developed.¹⁵

Chapter 24

Thoracic Trauma

Barbara E. McDevitt, MD, George L. Foltin, MD,
and Arthur Cooper, MD, MS

Key Points

Thoracic trauma is the second leading cause of death in children after trauma to the central nervous system.

There are anatomic and physiologic differences between children and adults that impact on both diagnosis and management.

The chest roentgenogram remains the number one screening modality for the evaluation of thoracic injury, but it is crucial that evidence-based criteria be developed to select the most appropriate and sensitive of the rapidly developing armory of diagnostic modalities.

The physician assessing the pediatric patient must recognize the need for acute intervention in life-threatening thoracic injuries, particularly with regard to tracheal intubation, chest decompression and drainage, volume resuscitation, and, in rare instances, pericardial decompression and resuscitative thoracotomy.

The differential diagnosis of immediate life-threatening thoracic injuries is challenging, and is best accomplished through a systematic approach.

The majority of thoracic injuries can be managed conservatively, the most common intervention being a thoracostomy tube.

It is essential to be aware of the probability of coexisting injuries.

Pediatric patients with life-threatening thoracic injuries must be stabilized, then transported to trauma centers with pediatric capabilities, when such resources are not available on site.

Introduction and Background

Trauma remains the leading cause of death in the pediatric population between 1 and 14 years of age, resulting in more fatalities than all other diseases combined. Traumatic brain injury is the foremost killer in this age group, but thoracic trauma is the second most important source of lethal injury in children. Although it is important to recognize that, in contrast to adult trauma, pediatric trauma is primarily a disease of the airway and breathing, rather than of the circulation, it is also important to understand that the observed derangements of airway and breathing in injured children typically have a neuroventilatory cause, rather than a cardiorespiratory cause. In other words, observed derangements of airway and breathing in pediatric trauma patients stem far more often from the cardiorespiratory effects of traumatic brain injury than from thoracic injuries.

Historical data from the National Pediatric Trauma Registry, which was comprised mostly of pediatric trauma centers from children's specialty units, show that major thoracic trauma is relatively uncommon in children, occurring as the only body region injured in only 1%, but as the principal anatomic diagnosis in approximately 6%, of children admitted to pediatric trauma hospitals. Yet, the case fatality rates associated with these injuries have been shown to be as high as 15%, and may increase significantly when injury to other organ systems is present, although thoracic injury itself is rarely the proximate cause of death. Hence, physicians caring for injured children must be familiar with the recognition, evaluation, and management of thoracic injury in children, as well as the mechanisms of injury that result in thoracic trauma.¹⁻⁸ These will vary by age, geographic location, and trends in popular sports, as well as community compliance with injury prevention measures. Blunt trauma is the most frequent cause, though penetrating trauma regrettably afflicts the adolescent population. Because of anatomic, physiologic, and epidemiologic differences, children must be assessed and managed differently from adults. The development of a systematic diagnostic approach to the evaluation of thoracic injuries in children continues to evolve as better diagnostic modalities emerge.

Blunt thoracic injuries outnumber penetrating thoracic injuries by a ratio of 5 : 1. Together, motor vehicle occupant and pedestrian injuries account for about three fourths of all blunt thoracic injuries in children. Falls, bicycle and motorcycle accidents, and miscellaneous injuries account for the remainder. Gunshot and stab wounds are responsible for nearly all penetrating injuries, in a ratio of slightly less than 2 : 1. About one in six children with an intrathoracic injury will die, but those with blunt injuries die mostly from associated injuries, while those with penetrating injuries die nearly always from the injury itself.¹

However, data from the National Trauma Data Bank™ (<http://www.ntdb.org>), which currently comprises the largest repository of pediatric trauma registry data available worldwide, reflect a somewhat older population than its forerunner, the National Pediatric Trauma Registry, consistent with the far greater number, and proportion, of general trauma centers that contribute to this database. As of 2006, this database contained 241,457 pediatric cases from 612 North American trauma centers, of whom 31,138 (13%) had thoracic injuries. Of these, 59% had injuries to the chest wall or diaphragm, 38% had injuries to the lungs, 3% had injuries to the heart, and <1% had injuries to the tracheobronchial tree or the esophagus. By contrast, among those who died with thoracic injuries, 51% had injuries to the chest wall or diaphragm, 39% had injuries to the lungs, 9% had injuries to the heart, and <1% had injuries to the tracheobronchial tree or the esophagus, findings which do not differ statistically versus survivors, but for the greater lethality of cardiac injuries.

Recognition and Approach

Specific attention to the diagnosis and treatment of the injured child has resulted in significant decreases in the morbidity and mortality of all traumatic injuries, including those to the pediatric cardiorespiratory system. This has been achieved by developing standards of care for injured children that build upon the American College of Surgeons Committee on Trauma's Advanced Trauma Life Support® (ATLS®) protocols for the injured adult, but address the special problems encountered in the pediatric population, best described in the American Heart Association and American Academy of Pediatrics Pediatric Advanced Life Support guidelines.^{9,10} As a result, the primary survey in children, which remains directed toward priority assessment and stabilization of airway, breathing, and circulation, applies these principles based upon key pediatric differences in anatomy and physiology that require a modified approach. For this reason, a firm understanding of the pathophysiology unique to pediatric thoracic trauma is paramount.

As with other body regions in pediatric patients, the bony and cartilaginous structures of the chest wall in childhood are fairly flexible, and therefore less likely to fracture. However, the rarity of chest wall fractures in the pediatric population is a double-edged sword, for kinetic energy is absorbed when a bone breaks. Absent such fractures, forces of injury are not absorbed by the body's outer shell, but directed toward its inner assets. Since the child's thinner muscles also offer less protection to the thoracic and abdominal organs, underlying lung tissue is frequently bruised by the transmitted forces. As a result, pulmonary contusions,

which can cause ventilation-perfusion mismatch and arterial hypoxemia, are the most common life-threatening thoracic injuries found in the pediatric population, and threaten respiration in all children with major thoracic trauma.¹¹⁻¹³

Another unique feature of the pediatric chest wall is the high elastin content of the mediastinum and its structures. This makes the mediastinum both more mobile and more susceptible to wide shifts, which can lead to a significant compromise of major organs and vessels in the presence of extrapulmonary collections of air or blood within the thorax, such as those associated with pneumothorax and hemothorax, especially if under tension. Tension pneumothorax, in particular, is especially poorly tolerated by children, and can predispose to rapid demise due to both ventilatory and circulatory compromise, as the contralateral lung is compressed and the venae cavae are torsed at the thoracic inlets, causing both profound respiratory distress, and obstructive shock due to impeded venous return.

Children sustaining blunt trauma also experience significant aerophagia, with subsequent gastric dilation. As children are diaphragmatic breathers, owing to the more horizontal alignment of their ribs and the relative weakness of their intercostal muscles, gastric dilation, by pushing upward on the diaphragm, decreases vital capacity and impairs both spontaneous and assisted ventilation. At the same time, since children have both a larger oxygen consumption and a smaller functional residual capacity than adults, they are more susceptible to hypoxemia. This is especially problematic in physiologically stressed infants, whose diaphragmatic muscles often tire quickly, causing sudden apnea.

Cardiac function in children initially may be able to compensate for hypoxemia. Cardiac output in children is maintained chiefly through increases in heart rate, since the smaller chamber size and thicker ventricular walls decrease myocardial compliance, thereby limiting the compensatory potential of Starling forces. When hypoxemia is present, the child's body first responds with a reflex tachycardia. Gastric dilation therefore further compromises resuscitation following major thoracic trauma through the vagally mediated decreases in heart rate commonly observed in small children with gastric distention.

Cardiac function in children may also be able to compensate for up to a 40% blood loss. This can lead to initial underestimation of the child's degree of hypovolemia due to major hemorrhage. Fortunately, most intrathoracic bleeding is self-limited. The lungs fill most of the thorax, hence are the most common source of hemorrhage. However, they contain an abundant supply of tissue thromboplastins in pulmonary parenchyma, with the result that most bleeding rapidly stops. Injuries to intrathoracic vessels, including both the heart and great vessels, well protected as they are by the sternum and the spine, and to the somewhat less well protected intercostal vessels, are the exception to the rule that most intrathoracic bleeding is self-limited, since vascular hemorrhage rarely stops spontaneously. Moreover, as children have a blood volume comprising some 8% of their total body mass, which slightly exceeds that of adults, a greater proportion of blood must be lost before hypovolemia becomes evident, which can also contribute to a missed diagnosis of shock. Thus, failure to account for the vigorous compensatory response to hypovolemia, and the proportionately larger

blood loss needed to produce shock, may each forestall early intervention to prevent circulatory collapse.

Evaluation

Trauma to the chest may involve injury to the thoracic cage and its contents, including the lungs, heart, great vessels, tracheobronchial tree, and esophagus. Injuries to these organs may manifest acutely during the primary survey, or their presentation may be gradual and insidious and only diagnosed by a careful secondary survey. Continuous evaluations are mandatory once the child is admitted to the hospital for treatment.¹⁴

Injuries to the thorax can cause sudden and significant cardiorespiratory compromise almost immediately. If not recognized and promptly treated, the result may be lethal. It is therefore imperative for the treating physician to detect all underlying injuries, decide the priority of treatment, and begin to reverse the pathophysiologic changes induced by the injuries. The American College of Surgeons Committee on Trauma's ATLS® protocol includes a standardized assessment of the patient's airway, breathing, and circulation that should enable the treating physician to recognize, evaluate, and manage life-threatening thoracic injuries in priority sequence, as shown in Table 24–1.⁹ Immediately life-threatening injuries to the airway (obstruction), breathing (tension pneumothorax, flail chest, open pneumothorax), and circulation (massive hemothorax, cardiac tamponade) can usually be detected during the primary survey. Potentially life-threatening injuries to the airway (tracheobronchial disruption), breathing (pulmonary contusion, traumatic diaphragmatic hernia, traumatic asphyxia), and circulation (blunt cardiac injury, aortic disruption) are more often detected during the secondary survey, as are injuries that affect multiple intrathoracic structures (such as mediastinal traversing injuries), and injuries that affect the integrity of the alimentary canal (esophageal disruption) and present with sepsis if initially overlooked.

Clinical Evaluation⁹

In performing the primary survey, the treating physician will look first for airway patency and maintainability, as judged by the absence of abnormal nasopharyngeal or oropharyngeal sounds (snoring, gurgling, stridor, or hoarseness) and the presence of spontaneous air movement at the nares. Next assessed is breathing, through evaluation of ventilation (chest rise, air entry, respiratory effort and rate) and oxygenation (central skin and mucous membrane color, sensorium). Last assessed is circulation, through examination for major hemorrhage (external and internal), as well as tissue perfusion (pulse rate and character, peripheral skin and mucous membrane color, temperature and moisture, capillary refill, urinary output). This is because hypotension (the cardinal sign of decompensated shock) does not occur until very late in the downward spiral of circulatory deterioration, when the opportunities for successful resuscitation are limited.

Ensuring an open airway and facilitating adequate gas exchange are the major goals of treatment during the primary survey. Failure to detect the most common immediate life-threatening thoracic injury, tension pneumothorax, which can cause sudden and severe respiratory and circulatory

Table 24–1 Principles of Advanced Trauma Life Support® (ATLS®)⁹

Primary Survey and Resuscitation

Airway/cervical spine

- Open: jaw thrust/spine stabilization
- Clear: suction/remove particulate matter
- Support: oropharyngeal/nasopharyngeal airway
- Establish: orotracheal/nasotracheal intubation*
- Maintain: primary/secondary confirmation[†]
- Bypass: needle/surgical cricothyroidotomy

Breathing/chest wall

- Ventilation: chest rise/air entry/effort/rate
- Oxygenation: central color/pulse oximetry
- Support: distress → NRB/failure → BVM
- Chest wall: ensure integrity/expand lungs
 - Tension pneumothorax: needle, chest tube[§]
 - Open pneumothorax: occlude, chest tube
 - Massive hemothorax: volume, chest tube

Circulation/external bleeding

- Stop bleeding: direct pressure, avoid clamps
- Shock evaluation: pulse, skin perfusion, CRT, LOC[†]
- Blood pressure: avoid over/undercorrection
 - Infant/child: low normal $\geq 70 + (\text{age} \times 2)$ mm Hg
 - Adolescent: low normal ≥ 90 mm Hg or significant change
- Volume resuscitation: Ringer's lactate (RL) → packed red blood cells (PRBC)
 - Infant/child: 20 ml/kg RL, repeat $\times 1-2 \rightarrow 10$ ml/PRBC
 - Adolescent: 1–2 L RL, repeat $\times 1-2 \rightarrow 1-2$ U PRBC

Disability/mental status

- Pupils: symmetry, reaction
- LOC: GCS
 - Track and trend as a vital sign
 - Significant change ≥ 2 points
 - Intubate for coma (GCS ≤ 8) or significant change
- Motor: strength, symmetry
- Abnormality/deterioration: call neurosurgeon
 - Mild TBI (GCS 14–15): observe, consider CT for history of LOC
 - Moderate TBI (GCS 9–13): admit, obtain CT, repeat CT 12–24 hr
 - Severe TBI (GCS 3–8): intubate, ventilate, obtain CT, repeat CT 12–24 hr

Exposure and environment

- Disrobe: cut off clothes
- Logroll: requires four people
- Screening examination: front and back
- Avoid hypothermia: keep patient warm!

Adjuncts (Primary Survey and Resuscitation)

Foley catheter unless contraindicated[‡]

Gastric tube unless contraindicated**

Secondary Survey and Re-evaluation

History and physical examination: SAMPLE history, complete examination

Adjuncts (Secondary Survey and Re-evaluation)

Imaging and laboratory studies: plain radiographs,^{††} special studies^{††}

*Rapid sequence induction technique: etomidate then succinylcholine.

[†]Primary: chest rise, air entry; secondary: exhaled CO₂ detector, esophageal detector device. Watch for DOPE: **D**islodgement, **O**bstruction, **P**neumothorax, **E**quipment failure.

[§]Do not wait for confirmatory chest x-ray!

[†]Consider obstructive and neurogenic as well as hypovolemic shock; exclude tension pneumothorax, cardiac tamponade, spinal shock.

[‡]Contraindications: meatal blood, scrotal hematoma, high-riding prostate.

**Contraindications: cerebrospinal fluid otorrhea, basilar skull fracture, midface instability.

^{††}Chest, pelvis, lateral cervical spine; others as indicated

^{†††}Focused Assessment by Sonography in Trauma (FAST), CT as indicated.

Abbreviations: BVM, bag-valve-mask; CRT, capillary refill time; CT, computed tomography; GCS, Glasgow Coma Scale; LOC, level of consciousness; NRB, non-rebreather mask; SAMPLE: Signs/symptoms, Allergies, Medications, Pertinent past history, Last oral intake, Events leading up to the injury; TBI, traumatic brain injury.

collapse, and to which infants and young children are especially prone, is catastrophic. Therefore, careful and frequent re-evaluations are required to ensure that tension pneumothorax is not overlooked.

Abnormalities in the primary survey are addressed as they arise, since accurate evaluation of each step in the delivery of oxygen to the tissues (airway/ventilation, breathing/oxygenation, circulation/perfusion) presumes the integrity of the previous step. Adjuncts to the primary survey that will assist in the evaluation of each of these steps include vital signs (appropriate for age), pulse oximetry (demonstrating adequate oxygen saturation [S_pO_2]), end-tidal capnography (confirming gas exchange [$ETCO_2$]), and, with respect to the thorax, a supine chest roentgenogram (identifying pathologic findings). Evidence of respiratory distress or compensated shock mandates urgent resuscitation. Evidence of respiratory failure or decompensated shock mandates emergent resuscitation.

In performing the secondary survey, the complete physical examination for thoracic injuries will assess for visible contusions, subcutaneous emphysema, chest wall stability, and other palpable abnormalities (by inspection and palpation), and for abnormal collections of air or blood within the thoracic cavity (by percussion and auscultation).

Injuries commonly requiring immediate intervention in the pediatric patient include immediate life-threatening thoracic injuries such as airway obstruction, tension pneumothorax with respiratory insufficiency, and massive hemothorax with shock. Less frequently encountered are open pneumothorax, flail chest, and cardiac tamponade. Clinical stabilization with appropriate interventions must be accomplished in an orderly and timely manner to prevent further respiratory or cardiac decompensation. Injuries requiring delayed intervention in the pediatric patient include potentially life-threatening thoracic injuries that in most cases will not be detected without radiographic or laboratory tests, or ongoing monitoring and continuous reassessment of the patient's clinical status.

Immediately Life-Threatening Thoracic Injuries⁹

AIRWAY

Airway obstruction most commonly results from passive closure of the upper airway due to unconsciousness, which leads to loss of tone in the muscles of the head and neck and subsequent collapse of hypopharyngeal soft tissues across the glottic inlet. It may also be caused by particulate matter that becomes lodged in the funnel-shaped upper airway above, at, or below the level of the vocal cords, but above the cricoid ring. Rare causes of airway obstruction include laryngeal hematoma and fracture. Most episodes of airway obstruction are relieved in the normal course of airway opening and positioning during the primary survey, but may not be recognized unless abnormal sounds, such as snoring (soft tissue obstruction), gurgling (excessive hypopharyngeal secretions), stridor (particulate matter obstruction), and hoarseness (direct laryngeal trauma) are present.

BREATHING

Tension pneumothorax develops when sufficient air accumulates in the pleural space to compress the ipsilateral lung and to shift the mediastinum toward the opposite side and

compress the contralateral lung. It is often missed on initial examinations, and may only be diagnosed after assisted ventilation adds to the volume of the entrapped gas and leads to further deterioration. Confirmatory chest roentgenograms should not delay prompt intervention via needle decompression in patients who present with clinical symptoms and signs of tension pneumothorax. These include air hunger, decreased or absent breath sounds on the ipsilateral side, a hyperresonant percussion note on the ipsilateral side, shift of the trachea toward the contralateral side, and distention of neck veins (uncommonly observed in small children and those with short necks). Any patient with thoracic trauma who presents with severe respiratory and cardiovascular compromise should be considered for empirical needle decompression, which is both diagnostic and therapeutic.

Flail chest is uncommon in children, and results from two or more adjacent fractures in two or more adjacent ribs that cause instability in the chest wall and compromise in the ventilatory effort. Most flail segments in children are relatively small, and do not directly affect ventilation due to spasm of the adjacent muscles, but indirectly affect oxygenation owing to the sizeable pulmonary contusions that are invariably associated with flail chest. However, if flail segments are large and posterolateral, ventilation is adversely affected, as the damaged chest wall caves in during inspiration. Diagnosis is confirmed when bony crepitus is palpated in association with a free-floating segment of chest wall.

Open pneumothorax is recognized by the presence of a defect in the chest wall that allows air to move freely between the atmosphere and the pleural cavity. The result is paradoxical respiration, in which the lung collapses during inspiration, and expands during expiration, as air enters and exits the pleural cavity via the defect during inhalation and exhalation, rather than entering and exiting the lungs via the trachea and bronchi. It is uncommon in children, and results by definition from penetrating trauma. Open pneumothorax will exist whenever there is a defect in the chest wall that is larger than one half to two thirds the size of the corresponding intercostal space. Immediate treatment is needed to avoid rapid progression of respiratory failure to respiratory arrest.

CIRCULATION

Massive hemothorax develops as a result of either blunt or penetrating trauma that causes injury to lung parenchyma or intrathoracic vessels and leads to accumulation of blood in the pleural space. Bleeding is usually self-limited in parenchymal injury due both to the high concentration of pulmonary thromboplastins and the tamponading effect of entrapped blood, but may rapidly accumulate in vascular injury due to the ongoing hemorrhage that produces external manifestations of shock. Massive hemothorax is the leading thoracic cause of shock following thoracic injury. Massive hemothorax may also develop following inadvertent misplacement of a chest tube into the lung, liver, or spleen. Children with massive hemothorax may initially present with minimal symptoms but can rapidly progress to severe dyspnea, tachypnea, tachycardia, and cardiovascular collapse due to hypovolemic shock. Late presentations may include chronic atelectasis with ventilation-perfusion mismatch,

pneumonia, empyema, sepsis, or fibrothorax. Initial evaluation includes chest roentgenograms with or without computed tomograms. Beyond these, minimally invasive techniques such as video-assisted thoracoscopic surgery (VATS) have been used to both diagnose and evacuate residual hematomas.¹⁵⁻¹⁸

Cardiac tamponade exists when a sufficient volume of blood accumulates in the nondistensible pericardial sac following penetrating trauma or blunt trauma (rarely in small children), thereby compressing the heart and compromising cardiac output. As blood further accumulates, the cardiac chambers become unable to fill, and cardiac output drops precipitously. Cardiac tamponade should be suspected whenever there is a penetrating injury to the imaginary square box bounded superiorly by the intermammary line, inferiorly by the costal margins, and bilaterally by lines running caudally from the nipples. It is heralded by the classic Beck's triad of muffled heart tones, jugular venous distention, and pulsus paradoxus, although pronounced tachycardia, followed by decompensated shock, are the most common and most consistent signs. The diagnosis is confirmed by the presence of fluid in the pericardial sac on Focused Assessment by Sonography in Trauma (FAST), or by pericardiocentesis, which is both diagnostic and therapeutic, should FAST not be available to the treating physician. When pericardiocentesis is performed, an alligator clip emanating from the V lead of an electrocardiograph should be attached to the metal part of the large-bore needle used for the procedure in an attempt to identify the current of injury, which appears as a spike in the tracing when the myocardium is touched by the needle tip. The classic teaching that pericardial blood does not clot is false, and cannot be relied upon in actual practice.

Potentially Life-Threatening Thoracic Injuries

AIRWAY

Tracheobronchial injury is rare in children. When found, it follows penetrating trauma or violent blunt force impact to the chest. Blunt tracheobronchial injuries are typically located adjacent to the carina, where shear forces will be the greatest, and large airways are their thinnest, and unprotected by lung. Injuries may be complete or incomplete, such that small tears may not be manifest for several days. Tracheobronchial injuries should be suspected whenever there exists a persistent massive air leak via a thoracostomy tube. If the tear is complete, the fatality rate is as high as 20%, in part due to the tear's association with concomitant injury to the head, neck, spine, and chest, and in part due to its relative inaccessibility. Evaluation of tracheobronchial injury may include bronchoscopy as well as computed tomography, although immediate thoracotomy may be needed for diagnosis and treatment if rapid deterioration occurs before diagnostic imaging can be obtained.

BREATHING

Pulmonary contusion remains the most common thoracic injury in childhood, although its incidence has decreased markedly over the past decade following the introduction of mandatory child restraint systems. Caused by a direct force to the lung that leads to parenchymal bleeding and interstitial edema, it first presents with mild symptoms, but

as edema increases, ventilation-perfusion mismatch, hypoxemia, and hypoventilation may develop. Late complications may include atelectasis, pneumonia, and acute respiratory distress syndrome. Physical findings may include cyanosis, tachypnea, tachycardia, decreased breath sounds, and wheezing. Initial chest roentgenograms may not disclose the characteristic mixed alveolar and interstitial infiltrates for hours or days.

Traumatic diaphragmatic hernia is uncommon in children, but frequently occurs in association with penetrating trauma to the thoracoabdominal region, located between the intermammary line and the costal margins, and rarely occurs in blunt trauma, which often involves severe blunt force impact or improperly worn shoulder belts. In penetrating trauma, this injury is not readily revealed by diagnostic imaging, and may be found only upon surgical exploration. In blunt trauma, this injury is also commonly associated with multiple organ system trauma involving the liver, spleen, and gastrointestinal tract, and usually occurs on the left side, since a major etiology is pedestrian-motor vehicle crashes. Symptoms and signs of traumatic diaphragmatic hernia will not be immediately apparent unless associated with abdominal visceral herniation into the thorax. If present, they may include respiratory distress, decreased or atypical breath sounds, or a scaphoid abdomen. A chest roentgenogram will be diagnostic only with frank herniation, as manifested by the presence of the gastric bubble or gastric tube within the chest, but will be suspicious in the presence of an elevated or indistinct diaphragmatic silhouette. Definitive diagnosis may require evaluation by computed tomography or surgical exploration.

Traumatic asphyxia occurs more commonly in children than adults due to the increased compliance of their chest walls and the absence of fully developed valves in the superior and inferior venae cavae. It results from sudden massive compression of the chest. Direct compression on a closed glottis causes pressure to be transmitted to the heart, lungs, venae cavae, neck, and head. This increase in pressure may lead to bleeding in the brain and other organs. Physical examination typically reveals numerous petechiae of the head and neck, subconjunctival hemorrhages, and cyanosis above the clavicles. Diagnosis is directed toward underlying complications associated with massive blunt thoracic injury.

CIRCULATION

Blunt cardiac injury refers to a constellation of injuries to the heart, including myocardial contusion, valvular and ventricular injuries, and commotio cordis, all of which are unusual in children following blunt trauma.¹⁹⁻²⁴ Manifestations of myocardial contusion include dysrhythmias, hypotension, and elevated cardiac enzymes. Definitive diagnosis is controversial, in part because it has few clinical implications. Electrocardiography is most useful, since it will detect the rare cardiac arrhythmia. Echocardiography is also useful to evaluate ventricular function but is rarely abnormal, and even when abnormal, is not predictive of clinical deterioration. Cardiac enzymes are no longer used routinely as predictors of complications in blunt cardiac injury, and while troponin I may predict echocardiographic abnormalities, its clinical significance has yet to be defined. Valvular and ventricular injuries, including rupture of the chordae tendineae

and the ventricular wall, are devastating events that can be diagnosed only by echocardiography. Commotio cordis is a unique pediatric traumatic cardiac event that usually results in sudden death. Associated with severe blunt force impact to the lower sternum, usually during a sports activity, it causes sudden ventricular fibrillation. Exact understanding of its mechanism remains to be delineated. Since the only effective interventions are immediate on-site cardiopulmonary resuscitation and automated external defibrillation, many jurisdictions are mandating that both be available at sports activities involving children.

Traumatic aortic disruption is rare in children, and when it occurs it is usually associated with significant injury to other intrathoracic organs following massive deceleration injury, although it is occasionally caused by penetrating injury, most often in adolescents. It carries a high mortality rate, as death often ensues prior to arrival at a treating facility. The chest roentgenogram remains the primary screening test, and typically demonstrates a widened mediastinum. However, it cannot be used for definitive diagnosis, since the portable anteroposterior supine film obtained per ATLS protocol is not accurate enough to supplant other tests. Actual aortic injury occurs in only 10% to 20% of patients with widened mediastinum on chest roentgenogram, while approximately 7% of aortic injuries are missed by chest roentgenogram. Thoracic aortography therefore remains the study of choice if traumatic aortic disruption is a likely possibility, as it establishes and defines the anatomy of the injury. However, it requires transport to the angiographic suite, and is therefore performed only if the screening film is abnormal, or it is clinically indicated. Computed tomography by rapid helical scanning with three-dimensional reconstruction may ultimately replace aortography. It is now used to exclude mediastinal hematoma in clinically stable patients with (1) equivocal chest roentgenograms, (2) negative chest roentgenograms but with signs of aortic disruption, and (3) suspected thoracic injuries who also require computed tomography of the abdomen. The roles of other imaging modalities are still being defined. Transthoracic echocardiography can rapidly detect pericardial tamponade and cardiac rupture in clinically unstable patients, but requires an experienced operator. Transesophageal echocardiography is a promising new technique, but it also requires an experienced operator. More invasive than computed tomography, it is both less invasive and less sensitive than thoracic aortography. The use of FAST is also rapidly evolving, but needs to be more specifically studied in its application to cardiac injuries in children.

Possibly Life-Threatening Thoracic Injuries

Simple pneumothorax may be caused by blunt or penetrating trauma, with or without fractured ribs. It occurs when air escapes into the pleural space due to a tear in the lung, tracheobronchial tree, esophagus, or chest wall, causing partial or complete lung collapse. As most pneumothoraces are due to lung injury, most seal quickly and do not progress to tension pneumothorax, causing increased intrathoracic pressure, mediastinal shift, both ipsilateral and contralateral lung collapse, and decreased cardiac output secondary to impaired venous return. As a result, the child with simple pneumothorax typically presents with mild to moderate symptoms, such as ipsilaterally decreased breath sounds, tachypnea, tachycardia, or pain, or may be completely asymptomatic. In such

circumstances, the injury may not be detected until a chest roentgenogram is obtained.

Simple hemothorax may also be caused by blunt or penetrating trauma, with or without fractured ribs. It occurs when blood leaks from injured lung parenchyma, but may also result from vascular or costal bleeding that stops spontaneously as increased intrathoracic pressure tamponades small bleeding veins or narrow venous plexuses. Bleeding arteries usually result in massive hemothorax rather than simple hemothorax, since intrathoracic pressure cannot exceed arterial pressure. Injuries to the great vessels are usually fatal at the scene, although patients with bleeding pulmonary veins occasionally survive.

Rib fractures are uncommon in young children, but incidence increases with age. The fourth through ninth ribs are most commonly fractured, and are associated with damage to abdominal organs. The first through the third ribs are less commonly fractured, but are associated with injuries to the trachea, bronchi, and great vessels. Manifestations may include bruising, localized pain, crepitus, or decreased respiratory effort and pain. Because the ribs are softer in children than adults, the presence of one or more rib fractures in children indicates that a substantial energy load was transferred to the chest. Rib fractures are therefore significant not only as a source of morbidity on their own, but also as a marker of severe injury, although recent evidence indicates that this association may not be consistent.²⁵⁻²⁸ Multiple rib fractures in infancy may indicate child abuse, or an underlying organic disorder such as osteogenesis imperfecta.

Sternal fracture is rare in children. Older data indicated close correlation with cardiac injury. However, more current studies show a less conclusive association.²⁹ Diagnosis is made by lateral chest roentgenograms or computed thoracic tomography.

Esophageal injuries are also rare in children. Because the esophagus is a well-protected organ that is very flexible and capable of self-decompression, it rarely sustains blunt injury. However, penetrating injuries that transverse the mediastinum may lacerate the esophagus. Diagnostic modalities include contrast fluoroscopy and endoscopy, and should be considered whenever there is unexplained gas in the mediastinum, or if food or saliva are observed to be draining from a properly placed chest tube.

Mediastinal traversing injuries are increasingly recognized as a cause of significant morbidity and mortality, particularly in adolescent boys engaged in violent behavior involving firearms. Patients who are unstable on presentation require immediate surgical intervention. Patients who are stable on presentation require immediate surgical consultation, in case of unexpected sudden deterioration, and for treatment of associated injuries. Diagnostic tests typically employed to exclude injury in stable patients may include chest roentgenography, computed tomography, contrast fluoroscopy, rigid or flexible bronchoscopy or esophagoscopy, and echocardiography.

Diagnostic Modalities

Clinical Examination

Over the past several decades, multiple modalities have been developed to facilitate the prompt and accurate diagnosis of

Table 24–2 Differential Diagnosis of Immediately Life-Threatening Thoracic Injuries

	Tension Pneumothorax	Massive Hemothorax	Cardiac Tamponade
Breath sounds	Ipsilaterally ↓	Ipsilaterally ↓	Normal
Percussion note	Hyperresonant	Dull	Normal
Tracheal location	Contralaterally shifted	Midline	Midline
Neck veins	Distended	Flat	Distended
Heart tones	Contralaterally shifted	Normal	Muffled

thoracic injuries. Classic *clinical signs* remain reliable indicators of intrathoracic injuries, and are typically used to guide initial diagnosis and treatment, as shown in Table 24–2. Although many investigators have attempted to develop clinical prediction rules to identify children with these injuries, definitive evidence-based protocols are still undergoing investigation.³⁰ However, children undergoing evaluation for blunt trauma have been found to have an increased risk of thoracic injury if they present with certain clinical manifestations, including tachypnea, abnormal chest auscultation, low blood pressure, low Glasgow Coma Scale score, and femur fracture.

Use of FAST is rapidly evolving, but needs to be more specifically studied in its application to thoracic injuries. It consists of a bedside transabdominal sonographic examination for abnormal fluid collections in the pericardial cavity, the subhepatic pouch (of Morison), the splenic fossa, and the retrovesical space.

Imaging Studies

Beyond the physical examination, *chest roentgenography* remains the primary screening tool used for evaluation of thoracic injuries. It can rapidly identify most of the immediate, potential, and possible life-threatening thoracic injuries, it can localize tubes and catheters, and it has the advantage of being inexpensive, readily available, and associated with minimal morbidity.³¹ Yet, while chest roentgenography remains an important screening tool, it can miss a significant number of injuries, and lacks specificity for mediastinal injuries. It can also underestimate the magnitude of pleural and parenchymal injuries, and incorrectly localize the placement of tubes.

For these reasons, *computed tomography* is increasingly used for definitive diagnosis of intrathoracic injuries in stable patients.^{32–38} It is a better test for detection and quantification of abnormal collections of air or blood (which are often missed on supine chest roentgenography), for inclusion or exclusion of mediastinal hemorrhage due to aortic disruption (since mediastinal widening is typically exaggerated by supine chest roentgenography), and for documenting the position of tubes and catheters (which requires an additional lateral view on chest roentgenography that often proves difficult to obtain during initial evaluation and resuscitation). Yet, while it provides far greater sensitivity and specificity in the detection of thoracic trauma, its greater diagnostic accuracy must be weighed not only against its effect on the clinical management and outcome (recognizing that it is no more useful than other tests for most intrathoracic injuries), but also against its potential long-term radiologic side effects.³⁹ For example, computed tomography appears

to be more sensitive than chest roentgenography in the detection of small pneumothoraces, but the clinical import of this fact may be negligible, as most patients with small pneumothoraces are safely managed without tube thoracostomy.⁴⁰

Transthoracic echocardiography is the radiographic study of choice for cardiac injuries, including cardiac tamponade. It is less useful for great vessel injuries, which are not optimally visualized via subxiphoid or intercostals windows. When immediately available, it is somewhat more accurate for diagnosis of pericardial fluid, and it is ideal for diagnosis of valvular disruption. Unfortunately, it is rarely available during evening and weekend hours when seriously injured children are most likely to present.

Transesophageal echocardiography is a relatively new technique for diagnosis of cardiac and great vessel injuries, but it requires an experienced operator. While it is more invasive than helical computed tomography with intravenous contrast, it may be more sensitive in skilled hands for the diagnosis of aortic disruption.^{41,42} However, it is both less invasive and less sensitive than aortography for this purpose. Moreover, because it requires passage of a sonographic probe into the esophageal lumen, helical computed tomography with intravenous contrast may be preferred for most patients.

Thoracic aortography remains the “gold standard” for radiographic diagnosis of aortic disruption, since it establishes and defines the anatomy of the injury. It is not usually performed unless the chest roentgenogram shows a widened mediastinum or the computed tomogram shows a mediastinal hematoma and suggests aortic injury. Because it requires transfer to the angiographic suite for an invasive procedure that employs both an intra-arterial catheter and intravenous contrast, it is reserved for only high-risk patients, upon request of the thoracic surgeon who will perform the repair. The role of intra-arterial thoracic subtraction angiography needs further delineation.

Video-assisted thoracoscopic surgery is increasingly being used in diagnosis and treatment of intrapleural complications of intrathoracic trauma, such as trapped lung and empyema. Its role in diagnosis of major intrathoracic trauma is uncertain. Anecdotal reports of video-assisted thoracostomy and intracavitary missile retrieval have appeared. However, there currently appears to be no role for VATS in evaluation and management of thoracic injuries in the emergency department.

Laboratory Tests

Laboratory tests are of limited utility for the early diagnosis and treatment of thoracic injuries in childhood. *Hemoglobin*

concentration and hematocrit are likely to be misleading during the initial phases of resuscitation, as dilutional anemia from endogenous fluid shifts and exogenous fluid administration will not as yet have occurred, although both tests will be useful as a baseline for further measurements. Similarly, *arterial blood gases* will serve as an initial indicator of ventilation, oxygenation, and perfusion, but are more useful in terms of their trend, since all three functions can be reliably assessed more quickly via bedside monitoring or clinical tests, such as end-tidal capnography (ETCO₂), pulse oximetry (S_pO₂), and vital signs.⁴³ Blood type and crossmatch are routinely obtained in all children with significant injury.

Cardiac enzymes have played an important historical role in the diagnosis of blunt cardiac injury, particularly myocardial contusion. However, the clinical significance of this diagnosis in childhood is uncertain. As such, the role of cardiac enzymes has markedly decreased as a predictor of complications in patients with blunt myocardial contusion. Although abnormally high troponin I levels may predict echocardiographic abnormalities, the clinical importance of these findings has yet to be defined.⁴⁴

Management

Thoracic injuries pose a major threat to the integrity of the airway, breathing, and circulation, hence to ventilation, oxygenation, and perfusion of core organs and body tissues, thence to vital functions. As such, resuscitation must proceed simultaneously with assessment. Abnormalities of the airway, breathing, and circulation must therefore be treated in sequence, as soon as they are recognized, both to restore flow of oxygen through the series circuit composed of the tracheobronchial tree, the lungs, and the bloodstream, and to ensure accurate assessment of downstream segments of this circuit. It is therefore important that the stepwise pathophysiologic assessment of airway, breathing, and circulation advocated by the ATLS® Course of the American College of Surgeons Committee on Trauma be followed in detail.

The six immediately life-threatening thoracic injuries described previously are recognized and treated during the primary survey, while potential and possible life-threatening thoracic injuries are recognized and treated during the secondary survey. Meticulous attention to the early detection and optimal management of these injuries is the ideal way to ensure effective restoration of ventilation, oxygenation, and perfusion, hence the best chance the seriously injured child has of a full and complete physical and neurologic recovery. Indications for both tube thoracostomy and urgent thoracotomy are delineated in Tables 24–3 and 24–4.

Major Chest Injuries

Immediately Life-Threatening Thoracic Injuries

AIRWAY

An injured child who cannot easily breathe, cough, cry, or speak has *upper airway obstruction* until proven otherwise. The airway must be opened and repositioned, with a modified jaw thrust maneuver and bimanual cervical spine stabilization. The quality of any abnormal sounds heard will dictate the correct initial treatment. Snoring suggests soft

Table 24–3 Indications for Tube Thoracostomy

Immediate Life-Threatening Thoracic Injuries (Addressed during Primary Survey)

- Airway
- None
- Breathing
- Tension pneumothorax (after immediate needle decompression)
 - Open pneumothorax (after applying occlusive dressing)
- Circulation
- Massive hemothorax (after initiating volume resuscitation)

Potential Life-Threatening Thoracic Injuries (Addressed during Secondary Survey)

- Airway
- Tracheobronchial injury
- Breathing
- None
- Circulation
- None

Possible Life-Threatening Thoracic Injuries (Addressed during Secondary Survey)

- Airway
- None
- Breathing
- Simple pneumothorax
- Circulation
- Simple hemothorax

Special Considerations (Addressed during Secondary Survey)

- Esophageal injuries
- Mediastinal traversing wounds
- Thoracoabdominal wounds

Table 24–4 Indications for Urgent Thoracotomy

Emergency Thoracotomy (in the Operating Room)

- Airway
- Tracheobronchial injury with massive uncontrollable air leak
- Breathing
- Open pneumothorax with large chest wall defect
 - Traumatic diaphragmatic hernia
- Circulation
- Massive hemothorax
 - Immediate drainage of 20–25 ml/kg blood from chest tube
 - Ongoing drainage of 2–2.5 ml/kg/hr blood from chest tube
 - Cardiac tamponade (cardiopulmonary bypass advisable)
 - Traumatic aortic disruption (cardiopulmonary bypass advisable)
 - Blunt cardiac injuries needing surgical repair (cardiopulmonary bypass required)
- Other
- Esophageal injury (if disruption evident)
 - Mediastinal traversing injury (if hemodynamically unstable)
 - Completion of thoracotomy following successful resuscitative thoracotomy

Resuscitative Thoracotomy (in the Emergency Department)

- Airway
- None
- Breathing
- None
- Circulation
- Penetrating traumatic cardiac arrest with signs of life at the scene or thereafter

tissue obstruction for which airway opening and repositioning alone should be sufficient, followed in the absence of a gag reflex by insertion of an oropharyngeal airway that reaches from the mental foramen to the angle of the mandible. Gurgling suggests abundant pharyngeal secretions, which must be cleared through aggressive but gentle use of a large-bore oropharyngeal suction device. Stridor suggests a laryngeal foreign body, such as fractured dental fragments or small intraoral playtoys, that may require extraction under direct laryngoscopy using pediatric Magill or Rovenstine forceps, if a directly observable fingersweep is unsuccessful. Hoarseness suggests blunt laryngeal injury that may require medical or, rarely, surgical cricothyroidotomy if airway opening maneuvers fail, followed by definitive surgical repair if laryngeal fracture is present, a diagnosis that is made by computed tomography once definitive airway control has been obtained.

Endotracheal intubation using an uncuffed endotracheal tube will in due course be required for injured children under 8 years of age who present in respiratory failure, decompensated shock, or traumatic coma, or who cannot protect their own airway. An uncuffed tube is preferred for such children, not because of the “physiologic” mucosal “cuff” that is the serendipitous benefit of the funnel-shaped upper airway, the narrowest point of which is at the subglottic level of the cricoid ring, but because the larger outer diameter created by the plastic “balloon” cuff necessitates use of a tube with a smaller inner diameter than is ideal, thereby predisposing the tube to earlier obstruction from bloody or mucousy secretions than a tube of larger inner diameter. However, the tube need not be inserted the moment the need for it is recognized, so long as the airway can be temporarily maintained by other means. This gives time for the treating physician to rapidly assess the child for conditions such as tension pneumothorax that may worsen if the child is tracheally intubated before they are addressed.

Orotracheal intubation is the preferred approach in injured children requiring definitive airways. This is because the anterior, cephalad location of the larynx in children under 8 years of age precludes nasotracheal intubation in most emergent situations, while attempts at nasotracheal intubation may cause profuse adenoidal bleeding. In rare circumstances, tracheal intubation may not be possible due to laryngeal injury. Needle cricothyroidotomy followed by needle jet ventilation is preferred for such patients, since the hyoid bone is often more prominent than the thyroid cartilage in infants and young children, a fact that may predispose to misidentification of anatomic landmarks, which can lead to improper placement of the surgical cricothyroidotomy incision.

Rapid sequence intubation, using etomidate and succinylcholine after an adequate interval of suction and preoxygenation, is preferred for injured children requiring tracheal intubation, unless the Glasgow Coma Scale score indicates global unresponsiveness. Adjunctive use of lidocaine to blunt a potential rise in intracranial pressure remains controversial. Deterioration or desaturation of an intubated patient requires immediate re-evaluation of the airway. The mnemonic “Don’t be a DOPE” may serve to remind the treating physician of common pitfalls of endotracheal intubation such as esophageal or right mainstem bronchial

dislodgement, particularly when a patient is moved from the ambulance to the hospital stretcher, or from gurney to gantry, or vice versa, when undergoing computed tomography; obstruction by blood, secretions, kinking, or biting; tension pneumothorax, either from exacerbation of an existing or unrecognized tension pneumothorax, or creation of a new tension pneumothorax from overly zealous assisted bag-valve-mask or -tube ventilation, or ventilator-induced baro- or volutrauma; or equipment failure, most commonly the result of failure of oxygen supply, either from an empty tank or, in rare instances, inadequate delivery of wall oxygen.

BREATHING

All children with potential thoracic injuries require immediate administration of high-concentration oxygen, preferably humidified oxygen. Supplemental oxygen should be administered by a non-rebreather mask for children in respiratory distress or by assisted bag-valve-mask or -tube ventilation for children in respiratory failure or arrest. Supplemental oxygen is required even if the arterial oxygen saturation, whether measured by pulse oximetry or arterial blood gas analysis, is normal. This is because coexistent volume deficits may lead to increased peripheral oxygen extraction, hence mixed venous oxygen desaturation, even when the arterial oxygen saturation is found to be normal.

Adequate oxygenation presupposes adequate ventilation. To determine if ventilation is adequate, the treating physician should observe for adequacy of chest rise; listen for the presence, quality, and equality of breath sounds; judge the adequacy of respiratory effort by observing for signs of increased, labored, decreased, or absent work of breathing, such as accessory muscle use, head bobbing, grunting, and fatigue; and count the respiratory rate to ensure that it lies within the normal range. To determine if oxygenation is adequate, the physician should look for central cyanosis or pallor, assess whether the sensorium is intact, and measure arterial oxygen saturation; in general, respiratory distress is present when the oxygen saturation falls below 95%, while respiratory failure is present when it falls below 90%.

Correct treatment of immediate life-threatening thoracic injuries requires immediate differentiation between tension pneumothorax, massive hemothorax, and cardiac tamponade. This can be difficult in the first few moments after presentation to the emergency department, and each requires a different approach to immediate treatment. Such distinction is further complicated when an endotracheal tube is in place, since right mainstem bronchial intubation can lead to decreased breath sounds on the left, which can mislead the inexperienced physician to suspect pneumo- or hemothorax. The differential diagnosis of these conditions, once again, is delineated in Table 24–2.

Tension pneumothorax is decompressed immediately using a large-bore over-the-needle catheter, without waiting for the chest radiograph that will confirm the diagnosis, but at the expense of inappropriate delay that may result in the rapid deterioration and death of the patient. This catheter should be inserted via the second interspace on the midclavicular line, just above the third rib, to avoid injury to the neurovascular bundles that run immediately below the second rib. If tension pneumothorax is present, a gush of entrapped air will

be heard rushing from the catheter. The catheter should be left in place and attached to a Heimlich, or similar, one-way flap valve, until definitive tube thoracostomy can be performed (see Chapter 168, Thoracostomy). A chest roentgenogram can then be obtained to document lung re-expansion and correct tube placement.

Open pneumothorax is converted immediately to closed pneumothorax using an occlusive dressing. Classic teaching states that this presumably rectangular dressing should be taped only on three of its four sides, to allow escape of entrapped air that could lead to development of tension pneumothorax. This philosophy, however, is being replaced by the teaching that a tube thoracostomy should be immediately inserted to effectively drain any accumulated blood and/or intrapleural air. Definitive surgical repair will be required for open pneumothoraces caused by large defects in the chest wall.

The approach to management of *flail chest* is not infrequently misunderstood. Only rarely is it necessary to splint the chest wall since, barring the unusual circumstance when the floating segment is so large that it leads to paradoxical ventilation during inspiration, the muscles surrounding the “floating” segment become spastic, thereby splinting the chest wall without need for internal or external appliances. Moreover, the pathophysiology of open pneumothorax, excepting once again the presence of paradoxical ventilation, is related not to the “floating” chest wall segment, but to arterial hypoxemia due to the ventilation-perfusion mismatch associated with the invariably coexistent pulmonary contusions. Thus the initial treatment of flail chest is supplemental oxygen and appropriate analgesia, unless the “floating” segment is of such a large size that paradoxical ventilation requires “internal” splinting via mechanical ventilation.

CIRCULATION

Immediate life-threatening thoracic injuries chiefly affecting the circulation require volume resuscitation in addition to temporizing management and definitive treatment. As with endotracheal intubation for definitive airway control, definitive treatment is often temporarily delayed until intravascular volume has been substantially restored. The pneumatic antishock garment or medical antishock trousers are no longer used for treatment of hypotension, except for selected patients with unstable pelvic fractures, and have always been contraindicated for patients with thoracic injuries. Although no data are available in pediatric patients, permissive hypotension has been employed with limited success in adult patients, provided blood pressure is adequate to maintain cerebral perfusion and definitive surgical management is readily available.

The importance of hemorrhage control cannot be sufficiently emphasized. Volume resuscitation may transiently restore core organ perfusion, but dilutional anemia is too often the result, particularly when bleeding patients are held in the emergency department in a futile attempt to achieve hemodynamic stability. If volume resuscitation must be employed in the absence of a surgeon, packed red blood cells, in boluses of 10 ml/kg, should be administered as soon as possible to patients who are hypotensive on arrival in the emergency department, or who do not respond immediately

to 40 to 60 ml/kg of normal saline or lactated Ringer’s solution, rapidly infused in continuous aliquots of 20 ml/kg. Use of an autotransfuser should be considered for patients with intrathoracic hemorrhage.

Although *massive hemothorax* will often be detected during the breathing assessment on the basis of decreased breath sounds, it is on the circulation that it mostly impacts. Since children may sequester up to 40% of their blood volume in a hemithorax before the onset of cardiovascular collapse, due to the propensity of the mediastinum to shift when under tension from entrapped air or blood, volume resuscitation is essential. Once intravascular volume resuscitation is initiated and vital signs begin to normalize, tube thoracostomy should be expeditiously performed, followed by surgical intervention for cases in which the initial output from the chest tube exceeds some 25% to 30% of circulating blood volume, or 20 to 25 ml/kg, or the ongoing output from the chest tube exceeds approximately 2.5% to 3% of circulating blood volume per hour, or 2 to 2.5 ml/kg/hr. Due to the relatively high tissue thromboplastin content of pulmonary parenchyma, most bleeding from lung wounds will cease spontaneously. Hence, ongoing bleeding suggests vascular trauma, which in most cases results from injury to the intercostals vessels, typically the arteries.

Pericardial or *cardiac tamponade* must be treated expeditiously for a favorable outcome to be achieved. Since it can only result from a cardiac wound, immediate surgical repair is mandatory. Rarely seen following blunt thoracic trauma, penetrating trauma to the “box” that is bounded by the nipples superiorly and bilaterally and the costal margins inferiorly requires immediate FAST for diagnosis, followed by pericardiocentesis as soon as vital signs begin to destabilize, if a surgeon with experience in operative management of thoracic injuries is not immediately available. To perform pericardiocentesis safely, an alligator clip is attached to the needle of a large-bore through-the-needle catheter set, which in turn is attached to a V lead port of an electrocardiograph machine, and the needle is carefully inserted through the skin to the left of the xiphoid process under continuous electrocardiographic monitoring, and slowly advanced posterolaterally toward the tip of the scapula. Once blood is encountered, the physician can advance the catheter over the needle, withdraw the needle, remove whatever blood can be aspirated, and secure the catheter at skin level. While classic teaching states that pericardial blood does not clot, this is not true in the acute setting. Thus urgent surgical intervention is of the utmost importance.

Potentially Life-Threatening Thoracic Injuries

AIRWAY

Tracheobronchial injuries, although rare in children, must be urgently addressed. They are manifested chiefly by a continuous air leak through the waterseal chamber of the chest drainage collection device that persists once all external sources of air entrainment have been excluded, and are confirmed radiologically when a persistent pneumothorax is seen on chest roentgenography. Management consists first of increasing the suction on the chest drainage collection device from -10 cm H_2O pressure slowly to -25 cm H_2O pressure.

If this fails to resolve the pneumothorax, a second chest tube may be needed. Definitive treatment consists of bronchoscopic confirmation, followed by surgical repair if the air leak has not significantly decreased after 24 to 48 hours of conservative management, to which most tracheobronchial injuries will quickly respond.

BREATHING

Pulmonary contusions require adequate oxygenation and pulmonary toilet for effective treatment. The goal of therapy is to avoid progression to “adult” respiratory distress syndrome (ARDS), which now typically results from the development of ventilator associated pneumonia (VAP), although post-traumatic pulmonary insufficiency (PTPS), or “shock lung,” due to massive isotonic crystalloid infusion, was a common cause in years past. Prevention of VAP is best accomplished through meticulous attention to aseptic suctioning of intubated, mechanically ventilated patients, and avoidance of prophylactic antibiotics. Prevention of PTPS and ARDS due to overly zealous fluid administration is best achieved through appropriate fluid management, and selective fluid restriction.

Traumatic diaphragmatic hernia requires immediate definitive surgical repair. Ipsilateral tube thoracostomy should be avoided, as this will suck abdominal contents into the involved hemithorax, markedly worsening respiratory status. Although blunt torso injuries are the cause of most traumatic diaphragmatic injuries, penetrating thoracoabdominal injuries occasionally cause traumatic diaphragmatic hernias if the diaphragmatic defect is large. All penetrating thoracoabdominal injuries require tube thoracostomy, followed by abdominal exploration and diaphragmatic repair, via laparotomy or laparoscopy.

Traumatic asphyxia requires no specific treatment. It serves chiefly as a marker of the severity of impacting forces. As such, its presence mandates a careful search for other thoracic injuries that may require treatment. Definitive treatment of the normally transient neurologic sequelae of severe traumatic asphyxia remains expectant.

CIRCULATION

Blunt cardiac injury encompasses a spectrum of injuries from myocardial contusion to valvular or ventricular rupture. Myocardial contusion is treated by observation and continuous electrocardiographic monitoring, reserving antidysrhythmic therapy for the rare patient who develops electrical instability. *Commotio cordis* requires immediate advanced cardiac life support, starting with automated external defibrillation rather than cardiopulmonary resuscitation for witnessed arrests. Valvular rupture, which presents with sudden cardiac failure, and ventricular rupture, which presents with sudden cardiac tamponade, require immediate surgical repair.

Traumatic aortic disruption, for the small number of cases not immediately fatal at the scene, requires immediate surgical repair. Most surgeons experienced with the treatment of this injury employ cardiopulmonary bypass, although a small minority continues to “clamp and sew.” Preoperative management emphasizes controlled hypotension to avoid progressive dissection, or worse, intrathoracic rupture. A transfer agreement with a cardiac surgical center is obligatory where cardiopulmonary bypass is unavailable.

Possibly Life-Threatening Thoracic Injuries

Simple pneumothorax and *simple hemothorax* are both definitively treated by simple tube thoracostomy. Prophylactic antibiotic therapy should be avoided in both conditions. It is important that all air and blood collections be fully drained, but especially the latter, to prevent both empyema formation in the early postinjury stage or the late development of fibrothorax, or “trapped lung,” both of which require VATS if not formal thoracotomy. In both conditions the tube should be left in place for an average of 5 days, and may be removed when a chest roentgenograph obtained on water seal drainage but off suction reveals no evidence of recollection of air or blood.

Rib fractures and *sternal fractures* require no specific treatment beyond appropriate analgesia. Intercostal nerve blocks are sometimes employed for the former, especially in older children and adolescents. Opioids should be avoided to the extent feasible, due to their propensity to depress ventilatory drive and predispose the patient to atelectasis and pneumonia, particularly since patients with rib and sternal fractures may be splinting during breathing due to pleuritic or costal pain, making them more susceptible to infection. Incentive spirometry and early ambulation should be used to encourage deep breathing.

Esophageal injuries require urgent surgical intervention. For such injuries, open thoracotomy, direct repair, and mediastinal drainage are required to prevent the inevitable subsequent development of mediastinitis, which remains a lethal illness if left untreated. Early treatment of esophageal injuries excludes oral intake but includes intravenous antibiotics. For iatrogenic injuries resulting from traumatic attempts at endotracheal intubation, gastric intubation, or rigid esophagoscopy procedures, a similar approach is followed, although minor mucosal repairs are increasingly managed nonoperatively.

Mediastinal traversing injuries require either immediate operative intervention if there is evidence of hemodynamic instability, or expectant management if all diagnostic tests are negative. A surgeon experienced in the management of these complex injuries should be involved from the earliest stages of management. If hemodynamic instability is present, time is of the essence, and operative intervention cannot be delayed, since the heart or great vessels have likely been injured. If not, management may proceed at a less urgent, but still timely, pace, since failure to expeditiously recognize and treat potential injuries to the airways, the lungs, the esophagus, or the chest wall can also be fatal.

Resuscitative Thoracotomy

“Resuscitative” or “emergency department” thoracotomy is utilized only in cases for which there is a chance of recovery. In general, patients who present in blunt traumatic cardiac arrest have such a dismal outcome that such a heroic measure cannot be justified, as costs are high and risk to treating physicians is potentially higher. By contrast, patients who present in traumatic arrest from penetrating injuries have a real chance for recovery, if signs of life were present in the field or are lost on arrival or during resuscitation in the emergency department. Even so, resuscitative thoracotomy remains an advanced technique that should be used only by trained physicians.^{45,46}

The procedure is performed via left anterior thoracotomy through the fifth left intercostal space, extended as necessary across the midline, superiorly or inferiorly by sharply bisecting the costal cartilages, or further laterally. A rapid inspection is made for injury that may be amenable to temporary control. The pericardium is opened axially, parallel and anterior to the vagus nerve, and entrapped blood is rapidly evacuated with the hands and using suction. Open cardiac wounds may be controlled with a Foley catheter, or with skin staples, followed by aggressive resuscitation, and transfer to the operating room for definitive surgical management should the patient survive the resuscitation.

Resuscitative thoracotomy for massive intra-abdominal bleeding has largely been abandoned. While cross clamping of the distal thoracic aorta temporarily raises blood pressure in the upper body, it does so at tremendous expense. The lower half of the body receives no blood supply, except via collateral vessels, and the spinal cord may be grossly underperfused. The procedure also delays definitive control of intra-abdominal bleeding, which continues unabated until the abdomen is opened and packed, utilizing principles of damage control surgery that are far more likely to result in a favorable outcome.

An emergency department thoracotomy for penetrating injuries can be life saving. The pericardium is responsible for this, since without its presence, cardiac wounds would be uniformly fatal, from rapid exsanguination into the hemothorax. Neurologically intact survival is more difficult to achieve, but patients who present with a perfusing rhythm and acceptable, if marginal, vital signs can be expected to recover fully. Early involvement of a qualified surgeon is therefore essential to optimal results.

Minor Chest Injuries

Minor chest injuries are those confined to the soft tissues of the chest wall, and that in cases of penetrating trauma do not violate the parietal pleura. They are noteworthy chiefly because of their frequency. Blunt injury to the chest wall typically results in superficial contusions to the skin and subcutaneous tissues, most often overlying the bony prominences of the child's ribs, and does not require treatment beyond the symptomatic relief provided by warm compresses and oral analgesics. Penetrating injury to the chest wall is rarely associated with intrathoracic injury absent signs of respiratory distress, but great care is warranted during exploration of an apparently superficial penetrating wound.

Wounds that penetrate the deep fascia may require surgical exploration in the operating room. Likewise, contaminated wounds may also benefit from operative débridement by means of pulse jet irrigation prior to formal closure. Otherwise, superficial lacerations may be repaired in the emergency department, closing the wound in two layers whenever possible. Tetanus prophylaxis is given as appropriate.

Subcutaneous emphysema serves as an indicator of severe associated injury. Bone crepitus is associated with rib, sternal, or scapular fracture. Subcutaneous crepitus is associated with barotrauma. In either case, careful examination to rule out bone injury and pneumothorax is warranted.

Costochondral separation is a condition mainly affecting physically active children. It results when a shear force is

applied to one or more adjacent costochondral junctions, causing separation of the bone and the cartilaginous rib elements adjacent to the sternum. The condition is fairly painful, and typically requires oral analgesic therapy. It is self-limiting, usually resolving within a month, if excessive physical activity is avoided.

Penetrating Injuries

When first encountered, all penetrating injuries to the thorax must be considered to have violated the parietal pleura. Great care must be taken during exploration of the wound to avoid such violation if it has not yet occurred. "Sucking" chest wounds must be covered immediately with an occlusive dressing, followed immediately by tube thoracostomy for drainage of entrapped air and blood. All penetrating thoracic injuries must be deemed contaminated, and must be thoroughly cleansed and débrided prior to suture repair, in addition to appropriate antibiotic and tetanus prophylaxis as indicated. As with abusive injuries, the history obtained following penetrating trauma is likely to be inaccurate. As such, hospital admission is warranted, both to ensure that the child receives a full course of antibiotics, and to allow full involvement of social work and pastoral care services, whose skills are critical in determining the circumstances surrounding the injury. Finally, all gunshot and stab wound injuries in children must be reported to the police, and to the local child protective services.

Thoracoabdominal Injuries

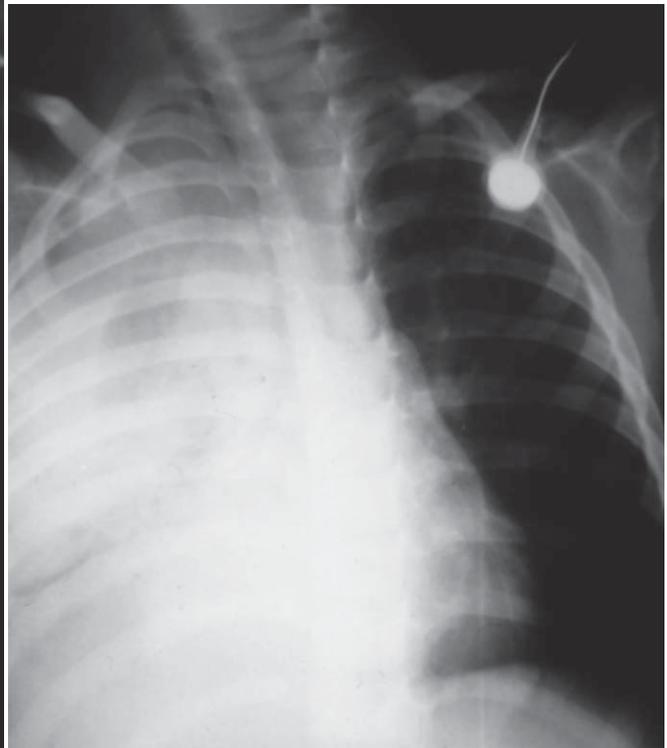

Thoracoabdominal injuries are penetrating injuries that traverse the diaphragm. They must be suspected whenever a penetrating injury is found anywhere between the nipples and the umbilicus. All potential thoracoabdominal injuries mandate immediate chest roentgenography, to identify possible intrathoracic air or blood, followed by insertion of a chest tube if present. All such injuries will also require exploratory laparotomy or laparoscopy, both to determine whether and where diaphragmatic penetration may have occurred, and to exclude other intra-abdominal injuries that also require operative repair.

Summary

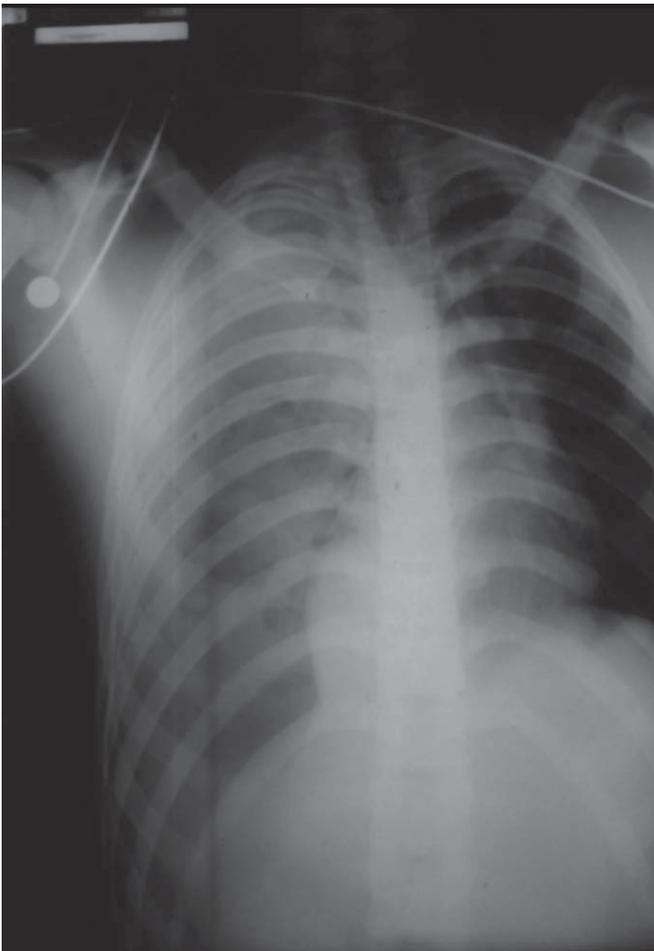

Serious thoracic injuries occur in nearly 1 in 15 cases of major childhood trauma, but are second only to central neuraxis injuries in their lethality. Most pediatric thoracic injuries are initially managed conservatively or by tube thoracostomy, although major thoracic injuries typically coexist with immediate or potential life-threatening to other body regions. Still, a high level of vigilance for thoracic injuries is never misplaced, since derangements of ventilation, oxygenation, and perfusion resulting from injury to intrathoracic components of the airway, breathing, and circulation substantially worsen the prognosis of associated injuries, particularly central neuraxis injuries, due to inadequate delivery of oxygen to damaged brain tissue. A physiologic approach to the emergent management of thoracic trauma best serves the needs of the injured child, whose greater oxygen requirements, smaller oxygen reserves, and early fatigueability call for both rapid restoration and meticulous maintenance of oxygen saturation, such that cellular respiration can be supported and irreversible shock can be avoided.

Abdominal Trauma

Frederick C. Blum, MD, George L. Foltin, MD, and Arthur Cooper, MD, MS

Key Points

Abdominal trauma is the third leading cause of trauma death in children after trauma to the central nervous system and the thorax.

There are anatomic and physiologic differences between children and adults that impact on both diagnosis and management.

The computed tomogram remains the most specific test for the evaluation of abdominal injury, but it is crucial that evidence-based criteria be developed to determine the role of Focused Assessment by Sonography in Trauma (FAST) for diagnosis of abdominal trauma in children, which has largely supplanted the role of diagnostic peritoneal lavage in adults.

The physician assessing the pediatric patient must recognize the need for acute intervention in life-threatening abdominal injuries, particularly with regard to volume resuscitation, gastric decompression, pelvic stabilization, and, in rare instances, the pneumatic antishock garment.

The differential diagnosis of life-threatening abdominal injuries is challenging, but not of immediate importance in the emergency department, where the focus should be on resuscitation and stabilization.

The majority of blunt abdominal injuries can be managed conservatively, but life-threatening injuries require observation in a pediatric intensive care unit and availability of surgeons experienced in the management of abdominal injuries in childhood.

It is essential to be aware of the probability of coexisting injuries.

Pediatric patients with life-threatening abdominal injuries must be stabilized, then transported to trauma centers with pediatric capabilities, when such resources are not available on site.

Introduction and Background

Trauma remains the leading cause of death in the pediatric population between 1 and 14 years of age, resulting in more fatalities than all other diseases combined. Traumatic brain and thoracic injuries are the two foremost killers in this age group, but abdominal trauma is the third most important source of lethal injuries in children, and the main source of initially unrecognized injury leading to mortality in pediatric patients. Although it is important to recognize that, in contrast to adult trauma, pediatric trauma is primarily a disease of the airway and breathing, rather than of the circulation, it is also important to understand that, when a hemodynamic abnormality is added to the neuroventilatory abnormality from which most observed derangements of airway and breathing actually result, the observed mortality rate in pediatric trauma patients has been shown to double, and is worsened further still if a cardiorespiratory derangement is also found to coexist.^{1,2}

Historical data from the National Pediatric Trauma Registry³ and current statistics from the National Trauma Data Bank (<http://www.ntdb.org>) show that major abdominal trauma is relatively uncommon in children, occurring as the only body region injured in only 3%. Yet the case fatality rates associated with these injuries have been shown to be as high as 15%, and may increase significantly when injury to other organ systems is present. Hence, physicians caring for injured children must be familiar with the recognition, evaluation, and management of abdominal injury in children, as well as the mechanisms of injury that result in abdominal trauma. These will vary by age, geographic location, and trends in popular sports, as well as community compliance with injury prevention measures. Because of anatomic, physiologic, and epidemiologic differences, children must be assessed and managed differently than adults. The development of a systematic diagnostic approach to the evaluation of abdominal injuries in children continues to evolve as better diagnostic modalities emerge.

Blunt abdominal injuries outnumber penetrating abdominal injuries by a ratio of 6:1. Together, motor vehicle occupant and pedestrian injuries account for about three fifths of all blunt abdominal injuries in children. Fall, bicycle, and miscellaneous injuries account for the remainder. Gunshot and stab wounds are responsible for all but one fifth of penetrating injuries, in a ratio of slightly more than 2:1. About 1 in 12 children with an intra-abdominal injury will die, but

4 of every 5 children dying from blunt abdominal injuries die from associated injuries, most often to the head, while 2 of every 3 children dying from penetrating abdominal injuries die from the injury itself.³

Recognition and Approach

Specific attention to the diagnosis and treatment of the injured child has resulted in significant decreases in the morbidity and mortality of all traumatic injuries, including those to the pediatric alimentary tract and associated organs. This has been achieved by developing standards of care for injured children that build upon the American College of Surgeons Committee on Trauma Advanced Trauma Life Support (ATLS) protocols for the injured adult, but address the special problems encountered in the pediatric population best described in the American Heart Association and American Academy of Pediatrics Pediatric Advanced Life Support guidelines.^{4,5} As a result, the primary survey in children, which remains directed toward priority assessment and stabilization of airway, breathing, and circulation, applies these principles based upon key pediatric differences in anatomy and physiology that require a modified approach. For this reason, a firm understanding of the pathophysiology unique to pediatric abdominal trauma is critical.

The pediatric abdomen is prone to injury for a number of reasons. The thinner layers of the abdominal wall provide less protection to underlying organs. Owing to the more horizontal orientation of the abdomen, the liver and spleen are not fully covered by the ribs, while the dome of the urinary bladder extends well above the pubic ramus. Most important, the abdomen cavity is more compact. Thus, impacting forces are concentrated in a smaller volume, such that intra-abdominal injuries are much more often multiple.

Perhaps the most important consideration in recognizing and approaching abdominal injuries is their propensity for delayed presentation. Injured children are frightened, and a tachycardic response to injury is to be expected. Therefore, tachycardia is not a reliable early indicator of intra-abdominal bleeding, although every child with intra-abdominal bleeding will certainly exhibit tachycardia. Moreover, the ability of the child's blood vessels, particularly the small arterioles, to vasoconstrict in the presence of hypovolemia and hypothermia is well known, such that hypotension is a notoriously late sign of hemorrhagic shock, leading to what has been called the "deceptive" presentation of shock in infants and young children. Unfortunately, while the child's compensatory mechanisms are excellent, they are relatively short lived in terms of compensatory response. Thus a high index of suspicion for intra-abdominal injuries, and the understanding that hemodynamic changes may at first be subtle, are the treating physician's most vital tools in the recognition and approach to management of abdominal injuries in childhood.

Intra-abdominal organs are bluntly injured in one of three ways.⁶ Solid organs can be compressed against the spine, followed by contusion, laceration, or disruption, with subsequent hemorrhage (Fig. 25-1A-C). Hollow organs can also be compressed against the spine, and can similarly rupture as intraluminal pressures increase (Fig. 25-1D, E, and M). Finally, the posterior attachments of both solid and hollow

organs to the abdominal wall can be torn, leading to massive hemorrhage as hepatic and mesenteric vessels are torn from the larger vessels into which they drain by shearing forces that typically follow upon sudden deceleration injuries. By contrast, penetrating injuries damage tissue in one of two ways. Direct injury by the penetrating vector along the path of its trajectory is responsible for most damage in low-velocity injuries, such as those caused by knives or handguns. However, in high-velocity injuries, such as those caused by high-powered rifles or automatic weapons in which the muzzle velocity is much higher, energy transfer to injured tissues is greatly increased according to the familiar formula, $KE = \frac{1}{2}mv^2$, in which high missile velocity is far more deadly than high missile mass. The result is a conical shock wave that both devitalizes adjacent structures and causes much more tissue destruction at exit than at entrance sites.

The most common cause of major trauma in childhood is the motor vehicle. Injuries to pedestrians are slightly more common than injuries to occupants in most series.⁷ The Waddell triad is perhaps the most widely known injury pattern of injury in childhood, and involves the head, abdomen, and thighs of the preschool or young school-age child who is struck by a moving vehicle. The bumper strikes the child in the thigh, causing a femur fracture, while the hood strikes the torso, causing a potential liver or spleen injury, depending upon whether the child is struck on the right or the left side. The triad is completed by the brain injury that results when the youngster's top-heavy body lands head first, after being thrown through the air following transfer of momentum from the moving vehicle to the injured child. Although the Waddell triad has been variously described to include the pelvis rather than the femurs or the abdomen, and while all components of the triad are present in no more than about 3% of cases, the illustrative value of the Waddell triad is self-evident.⁸ The young child struck by a moving vehicle is at high risk for injuries to the head, torso, and femurs, because of the biomechanics of energy transfer. Thus the child struck by a moving vehicle who presents, for example, with an "isolated" femur fracture must also be suspected of having sustained significant, if subclinical, injuries to the brain and abdomen. A careful history will often disclose a probable loss of consciousness, confirming the former, while a biochemical profile may reveal a clinically or radiologically unsuspected hepatic contusion, confirming the latter.

The lap and shoulder belt complex of injuries has been recently recognized in children improperly restrained as motor vehicle occupants during a crash. The lap belt complex is heralded by the Chance fracture, a hyperflexion fracture of a lumbar vertebral body, coupled with hematoma or perforation of an upper intestinal loop. While either or both of these may occur, severe injuries are typically heralded by associated contusions of the abdominal wall.⁹ The injury is the expected result of failure to use a booster seat for a toddler or preschooler, who is then improperly restrained solely by a lap belt that crosses the lower abdomen instead of the hips. The shoulder belt complex results from a similar failure to use proper restraints, and sometimes results in traumatic diaphragmatic hernia. Major blunt abdominal injuries in children due to airbag deployment are extremely rare.¹⁰

Another classic mechanism of injury commonly encountered in the injured child is the bicycle handlebar injury.¹¹

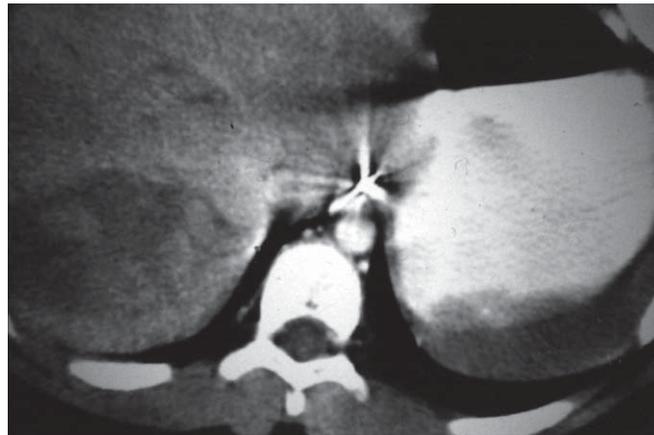

The child's front bicycle wheel strikes a solid object or falls into a hole, causing the handlebar to suddenly rotate as the bicycle abruptly stops, while momentum thrusts the child's upper abdomen forward into the end of the handlebar.¹² The result may be a liver, spleen, gastric, duodenal, or pancreatic injury, which may not be initially detected unless the mechanism of injury is clearly understood by the treating physician. Similar injuries also occur as the result of sledding or tobogganing mishaps in which the child's abdomen is struck by tree stumps or branches hidden beneath the snow. In addition, straddle injuries often occur when the child's perineum strikes the transverse bar between the handlebar and the saddle, resulting in urethral injuries, chiefly in boys.

Sports-related injuries are an uncommon cause of major blunt abdominal trauma in childhood. Blows to the flank sustained during contact sports such as football can lead to significant renal injury. Unintentional blows to the lower ribs or upper abdomen, such as might occur when striking a fielder's foot while attempting to slide into a base, or being kicked by a horse or similarly large animal, have been reported

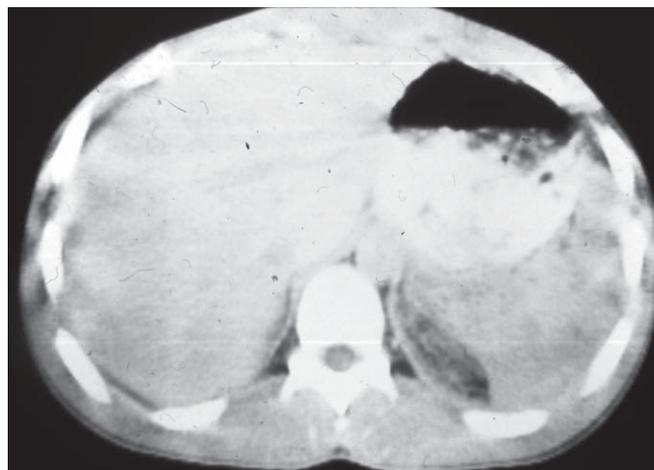

to cause isolated hepatic and splenic injuries. In like manner, unintentional blows to the upper abdomen from a baseball bat or a hockey stick are known to have caused isolated intestinal perforations. Falls sustained during play are perhaps the most common recreational injuries that occur during childhood, but rarely result in abdominal injuries, unless from extreme heights.^{13,14}

All-terrain vehicles are increasingly recognized as an important source of major blunt abdominal trauma in children.¹⁵ The higher center of gravity of these vehicles, coupled with the immature motor skills of the young child, make them especially dangerous in the pediatric population. About 1 in 20 serious injuries sustained by children riding all-terrain vehicles involve the abdomen, the spectrum of which injuries closely parallels that observed in children with bicycle handlebar injuries, although injuries are usually more serious, given the higher velocities attained by all-terrain vehicles. For example, a recent case report described abdominal aortic rupture associated with all-terrain vehicle injury.¹⁶

Abuse-related injuries merit special comment.¹⁷ Major blunt abdominal trauma resulting from physical abuse is caused by a forceful blow to the upper abdomen (Fig. 25–1F–L), and occurs in four distinct patterns, readily identifiable by associated vital signs.¹⁸ The first involves duodenal and jejunal hematomas. Such children typically present with bilious vomiting and stable vital signs in the absence of abdominal findings. The second is characterized by duodenal or jejunal perforations. These children also present with bilious vomiting, but are likely to be febrile and tachycardic, with the abdomen distended and tender on examination. The third involves significant disruption of solid organs, most often the liver, with associated intra-abdominal hemorrhage. These children usually present with acute anemia and compensated shock, which often, but not always, are self-limited owing to the thick, elastic capsules of the solid abdominal organs in children. The fourth is characterized by massive hepatic lacerations with or without cavohepatic or cavomesenteric disruptions. These children present in decompensated shock or in frank traumatic cardiopulmonary arrest, and are rarely salvageable. In none of these children will accurate histories be proffered, and most present 12 to 24 hours following injury. Unfortunately, no more than half of these children will have external marks to suggest the diagnosis of intra-abdominal injury. Thus a high index of suspicion is fundamental to making the correct diagnosis.

Evaluation

Trauma to the abdomen may involve injury to its muscular abdominal wall or the contents of any of its five distinct regions. The abdominal portion of the peritoneal cavity contains the liver, the gallbladder and biliary tree, the spleen, and most of the alimentary canal, including a short segment of distal esophagus, the entire stomach, the duodenal bulb, the entire jejunum and ileum, the transverse colon, and the anterior halves of the ascending and descending colons, as well as the dome of the urinary bladder in infants and younger children. The pelvic portion of the peritoneal cavity contains the sigmoid colon, the dome of the urinary bladder in older children and adolescents, and the supracervical uterus, fallopian tubes, and ovaries in girls. The central portion of the upper retroperitoneal space (designated as zone I) contains the great vessels of the abdomen, including the aorta and inferior vena cava and their major branches; the second, third, and fourth segments of the duodenum; the pancreas; and the retroperitoneal surface or “bare area” of the liver. The lateral portions of the upper retroperitoneal space (designated as zone II) contain the kidneys and adrenal glands, the upper two thirds of the ureters and gonadal vessels, and the posterior halves of the ascending and descending colons. The lower, or pelvic, retroperitoneal space, inferior and medial to the pelvic brim (designated as zone III), contains the iliac arteries and veins, the lower thirds of the ureters and gonadal vessels, the upper rectum, and the inferior surfaces of all sides of the urinary bladder (including the trigone). In addition, zone III contains the prostate gland, seminal vesicles, and vasa deferentia in boys; the cervix and upper vagina in girls; and, posterior to Waldeyer’s fossa, an intricate plexus of lumbosacral vessels and nerves. Injuries to these organs may manifest acutely during the primary survey, or their presentation may be gradual and insidious in their

onset, hence found only by a careful secondary survey, or perhaps even a tertiary survey performed once the child is admitted to the hospital for treatment.¹⁹

Injuries to the abdomen can cause severe and substantial cardiovascular compromise that is rapidly progressive. At the same time they can cause equally serious and significant intra-abdominal infections and septic shock of often insidious onset. If these conditions are not recognized and promptly treated, the result may be lethal. It is therefore imperative for the treating physician to detect all underlying injuries, decide the priority of treatment, and begin to reverse the pathophysiologic changes induced by the injuries. The ATLS protocol includes a standardized assessment of the patient’s airway, breathing, and circulation that should enable the treating physician to recognize, evaluate, and manage life-threatening abdominal injuries in priority order, as shown in Table 25–1.⁴ Immediately life-threatening abdominal injuries that derange the circulation (massive intra-abdominal bleeding, also called hemoperitoneum, or massive retroperitoneal bleeding, most often due to great vessel injury or unstable pelvic fracture) can usually be detected during the primary survey. Potentially life-threatening abdominal injuries to the circulation (solid organ injuries that do not cause decompensated shock) are more often detected during the secondary survey, as are injuries that affect the integrity of the alimentary canal (hollow organ disruption) and present with peritonitis, and finally sepsis if initially overlooked.

Clinical Evaluation

In performing the primary survey, the treating physician will look first for derangements of the airway and breathing, as delineated in Chapter 12 (Approach to Multisystem Trauma). Once these have been initially addressed, the treating physician looks next for derangements of the circulation. However, the abdomen discloses its secrets slowly and serially. Therefore, careful and frequent re-evaluations are required to ensure that such derangements are not overlooked.

Control of hemorrhage is the first goal of treatment during the primary survey, but intra-abdominal hemorrhage is internal rather than external, and is rarely detected by direct observation alone. Rather, it must first be suspected, then sequentially excluded, by means that involve indirect observations over time, such as those described later. Moreover, major intra-abdominal hemorrhage is detected chiefly through examination for circulatory instability, which requires ongoing evaluation of tissue perfusion (pulse rate and character, peripheral skin and mucous membrane color, temperature and moisture, capillary refill, urinary output). This is because frank hypotension (the cardinal sign of decompensated shock) does not occur until very late in the downward spiral of circulatory deterioration, when the opportunities for successful resuscitation are limited.

Abnormalities in the primary survey are addressed as they arise, since accurate evaluation of each step in the series circuit of substrate (oxygen/fuel) delivery to the tissues (airway/ventilation, breathing/oxygenation, circulation/perfusion) presumes the integrity of the previous step. Adjuncts to the primary survey that will assist in the evaluation of each of these include vital signs (appropriate for age), pulse oximetry (demonstrating adequate S_pO_2), end-tidal capnography (confirming gas exchange), and, with respect to the abdomen, a supine pelvic roentgenogram (identifying

Table 25-1 Principles of Advanced Trauma Life Support⁴**Primary Survey and Resuscitation****Airway/cervical spine**

- Open: jaw thrust/spinal stabilization
- Clear: suction/remove particulate matter
- Support: oropharyngeal/nasopharyngeal airway
- Establish: orotracheal/nasotracheal intubation*

^{||}Contraindications include meatal blood, scrotal hematoma, and high-riding prostate.

[¶]Contraindications include cerebrospinal fluid otorrhea/rhinorrhea, basilar skull fracture, and midface instability.

[‡]Chest, pelvis, and lateral cervical spine; others as indicated.

**Focused Assessment by Sonography in Trauma, CT as indicated.

Abbreviations: BVM, bag-valve-mask; CRT, capillary refill time; CT, computed tomography; GCS, Glasgow Coma Scale; LOC, level of consciousness; NRB, non-rebreather mask; PRBC, packed red blood cells; RL, Ringer's lactate; TBI, traumatic brain injury.

unstable fractures). Evidence of simple hypovolemia (compensated shock) mandates urgent resuscitation. Evidence of frank hypotension (decompensated shock) mandates emergent resuscitation.

In performing the secondary survey, the complete physical examination for abdominal injuries will assess for visible contusions, peritoneal irritation, pelvic stability, and other palpable abnormalities (by inspection and palpation), and for abnormal collections or movement of gas within the gastrointestinal tract (by percussion and auscultation). Mechanisms of injury reliably predict patterns of injury and their clinical presentations, and should form the basis of informed diagnosis. Thus mechanisms known to produce intra-abdominal or pelvic bleeding, or peritonitis, should lead the treating physician to tailor the physical examination, the imaging studies, and the laboratory tests specifically to detect and confirm intra-abdominal injuries that predispose to these physical findings. For example, children who present immediately after high-speed motor vehicle–pedestrian injury with signs of compensated or decompensated shock, such as simple hypovolemia or frank hypotension with altered mental status, should be suspected of having sustained major solid organ disruption, for which volume resuscitation followed immediately by computed tomography

(CT) or emergent laparotomy are warranted. By contrast, children who present in delayed fashion several hours after seemingly trivial injury with signs of frank peritonitis, such as abdominal pain, distention, or tenderness, with or without fever, vomiting, or sepsis, should be suspected of gastrointestinal or pancreatic injury, or minor solid organ disruption associated with persistent oozing, for which volume resuscitation followed in a timely manner by urgent laparotomy or CT are needed. Physical signs of immediately life-threatening abdominal injuries are shown in Table 25-2.

Injuries commonly requiring immediate intervention in the pediatric patient include immediately life-threatening abdominal injuries such as massive, uncontrolled intra-abdominal hemorrhage, and peritonitis associated with septic shock. Far more often encountered but far less often lethal are potentially life-threatening abdominal injuries such as minor, self-limited solid organ hemorrhage. Clinical stabilization with appropriate interventions must be accomplished in an orderly and timely manner to prevent further deterioration. Injuries requiring delayed intervention in the pediatric patient include potentially life-threatening abdominal injuries that in most cases are manifested by abdominal tenderness, as well as those that will not be detected without radiographic or laboratory tests, or ongoing monitoring and

continuous reassessment of the patient’s clinical status, chiefly by means of abdominal examination. For the most part, mild to moderate intra-abdominal organ injuries are now managed nonoperatively, unless radiographic findings indicate that the injury is of such magnitude that operative intervention is indicated, so reliance upon sophisticated diagnostic tools, if available, is important. The American Association for the Surgery of Trauma (AAST) Organ Injury Scaling (OIS) system is now recognized as the standard for correlation of clinical and radiographic findings, although physiologic status remains the best guide for patient care decisions.^{20–22} The grading system is applied both prospectively for description of injury severity based on radiographic findings, and retrospectively for performance improvement and research based on intraoperative findings when available, and is delineated in Table 25–3 for each of the major

Table 25–3 American Association for the Surgery of Trauma (AAST) Organ Injury Scaling (OIS)¹³**Liver****Grade I**

- Nonexpanding subcapsular hematoma, $<10\%$ of surface area
- Capsular tear, nonbleeding, <1 cm in depth

Grade II

- Nonexpanding hematoma, subcapsular or intraparenchymal, $10\text{--}50\%$ of surface area or <10 cm in diameter
- Bleeding capsular tear
- Laceration $1\text{--}3$ cm in depth, <10 cm in length

Grade III

- Subcapsular hematoma $>50\%$ of surface area, expanding or ruptured with bleeding
- Intraparenchymal hematoma, >10 cm or expanding
- Laceration >3 cm deep

Grade IV

- Ruptured intraparenchymal hematoma with bleeding
- Parenchymal disruption involving $25\text{--}75\%$ of lobe or $1\text{--}3$ segments

Grade V

- Parenchymal disruption of $>75\%$ of lobe or more than 3 segments
- Juxtahepatic venous injury

Grade VI

- Hepatic avulsion

Spleen**Grade I**

- Subcapsular hematoma, $<10\%$ of surface area
- Laceration/capsular tear, <1 cm in deep

Grade II

- Subcapsular hematoma, $10\text{--}50\%$ of surface area
- Intraparenchymal hematoma, <5 cm
- Laceration $1\text{--}3$ cm, without vessel involvement

Grade III

- Subcapsular hematoma, $>50\%$ of surface area or expanding
- Intraparenchymal hematoma, >5 cm
- Ruptured hematoma
- Laceration >3 cm or with trabecular vessel involvement

Grade IV

- Laceration of segmental or hilar vessels causing major devascularization $>25\%$ of spleen
- Parenchymal disruption involving $25\text{--}75\%$ of lobe or $1\text{--}3$ segments

Grade V

- Shattered spleen
- Injury of hilar vessels with completely devascularized spleen

Kidneys**Grade I**

- Contusion: hematuria without radiographic abnormalities
- Subcapsular hematoma: no parenchymal laceration

Grade II

- Perinephric hematoma confined to the retroperitoneum
- Laceration of renal cortex <1 cm in depth

Grade III

- Laceration >3 cm in depth

Grade IV

- Laceration through collecting system
- Vascular injury with contained hemorrhage

Grade V

- Vascular avulsion
- Shattered kidney

Pancreas***Grade I**

- Hematoma: minor contusion without duct injury
- Laceration: superficial laceration without duct injury

Grade II

- Hematoma: major contusion without duct injury
- Laceration: major laceration without duct injury or tissue loss

Grade III

- Laceration: distal transection without duct injury or tissue loss

Grade IV

- Laceration: proximal transection or parenchymal injury involving ampulla

Grade V

- Laceration: massive disruption of the pancreatic head

Duodenum***Grade I**

- Hematoma: involving single portion of duodenum

Grade II

- Laceration: partial thickness, no perforation
- Hematoma: involving more than one portion

Grade III

- Laceration: disruption $<50\%$ of circumference
- Laceration: disruption $50\text{--}75\%$ of circumference of D2

Grade IV

- Laceration: disruption $50\text{--}100\%$ of circumference of D1, D3, D4
- Laceration: disruption $>75\%$ of circumference of D2
- Laceration: involving ampulla or distal common bile duct

Grade V

- Laceration: massive disruption of the duodenopancreatic complex
- Laceration: devascularization of duodenum

*Advance one grade for multiple injuries to same organ.

intrabdominal organs commonly found to be injured in pediatric patients.

Solid Organs

Together with the spleen, the *liver* is the most commonly injured solid abdominal organ, with each of these organs being damaged in 27% of children with abdominal injuries who historically have required admission to a pediatric trauma center. Its central position in the upper abdomen beneath the epigastrium is responsible for this fact, together with the lesser degree of protection afforded the liver by the ribs in pediatric patients. Most liver injuries in childhood are fairly minor, as 70% of these injuries are either contusions, hematomas, or minor lacerations (AAST grade I). Moderate and major lacerations (AAST grades II–III) account for almost all the rest. Only ruptured hematomas, parenchymal disruptions, juxtahepatic venous injuries, and hepatic avulsions (AAST grades IV–VI) are likely to fail nonoperative management, which is successful in about 90% of hepatic injuries.

Similar to the liver, the position of the *spleen* beneath the soft lower ribs of the left upper quadrant of the abdomen is responsible for its high incidence of injury. In addition, in North America motor vehicles occupy the right side of the road, giving their drivers less time to stop for children darting into the road from the right, thereby exposing the left sides of pedestrians struck by motor vehicles. Most spleen injuries in childhood are relatively minor, as 70% of these injuries are either limited subcapsular hematomas, capsular tears, or relatively superficial lacerations (AAST grades I–II). Extensive subcapsular hematomas, intraparenchymal hematomas, deep lacerations (AAST grade III), segmental or hilar vessel injuries with devascularization (AAST grade IV), and shattering injuries (AAST grade V) account for the remainder, but only the latter two are likely to fail nonoperative management, which is successful in 95% of splenic injuries.

The *kidneys* are the third most commonly injured solid abdominal organs in childhood, and are also damaged in 27% of children with abdominal trauma. This is somewhat surprising, given their relatively well-protected position beneath the paraspinous muscles and the fact that they are embedded in fat pads enclosed by the tough fibrous envelopes of Gerota's fascia. Fortunately, and perhaps as a result of their protected location, most renal injuries in childhood are minor, involving only hematomas and contusions (AAST grade I), lacerations not involving the collecting system (AAST grades II–III), and major lacerations involving the collecting system (AAST grade IV). Vascular injuries with contained hemorrhage, vascular avulsions, and renal disruptions or shattering (grade V) are rare. However, although serious renal injuries are uncommon, 80% of such injuries are associated with other serious intra-abdominal injuries. Therefore, serious renal injuries, heralded by hematuria, serve as a marker of serious intra-abdominal injuries.

The *pancreas* is the fourth most commonly injured solid abdominal organ in childhood, and is damaged in 5% of children with abdominal trauma. Given its well-protected location in the middle upper retroperitoneal space, it is not surprising that it is infrequently injured. However, its position overlying the spinal column makes it subject to frank transection when forceful blows are applied to the epigas-

trium. Fortunately, most pancreatic injuries are minor and limited to mild traumatic pancreatitis. Pancreatic pseudocysts are the typical sequelae of pancreatic duct injuries, but rarely present before the third to the fifth postinjury day, and most ultimately resorb spontaneously. Pancreatic transections are rare, and many do not require operative management.

Hollow Organs

The *gastrointestinal tract* is the most commonly injured abdominal hollow organ in childhood, and is damaged in 21% of children with abdominal trauma. It is surprising that the gastrointestinal tract is not more frequently injured, given that it occupies both the greatest volume of the abdominal cavity and its most central location. Injuries to the stomach and duodenum represent about 25% of injuries to the gastrointestinal tract, with injuries to the small and large intestine representing the remainder, in roughly equal proportions. Most blunt injuries involve intramural contusions and hematomas, with disruptions being limited chiefly to fixed segments of intestine adjacent to bony prominences, such as the duodenum and proximal ileum. Most penetrating injuries involve transmural lacerations.

The *genitourinary tract*, exclusive of the kidneys, is the second most commonly injured hollow abdominal organ in childhood, and is damaged in 5% of children with abdominal trauma. The urinary bladder and urethra account for four fifths of these injuries and are usually associated with complex pelvic fractures. The ureters account most of the rest, as the genital organs in both boys and girls are small and primordial, and are rarely injured.

The *great vessels* of the abdomen and pelvis are the third most commonly injured hollow abdominal organs in childhood, and are collectively damaged in 5% of children with abdominal trauma, although no one blood vessel is individually damaged in more than 1% of children with abdominal trauma. However, mortality is high, approaching 50% overall, and approaching 90% for aortic injuries. Caval injuries are somewhat less lethal, with mortality in excess of 60%. Mortality in renal and iliac vessel injuries is 20% to 30%.

Bony Pelvis

The bony pelvis is the least commonly injured abdominal structure in childhood, accounting for less than 1% of abdominal injuries in children with abdominal trauma. The vast majority of pelvic fractures in childhood are simple and stable, and free of hemodynamic consequences.²³ However, as in adults, complex, unstable pelvic fractures are associated with life-threatening hemorrhage as well as damage to the genitourinary system. Most such injuries are associated with numerous other injuries, such as traumatic brain injury.

Diagnostic Modalities

Clinical Examination

The physical examination remains the cornerstone of timely diagnosis of intra-abdominal injuries in childhood. Classic *physical signs* remain reliable indicators of intra-abdominal injuries, and are typically used to guide initial diagnosis and treatment, as shown in Table 25–2. Although regarded as adjuncts to the primary survey, vital signs, especially heart

rate and blood pressure, are critical components of the clinical examination of the abdomen. The limited role of blood pressure in early diagnosis of circulatory instability is well known, but less well known is the significance of heart rate. No doubt, heart rate is a poor indicator of instability in infants and children, in whom fear and anxiety alone can drive the heart rate to supranormal levels. By contrast, in adolescents and young adults, the heart rate is a highly reliable indicator of circulatory instability. Just as infants and children have the ability to maintain systolic blood pressure via intense vasoconstriction in the face of hypovolemia, adolescents and young adults do so as well. However, in infants and children, the marked associated tachycardia (the upper limit of normal heart rate being estimated at the bedside using the formula, $150 - 5 \times \text{age in years}$) can result from causes other than hemorrhagic shock, while in the adolescent and young adult, a heart rate in excess of 100 beats/min indicates profound hypovolemia until proven otherwise, and should instigate an immediate search for an intra-abdominal source.

Much has been written about the technique of physical examination in childhood. Since the key information to be gleaned from the physical examination is a rapid determination of circulatory stability, vital signs and the status of tissue perfusion, as judged by pulse rate and character, skin color, temperature and moisture, and capillary refill time, are of paramount importance, recognizing that the latter is subject to environmental temperature in the examination room, which should be kept tolerably warm. Abdominal examination is secondary in importance to vital signs and tissue perfusion, and during the primary survey focuses only upon appreciation of findings that suggest blood loss, such as pelvic instability and abdominal distention. To detect the former, the pelvic wings should be compressed first bimedially to determine if the pelvis is grossly stable, then bilaterally to determine if the grossly stable pelvis is fully stable, since pelvic instability in the face of potential pelvic fracture connotes increased pelvic volume and extensive retroperitoneal bleeding. To detect the latter, the abdomen should be directly observed for signs of increased abdominal girth. If this is found, gentle percussion over the upper abdomen can be used to detect gastric dilation, a frequent concomitant of major trauma, particularly traumatic brain injury, in children due to associated aerophagia. If the percussion note is hyperresonant, the stomach should be intubated with a sump tube to decompress it. In most cases, the tube may be inserted via the nasogastric route, but if there is evidence of either basilar skull fracture or midface instability, the tube should be inserted via the orogastric route. If after careful gastric decompression, which in comatose patients should be undertaken only after an endotracheal tube has been placed to protect the airway, abdominal distention persists, the presence of intra-abdominal hemorrhage should be presumed until proven otherwise. However, neither the presence of intra-abdominal hemorrhage nor that of frank peritonitis can be excluded on the basis of a single abdominal examination, since such findings can develop over time. Therefore, serial abdominal examinations are mandatory, unless the findings on initial abdominal examination unequivocally indicate massive hemorrhage, frank peritonitis, or abdominal evisceration, all of which mandate emergent laparotomy.

Examination of the abdomen for signs of peritoneal irritation is performed as part of the secondary survey. Mild peritoneal irritation may indicate the presence of blood or chyme in the peritoneal cavity, but moderate to severe peritoneal irritation essentially always indicates hollow visceral disruption. Both altered mental status and painful distracting injuries, such as extremity fractures, can confound the abdominal examination, as can marked gastric dilation, which can mimic, as well as mask, the classic physical sign of peritonitis, parietal peritoneal irritation. This should be sought using gentle palpation that displaces the abdominal wall only minimally, and confirmed using gentle percussion. There is no need to confirm the presence of peritoneal irritation, also known as rebound tenderness, via marked displacement of the abdominal wall that is followed by rapid release. This will serve only to frighten the child, at best, or to cause the child extreme discomfort, at worst. Specific physical diagnosis of intra-abdominal injury is very difficult, if not impossible, in the emergency department. It is therefore sufficient in the emergency department to limit abdominal examination to simple maneuvers designed to detect findings that warrant emergent laparotomy, such as hemorrhage and peritonitis. This is true not only for the belly examination, but for the rectal examination as well, the purpose of which is to determine the presence or absence of blood or anterior tenderness.

Use of Focused Assessment by Sonography in Trauma (FAST) as an extension of the abdominal examination is rapidly evolving, but needs to be more specifically studied in its application to abdominal injuries. It consists of a bedside transabdominal sonographic examination for abnormal fluid collections in the pericardial cavity, the subhepatic pouch (of Morison), the splenic fossa, and the retrovesical space. Limited studies of abdominal FAST have been performed in children to date, but while initial studies suggested that its specificity and sensitivity were poor, recent studies suggest otherwise.²⁵⁻²⁸ However, since the main purpose of FAST in abdominal trauma is to detect the presence of intra-abdominal fluid presumed to be blood, and since modern management of solid organ injury is dependent on the physiologic status of the patient rather than the presence or absence of blood, its role at present remains controversial. What can be said with certainty is that the role of FAST in the diagnosis of abdominal injury is increasing. The presence of small amounts of intraperitoneal fluid, presumably blood, is unlikely to be associated with significant injury, while the presence of large amounts of intraperitoneal fluid uniformly indicates severe injury.²⁹⁻³¹ Moreover, FAST has the additional advantage that assessments can be performed serially, at the patient's bedside, especially in equivocal cases, thereby improving diagnostic accuracy.³²

In contrast to FAST, the role of diagnostic peritoneal lavage (DPL) is decreasing. DPL is highly sensitive for the presence of blood in the intraperitoneal cavity, but completely nonspecific with respect to its source. It may also fail to detect retroperitoneal bleeding, which further limits its utility. DPL is somewhat more useful in the diagnosis of hollow visceral injury, but most experts believe that serial physical examination is equally reliable. The procedure is ideally performed via an open technique, following decompression of the stomach and urinary bladder. It requires a small vertical cutdown on the abdominal midline just below the umbilicus.

Table 25–4 Criteria for Positive Diagnostic Peritoneal Lavage***Intraperitoneal Blood**

- Gross blood observed on paracentesis or in lavage effluent
- Inability to read standard newsprint through lavage effluent
- >100,000 RBCs/mm³ in lavage effluent

Intraperitoneal Soilage

- Gross food particles in lavage effluent
- Gross bile staining of lavage effluent
- Gross chyme or fecal staining of lavage effluent
- >500 WBCs/mm³ in lavage effluent
- >175 IU/dl amylase in lavage effluent
- >6 IU/dl alkaline phosphatase in lavage effluent
- Gram stain of lavage effluent positive for bacteria

*Blunt trauma.

Abbreviations: RBCs, red blood cells; WBCs, white blood cells.

The procedure is difficult for the inexperienced physician, and is best performed by the surgical consultant. The criteria for DPL to be deemed positive for bleeding or peritonitis are shown in Table 25–4.

Imaging Studies

Beyond the early identification of free intraperitoneal gas and subclinical pelvic fractures, the adjunctive supine chest and abdominal roentgenograms performed as part of the primary survey add little to the detection of abdominal injuries. However, they can occasionally reveal important clues to the differential diagnosis, particularly if there are physical signs of intra-abdominal injury, such as pelvic tenderness, ecchymosis or abrasions, hematuria or difficulty voiding, or abdominal distention.³³ They can also identify most rib, vertebral, and pelvic fractures, detect the presence of gastric dilation, and confirm the correct placement of gastric tubes. The abdominal roentgenogram can also suggest the presence of intraperitoneal or retroperitoneal blood or urine (ground-glass appearance of the abdominal cavity, blurring of psoas shadows), splenic laceration or hematoma (medial displacement of the lateral border of the stomach, as marked by the gastric tube, especially if the fundic mucosa has a sawtooth appearance, indicative of bleeding from the short gastric vessels), renal injury (scoliosis, obliteration of the nephric outlines and psoas shadows, in association with fractures of the lower ribs), and pancreatic contusion or hematoma (inferiorly displaced transverse colon). Unfortunately, the diagnosis of transmural duodenal injury (small retroperitoneal or perinephric gas bubbles or shadows on the right side of the abdomen, slightly below the liver) and duodenal or proximal jejunal hematoma (paucity of gas in the distal small intestine) are quite difficult, and the diagnosis of ileal, colonic, or vesical injury essentially impossible. Even so, the role of upper gastrointestinal contrast fluoroscopy, using air or sterile intravenous contrast administered perorally or via a gastric tube, is extremely limited, and reserved for stable patients suspected of duodenal or proximal jejunal injury, since extraluminal extravasation of contrast does not universally occur once it is given.

Intravenous urography, also known as intravenous pyelography, although largely supplanted by newer techniques, is still occasionally useful, and has two primary indications.

The first is in penetrating abdominal injury, when a “one-shot” intravenous urogram is obtained immediately prior to operative intervention in conjunction with the abdominal or pelvic roentgenogram, to confirm the presence of two kidneys and detect extravasation of urine from the kidneys, ureters, and bladder. The second is in blunt abdominal injury in which the presentation is delayed, and manifested only by significant hematuria (>20 red blood cells per high-power field [RBCs/hpf] on microscopic urinalysis). In this situation, it is still acceptable to obtain an intravenous urogram rather than CT to decrease radiation exposure, provided that the patient is otherwise stable.

Retrograde cystourethrography is a vitally important test for male patients in whom pelvic instability, blood at the urinary meatus, perineal or scrotal hematoma, or, in adolescents, a high-riding prostate precludes safe insertion of a urinary (Foley) catheter when indicated. It is typically performed by mixing half-strength intravenous contrast with sterile lubricating jelly, which is then injected retrograde into the urethra as a plain roentgenogram is obtained. If the urethra is demonstrated to be intact, the treating physician may safely proceed with insertion of the urinary catheter. If not, suprapubic cystostomy may be needed, depending upon the physiologic status of the patient and the advice of a urology consultant experienced in the management of injured children.

Double (peroral and intravenous) and triple (per rectum as well, if clinically indicated by the possibility of rectosigmoid or descending colonic perforation) contrast-enhanced CT has become the “gold standard” for definitive diagnosis of intra-abdominal injuries in stable patients. It is a better test for detection and quantification of abnormal collections of air or blood in the lower chest or in the abdomen (which are often missed on supine chest and abdominal roentgenography).³⁴ It is also more accurate for inclusion or exclusion of contusion, laceration, disruption, or extravasation of intravenous contrast from solid organs, such as “splenic blush” (which indicates persistent bleeding from the spleen or its hilum, the clinical significance of which remains uncertain in the pediatric population), and intraperitoneal or retroperitoneal contrast seepage from the upper or lower tracts of the collecting system (which indicates urinary leak, and has the same clinical significance in children as it does in adults).³⁵ Finally, it is especially good for documenting the positions of tubes and catheters (which on abdominal roentgenography requires an additional lateral view that often proves difficult to obtain during initial evaluation and resuscitation). Unfortunately, it cannot predict the need for operation, as this judgment is made on clinical grounds.³⁶ Moreover, while it is more sensitive than plain roentgenography and contrast fluoroscopy for the diagnosis of duodenal and proximal jejunal injury, contrast-enhanced CT cannot definitively exclude such injuries, since leakage of contrast from the intestine may or may not occur.³⁷ Yet, while it provides far greater sensitivity and specificity in the detection of most abdominal trauma than most other tests, its greater diagnostic accuracy must be weighed not only against its effect on the clinical management and outcome in potentially labile patients (recognizing that the patient must be physiologically stable in terms of both cardiorespiratory and hemodynamic status to safely undergo CT, since it takes up to 1 hour for peroral contrast to suffuse through the entire intestine), but

Table 25–5 Doses of Peroral and Intravenous Contrast Agents for Computed Tomography

Peroral Contrast

Meglumine diatrizoate (Hypaque), 1.5%, by mouth or via gastric tube

- Birth–2 yr: 60 ml
- 3–5 yr: 120 ml
- 6–9 yr: 180 ml
- >9 yr: 300–400 ml

Intravenous Contrast

Meglumine diatrizoate (Hypaque), 60%, by vein

- Step 1: Small intravenous test dose
- Step 2: Intravenous bolus, 2 ml/kg, maximum 50 ml
- Step 3: Intravenous infusion, 50–100 ml, during scanning

also against its potential long-term radiologic side effects in terms of late development of malignant neoplasia (especially when the potential diagnostic benefits from CT are marginal).^{38–40} Such risks are now being actively studied, and should lead to derivation and promulgation of a clinical decision rule that ascertains exactly which patients in whom the benefits exceed the risks. The preferred doses for peroral and intravenous contrast agents are shown in Table 25–5.

Abdominal ultrasonography also has a key role in the diagnosis of intra-abdominal injury in children. Not to be confused with FAST, abdominal ultrasonography, in the hands of a skilled ultrasonographer, is nearly as sensitive and specific as CT, and may be preferred for static imaging of the pancreas and kidneys. However, while it is both more time efficient than CT (when considering the added time for contrast suffusion), and obviates the need for administration of peroral or intravenous contrast (especially useful in patients with allergies to shellfish or iodinated contrast agents), it is more difficult for the novice physician to perform or read, and is less accurate than CT, although it is increasingly being used serially to follow healing of solid organ injuries.⁴¹

Laboratory Studies

Hematologic tests are of limited utility for the early diagnosis and treatment of abdominal injuries in childhood. Hemoglobin concentration and hematocrit are likely to be misleading during the initial phases of resuscitation, as dilutional anemia from endogenous fluid shifts and exogenous fluid administration will not as yet have occurred, although both tests will be useful as a baseline for further measurements. Similarly, arterial blood gases will serve as an initial indicator of core organ perfusion, but are more useful in terms of their trend, although they are more invasive than vital signs and urinary output.⁴² However, blood type and crossmatch are routinely obtained in all children with significant injury, especially those with hepatic, splenic, or, rarely, renal injuries likely to require transfusion in lieu of, or in addition to, operative management.

After blood type and crossmatch, the most important biochemical test is urinalysis. The presence of blood in the urine (>20 RBCs/hpf on microscopic urinalysis, to ensure that failure to pursue microscopic hematuria does not result in failure to detect potential congenital anomalies or renal tumors) mandates CT if the child presents early (to exclude

potential associated injuries as well as renal injuries), or intravenous urogram if the child presents late (for reasons noted earlier). However, some have argued that the standard used for adults (>50 RBCs/hpf) can also be applied to children.⁴³ Still others have suggested that CT may not be necessary at all if injuries appear minor.⁴⁴ The serum electrolytes (Na^+ , K^+ , Cl^- , HCO_3^-), blood urea nitrogen, and serum creatinine are valuable tests of renal function, and while they are virtually always normal in children with no previous history of kidney disease, they also serve as a baseline for management of fluids during and after resuscitation. Hepatic and pancreatic enzymes (serum aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, total and direct bilirubin, and alkaline phosphatase, as well as amylase and lipase) also play an important role in the diagnosis of blunt abdominal injury in childhood. Hepatic enzymes can detect a subclinical hepatic contusion or biliary leak, while pancreatic enzymes can detect unsuspected pancreatic injury, and by inference, since the tail of the pancreas extends into the hilum of the spleen, possible splenic injury as well, although the latter do not appear cost effective.^{45,46}

Management

Major Abdominal Injuries

Abdominal injuries pose an immediate threat to the integrity of the breathing (via associated gastric dilation) and circulation (via associated intra-abdominal hemorrhage), hence to ventilation, oxygenation, and perfusion of core organs and body tissues, thence to vital functions. As such, resuscitation must proceed simultaneously with assessment. Abnormalities of the airway, breathing, and circulation are therefore treated in sequence, as soon as they are recognized, both to restore flow of oxygen through the series circuit composed of the tracheobronchial tree, the lungs, and the bloodstream, and to ensure accurate assessment of downstream segments of this circuit. Of the three major functions—ventilation, oxygenation, and perfusion—evaluated during the primary survey, deficits of perfusion, although uncommon, are the most detrimental. Since most of these perfusion deficits are caused by intra-abdominal hemorrhage, the approach to resuscitation of the child with intra-abdominal injury must be timely, precise, and vigorous.

It is therefore vital that the stepwise pathophysiologic assessment of airway, breathing, and circulation advocated by the ATLS Course of the American College of Surgeons Committee on Trauma be followed in detail.⁴ The key immediately life-threatening abdominal condition, intra-abdominal hemorrhage due to solid organ injury or unstable pelvic fracture, is recognized and treated during the primary survey. The key potentially life-threatening abdominal conditions, minor hemorrhage due to minor solid organ injuries, frank peritonitis due to gastrointestinal disruption, are recognized and treated during the secondary survey. Meticulous attention to the early detection and optimal management of these injuries is the ideal way to ensure effective restoration of core organ perfusion, thus the best chance the seriously injured child has of a full and complete physical and neurologic recovery.

With the sole exception of massive gastric dilation that significantly impairs the airway (by causing pulmonary aspiration of acidic gastric contents), the breathing (by limiting

diaphragmatic excursion), and the circulation (by markedly increasing vagal tone, thereby causing reflex bradycardia in the infant and young child), immediately life-threatening intra-abdominal injuries result in intra-abdominal hemorrhage (hence deranged tissue perfusion), and require emergent volume resuscitation prior to definitive treatment.

However, major pediatric trauma is chiefly a disease of the airway and breathing (due to severe traumatic brain injury), rather than the circulation (due to ongoing major intra-abdominal hemorrhage), owing to the top-heavy body habitus of the infant and young child, which makes head injuries more common and torso injuries less common. Therefore, volume resuscitation must be guided by physical and laboratory signs of poor tissue perfusion: increased pulse rate; decreased pulse volume; pale, cool, skin that is mottled in infants and young children or clammy in older children and adolescents; increased capillary refill time; electrolytes that reveal high anion gap metabolic acidosis; arterial blood gases that reveal significant base deficit; and elevated serum lactate. In other words, the goal of volume resuscitation is not aggressive fluid administration, but appropriate fluid administration, since excessive water intake can significantly increase cerebral edema, and ultimately, intracranial pressure, complicating treatment of traumatic brain injury.

Volume resuscitation is administered via the intravenous or, in infants or young children in whom intravenous access is difficult, the anterior tibial intraosseous routes, unless the latter is contraindicated by ipsilateral lower extremity fracture. Intravenous access should always be attempted first (due to the serious, if rare, complications of intraosseous access such as osteomyelitis), using large-bore over-the-needle plastic catheters wide enough to rapidly deliver fluid or blood, but narrow enough to fit inside the preferred intravenous access site (either the median cubital veins in the antecubital fossae, or the greater saphenous veins just anterior to the medial malleoli). Insertion of two large-bore catheters above the diaphragm is preferred, although other sites may be used if these are unavailable. In general, peripheral intravenous access is favored over central venous access, although femoral venous access may be employed if there is no other option. Volume resuscitation is initiated using an isotonic balanced salt solution, such as lactated Ringer's solution, in continuously infused aliquots or "boluses" of 20 ml/kg (equivalent to 25% of the circulating blood volume of the infant or young child, the smallest volume reduction that typically results in systolic hypotension, defined by the formula, $70 + 2 \times \text{age}$ in years). These boluses may be repeated twice (administered thrice) before red blood cells must be transfused (in accordance with the 3:1 rule, which states that isotonic balanced salt solutions are only one third as effective as red blood cells as a plasma expander). Although no data are available in pediatric patients, permissive hypotension has been employed with limited success in adult patients, provided blood pressure is adequate to maintain cerebral perfusion, and definitive surgical management is readily available. The pneumatic antishock garment (PASG), or military antishock trousers (MAST), are no longer used for treatment of decompensated shock, except in selected hypotensive patients with unstable pelvic fractures, among whom the device is used not to correct abnormal hemodynamics, but to stabilize fracture fragments.^{47,48}

However, as crucial as volume resuscitation may be in children with intra-abdominal hemorrhage, the importance of stopping the bleeding cannot be sufficiently emphasized. Volume resuscitation may transiently restore core organ perfusion, but dilutional anemia is too often the result, particularly when bleeding patients are held in the emergency department in a futile attempt to achieve hemodynamic stability. If volume resuscitation must be employed in the absence of a surgeon, packed red blood cells (type specific if available, or type O, ideally Rh negative, if not) in continuous aliquots of 10 ml/kg should be administered as soon as possible to patients who are hypotensive on arrival in the emergency department, or who do not respond immediately to 40 to 60 ml/kg of lactated Ringer's solution, rapidly infused, as stated, in continuous aliquots of 20 ml/kg. Use of an auto-transfuser should be considered for patients with massive, ongoing intra-abdominal hemorrhage, but this is no substitute for emergent surgical consultation and intervention.

Detection of peritonitis is also vital to abdominal examination in the child. There is no test for peritonitis other than physical examination. Mild direct tenderness may indicate minor damage to an underlying organ, but does not indicate peritonitis. Marked direct tenderness, especially when associated with direct or referred rebound tenderness, are the key clinical signs of peritonitis, and together are called peritoneal irritation. The classic "boardlike" rigidity described in adult patients with peritonitis is rarely felt in pediatric patients. Instead, they present with involuntary guarding, termed *spasm*, which differs from boardlike rigidity in that the treating physician can displace the abdominal wall. Regardless, true peritoneal irritation always reflects an intra-abdominal catastrophe, and mandates emergent laparotomy, usually for repair of a ruptured hollow viscus.

Uncontrolled hemorrhage and frank peritonitis are the two main indications for emergent operative intervention in abdominal trauma, in children as well as adults. The former connotes solid visceral injury, and the latter hollow visceral injury. Other conditions mandate urgent laparotomy or laparoscopy as the situation warrants. The general indications for operative management in abdominal trauma are shown in Table 25–6.

Solid Organs

Modern management of nearly all solid organ injuries in childhood is nonoperative. Yet it is not nonsurgical, because operation is needed in a high proportion of pediatric trauma patients, and since, as with appendicitis, mature surgical judgment is required to decide whether, or when, operation may be indicated.^{49,50} As a general rule, children with liver, spleen, and kidney injuries will not require operative intervention for hemorrhage control unless the transfusion requirement exceeds half the blood volume (40 ml/kg) within the first postinjury day. However, this statement is somewhat misleading, since most patients who require operation declare themselves in the first few hours after injury, while patients whose transfusion requirement slowly approaches this limit 24 hours after injury are unlikely to rebleed later. This has led in recent years to reconsideration of the traditional approach to nonoperative management of solid organ injuries in childhood, such that extended stays in the pediatric intensive care unit are no longer the norm across North

Table 25–6 General Indications for Operative Management of Abdominal Organ Injuries

Blunt Trauma

- Hemodynamic instability despite adequate volume resuscitation
- Decompensated shock on admission
- Transfusion requirement > 40 ml/kg
- Physical signs of peritonitis
- Positive findings on diagnostic peritoneal lavage (if so decided by the trauma surgeon)
- Radiologic evidence of pneumoperitoneum
- Radiologic evidence of intraperitoneal bladder rupture
- Radiologic evidence of renovascular pedicle injury

Penetrating Trauma

- All gunshot wounds
- All stab wounds associated with:
 - Physical signs of shock or peritonitis
 - Blood in the stomach, urine, or rectum
 - Evisceration
- Radiologic evidence of intraperitoneal or retroperitoneal gas
- Positive findings on diagnostic peritoneal lavage (if so decided by the trauma surgeon)
- All suspected thoracoabdominal injuries

America, provided that nonoperative management is conducted in a hospital with a pediatric intensive care unit and ready access to a pediatric surgeon, a pediatric anesthesiologist, and ample blood products to ensure their availability when needed.^{51–53}

There is little doubt that general trauma surgeons with significant pediatric experience can successfully manage children with solid organ injuries using nonoperative treatment protocols.⁵⁴ However, neither a general trauma surgeon nor a pediatric trauma surgeon should attempt such management absent the availability of appropriate pediatric support, in terms of a pediatric intensive care unit and, most important, trained pediatric nursing. If these cannot be locally accomplished, and the injured child is stable enough for transfer to a pediatric-capable trauma center, transfer should be initiated as soon as possible after the primary survey has been completed, in accordance with preexisting transfer agreements well known to the treating physician. The time before transfer is effected is used to continue resuscitation, and to perform the secondary survey, without taking extra time to obtain imaging studies that will further delay transfer. However, if the child is unstable, operative management is appropriate. It is far better for such a child to safely remove a seriously damaged organ, even if likely salvageable under ideal circumstances, than to risk nonoperative management in an environment that is unprepared for it.

Liver injuries are suspected based upon clinical evaluation, and confirmed by abdominal CT. Upper abdominal tenderness, more right than left sided, may or may not be present. As stated, volume resuscitation is the foundation of early care, since nonoperative management will be successful in 90% of children with hepatic injuries. Operation is indicated in pediatric blunt trauma patients who are frankly hypotensive on arrival in the emergency department, or who respond only transiently to volume resuscitation, since patients with severe injuries, especially AAST OIS grade V injuries, have a poor outcome.⁵⁵ Urgent surgical consultation should be

obtained on patient arrival in the emergency department, but in no case should it be delayed beyond definitive diagnosis by CT. It should also be obtained in patients who present after “successful” nonoperative management, since, as with splenic injuries, delayed bleeding is known to occur.⁵⁶ Operation is nearly always indicated in penetrating trauma.

Spleen injuries are likewise suspected based on clinical evaluation, and confirmed by abdominal CT. Left upper quadrant tenderness and left shoulder pain (Kehr’s sign) may or may not be present. Once again, volume resuscitation is the foundation of early care, nonoperative management being successful in 95% of children with splenic injuries. The presence of a splenic blush on CT is not yet well studied in pediatric patients, but preliminary experience suggests that, as with FAST, it may add little to management of blunt trauma patients, since current treatment is physiologically based, and linked to transfusion requirement.³⁵ In the rare situation in which emergent operation is indicated, prior administration of multivalent pneumococcal vaccine could theoretically decrease the low incidence of overwhelming postsplenectomy infection, but there are no data proving this is so. Operation is nearly always indicated for penetrating trauma.

Kidney injuries are managed nonoperatively in virtually all instances. As with liver and spleen injuries, the diagnosis is suspected based on clinical evaluation, and confirmed by CT obtained on clinical grounds or for significant hematuria.⁵⁷ Renal injuries are typically minor, so volume resuscitation is needed only for severe injuries. This is also true of operative management, which is usually required for intraperitoneal leak from the collecting system, massive upper tract bleeding presenting as gross hematuria, severe disruption or shattering, and renal pedicle avulsion. Most blunt injuries with urinary leaks are managed nonoperatively, or by percutaneous nephrostomy, while most penetrating injuries with urinary leaks are managed by direct surgical repair. One-shot intravenous urography is mandatory whenever emergent surgical intervention is required and abdominal CT has not been, or should not, be obtained. Operation is needed in penetrating trauma only in severe cases (AAST OIS grade III–V).

Pancreatic injuries in children are also managed nonoperatively in virtually all instances. The diagnosis is suspected typically on clinical grounds, and confirmed by CT or ultrasonography and appropriate laboratory tests. Traumatic pancreatitis presents with epigastric pain, and is managed conservatively, giving nothing by mouth and administering intravenous fluids until pain disappears and biochemical abnormalities are resolved. Pancreatic pseudocysts present with soft but tender epigastric masses, and are also managed conservatively, substituting total parenteral nutrition for intravenous fluids if the pseudocyst is well established. Operative intervention is rarely required for blunt trauma, and is associated with complication rates that are significantly higher than nonoperative care, even in severe cases associated with transection of the pancreatic head, body, tail, or duct.^{58–60} Operation is nearly always indicated for penetrating trauma.

Hollow Organs

Gastrointestinal tract injuries require operative intervention only if transmural disruption is present.⁶¹ Unfortunately, it

is prohibitively difficult to identify such injuries without an operation. Neither CT nor contrast fluoroscopy is sufficient valid and reliable to exclude the diagnosis, although risk is increased if more than one organ is found to be injured.⁶² Thus the treating physician must wait for signs of peritoneal irritation to develop, or perform DPL, which can itself confound the abdominal examination if negative, and is no more accurate than CT or contrast fluoroscopy in ruling out intestinal perforation or laceration. Thus, in the absence of frank indications for laparotomy, serial abdominal examination, seeking signs of peritoneal information, is likely the most valid and reliable test available to the treating physician for diagnosis of gastrointestinal disruption. It is certainly the most cost effective. Gastrointestinal tract disruption is uncommon in blunt trauma but common in penetrating trauma. Signs of peritonitis always mandate urgent laparotomy.

Genitourinary injuries exclusive of the kidneys require organ-specific management. Ureteric injuries are detected by CT or intravenous urography, and require stented repair when involving the supravescical component or reimplantation when involving the intravesical component. Vesical injuries are detected by similar means, and confirmed by voiding cysturethrogram. Intraperitoneal injuries to the dome of the urinary bladder require direct operative repair. Extraperitoneal injuries to the base of the urinary bladder require catheter drainage. Injuries to the male and female genital tracts are rarely associated with blunt trauma, with the exception of urethral injury in boys, for which a trans-urethral stent, ideally a urinary catheter, is required. Injuries to the male and female genital tracts seldom occur in penetrating trauma, but require surgical repair.

Great vessel injuries always require operative repair, and are nearly universally detected at emergent laparotomy performed for massive, ongoing intra-abdominal hemorrhage that typically presents with decompensated shock.^{63,64} No preoperative tests are necessary, practical, or desirable, save for the one-shot intravenous urogram obtained for penetrating trauma whenever feasible. Survival is dependent upon immediate repair.

Bony Pelvis

Unstable fractures of the bony pelvis are detected clinically as described previously, and confirmed by pelvic roentgenography. Clinically unstable pelvic fractures require a pelvic sling, or similar device, to decrease pelvic volume and stabilize fracture fragments in an attempt to limit bleeding in the emergent phase of treatment. As stated, unstable pelvic fractures associated with hypotension may benefit from application and inflation of a PASG or MAST device, but are used in this situation to stabilize fracture fragments, hence limit further bleeding. Most pelvic fractures in childhood are simple and stable, and rarely require volume resuscitation. However, complex pelvic fractures, though rare, are both biomechanically and hemodynamically unstable, and require massive volume resuscitation. Closed pelvic fractures, via tamponade, will limit the ultimate amount of blood lost, provided operative intervention, which opens tissue planes and counteracts this tamponade, is not required for other reasons. Open pelvic fractures present an extraordinary management challenge, for which interven-

tional radiology and external fixation are typically both required.

Abdominal Compartment Syndrome

A recent development in trauma surgery has been the recognition of abdominal compartment syndrome. Presumed to be due to reperfusion injury after prolonged operative treatment and resuscitation, and mediated by superoxide radicals, abdominal compartment syndrome results in massive edema of all intra-abdominal organs in the afflicted patient, impeding ventilation and oxygenation via upward pressure on the diaphragm, and impeding perfusion of intra-abdominal organs via compromised circulation. Rarely observed in the emergency department, the condition is recognized by intravesical pressures that exceed 25 cm H₂O, and treated by release of pressure, typically by reoperation for placement of a Bogota bag, much as a Silon pouch is used for neonates undergoing delayed primary closure of gastroschisis or omphalocele, until such time as edema resolves and delayed primary closure can be safely effected. It is mentioned here because some emergency departments may rarely receive patients with abdominal compartment syndrome in transfer from other hospitals.

Trauma Laparotomy

It is axiomatic that optimal stabilization of the trauma patient frequently requires surgical intervention. Contemporary surgical management of abdominal injuries therefore relies heavily on “damage control.” A midline incision is swiftly made, and all four quadrants are packed. A rapid but careful inspection is then made for sources of bleeding and soilage. Sources of bleeding that can be readily controlled by repair or ligation are then addressed, leaving packing in place to apply direct pressure to other bleeding sites. Sources of soilage are then similarly readily controlled by stapling or ligation, after which the abdomen is speedily irrigated with warm saline solution, and temporarily closed with towel clips or Bogota bag. The patient is then fully resuscitated either in the operating room or the intensive care unit, until such time as normal body temperature is restored, metabolic derangements are corrected, and hematologic deficiencies are addressed, both in terms of oxygen-carrying capacity and with respect to blood clotting factors, which are adversely affected by hypothermia, hypocalcemia, dilution, and consumption. Once the patient is fully stabilized, definitive operation can proceed, and needed repairs can be performed.

Trauma Laparoscopy

The role of trauma laparoscopy is in evolution. To date, it has mostly been employed to determine whether abdominal penetration has occurred in questionable cases, and for diagnosis, and occasionally diaphragmatic repair, of potential or actual thoracoabdominal injuries. Theoretically, its application to trauma surgery is limited only by the speed and skill of the operating surgeon. However, at this point, its uses are limited to cases in which good visibility is assured, and active bleeding and soilage are not encountered.

Minor Abdominal Injuries

Minor abdominal injuries are those confined to the soft tissues of the abdominal wall, and which in cases of penetrat-

ing trauma do not violate the parietal peritoneum. They are noteworthy chiefly because of their frequency. Blunt injury to the abdominal wall typically results in superficial contusions to the skin and subcutaneous tissues, although occasionally the rectus muscles also, and does not require treatment beyond the symptomatic relief provided by warm compresses and oral analgesics. Penetrating injury to the abdominal wall is rarely associated with intra-abdominal injury absent signs of compensated or decompensated shock or parietal peritoneal irritation, but great care is warranted during exploration of an apparently superficial penetrating wound, since it is all too easy to explore a wound to such a depth that the abdomen is entered.

Wounds that penetrate the transversalis fascia may require surgical exploration in the operating room, either by laparotomy or by laparoscopy. Likewise, contaminated wounds may also benefit from operative débridement by means of pulse jet irrigation prior to formal closure. Otherwise, superficial lacerations may be repaired in the emergency department, closing the wound in a minimum of two layers whenever possible. Tetanus prophylaxis is indicated for all contaminated wounds.

Penetrating Injuries

When first encountered, all penetrating injuries to the abdomen must be considered to have violated the parietal peritoneum. Great care must be taken during exploration of the wound to avoid such violation if it has not yet occurred. All penetrating gunshot wounds to the abdomen require exploratory laparotomy, as do those stab wounds associated with shock, peritonitis, evisceration, or blood in the stomach, urine, or rectum on insertion of a gastric tube or urinary catheter or digital examination. The remainder may be observed via serial physical examination. All penetrating abdominal injuries must be deemed contaminated, and must be thoroughly cleansed and débrided prior to suture repair, in addition to appropriate antibiotic and tetanus prophylaxis as indicated. As with abusive injuries, the history obtained following penetrating trauma is likely to be inaccurate. As such, hospital admission is warranted, both to ensure that the child receives a full course of antibiotics, and to allow full involvement of social work and pastoral care services, whose skills are critical in determining the circumstances surrounding the injury and minimizing the likelihood of recidivism. Finally, all gunshot and stab wound injuries in children must be reported to the police, and to local child protective services as well, if there is any hint that the injuries may have resulted from parental abuse or neglect.

Thoracoabdominal Injuries

Thoracoabdominal injuries are penetrating injuries that traverse the diaphragm. They must be suspected whenever a penetrating injury is found anywhere between the nipples and the umbilicus. All potential thoracoabdominal injuries mandate immediate chest roentgenography, to identify possible intrathoracic air or blood, followed by insertion of a chest tube if present. All such injuries will also require exploratory laparotomy or laparoscopy, both to determine whether and where diaphragmatic penetration may have occurred, and to exclude other intra-abdominal injuries that also require operative repair.

Table 25–7

Triage Guidelines for Emergency Management of Abdominal Trauma

Blunt Trauma*

Hemodynamically stable patient

- Negative indications for CT → acute care area
- Positive indications for CT → CT negative → acute care area
- Positive indications for CT → CT positive → PICU vs. OR

Hemodynamically unstable patient

- Responds well to volume resuscitation → CT negative → PICU
- Responds well to volume resuscitation → CT positive → PICU vs. OR
- Responds poorly to volume resuscitation → OR

Penetrating Trauma*

- Gunshot wound → OR
- Stab wound → OR vs. PICU vs. acute care area
 - Hypotension or peritonitis → OR
 - Blood in the stomach, rectum, or urine → OR
 - Evisceration → OR
- Thoracoabdominal wounds → OR

*If signs of peritoneal irritation, a laparotomy or OR is indicated. Abbreviations: CT, computed tomography; OR, operating room; PICU, pediatric intensive care unit.

Summary

Serious abdominal injuries occur in nearly 1 in 10 cases of major childhood trauma, and follow only central neuraxis injuries and intrathoracic injuries in their lethality. Most pediatric abdominal injuries are initially managed nonoperatively, although major abdominal injuries typically coexist with immediately or potentially life-threatening injuries to other body regions. A high index of suspicion for abdominal injuries is always warranted, since derangements of ventilation, oxygenation, and perfusion resulting from injury to intra-abdominal organs that affect the integrity of the airway, breathing, and circulation substantially worsen the prognosis of associated injuries, particularly central neuraxis injuries, due to inadequate delivery of blood to damaged brain tissue. A physiologic approach to the emergent management of abdominal trauma best serves the needs of the injured child, whose vigorous hemodynamic compensation but limited circulatory reserves call for both rapid restoration and meticulous maintenance of circulating volume, so cellular respiration is supported and irreversible shock is avoided (Table 25–7).

Chapter 26

Burns

Nicholas Tsarouhas, MD and Paula Agosto, RN, MHA

Key Points

Proper management of the burn patient requires the clinician to be comfortable with the classification of burns by both depth and body surface area.

It is crucial to anticipate and be able to manage the possibility of fulminant airway edema in the burn patient.

The profound fluid needs of the burn patient with circulatory impairment require familiarity with weight-based and body surface area–based calculations.

The goal of burn wound management is to reduce the risk of infection while minimizing the likelihood of an adverse cosmetic outcome.

The decision to admit and/or transfer a child to a burn center depends on many factors, including the risk of infection, cosmetic and functional outcomes, pain control, complexity of wound care, age, associated morbidities, underlying medical conditions, and social concerns.

Causes

The leading causes of burns in children are scalds, flame burns, and electrical injuries.³ Children less than 5, especially boys, are the highest risk group. In toddlers, scald burns from hot liquids account for 80% of all thermal injuries.³ Toddlers also are commonly burned from touching hot metals such as stoves, grills, and home space heaters. School-age children often sustain thermal burns from play with dangerous equipment such as matches and cigarette lighters. Teenagers are more commonly burned from risk-taking activities, fireworks, and careless use of flammable substances. Household fires caused by unattended cigarettes or candles are a major contributor to pediatric burn injuries and death in all age groups. Cigarettes alone are responsible for 35% of the fatal house fires in the United States.⁴

Anatomy and Physiology

The skin is the organ most visibly affected by burns. It consists of two main layers: the epidermis and the dermis. The epidermis (the outer layer of skin) is formed from several layers of stratified epithelium. The dermis is composed of connective tissue, which is tough and elastic. The nerve endings concerned with the sensation of touch and temperature are located in the dermis. Structures within the skin include sweat glands, hair follicles, and sebaceous glands. A layer of subcutaneous fat separates the skin from underlying structures. In addition to its cosmetic importance, the skin protects the body against infection, regulates body temperature, and serves as a barrier to prevent fluid loss.

Pathophysiology

Thermal Burns

The thinner skin of young children accounts for deeper burns as compared to adults. Thermal energy damages skin in proportion to intensity and duration. Once tissue is damaged, blood supply and cellular activity increase in the injured area, causing heat and redness. The damaged tissue and mast cells ooze various enzymes and histamine, which trigger vasodilation and increased capillary permeability. Swelling and edema then develop as the capillary walls leak inflammatory exudate (containing plasma, antibodies, and some red blood cells and white blood cells) into the surrounding tissue. Macrophage cells begin to arrive at the wound site to defend against bacteria and help clear blood clots, damaged tissue, and other debris.⁵

Introduction and Background

Epidemiology

Burns continue to be a major source of morbidity and mortality in the pediatric population. In the United States in 2001, there were more than 181,000 fire- and burn-related injuries, and 672 deaths in children up to age 19 years.¹ In children 1 to 9 years old, burns rank third among injury-related deaths.² Most pediatric deaths occur as a result of house fires. Lower socioeconomic areas account for the highest death rates. While the incidence of burns continues to drop in the United States, it is important to remember that many burns are not reported; therefore, most data underestimate the true scope of this public health issue.³

Inhalation Injury

While thermal burns account for major fire-related morbidity, mortality is intimately tied to inhalation injury and carbon monoxide (CO) poisoning. Inhalation of toxins associated with flame smoke accounts for 80% of burn-related deaths.⁶ Direct thermal injury may lead to upper airway edema and obstruction. Some combustion of soot particles continues, and these small particles may be carried into the lung. Additional clinical consequences include systemic capillary leak, bronchospasm from aerosolized irritants, small airway occlusion from sloughed endobronchial debris, impaired ciliary clearance, loss of surfactant, increased dead space and intrapulmonary shunting from alveolar flooding, decreased lung compliance from interstitial and alveolar edema, decreased thoracic compliance from chest wall burns, and, later, infection of the denuded tracheobronchial tree (tracheobronchitis) or pulmonary parenchyma (pneumonia).⁷ The evaluation and management of smoke inhalation is covered in detail in Chapter 143 (Inhalations and Exposures).

Carbon Monoxide Poisoning

Smoke inhalation is commonly associated with CO poisoning, as levels of CO may reach 10% in house fires.⁸ CO impairs oxygen delivery and utilization. It binds tightly to hemoglobin with an affinity 250 times that of oxygen. CO also binds to cytochrome oxidase, thus interfering with cellular oxidative energy metabolism.⁹ The net result of this impairment in the delivery, release, and use of oxygen is tissue and cellular hypoxia. The evaluation and management of CO poisoning is covered in detail in Chapter 143 (Inhalations and Exposures).

Electrical Injury

Electrical burns result in over 1500 deaths per year¹⁰ and 2% to 3% of all admissions to hospital burn centers.¹¹ Electrical burns result from thermal energy that is produced as an electrical current passes through the body. The amount of thermal energy produced is directly proportional to the degree of the electric current. Nerves, muscles, and blood vessels have low electrical resistance, so electricity will preferentially flow through these structures. Alternating current, which is found in household electricity, produces muscle tetany caused by the continual contraction and relaxation of the muscle with each cycle. One of the most common pediatric electrical injuries occurs as a result of a child biting an electrical cord.

Direct current, found in lightning, poses its greatest risk when the current traverses the heart, resulting in ventricular fibrillation or asystole. While 70% to 80% of those struck by lightning survive,¹² 100 fatalities occur in the United States each year.¹³ The major cause of arrest in these patients is the result of dysrhythmias, myocardial damage, or respiratory arrest with asphyxia. The evaluation and management of electrical injuries is covered in detail in Chapter 142 (Electrical Injury).

Chemical Burns

Nearly 100,000 chemical burns are reported in the United States each year.¹¹ Fortunately, the overwhelming majority of these prove to be relatively benign. In most cases, the burn is a result of a direct chemical injury. Acid burns result in coagulation necrosis, which usually limits the depth and penetration of the burn. Common household products that contain acids include drain cleaners (sulfuric acid or hydrochloric acid), toilet cleaners (hydrochloric acid or phosphoric acid), and car batteries (sulfuric acid).¹⁴

Alkalis produce liquefactive necrosis, thus causing deeper penetration and a more significant burn. Alkalis include lye (sodium hydroxide), fertilizers (anhydrous ammonia), oven and drain cleaners (sodium or potassium hydroxide), paint strippers (sodium hydroxide), and various detergents.¹⁵ Consultation with a poison control center should be considered when evaluating children with chemical burns, to assess the possibility of associated systemic toxicities in addition to the cutaneous burn. The evaluation and management of chemical burns is covered in detail in Chapter 143 (Inhalations and Exposures).

Recognition and Approach

Classification of Thermal Burns

Depth

Traditionally, burns have been classified as first, second, third, and even fourth degree. Many experts now recommend that this nomenclature be replaced by the designations of superficial, superficial partial thickness, deep partial thickness, and full thickness (Table 26–1). It is often difficult to correctly identify the depth of the burn, however, and it is common to have several depths exhibited in one injury. The center usually has a higher degree of burn than the periphery.

First-degree or superficial burns are limited to the epidermis. They are characterized by painful, erythematous,

Table 26–1 Classification of Burns by Depth

Burn Type	Histology	Appearance	Pain?	Healing	Scarring?
Superficial/first degree	Epidermis only	Painful, erythematous, nonblistered	Painful	3–5 days	None
Superficial partial thickness/second degree	Complete destruction of epidermis and <50% of dermis	Erythematous, blistering, moist	Painful	2 wk	Possible
Deep partial thickness/second degree	Complete destruction of epidermis and >50% of dermis	Paler, drier, blistering	May be less painful	Several weeks	Likely
Full thickness/third degree	Complete destruction of epidermis and dermis	Pale and white, or charred and leathery	May be painless	Months	Always

nonblistered areas of inflammation. An example is a severe sunburn. Importantly, when body surface area (BSA) calculations are performed to estimate the amount of burn, first-degree burns are not included. Generally, these burns heal within 3 to 5 days with no scarring.

Second-degree or partial-thickness burns extend into the dermis. Superficial partial-thickness burns result in the complete destruction of the epidermis and less than 50% of the dermis. These burns are erythematous, blistering, moist, and painful. There is pain because intact sensory nerve receptors are still exposed. These usually heal in 2 weeks, though scars are possible. Deep partial-thickness burns result in the complete destruction of the epidermis and greater than 50% of the dermis. They are often paler and drier, and may be less painful as there is some destruction of cutaneous nerves. These take many weeks to heal, and scars are likely.

Third-degree or full-thickness burns extend into the subcutaneous tissues. Full-thickness burns result in the complete destruction of the epidermis and the dermis. Their appearance may be pale and white, or charred and leathery. These are usually nontender as there is widespread destruction of cutaneous nerves. Healing is slow, and skin grafting is usually needed.

Some experts add an additional category of fourth-degree burns. These involve destruction of the underlying structures such as muscles, tendons, nerves, and bones. Severe electrical burns are an example of this type.

Body Surface Area

BSA estimates are important in the initial evaluation and management of burns. These calculations help guide volume resuscitation, decisions to admit, transfer to burn centers, and prognosis. Importantly, only second- and third-degree burns are included in the BSA calculation, because superficial burns have little impact on patient care and outcome.

The “rule of nines” (Table 26–2) is a convenient and rapid method of estimating the extent of BSA burned in adolescents. It divides the surface area of the body into areas of 9%. When all body areas of these 9% segments are summed, 1% remains, which is assigned to the genitalia and perineum. It is inaccurate for children, however, as they have relatively larger heads and smaller extremities.

The rule of nines is good for a quick estimate in children older than 9 years. For patients who are 9 years and younger, a more precise method of burn size estimation should ultimately be used. The Lund and Browder chart¹⁶ (Fig. 26–1) subdivides body areas into segments and assigns a propor-

tionate percentage of body surface to each area, based on age. The lower extremity is divided into upper leg, lower leg, and foot, rather than being considered as a whole. The head of a baby is proportionately much larger than any other area of the body. As a child grows, the head becomes relatively smaller as compared with the rest of the body, and the lower extremities assume more BSA.

Another method of estimating burn injury extent uses the size of the child’s hand. The BSA represented by the hand is set at 1%. Some experts advocate including the fingers, while others do not. A better estimate of the palm itself may be 0.5%¹⁷; one study estimated the palm at 0.4%, and the entire hand at 0.8%.¹⁸ This method is both quick and useful for areas of irregular or nonconfluent burns.

Recognition of Child Abuse

Between 10% and 20% of burns in children are intentionally inflicted.¹¹ Most inflicted burns are scald or contact burns that have recognizable patterns (Table 26–3). Toddlers submerged in hot water, particularly as punishment for toilet training misfortunes, present with a characteristic scald burn to the buttocks, perineum, thighs, and feet (see Chapter 119, Physical Abuse and Neglect). The primary care provider needs to have a high index of suspicion when the history of the injury does not match the pattern of the burn, or is not consistent with the child’s developmental age. While the burn needs to be promptly treated, the provider is mandated to report all suspicious injuries to the appropriate social services and child protective agencies.

Evaluation

Immediate Emergency Department Evaluation

Airway Assessment

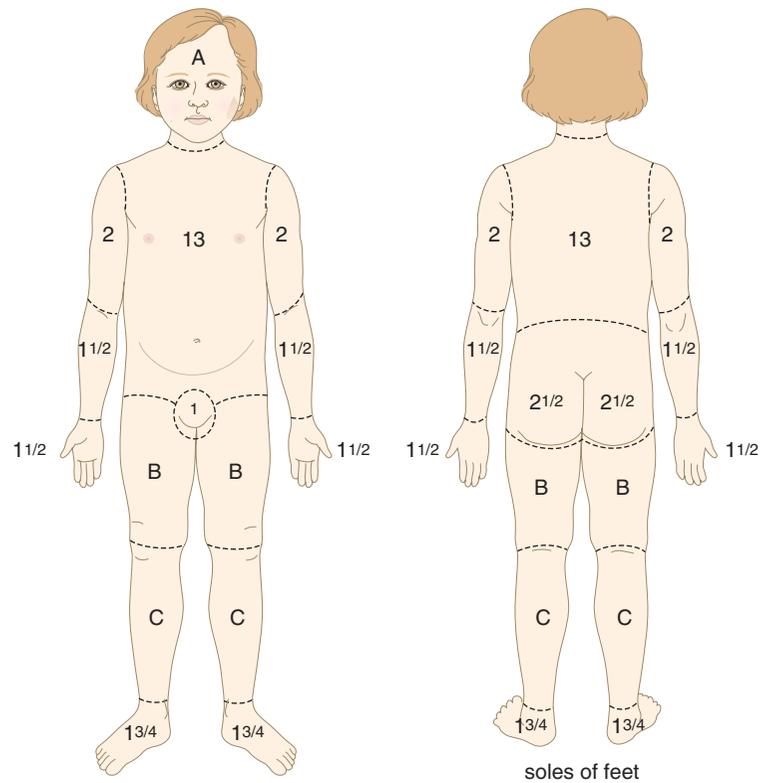

Inhalation of hot gases can burn the airway, and lead to rapidly progressive airway edema and obstruction. The child’s airway is exquisitely sensitive to swelling, as airway resistance increases as the fourth power of the radius. Thus even small degrees of edema may have catastrophic airway implications.

Every emergent evaluation, regardless of the injury, begins with an airway assessment. The evaluation commences with an “across the room” inspection of the child’s airway patency. The crying child, at the very least, is able to maintain the airway at that point in time. The child who is quiet or exhibiting signs of distress is more ominous. The usual signs and symptoms of airway compromise should be sought: stridor, hoarseness, drooling, gagging, coughing, and increased work of breathing. Additional signs of concern include burns to the face, singed facial hairs, and carbonaceous sputum.

Body Area	Relative Percent Burn
Head and neck	9%
Anterior/posterior torso	18% each (36%)
Lower extremity	18% each (36%)
Upper extremity	9% each (18%)
Genitalia/perineum	1%
Total	100%

*Note: Less accurate for children 9 years and younger, who have relatively larger heads and smaller extremities.

FIGURE 26-1. Classification of burns by body surface area: the Lund and Browder chart. (Adapted from Thermal injury. In Barkin RM [ed]: Pediatric Emergency Medicine, 2nd ed. St. Louis: Mosby, 1997, p 490.)

It is important to remember that cervical spine trauma may be present. Often, patients have jumped or have fallen from burning buildings. If the history is unclear or unknown, patients must be cervically immobilized until clinical or radiographic assessment and clearance is completed.

Breathing Assessment

Bronchospasm is very common from the extreme irritative properties of inhaled smoke and toxic gases. Once again, the patient in respiratory distress should be obvious at the onset. Tachypnea, retractions, grunting respirations, coughing, and

nasal flaring are all clues to the severity of the distress. Concerning lung auscultatory sounds include wheezing, rales, and decreased breath sounds. Cyanosis is a late sign of critical compromise.

A pulse oximeter reading of oxygen saturation is useful in many cases, but it is crucial to remember that victims of CO poisoning will look pink and have a normal oxygen saturation, despite being hypoxemic. An arterial blood gas with co-oximetry is mandatory. Equally important is the fact that the initial chest radiograph may be normal. Over the course of a few hours, infiltrates, and even complete opacification may develop.

Circulation Assessment

Burn patients may experience profound circulatory impairment (“burn shock”). Shock may develop in children with 15% to 20% BSA burns.¹¹ Large burns release vasoactive mediators that result in systemic capillary leakage. Cardiac output is decreased by circulating factors that depress myocardial function, which may lead to shock.

Important indicators of circulatory integrity include mental status, skin color and temperature, capillary refill, pulses, heart rate, and blood pressure. While hypotension is a late and ominous sign of circulatory failure in children, hypertension is also seen in severely burned children. Other important parameters to guide fluid management include urine output and, in some cases, central venous pressures. Basic metabolic chemistries and blood gases for pH are also important to assist in the fluid management of these patients.

Mental Status Assessment

Alteration in mental status should prompt a thorough assessment for the underlying etiology. Possible life-threatening etiologies include anoxia from asphyxiation, hypercarbia from hypoventilation, CO intoxication, hypovolemia with resultant cerebral hypoperfusion, traumatic brain injury, and seizures. Other causes may include pain, anxiety, drugs, and alcohol.

Children with large burns, although alert in the first hours after injury, may become obtunded secondary to fluid shifts, pain medication, sleep deprivation, and exhaustion.¹⁹ Nevertheless, computed tomography scans should be obtained when the etiology of the mental status aberration is unknown, to exclude occult head injury. Blood gases with co-oximetry, electrolytes, and toxicologic screens also add useful information.

Life-Threatening Complications

Infection

Infection remains the leading cause of morbidity and mortality in burn patients.²⁰ The overall reported incidence of infections in burned children is 13.6%.²¹ Necrosis of burned tissue produces a protein-rich medium that encourages bacterial growth. Inevitably, all burns become colonized by skin flora and potentially pathogenic organisms that may invade this breached epithelial barrier and lead to infectious complications. Inhalation injury to the respiratory tract may lead to lethal pulmonary disease. Importantly, seriously burned children also have a global immunosuppression that compounds their infection susceptibility.⁷

The most common burn infection is a cellulitis. This usually occurs in the first few days after the burn. Any progressively expanding area of erythema, induration, and tenderness around a burn’s margins should raise suspicion of a cellulitic infection. Unfortunately, the inflammatory response that ensues after a burn also may easily be confused with a cellulitis. Moreover, fever, which is common with cellulitis, is often seen in the setting of an uninfected burn, as an expected physiologic inflammatory response. While laboratory studies are occasionally helpful, close clinical observation for progression is crucial.

Invasive burn wound infections also occur. A rapid proliferation of bacteria in burn eschar may proceed to invade underlying viable tissues. Clinical signs of an invasive burn wound infection include (1) a change in color of the wound; (2) a dark brown, black, or violaceous discoloration of the wound; (3) hemorrhagic discoloration of subeschar tissue; (4) conversion of a burn from partial thickness to full thickness; (5) new drainage; and (6) a foul odor.²² Additionally, fever and other systemic signs of toxicity may be present.

Gram-positive organisms, typically *Staphylococcus aureus* and group A β -hemolytic streptococcus (GABHS), are the predominate pathogens in early burn infections (Table 26–4). Gram-negative organisms, especially *Pseudomonas aeruginosa*, colonize the eschar and should be considered when infections develop after a week. *P. aeruginosa* infection classically presents with the green pigment pyocyanin. Ecthyma gangrenosum should also raise suspicion for *P. aeruginosa* infection. These deep cutaneous erosions, usually seen in immunocompromised patients, often begin as vesicles, which pustulate, and then progress rapidly to gangrenous ulcers. Sepsis is common.

Bacteroides and other anaerobic bacteria are occasional isolates from serious burn infections. In extensively burned patients who develop late infections, *Candida* and other fungi should be considered.²⁰ Viral infections of burns, most commonly herpes simplex virus (HSV) or cytomegalovirus, are usually heralded by a vesicular eruption.

Systemic Inflammatory Response Syndrome

Systemic inflammatory response syndrome may follow severe burns. The common presentation is fever, tachypnea, tachycardia, shock, and multisystem organ failure. The hyperactive immune response causes a generalized inflammation that damages healthy tissue as well as infected burn wounds. Microvascular permeability leads to decreased tissue oxygenation, and blood flow is reduced due to microthrombi. During

Table 26–4 Pathogens Responsible for Burn Infections

Early Infections

Staphylococcus aureus
Group A β -hemolytic streptococcus (GABHS)

Late Infections

Pseudomonas aeruginosa and other gram negatives
Bacteroides and other anaerobic bacteria
Candida and other fungi
Herpes simplex virus, cytomegalovirus, and other viruses

this reaction, the intestinal and, possibly, the respiratory barriers to infection are damaged, allowing the entry of additional bacteria into the circulation.⁶ Aggressive supportive care remains the therapeutic mainstay.

Myoglobinuria

Myoglobinuria secondary to muscle breakdown and widespread cell death (rhabdomyolysis) is seen when BSA burns approach 30%. Myoglobin accumulates in the kidneys at alarming rates and may lead to fulminant renal failure. Strict attention to the urine output, urinalysis, and fluid therapy is crucial.

Special Considerations

Eye Burns

Serious corneal burns are generally obvious on physical examination, with the cornea having a clouded appearance. More subtle injuries can be detected after topical fluorescein application. In general, any burns of the eyes or eyelids require urgent ophthalmologic consultation.

Ear Burns

The most important aspect of managing deeply burned ears is to prevent auricular chondritis. This serious complication results from the poor blood supply of the cartilage of the external ear. The prevention of infection is paramount as infected cartilage liquefies, losing its structural integrity. Topical mafenide acetate has been shown to sharply reduce the incidence of auricular chondritis.²³

Hand Burns

Preservation of the functional integrity of the hand mandates specialized attention. Hand surgery consultation is mandatory. During the first 24 to 48 hours, adequate blood flow must be ensured. The adequacy of perfusion can be judged by temperature and the presence of pulsatile flow detectable by Doppler in the digital pulp. If there is any question, escharotomy or fasciotomy should be done. Subsequently, the hands should be splinted in a position of function, with the metacarpophalangeal joints at 70 to 90 degrees, the interphalangeal joints in extension, the first web space open, and the wrist at 20 degrees of extension.²³

Management

Emergency Stabilization

Airway

Humidified oxygen (100%) should be administered immediately to all burn patients. As burn patients may also have cervical spine trauma, the head should be maintained in neutral position, and any airway manipulation should presume the presence of a cervical spine injury. The jaw thrust should be the airway opening maneuver of choice, as opposed to the chin lift, which could extend the neck and damage the spinal cord. Endotracheal intubation should only occur with the assistance of someone maintaining in-line cervical stabilization.

Because the airway is so precarious, experts recommend early intubation, as edema and obstruction can develop rapidly.²⁴ In anticipation of a distorted and edematous airway,

endotracheal tubes (ETTs) with smaller diameter than usual for age should be readily available. Once the tube is in place, it should be very carefully secured, as reintubation may be impossible if it is dislodged. One safe method of securing the ETT in the burn patient is to tape both under and over the ears.²⁵

Breathing

Once the airway is secure and oxygen is being delivered, attention turns to the adequacy of oxygenation and ventilation. The clinical assessment is augmented by electronic end-tidal CO₂ monitoring and pulse oximetry. It is vital to remember, however, that in the presence of elevated carboxyhemoglobin levels (common with smoke inhalation) pulse oximetry overestimates the true oxyhemoglobin saturation.²⁶ Thus, arterial blood gas determination (with co-oximetry) is mandatory.

If the patient's breathing is judged to be suboptimal, ventilatory support is necessary. Hand ventilation with a bag-valve-mask apparatus should be employed initially while preparations are made for endotracheal intubation. Ideally, an anesthesia (Mapleson) bag should be used to manually ventilate, as it allows one to assess lung compliance, which is often compromised in the setting of smoke inhalation. The bronchospasm that commonly accompanies smoke inhalation should be treated with aerosolized β_2 -agonists (albuterol, levalbuterol), terbutaline, and/or epinephrine. Corticosteroids have not been shown to be of benefit in decreasing the tracheobronchial inflammation induced by smoke inhalation.²⁷

If endotracheal intubation and mechanical ventilation are required, there are a few important medication selection considerations. The most common sedative choices are thiopental, midazolam, ketamine, and etomidate. Because thiopental is associated with hypotension, it should be avoided in the burn patient with circulatory insufficiency or shock. While etomidate and midazolam are fine choices, ketamine has the added benefit of being a bronchodilator, which may be useful in the setting of smoke-induced bronchospasm. The muscle relaxants of choice are usually the nondepolarizers (vecuronium, pancuronium, rocuronium). Nondepolarizing muscle relaxants are preferred over succinylcholine for burns that are more than 48 hours old.

Once mechanical ventilation is initiated, air trapping should be anticipated. Adequate expiratory times should be ensured, and one should be alert for dynamic hyperinflation.²⁸ Inflating pressures to greater than 40 cm H₂O should be avoided, unless there is severely impaired chest wall compliance.⁷

Circulation/Fluid Therapies

Adequate vascular access is required to support the resuscitation needs of the severely burned patient. Peripheral vascular access can be difficult to secure in hypovolemic burn patients, especially young children. When necessary, it is acceptable to place an intravenous (IV) line through the burn wound.²⁹ Central access is generally required in children with large burn injuries.⁷ The intraosseous route should be used in the unstable child needing fluid therapy in whom rapid vascular access is not easily obtained.

Burns greater than 15% to 20% BSA will produce hypovolemic shock unless appropriately managed with crystalloid

fluid replacement. Burns less than 15% are not associated with massive capillary leak; therefore, formal fluid resuscitation is not required.³⁰ Isotonic saline, most commonly lactated Ringer's solution, is recommended for resuscitation in the first 24 hours after a significant burn.⁷ Lactated Ringer's solution contains physiologic concentrations of major electrolytes. The lactate serves as a buffer, which may lessen the propensity for hyperchloremic acidosis.³⁰ Normal saline, however, is an acceptable alternative. An initial fluid bolus of 20 ml/kg is recommended. Large volumes of fluid are needed, however, for proper resuscitation, because only 20% to 30% of the isotonic fluid remains in the intravascular space.³¹

The initial fluids should not contain potassium, as cell breakdown (common to massive burns) releases a large amount of intracellular potassium. This hyperkalemia could have devastating effects on both the heart and kidneys. Albumin also should be avoided initially, as edema may be increased by albumin use in the first 24 hours because of capillary leak. Once capillary integrity is restored and intravascular volume is replete, colloid may be helpful for volume expansion and preservation of serum oncotic pressure.

Some experts have recommended the use of 3% sodium chloride solution during resuscitation. The theory is that the hypertonic saline might preserve intravascular volume and decrease edema. However, other experts disagree. One particular study found that hypertonic sodium resuscitation was associated with renal failure and death.³²

The Parkland formula³³ and its variations have become the standard method for calculating the initial fluid requirements of severely burned patients. During the initial 24 hours after injury, the patient receives 4 ml/kg/%BSA burn of lactated Ringer's solution in addition to maintenance fluids. Half of this total is given in the first 8 hours after injury, and the remainder is given in the subsequent 16 hours.

It is universally acknowledged that the Parkland formula, while quick and easy to use, underestimates the needs of young children, as it is strictly based on weight. Weight-based formulas are suboptimal because BSA correlates imprecisely with weight in growing children. Using weight-related formulas may lead to the administration of less than maintenance fluids to smaller children. Thus, maintenance fluids should be added to the Parkland calculation for children younger than 5 years.

An alternative is to use a surface area–related formula, such as the one devised by Carvajal.³⁴ The Carvajal formula recommends that, in the first 24 hours, in children less than 5 years old, the following formula be used: 5000 ml/m²/%BSA burn, plus 2000 ml/m². As with the Parkland formula, half of this total is given in the first 8 hours after injury, and the remainder is given in the subsequent 16 hours.

Dextrose

Smaller children (<20 kg) are at risk for hypoglycemia. In cases of documented hypoglycemia, the child should receive a dextrose bolus of 0.5 g/kg. This is most easily accomplished by the administration of 5 ml/kg of a 10% dextrose solution. Euglycemic children less than 20 kg should receive lactated Ringer's solution with 5% dextrose at maintenance rates. The gluconeogenic capacity of older children and adolescents is such that no glucose-containing solutions are usually required during resuscitation.⁷

Environmental

Thermoregulation may be significantly affected due to the profound skin loss in extensive burns. It is important to maintain the body temperature within normal limits. This is especially crucial in infants and small children. In the hypothermic child, active warming should be initiated as soon as possible in an environmentally controlled room. Warming blankets, heat shields, and warm intravenous fluids may be necessary.³⁵

Additional Interventions

Analgesics

Opiates continue to be the mainstay of analgesic therapy in burn patients. Burn patients are exquisitely sensitive to narcotics.²⁹ Basic science studies suggest that systemic opiates (in particular, morphine) have an added effect on burn pain, as inflammatory burn states may lead to an increased expression of peripheral opioid receptors. This enhanced potency of morphine is due to its action on these peripheral opioid receptors.³⁶ Morphine sulfate is most commonly used at 0.1 mg/kg. Multiple doses are often necessary. Side effects of morphine include hypotension and respiratory depression. The IV route is best, as systemic absorption is more variable by intramuscular and oral routes. Importantly, analgesics should be used not only at the initial burn presentation, but also with dressing changes.

Antibiotics

Prophylactic systemic antibiotics are contraindicated in burn care, as their use has been shown to increase the risk of more virulent and resistant organisms.^{29,35,37,38} Antibiotic therapy should be initiated only if the clinical suspicion for an infected burn is high. A progressively expanding burn cellulitis should be treated with topical mafenide acetate and a systemic semisynthetic penicillin to cover for GABHS and *S. aureus*, or a broad-spectrum β -lactam antibiotic if culture results are unavailable.²² Invasive burn wound infections can be life threatening, and generally require treatment with a combination of surgery and antibiotics.²³

Topical antifungal agents (clotrimazole) are used for localized fungal infections, but any suspicion of disseminated fungal infection should be aggressively treated with IV amphotericin B, possibly with the addition of 5-flucytosine.²² Topical acyclovir (5%) may be used in patients with documented localized HSV infections, but similarly, any suspicion of disseminated HSV infection should prompt treatment with IV acyclovir.²² Routine use of topical antibacterials, such as silver sulfadiazine and mafenide acetate, is discussed later.

Nasogastric Tube

A nasogastric tube is usually recommended in children with large burns, as air swallowing and gastric dilation (especially in crying children) are common. Some guidelines recommend that children should be placed on “nothing by mouth” status for the first 24 to 48 hours to avoid complications associated with an intestinal ileus. However, there is evidence that the initiation of enteral feeding immediately after a burn has been shown to be safe and effective in patients with serious thermal injuries.^{39,40}

Bladder Catheterization

Bladder catheterization (with a Foley catheter) is important in severely burned patients to monitor the adequacy of fluid resuscitation. The minimum acceptable urine output should be 1 ml/kg/min. Additionally, male patients with burns near the perineum should have a catheter placed as penile edema may ultimately complicate urination. Importantly, the foreskin should be over the bladder catheter after insertion to prevent the development of paraphimosis.⁷

Peptic Ulcer Prophylaxis

Reduced splanchnic blood flow is a common complication in patients with widespread burns.⁷ Consequently, gastroduodenal ulcers (“Curling” ulcers) are common in these systemically stressed patients. Histamine₂ receptor antagonists (cimetidine, ranitidine, famotidine) are commonly recommended as prophylaxis against these peptic ulcers.

Tetanus Prophylaxis

As burns are tetanus-prone wounds, tetanus immunity must be addressed. In children who have completed their primary series of immunizations, active immunization with tetanus toxoid is indicated, unless one has been administered within the previous 5 years. If the primary series is incomplete, the patient should also receive passive immunization with tetanus immune globulin, especially in deep or heavily contaminated burns. If the immunization status is unknown or questionable, prophylaxis should be empirically administered.

Hyperbaric Oxygen Therapy

Hyperbaric oxygen therapy is frequently used in patients who are victims of smoke inhalation. Its primary purpose is to rapidly clear the blood of carboxyhemoglobin, thus minimizing the risk of permanent neurologic sequelae in patients who have been poisoned with CO. While carboxyhemoglobin levels are important, they cannot be used alone to dictate the need for hyperbaric therapy (see Chapter 143, Inhalations and Exposures).

Steroids

Most experts agree that there is no role for steroid use in the management of burn victims.^{29,41,42} The use of prophylactic steroids increases both infectious complications and mortality. Table 26–5 summarizes the emergency management of the burn patient.

Burn Wound Management

Initial Care

The goal of burn wound management is to reduce the risk of infection while minimizing the likelihood of an adverse cosmetic outcome. Initially, any burnt clothing, debris, and jewelry must be gently removed. The wounds should be cleansed with warmed, sterile normal saline, and then covered loosely with clean sheets.

Escharotomy

Circumferential burns to the chest may interfere with the patient’s ability to ventilate and may require an escharotomy. Circumferential burns of the extremities may warrant escharotomy to prevent distal tissue ischemia. Distal pulses should be monitored with Doppler ultrasound. Surgical consulta-

Table 26–5

Summary Emergency Management of the Burn Patient

Emergency Stabilization (ABCDEs)

Airway

- Assess patency
- Administer oxygen
- Maintain cervical spine immobilization
- Consider early endotracheal intubation with smaller than anticipated tube size based on age

Breathing

- Assess adequacy
- Assist mechanically if necessary
- If smoke inhalation:
 - Consider bronchodilators
 - Monitor arterial blood gas with co-oximetry

Circulation

- Assess integrity
- Establish intravenous access (peripheral/central)
- Give fluid bolus with lactated Ringer’s solution
- Calculate burn depth and body surface area:
 - Lund and Browder chart
 - Rule of nines
 - Palm of hand
- Calculate fluid requirements
 - Parkland formula
 - Carvajal formula

Dextrose

- Check glucose level
- Treat hypoglycemia

Disabilities (Neurologic)

- Evaluate mental status
- Check for smoke-related causes (carbon monoxide, etc.)
- Perform head computed tomography scan if trauma a possibility

Environmental

- Check body temperature
- Maintain euthermia

Exposure

- Evaluate for circumferential burns
- Perform escharotomies when necessary
- Institute initial burn wound management

Additional Interventions

- Removal of rings and jewelry
- Analgesics
- Nasogastric tube
- Bladder catheterization
- Peptic ulcer prophylaxis
- Tetanus prophylaxis
- Hyperbaric oxygen therapy
- Attention to psychosocial needs of patient/family

Disposition

- Admission decision making
- Arrangements for transfer to burn center
- Social services (especially if child abuse concerns)

tion and intervention are mandatory when this is a concern.

Débridement

Loose necrotic tissue should be carefully débrided, using meticulous antiseptic technique, to reduce the risk of infection. One method involves using a saline-soaked gauze to gently wipe away the necrotic tissue of noncontact blisters. One should wipe in parallel to the periphery of the burn’s margins, as opposed to wiping perpendicularly *toward* the margins, in order not to extend the wound further. Figure 26–2 depicts this wound débridement technique. The rest of the burn

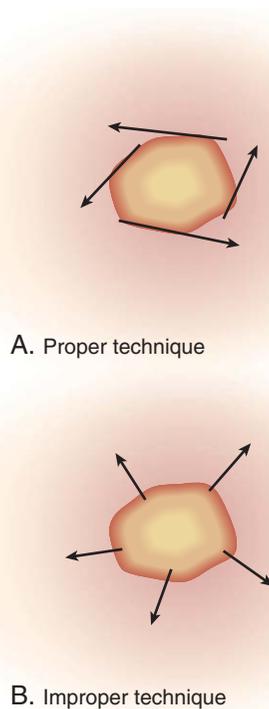

FIGURE 26-2. Wound débridement. **A**, Proper technique: one should débride in parallel to the periphery of the burn's margins. **B**, Improper technique: avoid débriding perpendicularly toward the margins, so as not to extend the wound further.

should also be gently débrided with gauze to remove additional wound debris and exudate. There appears to be no benefit to antimicrobial prophylaxis during débridement in children.⁴³

Controversy still exists over the management of blisters. Many experts prefer to leave blisters intact, débriding only those blisters that have spontaneously broken. It is generally believed that the biologic dressing afforded by the intact blister outweighs other considerations. Others, however, believe that large blisters (>1 to 2 cm) should be broken and débrided.^{35,42} These experts believe that leaving blisters intact may interfere with assessment and with joint mobility.⁴⁴ Still others advocate relieving uncomfortable pressure by aspirating the burn fluid from tense blisters, leaving the epithelium to act as a biologic dressing.^{45,46}

Topical Antibiotics

After the burn has been cleaned and débrided, attention must be given to controlling bacterial density and decreasing the likelihood of a burn wound infection. A number of agents are effective as topical antimicrobials in burn wound care. They are generally divided into potent agents that are designed to prevent burn wound invasion (silver sulfadiazine, mafenide acetate, and silver nitrate), and milder agents (bacitracin, Neosporin, Polysporin, and mupirocin) that are used to treat small or superficial wounds. The more potent agents may delay epithelialization and should be reserved for use in managing more extensive and deeper burns. The milder agents, when used in combination with nonadherent gauze, provide a comfortable, protective environment that promotes epithelialization of the wound.³⁵

Silver sulfadiazine (Silvadene) cream is the most commonly used topical agent. It is bacteriostatic, but poorly diffusible and limited in its penetration of the burn wound. It is painless upon application and has a soothing effect. It should not be used on the face secondary to the risk of skin discoloration. The bacterial spectrum of Silvadene includes *S. aureus*, GABHS, *Escherichia coli*, *Klebsiella* species, *P. aeruginosa*, *Proteus* species, and *Candida albicans*.⁶ Side effects include transient leukopenia (5% to 15%),⁶ rash (5%),⁴² and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency.

Mafenide acetate 5% cream is bacteriostatic, freely soluble, and readily diffuses through burn eschar to the viable tissue interface. This antibiotic also has the broadest spectrum against *Pseudomonas* species and other gram-negative organisms. The principal limitations of this agent are (1) the pain produced when applied to partial-thickness wounds, and (2) the inhibition of carbonic anhydrase that predisposes to the development of metabolic acidosis. Use of this agent is generally limited to wounds with or at high risk for invasive infection.³⁵

Silver nitrate solution (0.5%) is an effective agent, but has decreased in popularity over the past two decades. It is painless upon application, has a wide spectrum of antimicrobial activity, and has no known bacterial resistance. Its use is limited due to its staining, requirement for greater nursing care, and the leeching of electrolytes from the wound.³⁵

Dressings

The use of light occlusive dressings is generally believed to prevent bacterial infection and enhance the rate at which wounds epithelialize. Additionally, optimal dressings should absorb exudates, prevent the wound from further damage, and cause minimal pain upon removal. Many centers use petroleum or mesh gauze as the first layer on the wound. This provides a moist environment that promotes healing, and doesn't stick to the wound upon removal. This gauze is then covered with multiple layers of absorbent padding to better protect the wound from additional trauma.

While not a standard for emergency department use, Biobrane, a bilaminar temporary skin substitute, is sometimes used. This biosynthetic wound dressing is constructed of a silicon film with a nylon fabric partially embedded in the film. The fabric presents to the wound bed a complex, three-dimensional structure of trifilament threads to which collagen has been chemically bound.⁴⁷ One prospective study found that the treatment of partial-thickness burns with Biobrane was superior to topical therapy with 1% silver sulfadiazine.⁴⁸ While different uses have been advocated for this dressing, its use in partial-thickness burns has remained controversial. One of the concerns that has been raised against the use of Biobrane in this setting is infection. Infection rates from 5% to 22.6% have been reported.⁴⁹⁻⁵¹

Disposition

Indications for Admission

It is often difficult to decide the disposition of pediatric burn patients. While many guidelines exist that define specific BSA percentages, as well as wound severity, these alone cannot be the sole determinants. The risk of infection,

cosmetic and functional outcomes, pain control, complexity of wound care, age, associated morbidities, underlying medical conditions, and social concerns all must be factored into this complicated decision. Table 26–6 lists some useful parameters to assist with this decision making.

Indications for Transfer to a Burn Center

Most experts agree that burn centers have improved survival and reduced morbidity in burn patients. Many publications list factors to consider when deciding which children should be transferred to a burn center.⁵² Many of these parallel the indications to admit noted previously. For example, burn patients with preexisting medical disorders often require transfer, as issues related to these disorders could complicate management, prolong recovery, and affect mortality. While trauma is often cited as a reason to transfer, the burned patient initially should be stabilized in a trauma center before being transferred to a burn center. Burned children in hospitals without qualified personnel or equipment should be transferred. Transfer should be considered in all children who will require special social, emotional, or long-term rehabilitative care. Importantly, these factors should be considered as guidelines, rather than rigid protocols.

Out-of-Hospital Care

Emergency Medical Services providers follow many of the management strategies outlined earlier. Most importantly, they must be cognizant of the risk of impending airway compromise; therefore, they must always be vigilant about the need for early endotracheal intubation. Oxygen (100%) should be administered and breathing should be supported, while maintaining cervical spine immobilization as necessary. At least one, but preferably two peripheral IV lines should be started in patients with significant burns. Lactated Ringer's solution should be infused, usually in boluses of 20 ml/kg. Great care must be taken to ensure that the patient's body temperature is maintained, as hypothermia is an important problem in young children with large burns.

Discharge Care**Medications**

Acetaminophen or ibuprofen are commonly used analgesics at discharge. Narcotics, such as codeine or hydrocodone, however, may be necessary in cases of larger, painful burns. As burns are pruritic, medications such as hydroxyzine, diphenhydramine, and newer antihistamines may be helpful, especially when used in conjunction with moisturizing creams or lotions.³⁵

Wound Infection

The parents should be advised to return with the patient if there are signs of infection: redness, swelling, tenderness, and purulent discharge. Of course, many of these signs are normal in the course of burn healing, so it is not always easy to distinguish a burn infection from a normally healing burn wound. It is common for Silvadene-treated burns to form a greenish serous drainage that is easily mistaken for purulence. Furthermore, while many associate the development of a fever with an infection, it is important to remember that burn patients may develop low-grade fevers a day or two after the burn—even in the absence of infection.

Wound Care

The parents should be instructed to keep the wound clean and dry. They can clean the wound with soap and lukewarm water. Some recommend saline solutions. The parents may débride loose nonviable tissue, and wash off accumulated exudates and topical antibiotic residues.

After the wound has been cleaned, topical antibiotic ointments or creams may be applied. These topical antibiotics, typically Silvadene or Polysporin, are usually applied twice daily until the wound has completely re-epithelialized. This process usually takes 5 to 10 days for superficial wounds and 10 to 14 days for medium-depth wounds.³⁵ It is important to use clean, but not necessarily sterile technique when performing burn wound care at home.⁵³

The wound is dressed with a light, nonadherent dressing following the application of the topical antibiotic. Most experts recommend twice-daily dressing changes.⁵³ On smaller wounds, however, once daily should suffice.³⁷

Follow-up Care

Follow-up care of all partial- and full-thickness burns is extremely important. The wound should be examined by a clinician every 2 to 3 days. The parents and patient should be instructed to return 4 to 6 weeks later to assess for hypertrophic scar and pigment changes. Patients should also be instructed to avoid ultraviolet light exposure (i.e., sunlight) during the time of wound maturation because the wound may become permanently hyperpigmented. The use of a sun block (>30 sun protection factor) is recommended for at least 1 year for any patient whose wounds are exposed to sunlight.³⁵

Approach to the Child and Family

An important component to the management of the severely burned child centers around the psychosocial trauma that this injury has on the family. Parents may be experiencing

feelings of guilt, anger, anxiety, and fear. These feelings are often sensed by the child. Gentle reassurance in a calm, quiet manner will assist in soothing those involved.

The age of the child will dictate the specific approach. For the child younger than 2 years, communication is most effective through the parents. Children of this age have little understanding of what is happening, but usually feel a sense of security when a parent is present. For the 2- to 7-year-old child, careful reassurance and explanation in words that the child can understand are vital, as these children often believe that injury, discomfort, and painful procedures are a punishment for bad behavior. For the 7- to 11-year-old, clear, simple explanations are required. Children who are ill or in pain often regress. They should be reassured that it is acceptable to cry when they feel pain, otherwise they might feel ashamed and uncomfortable. Above 11 years, children are able to comprehend the outcome of their injuries, and will want precise information, particularly regarding potential scarring.⁵⁴

The parents, also, will want clear information about what to expect. Parents often feel that they lose control of their child's well-being in the clinical environment. Including them in the care of their child, ensures partnership, and helps to give them control in the child's care.

Summary

Prognosis

A study looking at burn survival rates in children from 1974 to 1980, versus from 1991 to 1997, concluded that survival rates after burns have improved significantly for all children. Furthermore, even children with large burns should survive today.⁵⁵ Importantly, the large majority of those who survive serious burns have favorable long-term outcomes.⁵⁶⁻⁵⁹ Even those who survive massive injuries can be expected to have a satisfying quality of life.⁶⁰⁻⁶³ Advances in resuscitation, intensive care, mechanical ventilation, vascular access, antimicrobials, analgesia, nutrition, surgical intervention, and wound care have all contributed to improvements in survival and quality of life.⁵⁵

Prevention

During the past two decades, fire-related deaths have declined. This is due to improved fire-fighting techniques, enhanced emergency medical services, and widespread educational programs aimed at both children and adults.⁶⁴ For example, the use of home smoke detectors has dramatically reduced the severity of burn injuries, resulting in an estimated 80% reduction in mortality and a 74% decrease in injuries from residential fires.^{64,65} The use of flame-resistant childhood sleepwear has further contributed to these reductions.

Lowering the temperature of the water on the thermostats of water heating units has also made a significant impact. The contact time for a scald burn drops significantly as water temperature rises above 120° F. For this reason, it is recommended that hot water heaters be set at or below 120° F. A water temperature of greater than 140° F (common in hot water heaters) causes severe burns in less than 5 seconds in children.⁶⁶ The bath water temperature should always be checked first by an adult.

Parents and caregivers should be warned of the common summertime burn dangers from fireworks, barbecue grills, and campfires. Even excessive sun exposure can lead to sunburns with serious consequences. Winter burn threats include wood stoves and electric and kerosene space heaters.

Advances in our abilities to evaluate patients and manage their burn-related morbidities have led to dramatic improvements in the overall care of burned children. Nevertheless, prevention remains our first defense against these tragedies. Research should continue to focus on creative new strategies to ensure the safety of our children.

Chapter 27

Neurovascular Injuries

Isabel Barata, MD

Key Points

Emergency department management of vascular or nerve injuries require a meticulous and expeditious workup in order to prevent long-term morbidities.

Blunt and penetrating extremity injuries require different clinical approaches.

Diagnostic studies to evaluate the presence of a vascular or nerve injury should not delay the transfer of a patient to the operating room.

Introduction and Background

Traumatic injury disproportionately affects the young and is the leading cause of death and disability in the pediatric age group; however, vascular injuries in pediatric patients are rare. The majority of vascular injuries that occur in children are extremity injuries related to fractures¹ or broken glass.² Motor vehicle accidents, heavy machinery–related injuries, and falls cause a small proportion of blunt vascular injuries secondary to decelerating or crushing forces. Vascular injuries are usually caused by penetrating trauma from glass, bullets, and knives. Penetrating peripheral vascular injuries secondary to gunshots or stab wounds are more common in males than in females.

Recognition and Approach

Blunt trauma causes vascular injury due to either tensile or shear strain. Tensile strain leads to longitudinal forces causing vessel or intimal rupture, which exposes flowing blood to a large surface area rich in thrombogenic substances, resulting in a local thrombosis. Shear strain is secondary to lateral forces acting on the vessel wall and can result in partial or complete transection.

Penetrating injuries cause damage to vascular structures by direct injury secondary to stab or low-velocity missile wounds and/or high-velocity injury. Velocity and mass will influence the missile's destructive power. These types of injuries can cause severe damage, even in the absence of direct vascular trauma. Direct vascular injury can lead to partial or

complete transection, contusion, laceration, and arteriovenous fistula formation. Indirect injuries can be more subtle in presentation and include vessel spasm, external compression, mural contusion, thrombosis, and aneurysm formation.

Peripheral vascular injuries to extremity tissues can be tolerated without ischemia when collateral vascular flow is present and adequate. This may not always be the situation, depending on the mechanism, location, and extent of injury and on the patient's baseline circulation to the involved extremity. In general, extremity tissues tolerate 4 to 6 hours of ischemia before irreversible injury occurs.

Evaluation

Vascular and Nerve Injury

Upper Extremity Injuries

FRACTURES

Approximately 75% of all fractures sustained by children occur in the upper extremities and frequently occur during a fall with an outstretched hand. Most of these injuries involve the wrist and forearm. The elbow accounts for approximately 3% to 7% of all fractures in children.³ The majority of elbow fractures in children are supracondylar fractures of the humerus⁴ (Fig. 27–1).

Elbow fractures are challenging due to the high potential for limb-threatening damage to neurovascular structures. The neurovascular examination is often difficult in a crying and frightened child; however, it must be done before the child is sent for radiographs. Pulses, capillary refill, and skin temperature of the extremity being evaluated should be checked. A brief overview of the sensorimotor evaluation of the hand is outlined in Table 27–1.^{5,6} No one test has been accepted as the standard procedure for the evaluation of sensation. The various sensory tests available for patient assessment will yield different information regarding the integrity of the quickly and slowly adapting sensory receptors. Tests such as provocative maneuvers and sensory thresholds (cutaneous and vibration) will be more sensitive in the evaluation of patients with nerve compression, and will yield better functional information in patients with nerve injury. In adult patients, one of the preferred methods to assess sensation is two-point discrimination, which may be of limited value in children depending on the age and degree of cooperation. When diagnosis of vascular trauma is uncertain, the following signs and symptoms may indicate peripheral ischemia:

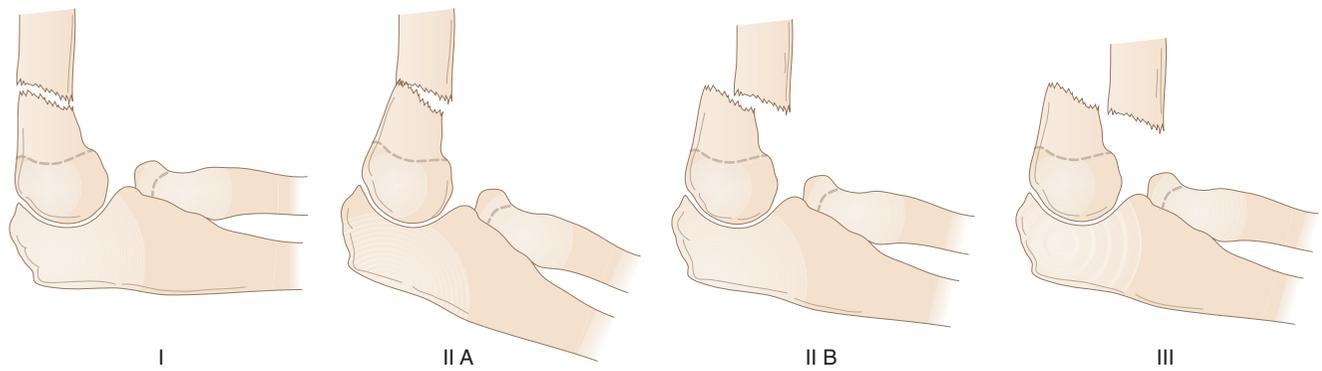

FIGURE 27-1. Modified Gartland grading of supracondylar fractures of the humerus in children.

Table 27-1 Neurovascular Examination of the Upper Extremity		
	Sensory	Motor
Radial nerve	Dorsal thumb web space	Raise the thumb (give “thumbs-up” sign) or raise the wrist
Median nerve	Volar tip of the index finger	Flex the thumb or index finger (make an “O” with the thumb and index finger)
Ulnar nerve	Volar tip of the lateral border of the small finger	Move the index finger medially and laterally, or flex the tip of the fifth finger

Table 27-2 Supracondylar Fracture Displacement Direction and Associated Nerve Injuries	
Fracture Displacement	Nerve Injury (Most Common)
Posterolateral	Median nerve: Up to 80% Anterior interosseous nerve
Posteromedial	Radial nerve
Anterolateral	Ulnar nerve

pain, pallor, paresthesias, pulselessness (palpable pulse does not exclude diagnosis), prolonged capillary refill, and paralysis (the 6 Ps). Increased pain and decreasing sensation are cardinal signs that a compartment syndrome is beginning.⁷

Vascular injury to the brachial artery and neural injury to the median, radial, and ulnar nerves can occur from stretching, entrapping, or disrupting the neurovascular structures. The incidence of neural and vascular injuries associated with humeral supracondylar fracture has been reported as nerve injury only in 6% to as high as 16% of patients,^{8,9} vascular compromise only in 2.9% of patients, and combined nerve and vascular injury in 2.9%.⁹ Median nerve injuries accounted for 58.9% of nerve injuries, followed by radial (26.4%) and ulnar (14.7%).⁹ The supracondylar fracture of the humerus in children can be due to an extension-type fracture, in which the condylar complex shifts posterolaterally or posteromedially, or, in a smaller number of cases, a flexion-type fracture in which the condylar complex shifts anterolaterally.¹⁰ Posterolateral fracture displacement correlates with median nerve and vascular compromise.¹¹ Up to 80% of median nerve injuries involve the anterior interosseous nerve.^{9,12-14} Posteromedial fracture displacement correlates with radial nerve injury. Anterolateral fracture displacement in a flexion-type fracture is more frequently associated with ulnar nerve damage^{15,16} (Table 27-2).

Secondary injuries can also occur in two primary ways: (1) during manipulation of the fracture, the nerves and/or vessels can be stretched or entrapped between the fracture ends; and (2) treatment in the hyperflexed position (used when only closed reduction is performed) can compromise the vascu-

larity of the forearm, eventually resulting in Volkmann’s contracture. The rate of iatrogenic nerve injury has been reported to be 2% to 3%.¹⁷ The radial pulse is reported to be absent before reduction in 7% to 12% of all fractures and in up to 19% in displaced fractures. After reduction, the pulse is restored in 80% of cases. Injury to the nerves can also exist due to swelling of the tissues around the elbow irrespective of the treatment.

A wide variety of treatments has been recommended for displaced supracondylar fractures, ranging from nonoperative treatment through closed reduction and percutaneous Kirschner wire transfixation to open reduction with more or less stable internal fixation. The management is determined by the difficulty in obtaining and maintaining reduction and by the involvement of neurovascular structures.

BLUNT INJURIES

Blunt extremity vascular injury associated with blasts (e.g., fireworks) can be associated with fractures, amputations, dislocations, and digit neurovascular injury.¹⁸

PENETRATING INJURIES

A study of penetrating injuries of the upper extremity in which the mechanism of injury was stabbing in 39%, bullet in 51%, pellets in 4%, and dog bites in 6% found that the proximity of the injury to neurovascular bundles was a poor predictor of arterial injury, and long-term morbidity was mainly associated with nerve injuries.¹⁹ Injuries to the upper extremity due to gunshot wounds are common.²⁰ The extent of soft tissue disruption and the type of fracture depends on the energy of the gunshot. Injuries resulting from low-energy gunshot wounds are more likely to have less soft tissue, bone, and neurovascular disruption. High-energy gunshot wounds cause more soft tissue disruption, bone loss, complex comminuted and unstable fractures, and neurovascular injuries.²¹

In high-energy gunshot-induced fractures, the first choice for initial stabilization is the use of external fixation, providing stability for vascular repair and access to the wound for débridement and subsequent soft tissue surgery.²¹

Small laceration injuries to the upper extremity have the potential to conceal an underlying deep injury. In patients with injuries from glass and knife lacerations, it was found that extensor tendons were more commonly injured and that patients had the following injuries: a single tendon injury in 92.5%, a single deep structure injury in 59.3%, a single nerve injury in 18.7%, a single artery injury in 14.9%, and a combination of tendon, nerve, and artery injuries in up to 14.9%.²²

Lower Extremity Injuries

Fractures of the femoral supracondylar region are common in adolescents and middle-aged adults. Most often they are the result of high-energy blunt trauma such as motor vehicle collisions or industrial injuries. These fractures are usually associated with injuries to the neurovascular bundle. Blunt vascular injuries in the lower extremities occur most commonly in the anteroposterior tibial arteries.²³ The neurovascular injuries are even more complex when they are the result of penetrating trauma such as missile injuries.^{24,25} Peripheral nerve injuries can result from either blunt or penetrating trauma with resulting injuries of the femoral, sciatic, peroneal, or tibial nerves. On physical examination, patients with femoral neuropathy demonstrate weakness on knee extension and sensory deficit in the area just superior and medial to the patella, with diminished or absent knee deep tendon reflexes. Findings in sciatic neuropathy are weakness of the hamstring muscle and all muscles below the knee, sensory loss in the posterior thigh and most of the leg below the knee, and absent or diminished ankle deep tendon reflexes. Peroneal nerve injuries are associated with weakness of the extensor hallucis longus muscle, with inability to dorsiflex the foot or move the toes, and sensory loss in the first toe and first web space (Table 27–3).

FRACTURES

Traumatic forces applied to the immature knee result in fracture patterns different from those in adults. Trauma that would result in a ligament injury in an adult is likely to cause in a child or adolescent an injury to the growth plate (physis) as well as the adjacent areas of the femur, tibia, or patella. The relative abundance of cartilage in the knee of the growing child may make the diagnosis of certain injuries more challenging. Certain fractures, such as hyperextension injuries to

the distal femoral or proximal tibial epiphysis, or displaced tibial tuberosity fractures, may be especially susceptible to neurovascular problems.²⁶ Important neurovascular structures are in close proximity to the knee joint. The femoral artery moves from medial to posterior in the popliteal fossa as it courses through the adductor canal just proximal to the distal femoral metaphysis. The popliteal artery bifurcates just proximal to the articular surface of the knee. The posterior tibial nerve lies adjacent to the popliteal artery. The peroneal nerve courses around the lateral aspect of the fibular head.

Distal femoral fractures account for approximately 7% of all physeal fractures.²⁷ A common mechanism of injury is hyperextension causing an anterior displacement of the epiphysis. Displacement of the fracture in the sagittal plane may be associated with neurovascular injury in the popliteal fossa and instability on closed reduction. Physeal fracture displacement in the coronal plane is not associated with other injuries, and the joint may be stable after closed reduction.²⁸ Clinically, the thigh may appear angulated and shortened compared with the contralateral thigh. The pain, knee effusion, and soft tissue swelling usually are severe.

The Salter-Harris (SH) classification system (Fig. 27–2) provides general guidelines regarding the risk of growth disturbance, but there are no clinical methods for quantifying the true extent of physeal damage in an acute injury. Hemiarthrosis may be more severe in SH III and SH IV fractures, and vascular examinations may reveal diminished or absent distal pulses. Neurologic symptoms also may be evident dis-

Table 27–3 Neurovascular Examination of the Lower Extremity

	Sensory	Motor
Femoral nerve	Area superior and medial to the patella	Weakness on knee extension Diminished or absent knee deep tendon reflexes
Sciatic nerve	Posterior thigh and leg below the knee	Weakness of the hamstring muscle and all muscles below the knee Absent or diminished ankle deep tendon reflexes
Peroneal nerve	First toe and first web space	Inability to dorsiflex foot and move toes

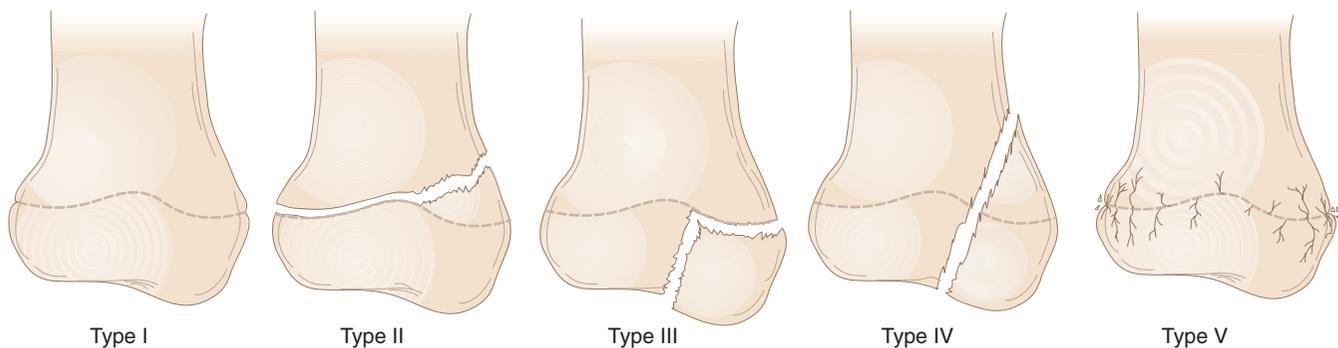

FIGURE 27–2. Classification of epiphyseal fractures according to the Salter-Harris system.

tally due to disruption of the posterior tibial and common peroneal nerve distributions.

Treatment for distal femoral physeal fractures varies according to severity of injury. Displaced SH I or SH II fractures are treated with closed reduction and splinting with a hip spica cast. SH III and SH IV injuries usually require anatomic reduction, which cannot be obtained with closed reduction, and are very often unstable. Operative treatment is required since even slight residual displacement can result in formation of a bone bar that causes limb-length discrepancy and angular deformity. Whereas fractures involving the tibia and fibula are the most common lower extremity pediatric fractures, those involving the proximal tibial epiphysis are among the most uncommon, comprising less than 2% of all physeal injuries,²⁹ but have the highest rate of complications. The injury is usually due to anterior-posterior forces with increased risk of neurologic and/or vascular compromise, with the potential for the development of a compartment syndrome as well. When displacement occurs, the popliteal artery is vulnerable. At the tibial metaphysis, the artery is just posterior to the popliteus muscle. SH I injuries occur at an earlier age (average age 10 years). Half of SH I injuries are nondisplaced and diagnosed by stress radiographs only. SH II are the most common type, and one third are nondisplaced. SH III injuries are often associated with lateral condyle fractures or medial collateral ligament injuries. SH IV injuries are often associated with angular deformity. SH V injuries are usually diagnosed retrospectively. Anterior physis closure can cause significant genu recurvatum. Complications of these injuries include vascular insufficiency and peroneal nerve palsy.²⁸

PENETRATING INJURIES

In a study of penetrating injuries, caused by gunshot wounds in 58.3% of patients and fragments of mines or other explosive devices in 41.7%, it was found that 18% of the injuries were supracondylar fractures, with associated neurovascular bundle injuries in 38% and vascular injuries in 34%. Patients required external fixation in 86% of cases and primary reconstruction of large blood vessels in 32% of limbs.²⁵ A similar study looking at injuries resulting from infantry weapon missiles in 70.7% of patients and explosive devices in 29.3% found that associated neurovascular bundle injuries were present in 26.8% of patients.²⁴

Nerve and tendon lacerations of the foot and ankle region are relatively common. Acute nerve and tendon injuries should be repaired with appropriate techniques at the time of initial wound exploration. Primary nerve repair may help minimize the risk of painful neuroma formation; primary tendon repair can lead to better functional results than delayed repair.³⁰

Compartment Syndrome

Acute compartment syndrome is a potentially devastating condition in which the pressure within an osseofascial compartment rises to a level that decreases the perfusion gradient across tissue capillary beds, leading to cellular anoxia, muscle ischemia, and death (see Chapter 22, Compartment Syndrome). A variety of injuries and medical conditions may initiate acute compartment syndrome, including fractures, contusions, bleeding disorders, burns, trauma, postischemic swelling, and gunshot wounds. Diagnosis is primarily clinical (pain out of proportion to the injury or

physical findings), supplemented by compartment pressure measurements. Nerve blocks and other forms of regional and epidural anesthesia may contribute to a delay in diagnosis. Basic science data suggest that the ischemic threshold of normal muscle is reached when pressure within the compartment is elevated to 20 mm Hg below the diastolic pressure or 30 mm Hg below the mean arterial blood pressure.³¹ On diagnosis of impending or true compartment syndrome, immediate measures must be taken. Complete fasciotomy of all compartments involved is required to reliably normalize compartment pressures and restore perfusion to the affected tissues.

Recognizing compartment syndromes requires having and maintaining a high index of suspicion, performing serial examinations in patients at risk, and carefully documenting changes over time. In a retrospective study of upper extremity fasciotomy at a level I trauma center, it was found that the mechanism of injury was penetrating trauma (gunshot wounds in 37% and stab wounds in 11%), blunt or crush in 33%, and burns in 18% of cases. Fifty-six percent of patients had vascular injuries and 33% of patients had fractures. The decision to perform fasciotomy was clinical in 75% of patients, and only 22% of patients had compartment pressures measured (range, 40 to 87 mm Hg; mean, 52).³²

Thoracic/Abdominal Injuries

Pediatric truncal vascular injuries are rare, but the reported mortality is high (35% to 55%) and similar to that in adults.³³ Thoracic injuries are primarily due to blunt rupture, which accounts for 85% of cases, 75% being motor vehicle collision related.³⁴ In contrast, penetrating thoracic injuries are rare in children less than 13 years old.³⁵ The most common thoracic vascular injury is to the aorta. Studies have shown that concomitant injuries such as traumatic brain injury, pulmonary contusion, rib fractures, hemothorax, cervicothoracic spine injury, femur fracture, and other orthopedic injuries occurred with 83% of thoracic aortic injuries and multiple vascular injuries occurred in 25% of cases.³² Abdominal vascular injuries were primarily due to a penetrating mechanism, and the vessel most commonly involved was the inferior vena cava, followed by the aorta and less commonly the iliac artery/vein, superior mesenteric artery/vein, hepatic vein, portal vein, splenic artery/vein, and renal artery/vein.³³ Concomitant injuries associated with abdominal vascular injuries included small bowel, spleen, pancreas, large bowel, stomach, duodenum, liver, kidney, bile duct, bladder, diaphragm and orthopedic injuries. The survival and subsequent complications of patients with vascular injuries, regardless of which body cavity or vessel was injured, were related to the initial hemodynamic status. Patients presenting with blood pressure of less than 90 mm Hg had 100% mortality rate, and all patients with blood pressure greater than 90 mm Hg survived.^{33,36} For further information on specific evaluation and management, see Chapter 24 (Thoracic Trauma) and Chapter 25 (Abdominal Trauma).

Neck

Vascular injuries of the neck are not as common in children as in adults; however, a delayed diagnosis of injury to a major cervicothoracic vessel from blunt trauma may cause significant adverse sequelae. The presence of cervicothoracic “seat belt sign” has been reported in the adult population to be

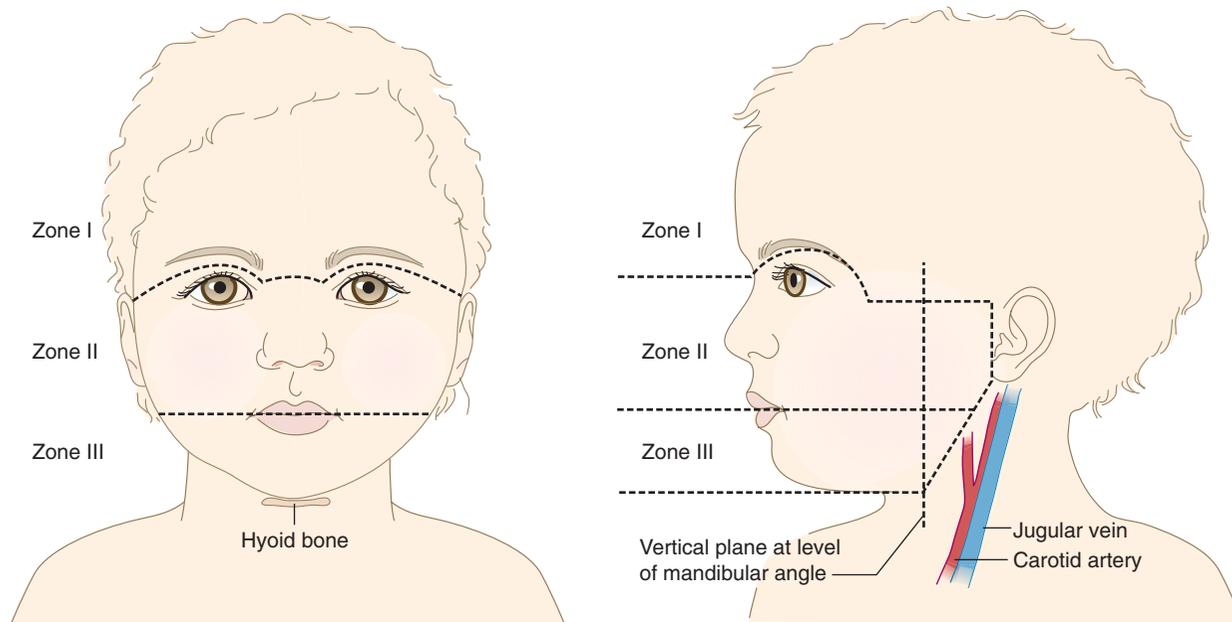

FIGURE 27-3. Anatomic divisions of the face into three areas for penetrating injuries: Zone I, above the angle of the mandible to the base of the skull; Zone II, from the angle of the mandible to the cricoid; and Zone III, below the cricoid to the suprasternal notch/clavicles.

associated with blunt vascular injury in anywhere from 0.24% to 3% of cases.^{37,38} The presence of vascular injury was strongly associated with a Glasgow Coma Scale score less than 14, an Injury Severity Score greater than 16, and the presence of a clavicle and/or first rib fracture in adult patients. Pediatric patients have a higher incidence of seat belt sign as compared to adult patients; however, vascular injuries and cervical spine fractures are rare.³⁷

Penetrating neck trauma in children may lead to potentially life-threatening injuries. Several studies of penetrating trauma to the head and neck in children have found that the risk for vascular and neurologic injuries is high.^{33,39,40} The most commonly affected vessel is the carotid artery, followed by the vertebral artery, internal jugular vein, and facial artery. The immediate threats to life with neck injury are loss of airway due to expanding hematomas or laryngotracheal injuries, massive arterial bleed from neck or associated mediastinal/chest bleed, associated tension pneumothorax, and disruption of cerebral perfusion resulting in a cerebrovascular accident. The pediatric approach to patients with neck injuries emphasizes the selective approach to neck exploration.³⁹ Hemodynamically unstable patients, patients with expanding hematomas, air bubbling from a wound, or respiratory distress, and patients with suspected tracheal or esophageal injuries need emergency surgical exploration. Children who are hemodynamically stable should have an appropriate preoperative diagnostic evaluation followed by clinical observation. Nonoperative observation of penetrating zone II neck injuries (Fig. 27-3) is safe if active observation can be performed and the facilities for immediate operative intervention are available.^{41,42}

Diagnostic Evaluation

Extremities

Careful neurologic (Table 27-4; see also Table 27-1) and vascular evaluation is important since many nerves and

Table 27-4 Orthopedic Injuries and Associated Nerve Injuries

Orthopedic Injury	Nerve Injury
Elbow supracondylar fracture	Median, radial, or ulnar
Acetabulum fracture	Sciatic
Hip dislocation	Femoral
Femoral shaft fracture	Peroneal
Femoral distal physeal fracture	Tibial or peroneal
Knee dislocation	Tibial or peroneal
Proximal tibial physeal fracture	Peroneal

arteries run within the same bundle. If a peripheral nerve injury is present, there is a good chance that the artery is also injured. Physical examination, as already mentioned, should look for the 6 Ps. However, the physical examination alone is often inadequate for predicting arterial trauma. Patients with a history of severe hemorrhage at the scene, diminished or unequal pulses, nonpulsatile hematoma, and decreased two-point discrimination in an anatomic nerve distribution should have a Doppler examination for pulses and arterial pressure index (API). The API can be used as a screening tool for clinically significant arterial compromise.⁴³⁻⁴⁶ It is obtained by measuring systolic blood pressure in the injured and uninjured extremity and calculating brachial-brachial or ankle-ankle blood pressure ratios to detect penetrating vascular injury.⁴³⁻⁴⁵ It can also be used in patients with blunt vascular injury.^{43,46} If none of the hard signs of vascular injury, such as pulsatile hemorrhage, a palpable thrill or audible bruit, or a pulseless limb, is present, the cutoff for imaging is an API less than 0.9 between sides, which has a sensitivity of 95% to 97% and a negative predictive value of 99%.⁴³⁻⁴⁵ This ratio is only useful for injuries proximal to the elbow or knee, as distal injuries do not require repair if hard signs are absent due to division of the blood supply

into two main arteries with collateralization. Also, an API may be difficult to determine in certain injuries that preclude cuff placement at the wrist or ankle or in patients with hypovolemia. The API combined with physical examination was used in a study of penetrating extremity trauma to decide which patients needed angiography. In this study, 4% of patients with hard signs of vascular injury went to the operating room, 17% without vascular compromise underwent operative procedures or were admitted for other injuries, 23% with nonproximity wounds were discharged, and 55.7% with a negative physical examination and normal API were discharged from the emergency department. The authors concluded that angiography is only indicated for symptomatic patients or asymptomatic patients with abnormal APIs.⁴⁵ Also, the API can be used in patients with blunt trauma; an ankle-brachial index less than 0.9 suggests vascular injury.⁴⁶

Plain radiographs help diagnose fractures, foreign bodies, or missiles that may be responsible for neurovascular compromise. If plain radiographs fail to reveal a fracture, a stress radiograph, computed tomography scan, or magnetic resonance imaging study may help to establish the diagnosis.

Duplex ultrasonography images the vessel and measures blood flow and velocity. Color flow duplex scanning has been shown to be useful postoperatively to manage children who have undergone various procedures to establish a radial pulse after type 3 supracondylar fractures of the humerus.⁴⁷ It is a noninvasive alternative to angiography in monitoring occult injuries. It may be particularly advantageous in small children since it can be performed serially at the bedside; however, it is an operator-dependent test.

Digital subtraction angiography is more sensitive than angiography in detecting extravasation of contrast material⁴⁸; however, it is very sensitive to motion artifact. It involves manual contrast injection followed by immediate radiography.⁴⁹ It is rapid and accurate, and does not require transportation of an unstable patient to an angiography suite. Digital subtraction angiography is currently used in young children, as formal angiography is difficult to obtain in an uncooperative patient.

Multidetector-row helical computed tomographic arteriography (MDCTA) is emerging as a new way to study arterial anatomy. It is noninvasive and allows evaluation of different body areas simultaneously. In one study of adult patients, MDCTA adequately demonstrated the nature and location of all arterial injuries when compared with conventional arteriography or surgical exploration.⁵⁰ MDCTA is a reliable technique for the detection and characterization of traumatic extremity arterial injuries in adult patients; however, it has not been studied in children.

Angiography in pediatric patients under 5 years of age poses the risk of iatrogenic injury due to the small caliber of the vessels. In addition, arterial spasm is more common in the pediatric patient and can complicate the use of angiography. Therefore, angiography should be reserved for patients with suspected arterial injury with an equivocal vascular examination (decreased pulse, abnormal API, abnormal ankle-brachial index, and bruits).⁵¹ Patients with obvious vascular injuries (bleeding or ischemia) should go to the operating room.

In summary, in the evaluation of blunt or penetrating vascular injury of the extremity, the following approach is

indicated. If the patient has hard signs of vascular injury, such as pulsatile hemorrhage, an expanding hematoma, a palpable thrill or audible bruit, or a pulseless limb, the patient requires immediate surgical exploration and vascular repair. Patients with no hard signs but either soft signs (e.g., history of large blood loss, decreased two-point discrimination, decreased or unequal pulses, and nonpulsatile hematoma) or injuries that are known to be associated with a high incidence of arterial damage should be screened with an API. If the API is greater than 0.9, a serial clinical evaluation should be performed. If the API is less than 0.90, further evaluation is indicated with either duplex ultrasonography or MDCTA, if studies show the latter evaluation to be useful in children. If these diagnostic tests are abnormal, then angiography is indicated. In patients with low likelihood of vascular injury (proximity injury, penetrating wound in proximity to vascular structures without clinical findings to suggest vascular compromise), duplex ultrasonography follow-up may be used.

Compartment Syndrome

If the history and physical examination suggest compartment syndrome, an orthopedic consultation should be obtained, and compartment pressures measured with commercially available monitors. The patient should be carefully followed with serial examinations and pressure measurements (see Chapter 22, Compartment Syndrome).

Neck

Traumatic injury to the major vessels of the head and neck can result in potentially devastating neurologic sequelae. Carotid duplex ultrasound is a noninvasive, rapid screening test for arterial injury. Conventional angiography has been the primary imaging modality used to evaluate these often challenging patients with both blunt neck trauma and penetrating wounds in zone I or zone III (see Fig. 27–3), carotid bruit, large hematoma, and suspected arterial injury. The absence of hemorrhage, expanding hematoma, bruit, thrill, or neurologic (hard signs) deficit reliably excludes surgically significant vascular injuries in penetrating zone III neck trauma, suggesting that angiography is not necessary.⁵² Hard signs in stable patients should mandate angiography because these vascular injuries may be amenable to endovascular therapy.⁵² Advances in cross-sectional imaging have improved the ability to screen for these lesions, which have been found to be more common than previously thought.⁵³ MDCTA screening increases the detected incidence of blunt vascular neck injury eightfold, with rates similar to angiography-based screening protocols. MDCTA screening significantly decreases blunt vascular neck injury–related morbidity and mortality in an efficient manner, underscoring its utility in the early diagnosis of this injury.⁵⁴ Other studies of blunt and/or penetrating neck injuries showed that MDCTA is adequate for the initial evaluation and triage of patients to conventional angiography or surgery for appropriate treatment, and as a guide to conservative management when appropriate.^{55,56}

In summary, if hard signs of vascular injury are present, the unstable patient requires operative management and the stable patient angiography. If the patient does not have hard signs of vascular injury, then MDCTA can be used as screening tool to guide further evaluation and intervention.

Management

After initial stabilization, a more detailed secondary evaluation is conducted to assess for vascular injury. Fractures are splinted and dislocations reduced since anatomic repositioning and splinting may help restore circulation in dislocations or fractures. If penetrating injuries, particularly high-velocity injuries, are near major vascular structures, the clinician should assume there is damage to those structures. It is important to control hemorrhage with direct pressure; however, blindly clamping a blood vessel should be avoided. Vascular status must be frequently reassessed and popliteal artery injuries carefully monitored because of minimal collateral circulation present in the lower extremity. Obvious vascular injury with evidence of ischemia is an indication for emergent surgical exploration. Prompt consultation with the trauma team is routine at most major urban trauma centers. If isolated peripheral vascular injury is present, the vascular surgeon should be consulted early in the management of the patient. Also, early intravenous antibiotics and tetanus immunization (if indicated) should be provided. If surgical consultation and appropriate diagnostic evaluation tools are not available at the primary institution, the patient must be transferred as quickly as possible after stabilization.

Summary

The goals in management of children with neurovascular injuries are stabilization of the patient and minimization of ischemic time. A thorough neurovascular examination is more difficult in young children. However, it should be performed and carefully documented. Children have a higher risk of developmental abnormalities secondary to ischemia. Prompt consultation, early intravenous antibiotics, and tetanus immunization if indicated are also important aspects of management. Prognosis depends upon ischemic time and number and extent of associated injuries. Associated nerve damage occurs in a large percentage of vascular injuries; 45% of those result in permanent deficits. After initial stabilization, if surgical consultation is not available, the clinician should arrange for transfer.

Apparent Life-Threatening Events

Andrew DePiero, MD

Key Points

The term *apparent life-threatening event* does not refer to a single diagnosis, but identifies a heterogeneous group of conditions with a common clinical presentation.

Potentially life-threatening conditions may present as apparent life-threatening events.

Infants who have experienced an apparent life-threatening event do not usually appear ill on presentation to the emergency department.

There is no standardized approach to the emergency department evaluation or management of infants who have experienced apparent life-threatening events.

Introduction and Background

Infants commonly present to the emergency department (ED) for evaluation of a possible apparent life-threatening event (ALTE). The term *apparent life-threatening event* does not refer to a single diagnosis, but identifies a heterogeneous group of conditions with a common clinical presentation. A formal definition from the National Institutes of Health in 1986 defined an ALTE as “an episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking or gagging. In some cases the observer fears that the infant has died.”¹ The term *apparent life-threatening event* replaces the previously used terms, “aborted crib death” and “near-miss SIDS,” to avoid implying a close association with sudden infant death syndrome (SIDS).¹

Despite this consensus definition of ALTE, controversy remains. Varying definitions lead to heterogeneity in clinical studies. Varying upper limits on age have been used. There are no generally accepted criteria for either the general appearance or the clinical stability of infants suspected of having experienced an ALTE. Some have proposed that the definition of ALTE be amended to include the lack of obvious

physical examination findings.² An infant who is in moderate respiratory distress may fit some definitions of ALTE, whereas only well-appearing infants with an entirely normal physical examination fit other definitions. Practitioners and researchers continue to struggle with what constitutes an ALTE (Table 28–1). Substantial variability exists with respect to age and clinical presentation. The absence of a reproducible, widely accepted clinical definition complicates any interpretation of the existing literature on this topic. Therefore, basing clinical practice on available evidence is problematic. Nonetheless, the varied definitions of ALTE are sufficiently similar to offer information on which to base a reasonable approach to these infants when they present to the ED.^{3–7}

Recognition and Approach

ALTEs are relatively uncommon. Limited epidemiologic data suggest the incidence is between 0.6 and 2.5 per 1000 live births.^{7,8} Historically, ALTEs were thought to be episodes that would have resulted in SIDS if someone had not intervened. The link between SIDS and ALTEs is unclear. In particular, the “back to sleep” campaign aimed at increasing the number of infants placed supine to sleep appears to have decreased the incidence of SIDS, but not ALTEs.⁹

Clinical Presentation

An ALTE is most often identified from historical data provided by caregivers. Cyanosis, apnea, and difficulty breathing are the most frequently reported symptoms.^{10,11} Other reported symptoms include abnormal movements, loss of consciousness, vomiting, choking, color change other than cyanosis (e.g., gray, red, or pale), gagging, and change in tone (i.e., limp or stiff). The episodes may occur while awake or asleep. Interventions by care providers range from vigorous stimulation to cardiopulmonary resuscitation. These events frighten most parents and care providers.

In the ED, personnel should obtain a history of the event, including a description of any associated symptoms and an account of any recent changes in the patient’s health (e.g., fever, upper respiratory tract symptoms). The past medical history should focus on any prior unusual episodes or behaviors, a perinatal history, and a description of any respiratory symptoms or symptoms associated with gastroesophageal reflux (see Chapter 35, Vomiting, Spitting Up, and Feeding Difficulties). The clinician should inquire about a family

Table 28–1 Varying Definitions of Apparent Life-Threatening Events

Working Definition	Age Range of Study Subjects
<i>Apparent Life-Threatening Event (ALTE)</i> —"An episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking or gagging" ¹	Not defined
"sudden occurrence of one or more of the following: breathing irregularity (e.g., apnea, labored or shallow breathing, choking and gagging), color change indicative of decreased oxygenation (e.g., cyanosis, pallor), altered muscle tone or mental status (e.g., hypotonia, hypertonia, clonic movements, and unresponsiveness)" ¹¹	<12 mo
"apnea monitor alarm or an episode associated with two or more of the following factors: apnea, color change, change in muscle tone, choking/gagging or the performance of CPR at the time of the episode . . . single episode within the previous 24 hours and presenting with stable vital signs" ¹³	<6 mo
"one or more symptoms of apnea, color change, choking or abnormal limb movements and provided this has caused sufficient concern in the observer to seek medical attention" ¹⁰	<12 mo
"unexpected change in behavior that alarmed the caregiver. The initial episodes can occur during sleep, awake or while Not defined feeding . . . some combination of apnea, color change, marked change in muscle tone, choking or gagging . . . In most cases . . . prompt intervention was associated with normalization of the child's appearance." ²⁴	
"episodes of cyanosis or pallor for which vigorous stimulation had been given by the caregivers" ³	<12 mo
"a cessation of breathing, cyanosis or change in the level of consciousness" ¹⁸	1–604 days
"apneic episodes accompanied by one or more of the following manifestations: cyanosis, hypotonia, loss of consciousness necessitating vigorous stimulation or resuscitation" ⁴	25 days–6 mo
"an event of prolonged apnea, hypotonia and cyanosis or pallor" ¹⁴	2–36 wk
"attack of an infant who, during presumed sleep, is found not breathing, cyanotic or pale, often limp and who has to be vigorously stimulated or ventilated mouth-to-mouth to be resuscitated" ⁵	Birth–24 wk

Abbreviation: CPR, cardiopulmonary resuscitation.

history of SIDS or other causes of infant deaths, ALTEs, seizures, metabolic disorders, and cardiac or respiratory abnormalities.

Infants who have experienced an ALTE typically appear well at the time of the ED evaluation. The physical examination of these infants is usually normal. Close monitoring may reveal further ALTEs in the ED. Some of the etiologies of ALTE can lead to rapid deterioration after a period of relatively well appearance. Being prepared for this eventuality is prudent and might be life saving (see Chapter 5, Monitoring in Critically Ill Children; and Chapter 7, The Critically Ill Neonate).

Important Clinical Features and Considerations

Serious etiologies of ALTEs may not be identified by a thorough history and careful physical examination. Because of this, the diagnosis of a truly life-threatening condition may be delayed as testing is undertaken. In particular, patients with infectious, traumatic, cardiac, and respiratory etiologies for their ALTEs are at risk for poor outcomes if the diagnosis is substantially delayed.

Many infectious diseases cause ALTEs (Table 28–2). Respiratory abnormalities are often associated with an infectious etiology. Respiratory syncytial virus (RSV) infections (including bronchiolitis), viral upper respiratory tract infections, and pertussis are the most frequently reported infectious causes of ALTEs.^{8,10–16} The symptoms for both RSV infections and pertussis are variable and may be subtle, particularly in young infants. Patients with RSV infections may present with rhinorrhea or apnea as the sole symptom, without wheezing as seen in cases of RSV bronchiolitis (see Chapter 57, Bronchiolitis). Young infants with pertussis may present with periods of apnea as the sole complaint. Cough may be a minor component of the clinical scenario or absent.

These young infants do not manifest the characteristic "whoop" of pertussis infections. Bacterial meningitis, perhaps the most feared infectious disease of infancy, has been reported in patients with an ALTE.^{12,14} Studies of ALTEs may not include any infants with bacterial meningitis simply due to sample size and the relative rarity of bacterial meningitis.^{10,11,13,15,16}

Accidental and nonaccidental trauma are important causes of ALTEs. In one case series, 2.5% of the infants presenting for evaluation of ALTEs harbored nonaccidental head injuries.¹² These infants tended to present with cardiorespiratory instability, signs of trauma on physical examination, or both. It has been suggested that all infants presenting with ALTEs have a fundoscopic evaluation for retinal hemorrhages.¹⁷ Given the inherent difficulties in performing fundoscopic examinations in infants in the ED, this is probably not a realistic expectation for emergency physicians. However, infants who have experienced an ALTE are typically admitted to the hospital. A fundoscopic examination can be performed during the infant's inpatient stay. Intentional suffocation and Munchausen syndrome by proxy may also be the cause of ALTEs. Although perhaps suspected at the time of the ED evaluation, these diagnoses are usually made during the inpatient stay.^{18,19}

The role of cardiac abnormalities as the underlying cause of ALTEs is unclear. In the largest reported series of patients evaluated for cardiac abnormalities after an ALTE, 62% had one or more dysrhythmias. These dysrhythmias included prolonged corrected QT intervals (30%), premature ventricular depolarizations (25%), and premature atrial beats (15%).²⁰ Most of these dysrhythmias are not clinically important or diagnostic. Other studies, however, have reported the incidence of dysrhythmias and structural cardiac abnormalities to be less than 1%.^{8,10,12–16}

The role of gastroesophageal reflux in ALTE is controversial. Gastroesophageal reflux symptoms are common in infancy.

Table 28–2 Differential Diagnosis for Apparent Life-Threatening Events

Cardiac	Atrial and ventricular septal defect Cardiomyopathy Double aortic arch Dysrhythmia Fibroelastosis Hypoplastic left ventricle Myocarditis
Gastrointestinal	Patent ductus arteriosus Gastroesophageal reflux Strangulated hernia Upper gastrointestinal bleed
Infectious	Bronchiolitis Croup Encephalitis Gastroenteritis Lower respiratory tract infection Meningitis Pertussis Pneumonia Sepsis Upper respiratory tract infection Urinary tract infection
Metabolic	β -Ketothiolase deficiency Carnitine deficiency Galactosemia Glutaric aciduria type II Hyperammonemia, undetermined disorders Hypocalcemia Hypoglycemia Hypomagnesemia Lactic acidosis, undetermined disorders Menkes' syndrome Mitochondrial fatty acid oxidation disorders Nesidioblastosis Reye's syndrome Urea cycle defects
Neurologic	Brain tumor Central apnea Cerebral artery infarct Craniosynostosis Epilepsy Febrile seizure Head injury Hydrocephalus Infantile spasm Intraventricular hemorrhage Seizure Subarachnoid hemorrhage Subarachnoid hemorrhage Ventriculoperitoneal shunt malfunction Werdnig-Hoffmann disease
Respiratory	Accidental smothering/asphyxia Anatomic airway obstruction/abnormalities Aspiration pneumonia Asthma Choking episode Foreign body aspiration Laryngomalacia Laryngostenosis
Other	Anemia Breath-holding spells Developmental delay Feeding difficulty/overfeeding Medications/toxins Munchausen syndrome by proxy Trauma Vaccine reaction Vagal reaction

Even though gastroesophageal reflux is diagnosed in an infant who has experienced an ALTE, this does not establish a causal relationship.²¹

Identifying risk factors for recurrent ALTEs or serious underlying etiologies is problematic. Definitional problems, heterogeneity of study populations, and small sample sizes lead to problems with reproducibility and external validity. Factors identified as being associated with a repeat ALTE or an identifiable cause include an abnormal physical examination, age greater than 2 months, low serum bicarbonate, high serum lactate, and a history of prematurity.^{11,12}

Management

The history and physical examination may suggest an underlying cause for an ALTE. When this is the case, an appropriate evaluation directed toward the presumptive cause is indicated. When the etiology is not clear based on the history and physical examination, a laboratory evaluation, radiographic evaluation, or both is likely indicated. The components of the most appropriate ED diagnostic evaluation of infants who have experienced an ALTE remain controversial. The differential diagnosis is large, and therefore the ED diagnostic evaluation is often extensive. Components of the “ALTE workup” may include cultures of blood, urine, and cerebrospinal fluid, a complete blood count, electrolytes (including a serum glucose), a catheterized urinalysis, and cerebrospinal fluid cell counts, glucose, and protein. If respiratory symptoms are present, a chest radiograph and tests for RSV and pertussis may be added. If the infant has an abnormal cardiac examination, a history of sweating with feeds, hepatomegaly on physical examination, or a murmur, an electrocardiogram, chest radiograph, and perhaps an echocardiogram may be added. If the history or physical examination is suspicious for nonaccidental trauma, a computed tomography scan of the head and a skeletal survey may be added. Metabolic etiologies are rare, but frozen samples of blood and urine obtained near the time of the event may help identify a metabolic disorder.

Unfortunately, in cases in which the history and physical examination fail to guide further evaluation, the yield of any particular diagnostic test is low. In the absence of an evidence-based approach for the diagnostic evaluation of these patients, several authors have presented their own recommendations (Table 28–3). These recommendations may be clinically useful. However, the differences suggest further research is needed to determine the optimal ED workup.^{8,10–13,22,23} In 2003, the European Society for the Study and Prevention of Infant Death published a consensus document titled “Recommended Clinical Evaluation of Infants with an Apparent Life-Threatening Event.”²⁴ This document states there is no standard minimal workup for infants who have experienced an ALTE. The history and physical examination should direct the diagnostic evaluation.²⁴

Summary

Evaluating infants who have experienced ALTEs is challenging. In many cases, an underlying etiology can be determined. However, this etiology may not be identified while the patient is in the ED. Diagnostic testing may identify abnormalities such as gastroesophageal reflux that are present, but not the underlying etiology of the ALTE. The utility of the

Table 28–3 Varying Recommendations for Diagnostic Testing for Infants Who Have Experienced Apparent Life-Threatening Events

Recommendations	Comments
Hemoglobin, glucose, lactate; chest radiograph; ECG; pertussis swab; urinalysis; hold (freeze) samples of blood and urine for metabolic and toxicologic studies ¹¹	Physical examination to include funduscopy for retinal hemorrhages
Glucose; hold (freeze) samples of blood and urine for metabolic and toxicologic studies ⁶	Authors recommend “considering” blood gases, lactate, and, in all patients under 28 days, CBC and bacteriologic cultures.
CBC, C-reactive protein, sodium, potassium, urea, calcium, magnesium, glucose, blood gas, ammonia, lactate, pyruvate, blood culture; urinalysis, urine culture, urine toxicology screen; hold (freeze) urine sample for metabolic studies; investigations for lower respiratory tract infection (chest radiograph, pertussis and RSV swabs); ECG; ultrasound of brain ¹⁹	Recommendations not specific to the ED. Authors recommend “considering” child abuse. No comment regarding timing or urgency to perform an ultrasound of the brain.

Abbreviations: CBC, complete blood count; ECG, electrocardiogram; ED, emergency department; RSV, respiratory syncytial virus.

components of the history and physician examination is variable. The yield of any individual diagnostic test is low. Hospital admission is typically indicated. Further research is needed to identify the most appropriate ED evaluation.

Inborn Errors of Metabolism

T. Kent Denmark, MD

Key Points

Children with known and previously undiagnosed inborn errors of metabolism present to emergency departments more commonly than is generally recognized.

An elevated ammonia level is useful for identifying children with previously undiagnosed inborn errors of metabolism presenting to the emergency department.

Of acute metabolic derangements resulting from exacerbations of inborn errors of metabolism, hypoglycemia has some of the most serious sequelae, but is easily diagnosed and treated in the emergency department.

Inborn errors of metabolism are caused by single gene defects.

Although older infants, children, and adolescents may develop abnormalities evident on physical examination due to the consequences of their inborn errors of metabolism, most of these children are not inherently dysmorphic.

Introduction and Background

Children with inborn errors of metabolism probably present to emergency departments more commonly than generally recognized. There are four main reasons the incidence of inborn errors of metabolism is likely underestimated in the emergency department. First, inborn errors of metabolism are caused by a single gene defect. As opposed to children with chromosomal disorders (e.g., Down syndrome), children with inborn errors of metabolism will have a normal phenotypic appearance and not manifest dysmorphism.^{1,2} Second, common emergency department presentations for children with previously undiagnosed inborn errors of metabolism include extreme presentations such as profound shock, fatal coma, and cardiopulmonary arrest.³ These children may not live long enough for a detailed differential diagnosis to be entertained. Emergency physicians are likely

to mentally classify these children as having “sepsis” or “full arrest” and never identify or acknowledge the underlying metabolic derangement even if identified at autopsy. Third, some children will have very mild manifestations of their inborn errors of metabolism.⁴ These children may become somewhat sicker than other children during common illnesses such as gastroenteritis, but harbor an undiagnosed inborn error of metabolism with relatively mild clinical features.⁵ In one study, more than 25% of children diagnosed with an inborn error of metabolism had presented to an emergency department for an acute complaint prior to the diagnosis being made.³ Some of these patients are identified in adulthood.⁶ It is likely that a substantial proportion of the population, especially in the subpopulation of developmentally delayed individuals,⁷ lives with undiagnosed inborn errors of metabolism. Fourth, even though there are currently more than 9000 recognized inborn errors of metabolism, more continue to be discovered.⁴ This suggests not all inborn errors of metabolism have been identified. Particularly in cases with milder manifestations, children may harbor inborn errors of metabolism that cannot be diagnosed yet.

Recognition and Approach

Each state in the United States screens newborns for inborn errors of metabolism.⁸ The first widely adopted screening test was developed in the early 1960s by Guthrie and Susi to identify phenylketonuria.⁹ According to the Centers for Disease Control and Prevention, each year 4 million newborns are screened for metabolic disorders.¹⁰ Severe disorders are detected in about 3000 (0.075%).¹⁰ In a population-based study from Italy, a similar incidence (0.04%) was reported.¹¹ There are problems with newborn screening that impact emergency department care. First, the infant is usually discharged from the nursery prior to the results of the screening tests being known. Clinical symptoms may appear and the infant may present to the emergency department before positive results return. Second, few inborn errors of metabolism are included in the mandated screening programs. The list of metabolic disorders for which each state screens is not uniform, and the number of disorders for which testing is mandated is relatively small.⁸ Although it is rare to find an older infant or toddler with undiagnosed phenylketonuria in the United States, the same cannot be said of many other inborn errors of metabolism. Third, as testing becomes more sophisticated, physicians' familiarity with these disorders

increases, and therapeutic interventions for affected individuals improve, it is likely that the prevalence of adolescents and young adults with recently diagnosed inborn errors of metabolism will rise. In one study, 11% of patients with an inborn error of metabolism survived beyond their 18th birthday.¹¹ Fourth, as with all tests, the test characteristics are imperfect. False-negative tests occur.⁴ For these reasons, the newborn screening tests provide an imperfect safety net for identifying inborn errors of metabolism.

Clinical Presentation

History

In many cases of exacerbations of inborn errors of metabolism, the history is frustratingly nonspecific (Table 29–1) (see Chapter 7, *The Critically Ill Neonate*). Reports of poor tone, lethargy, vomiting, or episodes of apnea are common to many serious disorders of infancy and early childhood. The rapidity and age of symptom onset are highly variable. The blocked metabolic pathways of inborn errors of metabolism may result in a rapid accumulation of devastating toxins, a slow accumulation of less injurious toxins, a cellular energy deficiency, or the inability to appropriately respond to changes in nutrition or nutritional status.¹² This heterogeneity results in signs and symptoms being identified in early infancy, later infancy, childhood, or adolescence; during intercurrent illnesses such as gastroenteritis; and at times when the schedule or composition of feedings change.¹ Because inborn errors of metabolism are genetic, the family history may be somewhat revealing. In particular, a history of unexplained deaths in the family and parental consanguinity are supportive of a diagnosis of an inborn error of metabolism. Of course, the family history would be expected to be unrevealing in cases arising from new genetic mutations.¹³

One relatively specific finding seen in some inborn errors of metabolism is a characteristic odor (Table 29–2). These odors are due to the accumulation of toxins. Characteristic odors have been described as arising from urine, stool, perspiration, cerumen, and saliva.¹⁴ The parents may report the unusual odor, or the clinician may identify it upon examination of a fresh specimen at the bedside.¹⁴ Another technique

for evaluating body fluids for characteristic odors is to place a small amount of the liquid specimen on filter paper, place this into a urine container, and allow the specimen to sit for several minutes at room temperature before an olfactory examination is undertaken.¹⁵

Physical Examination

Although older infants, children, and adolescents may develop abnormalities evident on physical examination due to the consequences of their inborn errors of metabolism, most of these children are not inherently dysmorphic. The physical examination is usually nonspecific. Failure to thrive as evidenced by poor weight gain may be apparent. Developmental delay may be recognized. In acute exacerbations, the child may present with clinically evident dehydration, lethargy, coma, weak muscle tone, hypothermia, or fever^{2,13} (see Table 29–1). Other serious but relatively nonspecific physical findings include seizures, jaundice, hepatomegaly or hepatosplenomegaly, cataracts, and dysrhythmias.¹⁶ Unfortunately, some children do not present until they are in cardiopulmonary arrest.^{2,13}

Ancillary Studies

The most helpful studies in evaluating children specifically for inborn errors of metabolism are a blood glucose measurement and an ammonia level. These tests are likely to fall within the context of a more generalized evaluation. There are two main reasons for this. First, in cases of previously undiagnosed inborn errors of metabolism, there is a broad differential diagnosis for the presenting signs and symptoms of an acute exacerbation of an inborn error of metabolism (Table 29–3). In most of these cases, it would be imprudent to dismiss alternative diagnoses without ancillary studies being performed during the emergency department course. Second, intercurrent illnesses may exacerbate known inborn errors of metabolism or cause previously undiagnosed inborn errors of metabolism to become clinically evident. In both instances, the intercurrent illness will need to be identified and treated in addition to the inborn error of metabolism. The ancillary studies needed to evaluate these children typically encompass a wide range of laboratory studies, including cultures and radiologic studies (see Chapter 7, *The Critically Ill Neonate*; Chapter 8, *Circulatory Emergencies: Shock*; and Chapter 11, *Altered Mental Status/Coma*).

Of the acute metabolic derangements resulting from exacerbations of inborn errors of metabolism, both acidosis and

Table 29–1 Frequency of Emergency Department Signs and Symptoms in Children with Previously Undiagnosed Inborn Errors of Metabolism

55%	Abnormal muscle tone
51%	Lethargy or coma
41%	Seizures
34%	Vomiting
31%	Psychomotor delay
31%	Hepatic dysfunction
21%	Failure to thrive
15%	Apnea
11%	Cardiopulmonary arrest
6%	Fever
4%	Hypothermia

Increased intracranial pressure
Infant botulism
Malrotation with midgut volvulus
Meningitis
Methemoglobinemia
Nonaccidental trauma
Seizure
Sepsis
Shaken infant
Supraventricular tachycardia

hypoglycemia have some of the most serious sequelae. Fortunately, hypoglycemia is easily diagnosed and treated in the emergency department (see Chapter 106, Hypoglycemia). For young infants, there continues to be some debate regarding the numeric interventional threshold for hypoglycemia.^{17,18} This debate is peripheral to the treatment of ill-appearing infants in the emergency department who may harbor an inborn error of metabolism. Many of these infants require the administration of a continuous infusion of dextrose, typically administered as dextrose 10% in water (D₁₀W), whether or not they are hypoglycemic. Acidosis is treated by reversing catabolism with IV fluids plus dextrose, liberal use of bicarbonate, as well as the addition of specific substances (e.g., vitamins and amino acids) based on the specific deficiency (see also Chapter 7, The Critically Ill Neonate).¹¹

An elevated ammonia level may be the first and most helpful test in identifying infants with inborn errors of metabolism. Although not all inborn errors of metabolism will manifest an elevated ammonia level, many do. These include organic acidurias (e.g., methylmalonic acidemia, propionic acidemia, isovaleric acidemia) and urea cycle defects. Mild to moderate hyperammonemia may occur in acutely ill neonates, particularly premature neonates, without an underlying inborn error of metabolism.¹⁹ However, an elevation of serum ammonia greater than 120 $\mu\text{mol/L}$ (200 $\mu\text{g/dL}$) in an infant outside of the neonatal intensive care unit who is not manifesting liver failure is strongly suggestive of an inborn error of metabolism.^{12,19} Ammonia collection requires immediate placement of the specimen on ice and rapid transport to the laboratory to avoid false-positive results.

A urinary test for reducing substances may be performed routinely in some clinical laboratories on specimens from infants and toddlers. The utility of these tests in the emergency department has not been explored. A urinary test for reducing substances will detect lactose, fructose, galactose, and pentose in addition to the more common glucose. In the absence of urinary glucose, a positive test is suggestive of an inborn error of metabolism affecting the metabolism of one of these other sugars. However, other signs and symptoms of liver failure typically lead to the diagnosis, rather than a positive test for reducing substances obtained in the emergency department.¹⁶

Important Clinical Features and Considerations

Idiopathic ketotic hypoglycemia and glutaric aciduria type I are two conditions associated with inborn errors of metabolism that might lead to substantial confusion.

Idiopathic Ketotic Hypoglycemia

The most common cause of hypoglycemia in toddlers and preschoolers between 1 and 5 years of age is idiopathic ketotic hypoglycemia.²⁰ This condition is not seen in school-age children or adolescents due to their greater muscle mass and larger glycogen stores. Toddlers and preschoolers presenting with idiopathic ketotic hypoglycemia usually present with lethargy or unresponsiveness following a period of fasting.²⁰ A reasonable scenario in which this occurs is a toddler who develops vomiting in the evening and presents the next morning hypoglycemic and unresponsive. These children are expected to have a history of normal growth, have no history of an acute ingestion, and have a prompt return to normal following administration of intravenous dextrose. Most of these children require no further workup for their hypoglycemic episode. Patients who have recurrent episodes, hepatomegaly, or growth retardation require further investigation.²⁰

Glutaric Aciduria Type I

One inborn error of metabolism deserving special attention for emergency physicians is glutaric aciduria type I. This disorder may mimic nonaccidental trauma manifesting chronic subdural hemorrhages and retinal hemorrhages. Glutaric aciduria type I does not present with a metabolic or lactic acidosis, hyperammonemia, or hypoglycemia. There are obvious challenges in considering an inborn error of metabolism in this setting. The indications for testing for glutaric aciduria type I in the emergency department are unclear. Glutaric aciduria type I can be identified from a positive test for urine organic acids with confirmation by an enzyme assay.^{21,22}

Management

The management of a child with an inborn error of metabolism follows the generalized approach appropriate for all seriously ill infants and children (see Chapter 7, The Critically Ill Neonate). Particularly in cases of undiagnosed inborn errors of metabolism, emergency physicians should expect to perform a “septic workup,” evaluate serum electrolytes, administer empirical antibiotics, identify and treat hypoglycemia, support the blood pressure, manage the airway, and address other serious problems as they do with other patients. There are, however, some management features that are relatively specific for children with inborn errors of metabolism.

Since many inborn errors of metabolism involve the accumulation of toxic metabolites from a component of feedings, the child should be kept *nil per os* (NPO) during the emergency department course. In general, critically ill children receive intravenous dextrose with maintenance fluids and are too ill to feed. Therefore, withholding feeds is seldom an issue in the emergency department.

In many instances, intravenous dextrose by continuous infusion is indicated. Like other serious illnesses in infants and children, hypoglycemia needs to be identified and treated promptly. For infants, this is typically accomplished by

administering a D₁₀W bolus of 5 to 10 ml/kg. For children, this is typically accomplished by administering a D₂₅W bolus of 2 to 4 ml/kg. In contrast to other serious illnesses, infants and children with inborn errors of metabolism may need a continuous infusion of dextrose both to avoid recurrent hypoglycemia and reverse a catabolic state. This is usually accomplished by adding 10% dextrose to the maintenance fluids.

The treatment of hyperammonemia is often guided by a conversation with a pediatric metabolic specialist. Treatment options include the administration of sodium benzoate, sodium phenylbutyrate, and hemodialysis.^{23,24}

Seizures in infants are distinct from febrile seizures and idiopathic seizures seen in older children (see Chapter 40, Seizures). In one study based in an emergency department, 42% of infants younger than 6 months of age presenting with a seizure had an underlying syndrome, malformation, or inborn error of metabolism.²⁵ Some children with acute exacerbations of inborn errors of metabolism will present to the emergency department with refractory seizures. These children characteristically have a normal blood glucose and serum sodium. In addition to standard treatment (e.g., the administration of an intravenous benzodiazepine), the administration of intravenous pyridoxine and folinic acid may be needed to stop the seizures in children whose inborn error of metabolism involve pyridoxine or folinic acid.²³

The greatest resources in treating children with known inborn errors of metabolism are the parents and the child's metabolic specialist. In general, parents are much more sensitive to the early "glazed" encephalopathic appearance in their children than physicians unfamiliar with the child.²⁶ Parents may carry specific instructions and information about their child with them to the emergency department. This information can be extremely helpful in guiding the child's management. A phone consultation with the child's metabolic specialist can also provide important guidance with respect to complications to anticipate and specific treatment. The child's metabolic specialist may also play a key role in getting the child transferred to a tertiary care pediatric facility.

In the unfortunate circumstances in which a resuscitation is coming to a fatal conclusion, sending some specimens to the laboratory prior to conclusion of the resuscitation may help the family. This may be the only opportunity to obtain useful evidence to answer questions and to counsel the family regarding future family planning.^{13,15} Several milliliters of urine should be collected and frozen, a tube of plasma separated from whole blood and frozen, and a snip of skin stored at room temperature.²⁷

Summary

Inborn errors of metabolism are "individually rare and collectively numerous."¹⁶ The prevalence of children, adolescents, and young adults with recognized inborn errors of metabolism is rising, and those with known and previously undiagnosed inborn errors of metabolism will present to the emergency department with increasing frequency. The addition of a serum ammonia level to the laboratory evaluation of these patients will identify many children with inborn errors of metabolism. For children with a known inborn error of metabolism, the parents and the child's metabolic specialist are extremely valuable resources for guiding management decisions.

Congenital Heart Disease

Alson S. Inaba, MD

Key Points

Infants with undiagnosed congenital heart disease generally present to the emergency department with congestive heart failure (left-to-right shunts), unresponsive cyanosis (right-to-left shunts), or profound shock (congenital obstructive left heart lesions). Discriminating between these major categories will aid in the initial evaluation and management.

Always consider the possibility of an undiagnosed congenital heart defect in the differential diagnosis of an infant who presents in severe cardiopulmonary distress.

The hyperoxia test may serve as a useful bedside diagnostic tool to differentiate between cardiac and pulmonary etiologies for central cyanosis in infants. When obtaining blood for the hyperoxia test, use the right upper extremity to avoid falsely depressed values caused by a right-to-left ductal shunt.

Suspect ductal-dependent cardiac lesions in infants who present with sudden onset of cyanosis or cardiovascular collapse within the first 3 weeks of life. Prostaglandin E₁ infusion may be life saving in these infants.

Introduction and Background

The incidence of congenital heart disease in the United States is approximately 8 to 10 cases per 1000 live births.¹⁻³ Currently about 1 million people in the United States have some form of congenital heart defect (CHD), and each year another 32,000 to 35,000 infants are born with some form of CHD. Heart disorders are the most common birth defect and are the leading cause of birth defect-related deaths during the first year of life. One third of all patients born with a CHD become critically ill during the first year of life, often within the first month of life.⁴

Despite newborn and prenatal screening, infants with undiagnosed CHDs can present to the emergency department (ED) with cardiopulmonary distress secondary to acute decompensation. Physicians must be able to manage a wide array of problems in these infants, including congestive heart failure (CHF), cyanosis, cardiovascular collapse, and multiple infections.

Recognition and Approach

Fetal Circulation and Circulatory Changes that Occur after Birth

The three major anatomic features of the fetal circulation are the presence of the ductus venosus, the ductus arteriosus, and a patent foramen ovale (Fig. 30–1). During fetal development, oxygenation of the fetal circulation bypasses the fetal lungs and is accomplished via the placenta. Blood that is oxygenated by the placenta is carried to the fetus via the umbilical vein, bypasses the fetal liver via the ductus venosus, and is delivered to the fetal heart via the inferior vena cava. Oxygenated blood entering the right atrium is preferentially shunted to the left atrium through the foramen ovale and then into aorta via the left ventricle (LV). This oxygenated blood is preferentially directed to the fetal coronary and cerebral circulations. In contrast, deoxygenated blood that returns to the fetal right atrium via the superior vena cava (SVC) is preferentially directed through the tricuspid valve and into the right ventricle (RV). This blood is ejected out of the RV via the pulmonary artery and bypasses the fetal lungs because of the higher vascular resistance in the fetal pulmonary circuit. This deoxygenated blood that bypasses the fetal lungs is shunted into the descending aorta via the ductus arteriosus. Therefore, the blood in the fetal descending aorta contains a mixture of both placentally oxygenated blood and deoxygenated blood from the fetal SVC.

After delivery, expansion and aeration of the infant's lungs causes a decrease in the pulmonary vascular resistance (PVR) with a concomitant increase in pulmonary blood flow. This increased oxygenation causes a physiologic closure of the umbilical arteries, umbilical vein, ductus venosus, and ductus arteriosus. An increase in blood flow to the infant's left atrium also promotes the closure of the foramen ovale. Although the ductus arteriosus functionally closes at about 10 to 15 hours of life, complete anatomic closure does not occur until about 2 to 3 weeks of life. Up until that time,

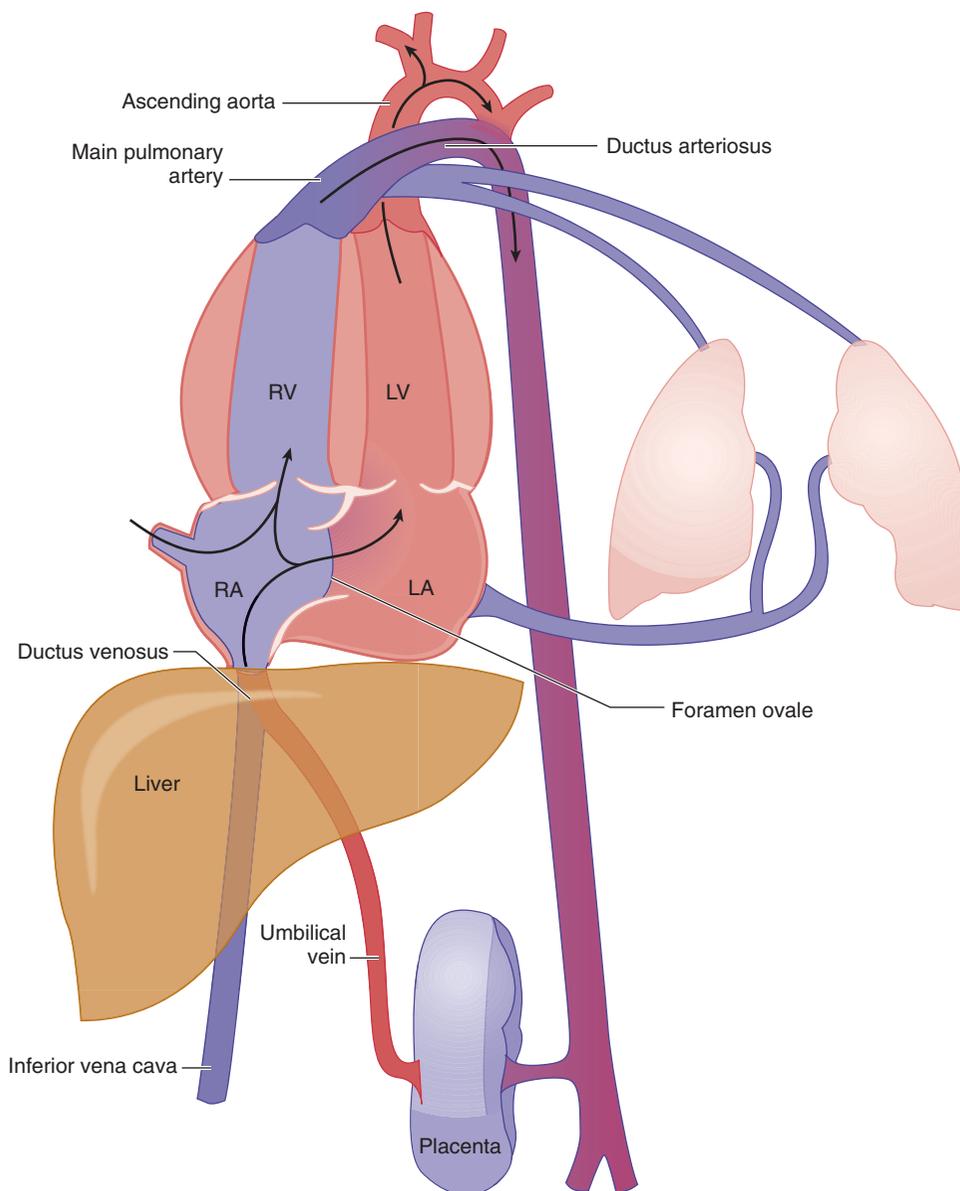

FIGURE 30-1. The fetal circulation, with arrows indicating the directions of flow. A fraction of umbilical venous blood enters the ductus venosus and bypasses the liver. This relatively highly oxygenated blood flows across the foramen ovale to the left side of the heart, preferentially perfusing the coronary arteries, head, and upper trunk. The output of the right ventricle flows preferentially across the ductus arteriosus and circulates to the placenta, as well as to the abdominal viscera and lower trunk. (From Zipes: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia: WB Saunders, 2005, p 1493. Copyright © 2005 Saunders, An Imprint of Elsevier.)

prostaglandin E_1 (PGE_1) has the potential to reopen the ductus arteriosus and improve cardiopulmonary hemodynamics in critically ill infants with certain CHDs.

In the absence of any CHD, transitional circulatory changes pose no physiologic problems to the infant. However, complete anatomic closure of the ductus arteriosus may pose acute life-threatening complications in infants with CHDs who are dependent upon the patency of the ductus arteriosus for survival. Infants with ductal-dependent CHDs typically present to the ED with acute circulatory collapse or acute cyanosis within the first 3 weeks of life.

Physiology of Major Congenital Cardiac Disorders

A few major underlying mechanisms are responsible for most congenital cardiac defects. These include left-to-right shunt lesions, right-to-left shunts, and lesions that obstruction the outflow from the right or left ventricle.

Left-to-Right Shunts

Left-to-right shunt lesions occur when there is an abnormal connection between the right and left side of the heart (atrial septal defect [ASD], ventricular septal defect [VSD], patent ductus arteriosus [PDA], and more complex endocardial cushion defects involving the atrial and ventricular septa). Since left heart pressures are generally higher than right-sided pressures, blood preferentially flows to the lower pressure right side of the heart across defects (i.e., ASD, VSD, PDA). The combination of normal venous return to the right side of the heart via the vena cava in addition to the excess flow from the left side of the heart tends to overload the lungs with excess blood (Figs. 30-2 and 30-3).

Eventually, excess flow leads to CHF. As the right atrium, RV, and pulmonary artery receive excess flow, they may dilate with time resulting in electrocardiographic (ECG) and radiographic changes of right atrial, right ventricular, and pulmonary artery enlargement (see Figs. 30-2 and 30-3). With an

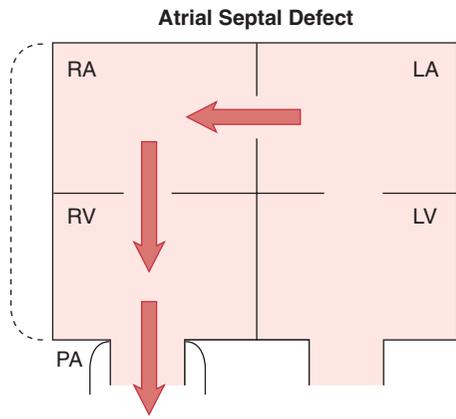

FIGURE 30–2. Atrial septal defect (ASD). Flow from higher to lower pressure chamber (left to right atrium) across an ASD can lead to dilation of right heart chambers and excess flow to lungs over a prolonged time, with occasional congestive heart failure in adults or teenagers. Abbreviations: LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. *Red arrow* signifies oxygenated blood; *blue arrow*, deoxygenated blood; *pink arrow*, partially oxygenated blood.

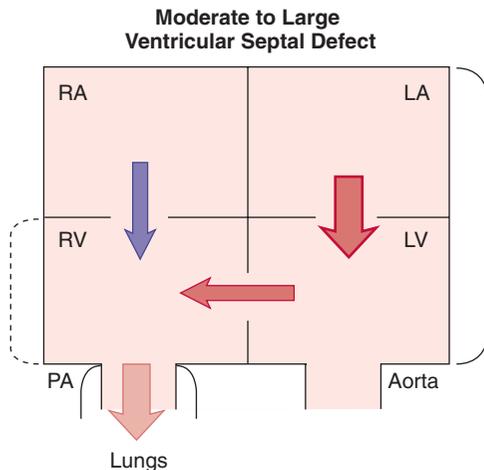

FIGURE 30–3. Ventricular septal defect (VSD). If large enough, blood flow across a VSD will cause chamber enlargement (*dotted arrows*) and provide excess flow to the lungs, with resulting congestive heart failure. Abbreviations: LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. *Red arrow* signifies oxygenated blood; *blue arrow*, deoxygenated blood; *pink arrow*, partially oxygenated blood.

ASD, the gradient between chambers is small and the excess flow provided to the lungs is minimal, and symptoms may take decades to occur. With VSDs, excess blood flow to the lungs depends upon the PVR and the size of the defect. Chambers that receive excess flow dilate, with resulting ECG and chest radiograph (CXR) changes. After delivery, PVR is normally elevated, and it may take weeks for the excess blood flow from left to right to overload the lungs and cause symptoms.

Hemodynamic consequences of a PDA mimic those of a VSD, with enlarged ventricles and pulmonary artery on ECG and radiography and delayed presentations due to the normal drop in PVR in the first few weeks to months following birth.

Right-to-Left Shunts

Right-to-left shunt lesions result in deoxygenated blood bypassing the lungs and being sent directly to the systemic

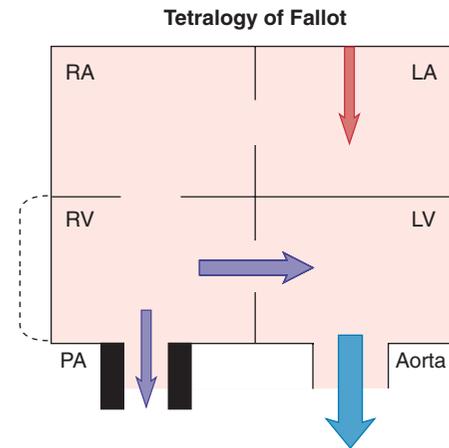

FIGURE 30–4. Tetralogy of Fallot. Pulmonary stenosis limits flow to the lungs via the pulmonary arteries, increasing right ventricular pressures and shunting deoxygenated blood (*blue arrow*) through the ventricular septal defect to the left ventricle (LV) and into the systemic circulation. In tetralogy, an overriding aorta is also present (not depicted in figure). Abbreviations: LA, left atrium; PA, pulmonary artery; RA, right atrium; RV, right ventricle. *Red arrow* signifies oxygenated blood; *blue arrow*, deoxygenated blood; *pink arrow*, partially oxygenated blood.

circulation. Pulmonary flow can be diminished (e.g., tetralogy of Fallot) or increased (e.g., D -transposition of the great arteries). Tetralogy of Fallot consists of a VSD and pulmonary stenosis with associated right ventricular hypertrophy and an overriding aorta. In this disorder, there is obstruction of flow to the lungs (pulmonary stenosis). Desaturated blood bypasses the lungs, traverses the VSD to the left side of the heart, and is sent into the systemic circulation (Fig. 30–4).

In D -transposition of the great arteries, the aorta and pulmonary arteries no longer connected to the left and right ventricles. Instead, the aorta arises from the RV and the pulmonary artery arises from the LV. The only way that blood can intermix with saturated blood reaching the systemic circulation is via an ASD or VSD. Because excess blood is supplied to the right side of the heart and pulmonary artery, right atrial enlargement, right ventricular hypertrophy, pulmonary artery dilation, and CHF occur.

Right Ventricular Outflow Obstruction

Right ventricular outflow obstruction can cause profound hypoxia. Disorders often involve a defect in the pulmonary valve, the infundibulum (the area below the pulmonic valve), or the peripheral pulmonary artery. In isolated pulmonary valve stenosis with an intact ventricular septum, valve cusps are deformed resulting in incomplete opening during systole. The obstruction to outflow from the RV to the pulmonary artery results in increased systolic pressures and right ventricular hypertrophy. Right-to-left shunting may occur through the patent foramen ovale in neonates with critical pulmonic stenosis. If this occurs, cyanosis is often present. Signs of right-sided CHF (e.g., hepatic enlargement) may occur. If an ASD or VSD is present, either right-to-left or left-to-right shunting may occur depending upon the degree of pulmonary stenosis and the subsequent increase in right ventricular pressures. High-grade stenosis will increase right ventricular pressures and cause a right-to-left shunt with cyanosis. Minimal stenosis with an ASD or VSD will lead to left-to-right shunt symptoms (i.e., CHF). However,

with time, pulmonary stenosis will worsen and the shunt may eventually reverse (Eisenmenger's complex) and become right to left, resulting in features consistent with cyanotic congenital heart disorders.

Persistent Pulmonary Hypertension of the Neonate

Persistent pulmonary hypertension of the neonate, also termed *persistent fetal circulation*, is a failure of the normal circulatory transition that occurs after birth and can be confused with congenital cyanotic heart defects. It is a syndrome characterized by marked pulmonary hypertension that causes hypoxemia and right-to-left extrapulmonary shunting of blood. Due to inadequate pulmonary flow, neonates develop refractory hypoxemia, respiratory distress, and acidosis. By definition, these infants have no evidence of a cardiac lesion. The most common causes include perinatal asphyxia and hypoventilation, although some cases are due to congenital disorders (e.g., hypoplasia of pulmonary vessels) while others are idiopathic. These neonates present with hypoxia and may develop right-to-left shunts with clinical features consistent with a cyanotic CHD. Management consists of assisting ventilation, providing oxygen, correcting acidosis, and administering inhaled nitric oxide (which relaxes the vascular smooth muscle in pulmonary vessels).

Left Ventricular Outflow Obstruction

Left ventricular outflow obstruction occurs due to defects in the left ventricle or aorta. These defects can cause profound shock and acidosis. In hypoplastic left heart syndrome, the left ventricle is malformed and unable to supply a pressure head to the systemic circulation. A patent ductus is required to supply right ventricular blood flow to restore systemic circulation. In addition, an ASD can help shunt oxygenated blood to the right heart as it, in turn, supplies blood to the systemic circulation (Fig. 30–5). Closure of the ductus can result in abrupt worsening of circulation, profound shock,

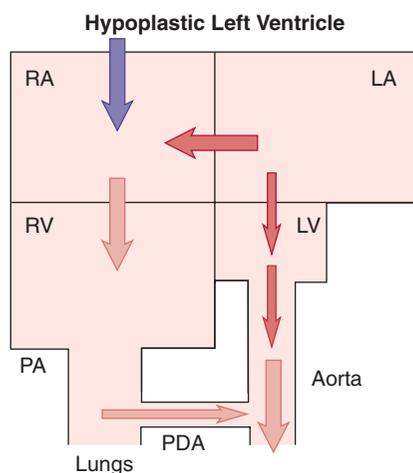

FIGURE 30–5. Example of hypoplastic left heart syndrome. Oxygenated blood (red arrow) returning from the lungs to the left atrium (LA) or left ventricle (LV) mixes with deoxygenated blood (blue arrow) returning from the systemic circulation (right atrium [RA] and right ventricle [RV]). The right ventricle supplies a pressure head and partially oxygenated blood (pink arrow) to reach the systemic circulation via a patent ductus arteriosus (PDA). Abbreviation: PA, pulmonary artery.

and acidosis. Infants with coarctation of the aorta and an interrupted aortic arch can present in a similar manner and also may require a patent ductus to ensure systemic circulation.

Clinical Presentations

Presenting Signs and Symptoms

The evaluation of an infant who presents to the ED with a possible underlying, undiagnosed CHD should focus on several key aspects in the history and the physical examination. Certain maternal infections as well as medication and drug use during the first trimester are associated with a higher incidence of congenital cardiac disorders. The presence of certain maternal medical conditions have also been associated with a higher incidence of cardiac disorders. For example, congenital heart blocks have been associated with maternal systemic lupus erythematosus and other collagen vascular disorders. Infants of diabetic mothers have a higher incidence of cardiomyopathy.

Infants with complex and severe underlying CHDs generally present to the ED in one of three manners: (1) with CHF that is responsive to oxygen, (2) with cyanosis that is unresponsive to oxygen with or without CHF, or (3) with pro-

Table 30–1 Categorization of Congenital Heart Disease*

CYANOSIS and Diminished Pulmonary Flow

- Tetralogy of Fallot
- Tricuspid atresia
- Ebstein's anomaly of the tricuspid valve
- Pulmonary atresia (with VSD or PDA)
- Severe pulmonary stenosis
- Hypoplastic right heart syndrome
- Double-outlet right ventricle with pulmonary stenosis
- Eisenmenger's complex (large VSD with eventual development of pulmonary hypertension and reversal of flow; due to pulmonary obstruction, blood flows from right to left through VSD)
- D-Transposition of the great arteries with pulmonary stenosis

CYANOSIS and Increased Pulmonary Flow (CHF) Unresponsive to Oxygen

- Transposition of the great arteries
- Total anomalous pulmonary venous return
- Persistent truncus arteriosus
- Double-outlet right ventricle (without pulmonary stenosis)
- Single ventricle
- Hypoplastic left heart syndrome

SHOCK

- Hypoplastic right heart syndrome
- Coarctation of the aorta
- Interrupted aortic arch
- Critical aortic stenosis

CHF (May Be Cyanotic but Are Responsive to Oxygen)

- Ventricular septal defects
- Atrial septal defect
- Patent ductus arteriosus
- Endocardial cushion defects
- Coarctation of the aorta
- Critical aortic stenosis

*Many disorders can present in varied fashion depending upon the specific associated defect and exact anatomic abnormality. Abbreviations: CHF, congestive heart failure; PDA, patent ductus arteriosus; VSD, ventricular septal defect.

Table 30–2 Most Common Congenital Cardiac Defects Diagnosed at Different Neonatal Ages

0–6 Days		7–13 Days		14–28 Days	
D-Transposition of great arteries	19%	Coarctation of aorta	16%	VSD	16%
Hypoplastic LH	14%	VSD	14%	Coarctation of aorta	12%
Tetralogy of Fallot	8%	Hypoplastic LH	8%	Tetralogy of Fallot	7%
Coarctation of aorta	7%	D-Transposition of great arteries	7%	D-Transposition of great arteries	7%
VSD	3%	Tetralogy of Fallot	7%	Patent ductus	5%
Other defects	49%	Other defects	48%	Other defects	53%

Abbreviations: LH, left heart; VSD, ventricular septal defect.

From Marino BS, Bird GL, Wernovsky G: Diagnosis and management of the newborn with suspected congenital heart disease. *Clin Perinatol* 28:91–136, 2001.

found shock (Table 30–1). The age and time of presentation in addition to the severity of presenting symptoms in an infant with an underlying CHD will vary depending upon the specific defect, the complexity and severity of the defect, and the timing of normal physiologic changes that occur as the fetal circulation transitions to that of the neonate (Table 30–2).⁵ In one study, 63% of infants with undiagnosed CHDs who presented to the ED had pulmonary edema.⁶ In general, the more severe defects with compromised pulmonary or systemic blood flow tend to present earlier during infancy, while less severe defects may not become clinically apparent until early childhood.

Congestive Heart Failure Responsive to Oxygen

Infants with CHD lesions with large left-to-right shunts (e.g., VSD) may initially go undetected in the first few weeks of life due to the relatively high PVR that persists immediately after birth. However, PVR diminishes rapidly in the first few months of life. This results in increased left-to-right shunting, resulting in excessive pulmonary blood flow. These infants present with progressive respiratory distress, wheezing, diaphoresis with feedings, poor weight gain, and failure to thrive.⁷ Due to the nonspecificity of their symptoms, they easily can be misdiagnosed as having viral respiratory infections or acute bronchospasm. Clinical features of CHF in infants bear no resemblance to those of their adult counterparts. On examination, diaphoresis, wheezing, and a gallop rhythm may predominate. With time, the liver enlarges. In contrast, infants rarely manifest jugular venous distention, basilar rales, or peripheral edema.

Cyanosis Unresponsive to Oxygen (with or without CHF)

The age of onset, associated symptoms, and location of an infant's cyanosis may provide valuable clues as to the etiology (i.e., cardiac, pulmonary, or hematologic etiologies). Central cyanosis involves tissues that receives blood from an internal carotid artery branch (tongue and mucus membranes), while peripheral cyanosis (acrocyanosis) involves tissues with an external carotid artery source (the lips, hands, and feet). Acrocyanosis is a common phenomenon in neonates secondary to cold stress and peripheral vasoconstriction. Central cyanosis always reflects a pathologic etiology and is therefore a more ominous sign compared to peripheral cyanosis. Infants with cyanosis secondary to CHDs may not exhibit as much respiratory distress as infants with cyanosis solely due to a pulmonary etiology. Thus, in a child who appears “comfortably blue,” a cardiac etiology as the cause for central

cyanosis may be more likely than a purely pulmonary etiology. Another important clinical clue as to the etiology of central cyanosis is that the cardiac etiologies of cyanosis usually worsen with crying, while cyanosis due to pulmonary etiologies may improve when the infant cries.⁵

The response to administration of 100% oxygen for 10 minutes (also known as the hyperoxia test) can help differentiate between cardiac and pulmonary etiologies of central cyanosis. If the patient's oxygen saturation increases by more than 10% or the arterial partial pressure of oxygen (Pao₂) rises by more than 20% to 30%, then the most likely etiology is pulmonary.⁵ The measured Pao₂ in patients with a pulmonary etiology for cyanosis should rise well above 100 mm Hg unless the degree of pulmonary disease that is present is severe. A Pao₂ that remains less than 50 mm Hg despite 100% oxygen is suggestive of a CHD with decreased pulmonary blood flow or right-to-left shunting. Infants with CHDs with an increased pulmonary blood flow due to left-to-right shunt lesions may exhibit a rise in their Pao₂ (up to 150 mm Hg) in response to 100% oxygen.⁵ Importantly, when obtaining blood for the hyperoxia test, the right upper extremity should be used. This will avoid misinterpretation due to falsely depressed values caused by a right-to-left ductal shunt.

Profound Shock or Congenital Obstructive Left Heart Syndromes

Infants with disorders that obstruct the left ventricular outflow tract or congenital obstructive left heart syndromes usually present early in life. These disorders consist of hypoplastic left heart syndrome, critical aortic stenosis, coarctation of the aorta, and an interrupted aortic arch. Infants with these anomalies generally present within a few days of birth with profound shock. In fact, they are often misdiagnosed as being in septic shock.⁸ Prominent features overlap with sepsis and include respiratory distress, feeding difficulty, and irritability. Physical examination often reveals cyanosis (55%), diminished upper extremity (32%) and lower extremity (70%) pulses with a pulse differential, and a murmur (53%). Radiography shows cardiomegaly in up to 85% of cases, while ECG abnormalities are noted in 80% of cases.⁸

Diagnostic Tests: Chest Radiographs, Electrocardiograms, and Various Laboratory Studies

A CXR is an essential component in the evaluation of any infant with a suspected CHD. Three important radiographic features requiring assessment are (1) the cardiac size (cardiothoracic ratio), (2) the shape of the cardiac silhouette, and

(3) the degree of pulmonary vascular markings. The easiest method of determining the heart size in children is to determine the cardiothoracic ratio, which is obtained by relating the largest transverse diameter of the cardiac shadow on the posterior-anterior view of the CXR to the widest internal diameter of the chest. The normal cardiothoracic ratio in neonates is up to 65%; this ratio drops to 55% in older children.⁹ However, the cardiothoracic ratio may not be accurate in the newly born and small infants, in whom a good inspiratory view is difficult to obtain. In addition, the presence of a large overlying thymic shadow may also make it difficult to accurately assess the cardiac size in infants. An enlarged heart shadow on a CXR more reliably reflects a problem with volume overload than a problem with pressure overload. Problems with pressure overload are better represented by electrocardiography.

The degree of pulmonary vascular markings is one of the key factors to consider when working through the differential diagnosis of CHDs. An increase in pulmonary vascularity is present when the pulmonary arteries appear enlarged and extend into the lateral third of the lung fields, or if there is an increased vascularity to the lung apices.¹⁰ Another criterion that suggests an increased pulmonary vascularity is if the diameter of the right pulmonary artery in the right hilum on the posterior-anterior view of the chest is wider than the internal diameter of the trachea.¹⁰ Categorization into cyanotic versus acyanotic disease and assessment of pulmonary blood flow can help differentiate among CHDs (Table 30–3). Three classic cardiac silhouettes that can be seen in CHDs are (1) the “boot-shaped” silhouette of tetralogy of Fallot (Fig. 30–6); (2) the “egg-on-a-string” silhouette of D-transposition of the great arteries (Fig. 30–7); and (3) the “snowman” or “figure-of-8” silhouette of total anomalous pulmonary venous return (TAPVR) (Fig. 30–8).

In a normal left-sided aortic arch, the aorta descends to the left of the midline and displaces the tracheal air shadow slightly toward the right of midline above the level of the carina. In contrast, the tracheal air shadow may be midline

or deviated toward the left in the presence of a right-sided aortic arch.⁵ This finding is important to note since a right-sided aortic arch may be present in up to 25% of the children with tetralogy of Fallot.¹⁰ Rib notching secondary to increased collateral blood flow along the intercostal vessels may sometimes be appreciated between the fourth and eighth ribs in older children with undiagnosed coarctation of the aorta. However, this rib notching is rarely visualized in children who are less than 5 years old.¹⁰

An ECG is another useful diagnostic tool in the evaluation of an infant with a suspected underlying CHD. However,

Table 30–3 Chest Radiography in Congenital Heart Disease

Acyanotic Congenital Heart Disease

Normal pulmonary flow	PS, MS or MR, AS, coarctation of the aorta
↑ Pulmonary flow	ASD, VSD, PDA, left-to-right shunts with pulmonary hypertension, atrioventricular canal

Cyanotic Congenital Heart Disease

↓ Pulmonary flow	Severe PS, pulmonary atresia, tetralogy of Fallot (normal or boot-shaped heart), L-TGA with PS, tricuspid atresia, Ebstein's anomaly (massive heart), Eisenmenger's complex
↑ Pulmonary flow	TAPVR (snowman sign [late finding], supracardiac venous return via dilated right & left superior vena cava), hypoplastic left heart, TGA (egg-shaped heart tilted on its side with a narrow mediastinum: “egg-on-a-string”) ± VSD, truncus arteriosus

Abbreviations: AS, aortic stenosis; ASD, atrial septal defect; MR, mitral regurgitation; MS, mitral stenosis; PDA, patent ductus arteriosus; PS, pulmonary stenosis; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; VSD, ventricular septal defect.

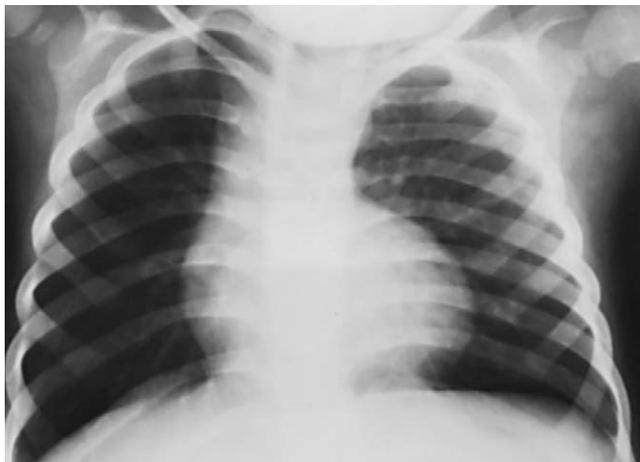

FIGURE 30–6. “Boot-shaped heart” of tetralogy of Fallot. The apex appears elevated due to right ventricular hypertrophy, the main pulmonary artery segment is missing, and there is diminished pulmonary blood flow. (From Park MK: Cyanotic congenital heart defects. In Park MK: Pediatric Cardiology for Practitioners, 4th ed. St. Louis: Mosby, 2002, p 191.)

FIGURE 30–7. “Egg-on-a-string” appearance of D-transposition of the great arteries. The cardiac silhouette is enlarged (egg shaped) while the mediastinum is narrow (stringlike) due to overlapping aorta and pulmonary trunk. Note the prominent pulmonary vascular congestion characteristic of this disorder. (From Park MK: Cyanotic congenital heart defects. In Park MK: Pediatric Cardiology for Practitioners, 4th ed. St. Louis: Mosby, 2002, p 176.)

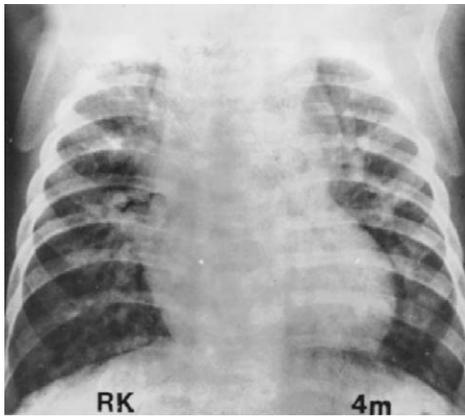

FIGURE 30–8. “Snowman sign” or “figure-of-8” sign in total anomalous pulmonary venous return. In the supracardiac type of this disorder, there are prominent venous structures returning blood to the right side of the heart, including right and left superior vena cava, and prominent left innominate vein. (From Park MK: *Cyanotic congenital heart defects*. In Park MK: *Pediatric Cardiology for Practitioners*, 4th ed. St. Louis: Mosby, 2002, p 204.)

ECG findings in infants and children can sometimes be problematic because various components of the ECG change according to the child’s age. At birth, the muscle mass of the RV is greater than that of the LV. However, by the end of the first month of life the LV assumes dominance. By 6 months of age, the LV-to-RV mass ratio is 2 : 1, which then reaches the adult ratio of 2.5 : 1 by adolescence. The durations of the PR interval, QRS complex, and QT interval all increase with age (see Chapter 63, Dysrhythmias).

A hemoglobin and hematocrit level may reveal a compensatory physiologic elevation (i.e., polycythemia) in infants with underlying cyanotic CHDs. Any concurrent medical illness or blood loss that produces an acute anemia in infants with underlying cyanotic CHD can precipitate an acute deterioration by compromising their oxygen carrying capacity. A hematocrit level also is helpful in evaluating whether an infant’s pallor is due to CHF-induced shock or anemia.

Limited studies have evaluated the utility and clinical accuracy of cardiac biochemical markers such as creatinine phosphokinase MB and cardiac troponin T in the pediatric population. Brain natriuretic peptide hormone (BNP) mediates arterial and venous vasodilation in response to ventricular wall tension and left ventricular filling pressures and is secreted by the ventricular myocytes. In children with CHF, BNP is elevated and correlates with the ejection fraction of the failing heart. Although studies are limited, measurement of BNP appears to be useful for diagnosing CHF in infants and children and for monitoring the effects of various treatments in children with CHF.^{11,12} When interpreting BNP results, clinicians must be aware that, during the first week of life, the mean plasma concentration of BNP in healthy newborn infants is 232 pg/ml and decreases to 48 pg/ml by the end of the first week. By 2 weeks of age, normal BNP levels are less than 33 pg/ml.^{13,14} In contrast, 85% of infants with a clinically significant VSD and nearly 100% with persistent pulmonary hypertension of the neonate will have a BNP greater than 40 pg/ml.^{15,16} Moreover, premature infants with a PDA almost always have a BNP value greater than 100 pg/ml.^{15,16} Importantly, normal BNP reference ranges may vary

Table 30–4

Ductal-Dependent Congenital Heart Defects (CHDs)

CHD that requires a patent ductus arteriosus to PRESERVE PULMONARY BLOOD FLOW (i.e., blood flow from the aorta to the main pulmonary artery):

- Tetralogy of Fallot
- Ebstein’s anomaly
- Critical pulmonary stenosis
- Tricuspid atresia
- Pulmonary atresia
- Hypoplastic right heart syndrome
- D-Transposition of the great vessels
- Infracardiac (subdiaphragmatic) total anomalous pulmonary venous return (TAPVR)*

CHDs that require a patent ductus arteriosus to PRESERVE SYSTEMIC BLOOD FLOW (i.e., blood flow from the main pulmonary artery to the aorta):

- Severe coarctation of the aorta
- Critical aortic stenosis
- Hypoplastic left heart syndrome
- Interrupted aortic arch

*Opening the ductus arteriosus can worsen hypoxia in patients with supracardiac TAPVR.

depending on infants’ degree of prematurity, their sex, and the specific immunoassay used. Limited studies also show elevated troponin I in infants with hypoplastic left heart syndrome (mean 1.5 ng/ml) and VSD (mean 0.6 ng/ml) who required cardiac surgery.¹⁷ However, use of this test in many other congenital defects and specific cutoffs for clinical decision making in the ED have not been defined.

Ideally, bedside echocardiography is required to define most congenital cardiac lesions. However, bedside echocardiography is not available in many EDs, and clinicians must rely upon the clinical examination, ECG, CXR, and limited bedside tests (e.g., arterial blood gases) to initiate treatment in these patients.

Important Clinical Features and Considerations

Ductal-Dependent Congenital Heart Disease

Infants with CHDs who present within the first 3 weeks of life with a sudden onset of cyanosis or cardiovascular collapse may have ductal-dependent cardiac lesions that respond to prostaglandin E₁ (PGE₁) administration.^{5,18} Closure of the ductus arteriosus in infants with certain defects causes life-threatening interruption of blood flow to the lungs, resulting in cyanosis (i.e., tricuspid atresia), or disrupted flow to the systemic circulation, producing shock (i.e., hypoplastic left heart syndrome)⁵ (Table 30–4). Measurements of oxygen saturations or Pao₂ values from the right upper extremity compared to values from the lower extremity in an infant with a suspected ductal-dependent lesion may further aid in the diagnosis. If the oxygenation in the lower extremity is significantly lower than that in the right upper extremity, coarctation of the aorta or an interrupted aortic arch should be suspected. However, if oxygenation is higher in the lower extremities as compared to the infant’s upper extremities, transposition of the great arteries should be suspected.¹⁹

Clinical Features of Hypercyanotic Spells in Tetralogy of Fallot

Tetralogy of Fallot accounts for approximately 10% of all CHDs and is the most common cause of cyanotic CHDs beyond infancy. Tetralogy of Fallot arises from a single embryologic defect in which the subpulmonic conus fails to expand, resulting in the four classic abnormalities: (1) right ventricular outflow tract obstruction; (2) a large, unrestricted, malaligned VSD; (3) an overriding aorta that receives blood flow from both ventricles; and (4) right ventricular hypertrophy due to the high pressure load from the right ventricular outflow tract obstruction. These anatomic defects collectively result in decreased pulmonary blood flow and varying degrees of right-to-left shunting of deoxygenated blood across the VSD.

The degree of cyanosis and the age of presentation are directly dependent upon the degree of right ventricular outflow tract obstruction. Infants with tetralogy of Fallot typically have worsening of their cyanosis during crying and feeding. Older children with tetralogy of Fallot may have cyanotic exacerbations during periods of physical exertion. Infants who have milder forms of right ventricular outflow tract obstruction may be acyanotic, and are sometimes referred to as “pink tets.” However, the majority of cases of tetralogy of Fallot will exhibit some degree of cyanosis. Infants with severe right ventricular outflow tract obstruction may exhibit profound cyanosis within the first few days of life and may even require a PGE₁ infusion to preserve pulmonary blood flow via left-to-right shunting from the aorta into the main pulmonary artery via a PDA.

A potentially life-threatening complication of tetralogy of Fallot is an acute hypoxic episode, also known as a “tet spell” or “hypercyanotic spell.” These episodes occur most commonly in infants between 2 and 4 months of age and may occur in other cyanotic cardiac disorders.²⁰

During a hypoxic spell, an event such as crying or defecation suddenly lowers the systemic vascular resistance (SVR), producing a large right-to-left shunt across the VSD and increased flow of deoxygenated blood into the systemic circulation. The decrease in the SVR with increased right-to-left shunting of deoxygenated blood across the VSD begins the cycle of a hypoxic spell. Acute hypovolemia and tachycardia can also precipitate these tet spells. The large right-to-left shunt through the VSD bypasses the lungs, which then causes a decrease in the Pao₂, an increase in the partial pressure of carbon dioxide (PCO₂), and a fall in the arterial pH. These metabolic changes then stimulate the respiratory centers in the brain to produce hyperpnea (deep and rapid respirations). This hyperpnea then increases the negative intrathoracic pressure during inspiration, which then causes an increase in the systemic venous blood return to the right side of the heart. This increased volume of blood in the RV is then shunted to the LV through the VSD due to the combination of the existing right ventricular outflow tract obstruction and the acute decrease in the SVR. This in turn further decreases the arterial oxygen saturation, which then further perpetuates the hypoxic spell (Fig. 30–9). Clinically these hypoxic spells are characterized by periods of hyperpnea (rapid and deep respirations), uncontrollable crying, and worsening cyanosis. The deep quality of the respirations in addition to the increase in the respiratory rate are what distinguishes

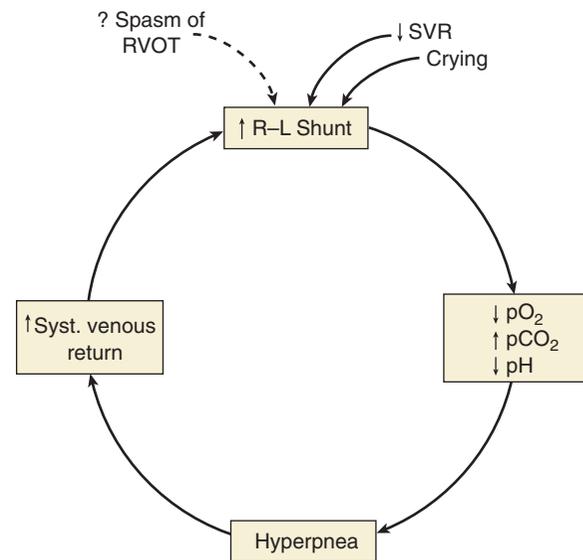

FIGURE 30–9. Mechanism of hypoxic spell. An event such as crying, defecation, or increased physical activity suddenly lowers the systemic vascular resistance (SVR), increasing the right-to-left ventricular shunt and worsening hypoxia. The decrease in the arterial partial pressure of oxygen (PO₂) stimulates the respiratory center, causing hyperventilation, which increases systemic venous return. Increased systemic venous return results in increased right-to-left (R-L) shunt, worsening cyanosis. (From Park MK: Pathophysiology of cyanotic congenital heart defects. In Park MK: Pediatric Cardiology for Practitioners, 4th ed. St. Louis: Mosby, 2002, p 122.)

the hyperpnea of a tet spell from the tachypnea due to other respiratory problems such as respiratory tract infections, which more commonly cause rapid but shallow respirations. Limpness, seizures, cerebrovascular accidents, and even death have been reported with more severe tet spells. During a tet spell, the intensity of the murmur decreases due to a decrease in blood flow through the right ventricular outflow tract obstruction and more blood being shunted from the RV to the LV through the VSD.

Respiratory Syncytial Virus Infections in Infants and Children with CHD

Infants with CHDs who develop respiratory syncytial virus (RSV) infections tend to have a higher rate of intensive care unit admissions and require mechanical ventilation more frequently than other infants with RSV infections.²¹ Children with CHDs who require hospitalization for RSV have a fatality rate that is two to six times greater than children without CHDs.²² In fact, the mortality rate from RSV is as high as 40% in infants with CHDs and 70% infants with CHDs plus pulmonary hypertension.

When evaluating infants with CHDs and respiratory symptoms, it is important to determine whether or not they have received prophylaxis (palivizumab) to decrease the probability of developing RSV infection and severity of disease.²³ Treatment of RSV bronchiolitis consists primarily of supportive measures such as providing supplemental oxygen, ensuring adequate hydration, use of bronchodilators (i.e., albuterol) in those children who seem to respond to such agents, and deep tracheal suction in more severe cases. Admission with continuous cardiopulmonary monitoring is required.

Management

Initial Stabilization and Management of Shock

The majority of the children who present to the ED with shock due to dehydration and hypovolemia are given intravenous (IV) fluids in 20-ml/kg boluses. However, this standard approach to hypovolemia cannot be routinely applied to infants with suspected CHDs who present with hypovolemic shock. Smaller (10-ml/kg) boluses should be considered in order to prevent fluid overload.⁵ Frequent reassessment is crucial in determining whether the infant's shock is solely due to hypovolemia or is due to a cardiac defect.

PGE₁ (alprostadil) can be potentially life saving in infants with CHDs and ductal-dependent systemic blood flow (e.g., hypoplastic left heart, coarctation of the aorta, critical aortic stenosis, or an interrupted aortic arch) or ductal-dependent pulmonary flow (tetralogy of Fallot, Ebstein's anomaly, critical pulmonary stenosis, pulmonary valve atresia, tricuspid atresia, D-transposition of the great arteries) (see Table 30–4).²⁴ PGE₁ is a potent vasodilator that acts to maintain the patency of the ductus arteriosus. PGE₁ can also maintain patency of the ductus venosus, aiding infants with TAPVR who have abnormal infradiaphragmatic obstructions or connections to the inferior vena cava. However, worsening hypoxia following its administration may also indicate that TAPVR (supradiaphragmatic form) is present and that PGE₁ should be discontinued. Although it is ideal to have echocardiographic confirmation of CHDs prior to initiating a prostaglandin infusion, this potentially life-saving therapy should be started immediately in any critically ill neonate with a suspected ductal-dependent CHD who presents in acute shock or cyanosis (e.g., failed hyperoxia test).⁶ The PGE₁ infusion is typically started at 0.05 to 0.1 mcg/kg/min. If there is no clinical response, the infusion rate may be increased to a maximum of 0.4 mcg/kg/min.²⁵

The effects of the prostaglandin infusion are usually seen within 15 minutes.¹⁹ Response to therapy is determined by assessing for improvements in systemic perfusion and pulmonary blood flow.⁶ Since one of the adverse reactions to a PGE₁ infusion is apnea, it may be worthwhile to intubate these infants prior to the initiation. Intubation will provide a secured airway, and controlled ventilations will help to decrease the infant's work of breathing.¹⁹ Other adverse reactions to a PGE₁ infusion include fever, seizures, bradycardia, hypotension, flushing, and decreased platelet aggregation.²⁶ Because sepsis should always be considered in the differential diagnosis of any critically ill infant, a full sepsis workup and appropriate empirical antibiotics should be considered in these infants if the diagnosis is uncertain.

Treatment of CHF

Although a wide array of disorders can cause CHF in pediatric patients, the primary etiology is an underlying CHD in infants, while myocarditis predominates in older children. The defects that are most likely to cause heart failure include left-to-right shunts (e.g., VSD, PDA, common atrioventricular canal, and truncus arteriosus), right-to-left shunts (e.g., D-transposition of the great arteries, TAPVR), and left heart obstructive lesions (e.g., hypoplastic left heart, severe aortic coarctation, critical aortic stenosis).²⁷ The specific treatment of CHF in any given case will depend upon whether there is

volume overload (left-to-right shunts), excess afterload (left heart obstructive lesions), rhythm abnormalities, or decreased contractility (e.g., cardiomyopathy). For example, inotropic agents and diuretics may be required in an infant with volume overload and decreased cardiac contractility, while vasodilating agents may be required in an infant with CHF due to increased afterload.

Acute stabilization of any infant who presents with CHF includes the administration of supplemental oxygen and administering agents to augment cardiac contractility and improve the cardiac output. Infants who present with severe respiratory distress may require intubation to support adequate oxygenation and ventilation. They also may benefit from elevation of the head and upper torso in addition to morphine sulfate (0.1 to 0.15 mg/kg per dose) administration.

Diuretics and other inotropic agents have been the mainstay of treatment for the majority of infants with CHF. Furosemide (Lasix) in a dose of 1 mg/kg per dose is the most common loop diuretic used to decrease preload. Although digoxin has remained as the most widely used inotropic agent to treat chronic CHF in infants and children, its acute use in decompensated CHF may be detrimental, increasing ischemia and worsening CHF.^{28,29} *Inotropes* are used to increase cardiac output and are particularly useful in infants with a depressed cardiac output. Inotropic agents include dopamine (5 to 10 mcg/kg/min), dobutamine, and epinephrine (<0.3 mcg/kg/min or > 0.3 mcg/kg/min when combined with a vasodilator). Importantly, vasopressors do not affect the neonatal cardiac system in a manner similar to older children and adults. Only one third of a neonate's heart is composed of contractile tissue, compared to two thirds of an adult heart. For this reason, neonates cannot alter their cardiac output by increasing contractility well. Myocardial norepinephrine stores are also immature and become rapidly depleted, making dopamine less effective in neonates and infants. Changes in adrenergic receptor expression during critical illness and production of local vasodilators during shock also can make neonates appear unresponsive to dopamine. In neonates, dobutamine is less effective than dopamine in raising blood pressure.³⁰ *Vasodilators* (e.g., nitroprusside) are used to decrease the pressure head against which the heart must pump blood to the body. Nesiritide (synthetic BNP) is an arterial and venous vasodilator with modest diuretic and natriuretic properties that has been shown useful in treating CHF in infants in limited studies, although its use is not yet routine.³¹ Amrinone and milrinone (phosphodiesterase inhibitors) have combined inotropic and vasodilating properties. Importantly, many other agents also have inotropic, vasodilator, or vasopressors effects at different doses (see Chapter 8, Circulatory Emergencies: Shock).

Management of Cyanotic Heart Disease

Most infants with cyanotic heart disease have either diminished pulmonary circulation, limiting the amount of oxygenated blood that reaches the systemic circulation, or increased pulmonary flow with a shunt that allows for deoxygenated blood to traverse from the right side of the heart to the left side of the heart and into the systemic circulation. PGE₁ can improve oxygenation in most of these patients. For infants with limited pulmonary circulation (e.g., pulmonary

stenosis, tetralogy of Fallot), opening the ductus arteriosus directly increases pulmonary flow, and thus more oxygenated blood returns to the systemic circulation. For disorders in which pulmonary hypertension plays a significant role, inhaled nitric oxide can reduce the hypertension and improve pulmonary flow.³² Low doses of magnesium sulfate (20 mg/kg/hr) may also diminish pulmonary hypertension by releasing endogenous nitric oxide and by directly reducing pulmonary and systemic vascular resistance.

For infants with increased pulmonary flow and CHF, opening the ductus allows oxygenated blood to traverse from the pulmonary arteries to the aorta (e.g., D-transposition of the great arteries). In TAPVR, PGE₁ can either improve or worsen cyanosis. With a subdiaphragmatic connection, PGE₁ can help dilate the ductus venosus and improve pulmonary venous flow. In supradiaphragmatic TAPVR, this agent dilates the ductus arteriosus, increasing right-to-left shunting and worsening cyanosis.

Any infant with a cyanotic CHD may develop a hypercyanotic spell from events that decrease SVR (e.g., crying, pain, defecation). This decrease in SVR increases right-to-left shunting, causing acidosis, worsened hypoxia, hypercarbia, and spasm of the right ventricular outflow tract. This further increases venous return to the right side of the heart, which leads to an increase in the right-to-left shunt. The overall treatment goals in the treatment of hypercyanotic spells are aimed at increasing the SVR, abolishing hyperpnea, and correcting the metabolic acidosis.³³ Although supplemental oxygen should be provided, oxygen alone will not reverse a hypercyanotic spell since there is a decrease in the amount of pulmonary blood flow and an increase in the amount of right-to-left shunting across the VSD. The infant should be picked up and placed in a knee-to-chest position.³⁴ Older children can be placed in the squatting position. Both of these maneuvers decrease the venous return to the heart and increase SVR, which in turn decreases the degree of right-to-left shunting through the VSD and increases the pulmonary blood flow. An IV fluid bolus in addition to vasoconstrictor administration (phenylephrine) will increase systemic blood pressure and SVR, which decreases shunting. Morphine (0.1 to 0.15 mg/kg) theoretically suppresses the respiratory center, and thereby abolishes the hyperpnea that is associated with a hypercyanotic episode. One potential adverse effect of morphine is that it may cause systemic vasodilation, further decreasing SVR. Although there are no current studies evaluating the use of other medications that may also suppress the respiratory centers, fentanyl and midazolam could be utilized for the same effect without the potential risk of endogenous histamine release seen with morphine. Ketamine (1 to 2 mg/kg IV or intramuscularly) has also been suggested for its sedative effect as well as for its effect on increasing the SVR.²⁰ Sodium bicarbonate may also be given to correct metabolic acidosis, reducing respiratory center stimulation. Most infants will respond to these measures and exhibit an improvement in their oxygenation and a decrease in their degree of cyanosis. Infants who do not improve may require a vasopressor such as phenylephrine (5 to 20 mcg/kg per dose by IV bolus) to increase the SVR and thereby decrease the degree of right-to-left shunting across the VSD.³⁵ Propranolol (0.02 mg/kg) has also been used as an adjunct to break the cycle in refractory hypercyanotic episodes.³³ Although the exact pharmacophysiologic mechanisms by which it accom-

plishes this is uncertain, propranolol is thought to increase the SVR and perhaps promote an increase in the pulmonary blood flow by reducing spasms of the right ventricular outflow tract obstruction.

Patients with repaired CHDs comprise a population of infants at risk for unique disorders and complications requiring specialized treatment (see Chapter 66, Postsurgical Cardiac Conditions and Transplantation).

Summary

Infants and children who present to the ED with undiagnosed or untreated congenital heart disease can pose a myriad of challenges. The possibility of an undiagnosed CHD must always be considered in the differential diagnosis of any infant who presents to the ED with recurrent or persistent respiratory infections, respiratory distress, cyanosis, or shock. Ongoing advances in the technology of bedside echocardiography may provide the ED physician with the opportunity to more accurately confirm CHDs within the ED.

While it may not be possible to identify the exact defect present in each patient, clinicians usually can categorize patients into major categories of disease (e.g., cyanotic lesions, acyanotic lesions, ventricular outflow tract obstruction). Based on these categories, management can be initiated. Importantly, ductal-dependent lesions must be suspected early so that administration of PGE₁ can begin promptly. Those infants with profound shock or a failed hyperoxia should be considered candidates for this agent.

Timely consultation with a pediatric cardiologist or a pediatric cardiovascular surgeon is also an essential component in the ongoing management of any infant or child with a suspected or known CHD.

Chapter 31

Excessive Crying

Marilyn P. Hicks, MD and Lance Brown, MD, MPH

Key Points

There are no evidenced-based guidelines for the emergency department evaluation of the infant with persistent, excessive crying.

There is a substantial subset of infants with persistent, excessive crying who harbor a serious illness.

Colic is a diagnosis of exclusion.

Introduction and Background

Infant crying occurs as a response to physiologic needs, such as hunger, cold, or discomfort. As such, crying is the primary form of nonverbal communication between an infant and his or her caregiver. As the demands of crying are met, conditioning occurs and infant-parent bonding is established. In 1962, Brazelton studied daily crying records of 80 infants during the first 12 weeks of life and described an escalation of normal crying from a median of 1.75 hours at age 2 weeks to a peak of 2.75 hours at 6 weeks, followed by a gradual decrease in total daily crying to approximately 1 hour daily at age 12 weeks.¹ Excessive crying occurs outside the normal cycle of infant demand and parental response.¹⁻⁵ Brazelton identified a subset of infants whom he referred to as “heavy fussers” who cried on average 1 hour more per day than the “light” fussers, who exhibited “normal patterns” of crying.¹

Some infants with acute, excessive crying harbor serious illnesses (Table 31–1). Differentiating infants at high risk for harboring a serious illness from others is a key task for emergency physicians. The body of medical literature addressing acute, excessive crying secondary to organic disease consists of Poole’s study of 56 healthy, afebrile infants presenting to an emergency department,⁶ a small case series,⁷ and case reports.⁸⁻¹¹ Poole’s study is significant in that nearly two thirds of the infants who presented with acute, unexplained, excessive crying had a serious etiology. In this study, neither the duration nor the intensity of the crying were related to the seriousness of the underlying condition.

Recognition and Approach

The definition of excessive crying is highly variable and largely dependent upon parental perception and assessment.¹² The majority of studies of excessive crying are concerned with the prevalence, etiology, and treatment of colic or the behavioral aspects of crying. The relevance of these studies to the practice of emergency medicine is minimal. Based on these studies and inherent definitional problems, the incidence of excessive crying is between 1.5% and 43% of infants.^{5,12-14} The epidemiology of serious illnesses in infants who present to the emergency department with a chief complaint of excessive crying is unknown. Parental misperception may account for some complaints of excessive crying. Clinical experience suggests new parents may present to the emergency department because they are uncertain how much crying is normal.

Clinical Presentation

The differential diagnosis of the infant with excessive crying is very broad and encompasses life-threatening as well as benign conditions (see Table 31–1). The differential diagnosis is to a certain degree age-based, specifically in reference to the very young infant in the first 2 months of life.

The history may identify “red flags” suggesting an increased likelihood of a serious condition being present (Table 31–2). Certain features of the history may require special attention. Breastfeeding mothers may be unaware that medications they are taking might be transmitted to their infant during feeds.¹⁵⁻¹⁷ Although present, use of illicit drugs or parental alcoholism may lead to false histories in an attempt to hide culturally stigmatized behavior. In Poole’s study, the history provided clues to the diagnosis in only 20% of infants.⁶

The physical examination may suggest the etiology of the excessive crying. In Poole’s study, the physical examination revealed the diagnosis in 41% of cases and provided clues to the diagnosis in another 13%.⁶ Therefore, a rather detailed physical examination directed at specific findings has good utility. While at the examination room doorway, the clinician should take note of the infant’s overall appearance, mental status, and parental interaction. The quality of the cry should be noted. A shrill or high-pitched cry suggests a central nervous system abnormality, and a weak and feeble cry is common to many serious illnesses. Vital signs should be evaluated, including blood pressure and pulse oximetry.

Table 31–1 Differential Diagnosis of Excessive Crying**Infectious**

Meningoencephalitis
Sepsis
Urinary tract infection
Osteomyelitis, septic arthritis, diskitis
Pneumonia, bronchiolitis
Otitis media
Gingivostomatitis, pharyngitis, thrush
Retropharyngeal cellulitis/abscess

Trauma

Nonaccidental injury
Accidental fracture, dislocation
Corneal abrasion or foreign body

Gastrointestinal

Malrotation with midgut volvulus
Intussusception
Gastroesophageal reflux disease
Constipation
Anal fissure
Milk protein allergy
Gastroenteritis
Appendicitis

Genitourinary

Incarcerated inguinal hernia
Testicular torsion, hydrocele

Cardiovascular

Supraventricular tachycardia
Myocarditis
Congestive heart failure
Coronary ischemia

Hematologic

Sickle cell disease
Iron deficiency anemia

Neurologic

Increased intracranial pressure
Hydrocephalus
Pseudotumor cerebri

Toxic-Metabolic

Neonatal drug withdrawal syndrome
Breast milk drug transmission
Immunizations
Ingestion
Electrolyte abnormalities
Inborn errors of metabolism
Hypoglycemia

Dermatologic

Eczema
Diaper dermatitis
Cellulitis, abscess
Hair tourniquet
Insect bites and stings

The infant's weight should be measured and compared to the birth weight (see Chapter 36, Failure to Thrive). The infant should be evaluated for paradoxical irritability. Normally, infants are soothed and calmed by being held and rocked gently in a caregiver's arms. Paradoxical irritability is present when an infant appears to be more comfortable when lying still than when gently rocked. Conditions such as meningitis may present with paradoxical irritability as the infant's inflamed meninges are aggravated by motion. In cases of pseudoparalysis of an extremity, an infant will fail to move

Table 31–2 "Red Flags" for Serious Etiologies Presenting with Excessive Crying**History**

Maternal drug use
Premature rupture of membranes
Perinatal maternal fever or infection
History of fever (particularly in the first 2 months of life)
Vomiting (particularly if bilious)
History of bloody stools
Decreased feeding or activity
Increased somnolence
Abnormal behavior or "spells"
Difficulty feeding, sweating with feeds, or poor weight gain
Recent antibiotic use
Recent trauma, unexplained bruising, or inconsistent history
Delay in seeking care
Caregiver intoxication
Caregiver mental illness

Physical Examination

Abnormal vital signs
Ill appearance
Persistent, unexplained tachycardia or tachypnea
Paradoxical irritability
Pseudoparalysis
Jitteriness
Abnormal muscle tone
Blood in the diaper
Low weight

an injured extremity such that it appears paralyzed. Inflammatory processes such as osteomyelitis and septic arthritis may present with pseudoparalysis.

Fluorescein staining of the eyes may reveal a corneal abrasion.¹⁰ Infants have rapidly growing fingernails and poor hand control, putting them at risk for corneal abrasions. Scleral injection is less likely to be present in young infants than in older children. If a topical ophthalmic anesthetic is instilled into the eyes in preparation for the fluorescein staining, the infant with a corneal abrasion may abruptly stop crying and resume normal activity. The ears should be examined for otitis media. If the ipsilateral tympanic membrane is intact and otitis media appears to be contributing to the crying, instillation of two to four drops of benzocaine/antipyrine (i.e., Auralgan) into the ear canal may be diagnostic if the infant abruptly stops crying and resumes normal activity. If the infant presents a quiet moment, the fontanelles should be evaluated for size and fullness, and the neck examined for evidence of trauma, adenopathy, or masses and for range of motion.

The clinician should assess the infant's work of breathing and auscultate the lungs. Abnormal breath sounds may be suggestive of pneumonia, bronchiolitis, or congestive heart failure. The heart should be auscultated for abnormal tones. The presence of a murmur, ventricular heave, or thrill suggests congenital cardiac disease. The clavicles should be palpated, assessing for fracture. In addition to observation of the chest for increased work of breathing and auscultation of the lungs and heart, the chest wall, ribs, and clavicles should be palpated for tenderness or deformity. Examination of the abdomen of the crying infant is exceedingly difficult and may require repeat assessments over time. The anal area should be examined for rash, signs of trauma, and fissures. Each finger and toe and the genitalia should be examined for hair

tourniquets (see Chapter 37, Minor Infant Problems). The scrotum should be examined for swelling, which may be suggestive of a hernia, a hydrocele, or testicular torsion (see Chapter 87, Testicular Torsion). The skin should be examined for bruises, abrasions, abscesses, burns, and scars. Bruising in young infants is uncommon and more likely to be a manifestation of abuse than in older children.¹⁸

Important Clinical Features and Considerations

Although the main objective of the emergency department visit for an infant with excessive crying is to identify serious illnesses, there are several benign causes amenable to treatment in the emergency department. These include corneal abrasions, hair tourniquets, oral thrush, nasal congestion, anal fissure, eczema, diaper dermatitis, constricting clothing, and overbundling (see Chapter 37, Minor Infant Problems). Although relatively common, colic is a diagnosis of exclusion.

Management

There is no specific treatment for excessive crying. There are no practice guidelines, and very limited evidence exists on which to base a management plan. If an infant can demonstrate an awake, calm period in the emergency department and has no “red flags” on history or physical examination, the infant is very unlikely to harbor a serious disease. Therefore, discharge home with follow-up the next day with the pediatrician or in the emergency department (e.g., on weekends and holidays) is probably a reasonable plan in these cases. If there is uncertainty as to the adequacy of the duration of the calm period, further observation in the emergency department is prudent. Simple causes of excessive crying such as constrictive clothing, overbundling, corneal abrasions, anal fissures, oral thrush, and hair tourniquets should have been identified and treatment should have been initiated following the physical examination. If a simple cause has been identified and the infant can demonstrate an awake, calm period after the simple cause has been addressed, it is reasonable to discharge the infant home with primary care follow-up.

Infants who cannot show a period during which they are awake, calm, and acting normally after simple causes have been ruled out pose a diagnostic dilemma. These infants have a relatively high likelihood of harboring a serious condition, but the differential diagnosis is extremely broad (see Table 31–1). To evaluate each infant for all of these conditions is not intuitively appealing. Clinical experience suggests one reasonable approach is to perform a septic workup, including a complete blood count, blood culture, catheterized urinalysis, urine culture, and cerebrospinal fluid studies (cell count, glucose, protein, and culture), and obtain a set of electrolytes, including glucose measurement. If nonaccidental trauma is suspected, a head computed tomography scan and skeletal survey of plain radiographs may be included in the workup. Other studies that may be rather simply added to the

workup include a serum ammonia level and venous pH (see Chapter 29, Inborn Errors of Metabolism) and an electrocardiogram to evaluate the infant for supraventricular tachycardia.

Summary

There are no evidenced-based guidelines specific to the infant with excessive crying. Crying episodes may resolve without any specific intervention on the part of the parents or health care providers. These infants are at a very low risk of harboring a serious illness. Colic is a diagnosis of exclusion. There is a subset of infants presenting to emergency departments with acute, unexplained, excessive crying who have serious organic disease. Infants who persist in having excessive crying after benign causes have been ruled out are at relatively high risk for harboring a serious illness. An extensive laboratory workup and admission to the hospital are indicated for these infants.

Fever in the Well-Appearing Young Infant

Kristine G. Williams, MD, MPH and David M. Jaffe, MD

Key Points

Febrile illnesses account for 10% to 20% of pediatric visits to emergency departments.

Due to immunologic deficiencies, neonates and infants (<3 months) are particularly susceptible to infections by certain organisms.

The clinical detection of serious infection is more challenging in the young infant than in other age groups because of a more limited behavioral repertoire.

A well-appearing young infant may still have a serious bacterial illness.

Judicious use of antibiotics and hospitalization continue to be goals in the evaluation and treatment of febrile infants.

Introduction and Background

Fever is one of the most common reasons for sick children to visit the emergency department, and it accounts for 10% to 20% of pediatric visits. Two thirds of all children will have visited a physician for the evaluation of fever by 2 years of age. Because of maturational immunologic deficiencies and a limited behavioral repertoire, febrile infants younger than 3 months of age are a distinct subset of this population. The unique characteristics of the young infant must be considered during evaluation and treatment.

By convention, fever in a young infant is defined as a rectal temperature of 38° C (100.4° F) or above.¹ Although axillary and tympanic thermometers are convenient, they are not reliable in young infants. In any case, temperature should not be the only factor used to make a management decision. This is particularly important if the infant is afebrile but has a history of irritability, poor feeding, lethargy, or any other behavioral change that is of concern to the parent. Although

the predictive value of hyperpyrexia (temperature > 40° C/ 104° F) is low for individual infants, there is a correlation between height of temperature and rate of serious bacterial illness (SBI). According to one study, SBI is found in approximately 26% of 4- to 8-week old infants with temperatures over 40° C.² The clinician needs to appreciate, however, that serious illness may also be present in infants with normal or below-normal body temperatures.

Serious bacterial infection is defined as the growth of a bacterial pathogen in cultures of specimens of the blood, urine, cerebrospinal fluid (CSF), bone, joint fluid, or stool. The most common bacterial pathogens causing SBI vary by age. In the first month of life, *Escherichia coli* and group B streptococcus (GBS) are the usual sources. From 1 to 3 months, SBI is still predominantly caused by GBS and *E. coli*, but other organisms such as *Listeria monocytogenes*, *Streptococcus pneumoniae*, *Neisseria meningococemia*, *Salmonella*, and *Haemophilus influenzae* are also found.³ Young infants are also at risk for serious infection from viruses, such as herpes simplex virus (HSV) and enterovirus. HSV is more common in infants born to mothers with primary rather than secondary HSV infection. Within the United States, enteroviruses are the most common cause of childhood aseptic meningitis and nonspecific febrile illness.⁴ Both HSV and enterovirus can cause life-threatening meningitis or encephalitis.

The young infant is particularly susceptible to infection because of an immature immune system. Neonates have definable deficiencies in specific antibody, complement, and other opsonins, and in phagocyte number and function.⁵ These deficiencies contribute to their increased susceptibility to GBS and other pyogenic bacteria. Serious infection from intracellular organisms is likely due to reduced attraction of macrophages to the site of infection because of insufficient generation of lymphokines and interleukins in those infants with an immature immune system. The neonate's susceptibility to HSV infection is thought to be due to a lack of passively acquired antibodies and the decreased activity of nonimmune and immune cellular cytotoxic mechanisms. The exact age at which most of the immune system reaches maturity is unknown, though the risk of severe infection with most of these pathogens seems to wane by 2 to 3 months of age.⁵

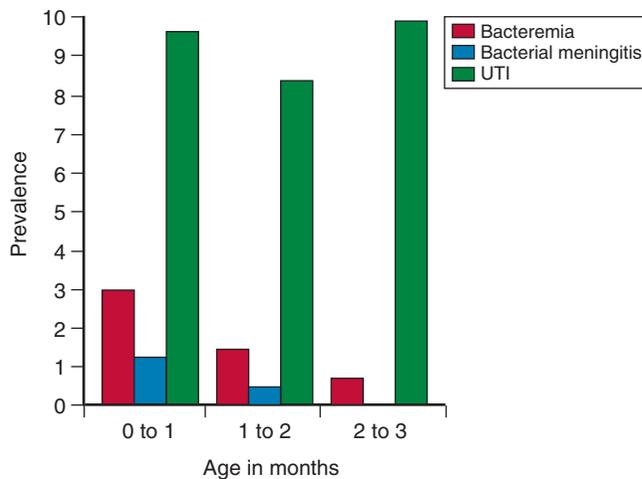

FIGURE 32-1. Prevalence of bacteremia, bacterial meningitis, and urinary tract infection (UTI) in febrile infants. Recognition and Approach

Based on data from a nationwide prospective cohort study conducted by the Pediatric Research in Office Settings (PROS) Network of the American Academy of Pediatrics, the rate of bacteremia and bacterial meningitis in febrile young infants appears to decrease with age.⁶ In a consecutive sample of 3066 infants ages 3 months or younger with temperatures of at least 38° C seen by office practitioners, the overall rates of bacteremia and bacterial meningitis were 1.8% and 0.5%, respectively. For infants up to 1 month of age, the rate of bacteremia was 3%, that of bacterial meningitis was 1.2%, and that of bacteremia with bacterial meningitis was 4.1%. As the infants matured, the rates decreased. By 1 to 2 months of age, the risk of bacteremia was 1.5%, that of bacterial meningitis was 0.4% and that of bacteremia/bacterial meningitis was 1.9%. Infants 2 to 3 months had rates of 0.7% for bacteremia, 0% for bacterial meningitis, and 0.7% for bacteremia/bacterial meningitis (Fig. 32-1). Age less than 30 days, higher temperatures, ill appearance, abnormal cry, and abnormal white blood cell (WBC) count (<5000 or >15,000 WBC/mm³) were associated with a high risk of bacteremia/bacterial meningitis. A low risk of bacteremia/bacterial meningitis (0.4%) was found in those who were well-appearing, 25 days of age or older, and with a temperature below 38.6° C.⁶ The overall prevalence of urinary tract infection (UTI) was 5% for the entire cohort and 9% for those tested for UTI.⁷ The rate was highest for girls (11.9%) and uncircumcised boys (19.5%). Infants younger than 30 days with a UTI had a rate of 17% for associated bacteremia. The risk of UTI-associated bacteremia decreased with age, with a rate of 8% for 1- to 2-month-old infants and 6% for 2- to 3-month-old infants.⁷ It is important to note that all laboratory testing was performed at the discretion of the practitioner after recording signs and symptoms and an overall assessment of clinical appearance. This practical approach worked well in this study setting, where over half

of the 1975 infants treated as outpatients were examined on more than one occasion. However, in the emergency setting, where infants are evaluated during a single visit, a more cautious approach is warranted.

A complete sepsis evaluation is recommended in a febrile infant ≤28 days of age.^{1,8-10} The sepsis evaluation should include a complete blood count (CBC) with differential count; a urinalysis; examination of the cerebrospinal fluid (CSF) for cells, glucose, and protein; and cultures of blood, urine, and CSF. If there are respiratory symptoms or diarrhea, a chest radiograph and a stool culture, respectively, should also be obtained. Hospitalization and administration of a parenteral antibiotic combination such as ampicillin and either cefotaxime or gentamicin is generally indicated until culture results are available.

While the approach to the infant ≤28 days of age is straightforward based on current data, controversy and variation exist regarding the evaluation and management of infants 29 to 60 days of age with fever. Many of these infants have self-limited viral infections. Routine hospitalization and administration of intravenous antibiotics may not be optimal as this practice is costly and associated with iatrogenic complications.¹¹ Prospective research on this population has resulted in criteria to help distinguish patients at low risk for bacterial disease from patients at high risk.¹² The purpose of defining these groups is to help identify which patients should be hospitalized and which patients can be treated as outpatients either with or without antibiotics. The Boston, Rochester, and Philadelphia strategies are results of this research. Although each approach is slightly different in terms of patient age, evaluation components, and management, any of them is a suitable guideline for helping the clinician identify infants at low risk for SBI (Table 32-1).

The study conducted in Boston tested the safety and efficacy of outpatient management of 503 one- to three-month-old infants judged to be low-risk for bacterial disease by screening criteria¹³ (see Table 32-1). All infants received intramuscular ceftriaxone, 50 mg/kg, at 24 and 48 hours and had close follow-up. Although 5% of the population initially judged to be low risk had bacterial disease, including bacteremia, UTI, and gastroenteritis, all recovered without incident and had no complications attributable to their initial outpatient management. The authors concluded that, although the clinical screening criteria did not satisfactorily discriminate between infants with and without SBI, all infants with SBI received appropriate therapy and were well at follow-up.¹⁵ After full evaluation for sepsis, outpatient management of low-risk febrile infants with intramuscular ceftriaxone seems to be a safe alternative to hospitalization. It is important that patients managed this way receive a full evaluation for sepsis, including a lumbar puncture, and close follow-up until final culture results are available.

Investigators in Philadelphia initially studied 747 infants 29 through 56 days of age to evaluate the efficacy of managing fever without routine hospitalization and antibiotic therapy.¹⁴ Infants not meeting all the low-risk criteria were hospitalized for parenteral antimicrobial therapy. Those judged to be low risk were assigned to either inpatient observation without antibiotics or outpatient care without antibiotics but with reexamination after 24 and 48 hours. There were no serious illnesses in the outpatient group who were observed without antibiotics.¹⁴ A follow-up study done to

Table 32–1 Summary of Low-Risk Criteria for Serious Bacterial Illness: The Boston, Philadelphia and Rochester Criteria

	Boston	Philadelphia	Rochester
Age	1–3 months	1–2 months	Birth–3 months
History	No antibiotics No immunizations past 48 hr	No immune deficiency	Term (>37 wk) No antibiotics Never hospitalized No unexplained hyperbilirubinemia No chronic or underlying illness Not hospitalized longer than mother
Physical Examination	Nontoxic No focal infection	Infant observation score ≤ 10 No sign of bacterial infection	Appears generally well No focal infection
Labs	WBC < 20,000 U/A: < 10 WBC/hpf or negative leukocyte esterase	WBC < 15,000 Band/neutrophil ratio < 0.2 Spun U/A: < 10 WBC/hpf, no bacteria CSF: < 8 WBC/hpf, negative Gram stain Stool (if diarrhea): < 5 WBC/hpf	WBC 5000–15,000 Absolute band count < 1500 Spun urine: < 10 WBC/hpf Stool (if diarrhea): < 5 WBC/hpf
CXR	(if obtained): No focal infiltrate	No focal infiltrate	

Abbreviations: CSF, cerebrospinal fluid; CXR, chest radiograph; hpf, high-power field; U/A, urinalysis; WBC, white blood cells.

evaluate the efficacy of this strategy 18 months after it was introduced found that none of 43 febrile infants 29 to 60 days old with SBI were identified as low risk. Thus the Philadelphia protocol for outpatient management without antibiotics for low-risk febrile infants 29 to 60 days of age was shown to be practical, reliable, and safe.¹⁵ However, when the criteria were applied retrospectively to 254 febrile infants less than 28 days of age, 109 (42.9%) of them would have been identified as at low risk for bacterial disease. Of these 109 infants classified as low risk for SBI, 5 had bacterial diseases (2 UTI, 2 bacteremia, 1 bacterial gastroenteritis). The authors concluded that the Philadelphia protocol does not adequately predict SBI in febrile neonates.⁸

The Rochester criteria, based on data from 233 infants birth to 60 days of age, were developed to identify which infants are at low risk for SBI. Only one of the infants classified as low risk was found to have SBI (*Salmonella* gastroenteritis without bacteremia), compared to 25% of the infants in the high-risk group.¹⁶ Unlike the Boston and Philadelphia studies, however, this study does not address the issue of hospitalization or antibiotic therapy. The Rochester criteria were evaluated prospectively in a sample of 931 well-appearing infants. SBI (all UTIs) occurred in 1% of the 511 infants who met all of the low-risk criteria.¹⁷ More than one third of the low risk infants were managed initially without antimicrobial therapy and experienced no untoward effects. The negative predictive value of the criteria was found to be 98.9% for SBI and 99.5% for bacteremia. The authors recommended that febrile infants less than 60 days of age who met all of the low-risk criteria could be managed as inpatients or outpatients by observation without antibiotics or with a single dose of intramuscular ceftriaxone after blood, urine, and CSF samples had been obtained for culture.¹⁷

Both the Boston and the Philadelphia management protocols have been applied retrospectively to infants in the first month of life. Within this age group, these strategies have a 97% negative predictive value. In other words, when the strategies were applied to infants birth to 28 days, 3% of the infants who fulfilled all the low-risk criteria were found to have SBI.⁹ Since infants less than 28 days of age have the

Table 32–2 Signs and Symptoms Associated with Neonatal Infection**Signs**

highest risk of SBI and the most limited behavioral repertoire, this suggests that all infants younger than 28 days of age should be managed with a complete sepsis evaluation and hospitalization.

Clinical Presentation

The young infant presenting with fever is a diagnostic challenge. The clinician must have a low threshold for concern because of the broad range of signs and symptoms associated with neonatal infection (Table 32–2). Since the scope of presentation ranges from well-appearing to toxic-appearing, the history and laboratory evaluation become extremely important in guiding the clinician's decisions.

The differential diagnosis for fever in the first few months of life includes bacterial infection acquired in utero, at delivery, in the nursery, at home, or because of an underlying anatomic abnormality (e.g., vesicoureteral reflux, posterior urethral valves, ureteropelvic junction obstruction). Viral infections are also a consideration. In particular, one should consider viruses acquired at birth, such as HSV, and those commonly spread by contact, such as enterovirus, respiratory syncytial virus (RSV), and influenza virus. The immunizations given at the 2-month check up, diphtheria/tetanus/acellular pertussis (DTaP) and *H. influenzae* type b (Hib), may cause fever for 24 to 48 hours after inoculation. However, immunizations should not be considered the cause of fever in a toxic-appearing infant. Although it is extremely rare that fever in this age group is caused by noninfectious causes, overbundling a young infant can cause temporary elevations in body temperature. If an infant is well-appearing, it is reasonable to unbundle the infant for 15 to 30 minutes and reassess the temperature prior to making management decisions. If the temperature normalizes, the infant still appears healthy and has not received an antipyretic, the infant can be considered to be afebrile.

A young infant with fever should first be evaluated for a toxic appearance. A toxic-appearing infant is one with a clinical picture of the sepsis syndrome—lethargy, signs of poor perfusion, hypoventilation, hyperventilation, or cyanosis. Because toxic-appearing infants under 12 weeks of age have a 17% chance of having bacterial infection, rapid evaluation and treatment are vital in these infants.¹⁸ After obtaining cultures of blood, urine and CSF, parenteral antibiotics should be administered. A broad-spectrum antibiotic such as ceftriaxone is effective against most organisms that cause sepsis. Ampicillin is recommended to cover *L. monocytogenes*. Acyclovir should be added if there is concern for herpes or herpes meningitis. Therapy should not be delayed if specimen collection is prolonged.

The rapid assessment of appearance is complex. Observation scales have been developed in an attempt to quickly identify serious illness in febrile children. One such scale, the Infant Observation Score (IOS), was created based on data from febrile children under 24 months.¹⁹ Patients were scored for quality of cry, reaction to parental stimulation, state variation, color, hydration, and response to social overtures. In children under 24 months of age, the score was reliable, predictive, specific, and sensitive for identifying serious illness in children.¹⁹ Subsequently, it was tested on febrile infants 4

to 8 weeks old, whose neurologic immaturity and limited behavioral range make scoring difficult and imprecise. In this age group, 22% of those with a score classifying them as low risk had serious illness.²⁰ This suggests that the IOS alone is not sufficient to identify serious illness in the 4- to 8-week-old infant. However, when it is used in combination with other examination and laboratory screening criteria, as it is in the Philadelphia criteria, it may be helpful in defining a low-risk population.

After the initial assessment, a thorough history and a detailed physical examination should be completed. Key historical questions focus on changes in the infant's behavior: increased or decreased sleeping, decreased feeding, irritability, respiratory distress, agitation, or lethargy. Since these infants are often only a few days or weeks old, the behavioral changes may be difficult for new parents to appreciate unless they are asked about them specifically. An infant with a history of documented fever at home who is afebrile in the emergency unit should be managed as if fever is present.^{21,22}

Very young infants with febrile illness have an inconsistent presentation. The neurologic and behavioral immaturity during the first few months of life may also confound the presentation. In the first month of life, most newborns sleep approximately 16 to 18 hours a day. The amount of time spent in sleep may make it difficult to assess whether an infant is more sleepy than usual. As the brain matures, the amount of time spent in a wakeful state increases, making some of the behavioral changes associated with illness more apparent. An understanding of the timing of some developmental milestones may help the clinician assess behavioral change, adding another dimension to the evaluation of the newborn infant²³ (Table 32–3). Older infants and children have a more established sleep/wake cycle and more complex social interaction, making deviations from normal more apparent.

The choice of diagnostic tests should be guided by the infant's age and presentation. A toxic-appearing infant or an infant under the age of 1 month should receive a full sepsis evaluation with a chest radiograph and stool culture, if indicated. Well-appearing infants and those older than 1 month may receive any combination of tests in the sepsis evaluation based on presentation. There is no single laboratory test that entirely predicts a bacterial disease, nor is there one that entirely rules out a bacterial disease.

A CBC should be obtained for all infants receiving a sepsis evaluation. In older infants and children, a high absolute neutrophil count (>10,000/mm³) is associated with higher

Table 32–3 Developmental Changes during the First 3 Months of Life*

Age (mo)	Sleep (hr/day)	Social	Movement	Vision	Hearing

[†]Beginning to develop more regular sleep pattern.

risk of bacteremia.²⁴ Although this has not been reproduced in young infants, the outcomes of the studies done in Rochester and Philadelphia suggest that a normal WBC count (between 5000 and 15,000/mm³) and a low band count can help stratify patients as being at low risk for SBI.^{14,16} Specifically, the investigators in Philadelphia were able to achieve 100% accuracy when prospectively identifying infants 1 to 2 months old at low risk for bacterial disease by incorporating a band-to-neutrophil ratio of less than 0.2.¹⁴

Blood cultures are the “gold standard” for determination of bacteremia. Although blood culture results are not available immediately, most true pathogens are detected by 24 hours. In the well-appearing infant, nonpathogenic organisms may be considered contaminants, especially if recovered after 48 hours.

Lumbar puncture (LP) is indicated if sepsis or meningitis is suspected, if the infant is 28 days of age or less, or if the clinician plans to administer antibiotics. Evaluation of the CSF should include cell count, differential, protein and glucose measurement, and Gram stain and culture. As normal values for serum WBC counts vary slightly by age (Table 32–4), so do normal values for spinal fluid²⁵ (Table 32–5). Since the CSF does not normally contain red blood cells, their presence indicates a traumatic LP or central nervous system (CNS) hemorrhage. The latter is more likely if the red blood cells do not diminish between the first and the last specimen tube. CNS hemorrhage may be a result of trauma or infection, particularly with HSV. In the healthy neonate, it is not unusual to see 8 to 10 WBC/mm³. There is typically a predominance of neutrophils in the CSF of patients with bacterial meningitis. Infants with bacterial meningitis will often have an elevated protein (>100 mg/dl) and a low glucose (<30 mg/dl) level. However, early in the course of meningitis, parameters also may be normal. If indicated by history or physical examination, the spinal fluid should also be sent

for herpes and enterovirus polymerase chain reaction (PCR) studies.

The decision to order a chest radiograph should be based on the infant’s symptoms. Routine ordering of chest radiographs is not indicated in the absence of respiratory signs.²⁶ However, the presence of retractions, rales, rhonchi, and isolated tachypnea or the presence of cough with another respiratory sign, such as tachypnea or retractions, is predictive of focal changes on a chest radiograph.

Stool samples are not indicated for all febrile infants. However, if the infant presents with watery or bloody diarrhea, a stool sample should be obtained for microscopic examination and culture. Bacterial enteritis is indicated by the presence of blood or greater than 5 WBCs per high-power field. Blood in the stool is associated with bacterial gastroenteritis, but it is a nonspecific finding also seen with rotavirus and other viral causes of diarrhea. Although WBCs may be present on stool smear in those infants with bacterial gastroenteritis, absence of WBCs does not indicate absence of bacterial disease.

UTIs are the most common of the serious bacterial illnesses in the well-appearing febrile young infant, occurring in approximately 7.5% of febrile infants under 8 weeks of age. Uncircumcised males and white girls are at highest risk.^{7,27} UTI should be considered in all febrile neonates because of associated bacteremia and sepsis. Although urinalysis alone has been shown to be a sensitive and independent indicator of the presence of UTI in older children, it is not so in infants. Appropriate evaluation for a UTI in infants includes a urinalysis and urine culture on a specimen obtained by catheter or suprapubic aspiration.²⁸

Viruses are a common cause of fever in the neonatal period. A nasopharyngeal swab for fluorescent antibody stain and culture should be considered in an infant with fever and wheezing, cough, tachypnea, or other respiratory symptoms, particularly during the winter months. The sample should be tested for RSV; influenza A and B viruses; parainfluenza 1, 2, and 3 viruses; and adenovirus. Enterovirus is the most common cause of aseptic meningitis. Detection of enterovirus by culture is limited by a sensitivity of only 65% to 75% and a processing time of 3 to 10 days. Compared with viral culture, the CSF PCR was 100% sensitive and 90% specific for the diagnosis of enteroviral meningitis in a study of febrile infants less than 3 months of age.⁴ PCR assays of serum and urine are also more sensitive than culture, but for the detection of enteroviral meningitis, CSF PCR is adequate.²⁹ Although concurrent viral and bacterial disease can occur, the detection of enterovirus by PCR in an otherwise well-appearing infant with normal laboratory results may help the clinician be judicious about using antibiotics. Herpes simplex virus PCR or culture should be obtained in infants with a concerning history or with seizures; signs of sepsis; characteristic skin, eye, or mouth lesions; or CSF findings suggestive of CNS hemorrhage. If the clinician suspects HSV, acyclovir should be started empirically.

Important Clinical Features and Considerations

Approximately 7% of febrile infants younger than 3 months of age have SBI, and the remainder are presumed to have a

self-limited viral cause for fever. It is important to consider whether infants with a self-limited viral illness have coexisting bacterial disease. It is generally believed that infants with objective evidence of a viral infection do not need a complete sepsis evaluation. RSV is a common cause of lower respiratory disease in infants. Patients typically present with symptoms such as wheezing, tachypnea, respiratory distress, apnea, and fever. Studies of older infants (>28 days) and children suggest that the risk of bacteremia in non-toxic-appearing patients with documented RSV infection is rare enough that routine cultures of blood and spinal fluid are not indicated.³⁰ In most of the studies, UTI was the most common concurrent SBI.³¹⁻³⁵ In a prospective study of 1248 infants under 2 months of age, the rate of SBI in RSV-negative infants was 12.5% as compared to 7% in patients with RSV. A sub-analysis of the data by age revealed that the overall rate of SBI in infants 28 days or younger did not differ significantly between those who were and those who were not infected with RSV (10.1% vs. 14.2%). In RSV-positive infants, the overall rate of UTI was 5.4% as compared to 10.1% in those without RSV.³¹ Although there is wide variability in diagnostic testing of young infants with bronchiolitis, the risks of bacteremia and meningitis in this population seem to be low if the infant is non-toxic appearing and older than 28 days. However, there continues to be a risk of UTI similar to that of a well-appearing febrile young infant without RSV. Thus it is prudent to obtain a urinalysis and urine culture of a catheterized urine specimen from the infant with fever. Despite the reassuring data about the risk of bacteremia and meningitis in infants under 90 days of age with RSV infection, in those 28 days or younger, it is best to assume that the risk of SBI is not changed by the presence of RSV and to perform a full sepsis evaluation.

Acute otitis media is the most common bacterial infection in children. Bacterial organisms are identified in 60% to 70% of cases when tympanocentesis is performed as part of a study protocol. *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* are the predominant organisms in all age groups, though gram-negative enteric bacilli and *Staphylococcus aureus* may also be found in the first month of life. Few studies specifically address the risk of bacteremia associated with otitis media. In developing the Rochester criteria, the authors noted that a diagnosis of otitis media was the only reason for considering nine infants to be at high risk, and none had SBI.¹⁶ However, a study of febrile infants younger than 8 weeks reported bacteremia in 1 of 24 patients with otitis media.²⁷ Although it is not common, infants with otitis media on examination are still at risk for invasive disease. A diagnosis of otitis media in a febrile infant 28 days or younger should not influence the patient's evaluation or management. It is reasonable to obtain a CBC, blood culture, urinalysis, and urine culture prior to initiating appropriate oral antibiotic therapy in febrile infants 29 to 60 days of age with otitis media. An LP is not necessary if the infant is well-appearing, has reliable follow-up, meets all other low-risk criteria, and will not be receiving parenteral antibiotics. Well-appearing infants 2 to 3 months of age with an unequivocal diagnosis of otitis media may be treated with appropriate oral antibiotic therapy without a laboratory evaluation. It is important to note that otitis media is a difficult diagnosis to make in very young infants since they often have narrow ear canals and indistinct landmarks. If the clinician is unsure about the

diagnosis of otitis media, it is best to approach the patient as a febrile infant without a source.

The introduction of the heptavalent pneumococcal vaccine has decreased the risk of serious infection with *S. pneumoniae*.^{36,37} The vaccine is given at 2, 4, 6, and 12 to 15 months of age. The four-dose regimen is highly efficacious against invasive disease and somewhat efficacious against otitis media and pneumonia. In particular, the rate of SBI in the African American population has decreased dramatically. However, the risk of invasive infection with *S. pneumoniae* in the infant less than 3 months of age has not changed significantly, likely due to the fact that only one vaccination is given during this time frame. Therefore, even if the infant has received a pneumococcal vaccination, it is prudent to consider that the infant is, in effect, not vaccinated.

Management

Although in the first 28 days of life, the risk of SBI in low-risk infants is small, most experts recommend an evaluation for sepsis.³⁸ This conservative approach is rooted in the difficulty in evaluating the behavioral state of neonates, the immature neonatal immune system, the rapid evolution of bacterial infections in this age group, and the possibility of life-threatening enteroviral or herpes meningoencephalitis. Based on current data, febrile infants ≤ 28 days of age should receive a full septic evaluation, admission to the hospital, and administration of parenteral antibiotics. Although the risk of infection with *L. monocytogenes* is low, it is still a possibility and ampicillin is indicated. The choice of a second antibiotic may vary. Gentamicin is a good choice for most patients ≤ 28 days of age, unless there is a concern for meningitis or for an unusual pathogen. Cefotaxime may be a better choice if meningitis is suspected (Table 32–6).

A combination of clinical evaluation and laboratory studies can be used to define a specific population of infants 29 to 60 days of age who appear well and are at low risk for SBI. The probability of having an SBI in a febrile young infant who meets all of the low-risk criteria is approximately 0.2% to 0.7%. Most experts agree that low-risk infants 28 to 90 days of age with reliable parents and good follow-up can be managed as outpatients with reevaluation in 24 hours. The infants should meet all the low-risk historical, clinical, and laboratory criteria except that infants with otitis media can be included in this category.^{10,16,17} Empirical outpatient therapy with ceftriaxone should be considered if an LP has been completed. It is optional to give a second dose of intramuscular ceftriaxone. If a child receives antimicrobials before a CSF specimen is obtained, it may be difficult to distinguish whether CSF pleocytosis with negative culture results on subsequent examinations is due to a virus or to partially treated meningitis. If it is unclear, a full course of parenteral antibiotic therapy is indicated.

As the rate of SBI in the low-risk 4- to 8-week-old infant is approximately 0.2% to 0.7%, an alternate strategy for low-risk febrile infants without an obvious source of infection is outpatient observation without antibiotics.^{10,17,18} Children managed in this way should have blood and urine cultures, but do not necessarily need spinal fluid collection. All of the patients should be reevaluated within 24 hours. Those who deteriorate should receive the remainder of the septic evaluation, be hospitalized, and receive antimicrobial therapy.

*Although the default is to obtain CSF for evaluation in febrile infants 29–60 days of age, in some cases LP may be deferred.

Abbreviations: BNR, band-to-neutrophil ratio; CBC, complete blood count; CSF, cerebrospinal fluid; hpf, high-power field; IM, intramuscular; IV, intravenous; LP, lumbar puncture; OM, otitis media; WBC, white blood cells.

Infants ages 29 to 60 days with otitis media should receive appropriate oral antibiotic therapy. A well-appearing infant with a UTI without bacteremia who is afebrile at reevaluation can be treated as an outpatient with a 10-day course of oral antibiotics chosen based on local sensitivity patterns. Infants who are ill appearing at reevaluation or who have positive blood or CSF cultures should be admitted for observation and antibiotic therapy.

Summary

Fever in the young infant is a common occurrence, and it has been established that a well-appearing young infant may have an SBI. The immunologic immaturity of infants makes them especially vulnerable to certain bacterial and viral organisms that can cause life-threatening disease. The limited range of behaviors of young infants makes diagnosing illness by physical examination challenging. It is necessary to have both a clear understanding of the risk of SBI and a practical and prudent approach to evaluation and management. The overall risk of SBI drops from 7% for all febrile infants 1 to 3 months of age to 0.2% to 0.7% if the infant meets all low-risk criteria

proposed by any of the Boston, Philadelphia, or Rochester strategies.

There is strong agreement among experts regarding the approach to infants ≤28 days of age. These infants should receive a full evaluation for sepsis, be admitted to the hospital, and receive parenteral antimicrobials. Acyclovir should be considered for any infant with a concerning history or with seizures; signs of sepsis; characteristic skin, eye, or mouth lesions; or CSF findings suggestive of CNS hemorrhage.

Infants ages 29 to 60 days should also receive a complete sepsis evaluation. Patients meeting all of the low-risk criteria of any of the prospectively evaluated studies mentioned previously may be treated as outpatients with intramuscular ceftriaxone and reexamination in 24 and 48 hours. Low-risk infants in this age category may also be observed as outpatients without antibiotics but with reevaluation in 24 and 48 hours. It is acceptable to defer LP in low-risk patients greater than 60 days of age who will not receive antibiotics. Non-toxic-appearing febrile infants 61 to 90 days of age should receive a complete history and physical examination and a limited laboratory evaluation. If they meet the low-risk

criteria, they can be observed as outpatients without antibiotics, but with reexamination at 24 and 48 hours.

This approach to infants between the ages of 1 and 3 months has been found to be safe and reliable in prospective research. Although the populations that present to the emergency department versus the clinician's office may be different, the PROS study suggests that there may be a subset of infants, even in the first month of life, for whom outpatient observation and close follow-up might be a reasonable option. This approach has not been proven for these youngest patients, but future research may help clarify this.

Urinary Tract Infection in Infants

Rakesh D. Mistry, MD, MS and Marc H. Gorelick, MD, MSCE

Key Points

The classic triad of urinary tract infection (UTI)—fever, frequency, and dysuria—are rarely all present in infants and children; symptoms are often nonspecific.

UTI should be suspected in infants younger than 12 months of age with fever without source, especially if other risk factors are present, such as female sex, Caucasian race, $\geq 39^{\circ}\text{C}$, fever greater than 2 days, and, for males, being uncircumcised.

In children who are not toilet trained, urine specimen for culture should be obtained by urethral catheterization or suprapubic aspiration.

The majority of infants and children with UTI can safely be managed as outpatients.

Prompt identification and treatment of UTI can prevent potentially serious sequelae, including renal scarring and chronic renal failure.

Introduction and Background

Urinary tract infection (UTI) results when microorganisms infect usually sterile sites within the urinary tract. Bacterial pathogens are responsible for the majority of cases, and are the focus of this chapter; however, viruses, fungi, and, rarely, parasites may also infect the urinary tract. Infection may occur in the lower urinary tract (cystitis), or ascend into the upper tract to include the ureters and kidney (pyelonephritis). The presentation in infants and young children with UTI is often nonspecific, making the diagnosis challenging. Differentiation of upper versus lower tract infection can be especially difficult. Moreover, failure to diagnose UTI may result in significant long-term complications. Therefore, an astute approach to diagnosis and treatment of UTI in the pediatric population is of great importance to emergency physicians.

Recognition and Approach

Epidemiology

Acute UTI is the most commonly occurring serious bacterial illness in infants and young children. Rates of infection vary greatly with respect to age, gender, and race. Peak incidence is in infants less than 12 months of age, with UTI rates of approximately 40 per 1000 patients, after which the incidence decreases until adolescence. The incidence of UTI is equivalent in males and females until the age of 3 months, at which point the infection rate for males drops. From 3 to 12 months of age, there is a fourfold increased risk of UTI in females compared to males; between the ages of 1 and 3 years, females are 10 times more likely to have a UTI. Of note, males less than 12 months of age are 10 times more likely to develop UTI if they are uncircumcised.¹

The overall prevalence of UTI in febrile infants less than 12 months of age evaluated in emergency departments has been estimated at 5%.^{2,3} In addition to female gender, there is a higher prevalence in whites, patients with fever of $\geq 39^{\circ}\text{C}$, and absence of an alternative source of fever.

Pathophysiology

Bacterial invasion of the urinary tract primarily occurs via ascending infection. Enteric pathogens present in the stool, or flora present on the skin, enter the urinary tract via the urethral opening. Pathogens then ascend via the urethra into the bladder, where they multiply and produce a local infection of the lower urinary tract, known as cystitis. The offending pathogen may continue to ascend into the upper urinary tract and kidney via the ureters, leading to pyelonephritis. Although the overwhelming majority of UTI develops via the ascending route, infants may also develop infection via hematogenous spread.

Several host properties increase the likelihood of an ascending infection. The shorter urethra in females provides a more direct route for ascending infection. Uncircumcised males often have colonization of the prepuce, increasing the chance of entry of pathogens via the urethral meatus.⁴ Decreased effectiveness of bladder emptying may also contribute to development of UTI. Patients with dysfunctional voiding, from neurogenic bladder or voluntary retention (e.g., in constipation) or from obstructive uropathies (e.g., posterior urethral valves), have impaired ability to clear bacteria that have ascended into the bladder. In addition, overdistention and increased bladder pressure facilitate

movement of pathogens into the ureters, increasing the propensity for upper tract infection. Children with special needs, such as frequent self-catheterization, or with indwelling urinary catheters and hardware, are also more prone to UTI.

Etiology

Similar to adults, the most common pathogens isolated in pediatric UTI are gram-negative enteric organisms of the family Enterobacteriaceae. Of these, *Escherichia coli* accounts for approximately 80% of all UTIs in children. Other gram-negatives commonly isolated include *Klebsiella*, *Proteus*, *Serratia*, and *Enterobacter*. *Pseudomonas* species are a rare cause of UTI, usually found in patients that are immunosuppressed or frequently catheterized. Virulence factors that facilitate adherence to the urinary epithelium, produce local inflammation, and impair host phagocytosis and cell lysis are common in gram-negative pathogens, enhancing their ability to produce UTI. Gram-positive organisms less frequently produce UTI. Of these, *Enterococcus* species are the most frequent, while group A and B streptococci and *Staphylococcus* species are rare causes. It is important to note that patients with recurrent UTI may develop multidrug-resistant strains of any of the aforementioned pathogens.

Clinical Presentation

The clinical presentation of UTI can be quite variable in the pediatric age group, ranging from the so-called occult UTI to the classic presentations of cystitis and pyelonephritis. Children who are preverbal or have yet to develop urinary continence pose a unique challenge, since classic historical and physical findings often present in adults are not easily identified. Furthermore, infants and young children with UTI often manifest nonspecific symptoms that mimic other common viral illnesses. Irritability and poor feeding are common complaints, and vomiting and/or diarrhea is present in one third of infants with UTI.^{5,6} Rarely, young infants may present with evidence of failure to thrive or jaundice.⁷ Although a common complaint, parental report of malodorous urine has been found to be of questionable historical value.^{5,8}

Fever is the most common presenting symptom of UTI in infants. Moreover, fever is increasingly being recognized as the lone symptom of UTI in infants. An estimated 5.9% to 7.5% of infants under the age of 12 months, presenting with fever without source, have a UTI.^{2,3,9} Additionally, UTI is frequently found in infants presenting with other distinct clinical illnesses; in a prospective study by Shaw et al., physicians attributed fever to other sources of infection in 64% of infants prior to diagnosis of UTI.³ More often than not the physical examination is unrevealing, further adding to the diagnostic challenge. Therefore, in these infants, consideration of UTI should be given in the presence of fever, with or without demonstrable source of infection.

The absence of clinical findings in infants and toddlers makes the distinction between cystitis and pyelonephritis difficult. Renal scintigraphy has demonstrated that up to 70% of children with febrile UTI have involvement of the kidney, leading to an increased incidence of renal scarring.¹⁰ Therefore, all patients with UTI in this age group should be presumed to have pyelonephritis, and treated accordingly.

As the child becomes toilet-trained, the clinical presentation of UTI becomes less problematic. Urinary frequency, hesitancy, dysuria, suprapubic abdominal pain, and low-grade temperature are common complaints in preschool- and school-age children with cystitis. Secondary enuresis (bedwetting after the child has fully developed bladder control) may also be a subtle sign of UTI in this age group. The physical examination is generally unremarkable in simple cystitis, but may reveal tenderness over the suprapubic region of the abdomen. In contrast, older children with pyelonephritis often complain of fever, rigors, and flank pain in the region of the affected kidney, in addition to urinary symptoms of lower tract disease. Physical examination may reveal an ill appearance, fever, abdominal tenderness, and profound tenderness over the costovertebral angle of the affected kidney.

In children with suspected UTI, history and examination for potential predisposing conditions should be sought. Frequent UTI is common in patients with neurogenic bladder, dysfunctional voiding, and intermittent bladder catheterization. History should include assessment for known anatomic abnormalities of the genitourinary tract, such as obstruction of the ureteropelvic junction, hydronephrosis, and vesicoureteral reflux, all of which increase risk of UTI. Inquiry about the path and flow of the urine stream may be helpful. Typically, infants with posterior urethral valves have slow emptying and dribbling while urinating, as opposed to a constant urine stream. A history of poor hygiene should be sought in recently toilet-trained females, who often acquire UTI as a result of incorrect hygienic techniques. Constipation and encopresis are frequent cause of UTI in children, as a result of voluntary retention and bladder neck obstruction.

On physical examination, careful attention should be given to the abdomen and perineum. Examination may reveal an overdistended bladder or presence of a stool mass from fecal impaction. Additionally, identification of a flank mass may be a sign of ureteropelvic junction obstruction or hydronephrosis. Examination of the genitalia and urethra may reveal important clues, such as a meatal stenosis, circumcision status in males, and labial adhesions in females.

Differential Diagnosis

Because many signs and symptoms in infants and children are neither sensitive nor specific, the differential diagnosis of UTI is broad. Infants may have vomiting and diarrhea, similar to gastroenteritis. Irritability should elicit consideration of meningitis. Dysuria and urinary frequency are often present with UTI, yet may be present in several other conditions. In females, vulvovaginitis and retained vaginal foreign bodies may present with dysuria. Erythema and inflammation of the introitus and labia, the presence of vaginal discharge, and a history of poor hygiene or bubble baths may provide important clues for these conditions. Exclusion of potential sexual abuse is also appropriate, as these children may present with urinary complaints. Young males with epididymitis may also complain of dysuria, and have sterile pyuria. For both genders, inflammatory processes of the abdomen, such as appendicitis, may produce irritability, vomiting, and pyuria on urine analysis, and should be considered and appropriately excluded. Urinary frequency also should prompt consideration of metabolic conditions such as diabetes mellitus, diabetes insipidus, and hypercalcemia,

although these diseases are rare. Impaired bladder distention from constipation, abdominal mass, or pregnancy may also produce urinary frequency.

Diagnosis and Testing

In older children and adolescents, the presence of signs and symptoms suggestive of UTI make the decision to perform tests to investigate for UTI relatively straightforward. The diagnosis of UTI in children under 2 years of age is less obvious. The inability to verbalize symptoms, lack of reliability of the physical examination, and high prevalence of UTI presenting as fever alone illustrate the need for accurate and reliable diagnostic testing strategies.

Physicians must have a reasonable index of suspicion but be selective in testing for possible UTI in febrile children less than 2 years of age. The results of large, emergency department–based studies have determined several risk factors for UTI in this subset of children. Female infants carry an increased risk of UTI with age ≤ 12 months, Caucasian race, ill appearance, fever $\geq 39^\circ\text{C}$, duration of fever ≥ 2 days, and absence of an alternative source of fever.^{2,3,11,12} White females without ascertainable source of their fever incur the highest risk of occult UTI, estimated at 15% to 20%. Using these risk factors, a clinical decision rule has been developed and validated to optimize testing strategies for febrile young females.^{12,13} The presence of three or more of these risk factors has a sensitivity of 88% and specificity of 30% in identifying UTI. This allows the physician to effectively identify a select population of febrile female infants for which testing is indicated, thereby decreasing the need for unnecessary tests and minimizing missed cases of UTI. For febrile male infants, no valid clinical decision rule for detection of UTI currently exists. Risk factors for UTI in male infants have been clearly identified, including age ≤ 6 months, absence of alternative source of fever,^{2,3} and being uncircumcised.^{1,3,9,14} Therefore, testing should be strongly considered in febrile male infants with the presence of these characteristics. The threshold for testing should be lower in children with a history of recurrent UTI, urogenital abnormality, recent bladder catheterization, or prolonged, unexplained fevers.

Isolation of pathogenic bacteria from the normally sterile urine is the “gold standard” for diagnosis of UTI. Therefore, growth of a pathogenic organism in urine culture indicates the presence of UTI. The difficulty in obtaining sterile urine for culture remains problematic, as a result of contamination. Clinicians need to be aware of the variation in interpretation of urine culture based on the method of collection.

Urine may be obtained via the midstream clean-catch method in cooperative children, and the results are quite accurate¹⁵ if appropriately done. Unfortunately, contamination rates of urine obtained via clean catch may approach 30%, depending on technique.^{16–18} As a result of potential contamination, permissive definitions of a positive culture are used. Growth of $\geq 10^5$ colony-forming units (CFU) of a urinary tract pathogen in culture is considered definitive for UTI using the clean-catch method. If there is a question as to the results of the culture, because of either mixed pathogens or isolation of an unusual urinary pathogen, the culture should be repeated.

In infants and young children, the clean-catch method is not feasible, and urine must be collected directly by urethral

catheterization or suprapubic aspiration. Because it is safe, rapid, and easily performed, urethral catheterization is currently the preferred urine collection method for infants and young children in the emergency department. Although better than the clean-catch method, contamination may still occur, and the classification of a positive urine culture is still not absolute. Using urethral catheterization, growth of $\geq 10^4$ CFU of a pathogen is considered definitely positive; 10^3 to 10^4 CFU of a single pathogen is considered suspicious for UTI and should be correlated with the clinical picture. Suprapubic aspiration remains the most specific method of collection of urine for culture. When performed correctly, there is virtually no risk of contamination. Therefore, presence of any bacteria in culture obtained via suprapubic aspiration is considered a UTI. The suprapubic method is rarely used due to technical demands, invasiveness, and relatively equivalent performance to urethral catheterization.¹⁹ Culture of urine via the bag collection method is not recommended; urine samples collected via the bag method are frequently contaminated, with rates as high as 87%.^{9,20,21}

Unfortunately for the emergency physician, results of urine culture are not available for 24 to 48 hours. Therefore, several rapid screening techniques have been developed to identify children at risk for UTI. The urine dipstick is inexpensive and can be performed at the bedside. Two components of the dipstick are useful for diagnosis of UTI: nitrites, which are formed by common urinary tract pathogens, and leukocyte esterase (LE), a product of urinary leukocytes. Nitrites are assessed as positive or negative, and LE is typically scored from trace to 4+. When used in combination, nitrites and LE perform very well as a screening method for UTI. The presence of any nitrites *or* LE has a sensitivity of 80% to 88%.^{22–26} When used individually, nitrites have a specificity of 98%, and 2+ or greater LE has a specificity of 84%; when used in combination, the specificity of nitrite *and* 2+ or greater LE is 96% to 99%.^{23,26} Microscopic urinalysis of centrifuged and uncentrifuged urine are common methods used to detect pyuria (≥ 10 white blood cells per high-power field or per cubic millimeter, respectively). However, both methods of microscopic urinalysis have consistently demonstrated specificity and sensitivity inferior to the urine dipstick in infants.^{23,26} Identification of any bacteria via Gram stain of uncentrifuged urine has a high sensitivity and specificity, similar to that of the urine dipstick,^{23,27} but is more expensive, technically difficult, and operator dependent. Recent investigations have cited superior sensitivity of enhanced urinalysis, which combines properties of conventional microscopic analysis and Gram stain. False-positive rates are higher than that of the urine dipstick,^{23,26,28,29} and enhanced urinalysis is the most expensive and least available method of screening. In summary, the urine dipstick appears to be the most useful of all screening tests. The false-negative rates for all screening tests preclude ruling out UTI based on their results; urine cultures should be sent for on any patient with suspected UTI.

Use of serum tests, such as complete blood count, C-reactive protein, and erythrocyte sedimentation rate, are nonspecific for UTI, and may only provide adjunctive evidence in the setting of the clinical presentation. Blood cultures are more likely to be positive in infants less than 6 months of age,³⁰ although the clinical course of UTI appears to be unaffected by the presence of bacteremia.^{31,32}

Imaging

Several imaging modalities are available for evaluation of the kidneys and urinary tract, including renal cortical scintigraphy with technetium-99m–labeled dimercaptosuccinic acid (“renal scan”), renal ultrasound, and voiding cystourethrogram (VCUG). Regardless of clinical symptoms, renal scans have demonstrated that between 70% and 80% of infants with UTI have pyelonephritis^{10,33,34}; however, this does not appear to affect subsequent management or outcome. Although imaging may assist in diagnosis of pyelonephritis, the use of imaging in the emergency department setting is of limited value. Renal scanning in the emergency department may be of value when the diagnosis of UTI is unclear. Emergency department renal ultrasound or CT scan is helpful when considering the presence of an abscess.

Although imaging studies are rarely indicated in the emergency department, they do have an important role in the subsequent evaluation of children with UTI. It is estimated that 20% to 49% of infants with first-time UTI will have an abnormality detected by renal ultrasound or VCUG, including vesicoureteral reflux, duplicated collecting systems, and obstructive uropathies, such as posterior urethral valves or ureteropelvic junction obstruction.^{5,35,36} As a result, the American Academy of Pediatrics published guidelines in 1999 recommending routine performance of renal ultrasound and VCUG for all children 2 to 24 months of age after first-time UTI.³⁷ The findings of a recent prospective trial of infants and young children with UTI suggest that the presence of urinary tract abnormalities does not significantly influence patient management or outcome.³⁸ Further studies will be needed to determine the usefulness of imaging after UTI. In addition, the issue of optimal timing for these imaging studies—during the acute UTI or after resolution of inflammation—has yet to be resolved.

Important Clinical Features and Considerations

Clinical Pearls

Maintenance of a high index of suspicion by the emergency physician is essential for diagnosis of UTI in the infants and young children. When cases of UTI are missed in infants, it is usually a result of nonspecific presentations or failure to perform screening tests as indicated.

As mentioned earlier, fever may be the only evidence of UTI in infants and young children, and is the most common presenting symptom. In addition, the physical examination is most notable for the lack of physical findings. Therefore, detection of UTI is highly dependent on the clinician’s knowledge of risk factors for occult UTI.

Lack of screening, secondary to the presence of a potential source of fever, is another common pitfall. It is important to recall that, among patients less than 1 year of age, UTI still occurs at greater than baseline risk, even in the setting of an upper respiratory infection, gastroenteritis, or otitis media. Attributing fever to other concurrent illnesses, without consideration of other risk factors, can lead to missed diagnosis of UTI.

Common childhood illnesses can easily confound the clinical picture of UTI in infants. Vomiting and diarrhea are common symptoms of UTI as well, and misdiagnosis of gas-

troenteritis is possible. Diarrhea occurs in UTI from the local inflammation of the bowel by an infected bladder and/or kidney. Irritability may lead the physician to the diagnosis of meningitis; in fact, cerebrospinal fluid pleocytosis has been reported in infants with UTI.³⁹

Potential Complications

The primary complication of UTI is renal scarring, which may lead to hypertension, impaired renal function, and end-stage renal failure. Renal scarring is described even after a single, first-time UTI, and is increased with presence of urinary tract abnormalities. The risk of complications from renal scarring is significantly increased with recurrent episodes of UTI and pyelonephritis.^{4,40} Recurrence of UTI is not uncommon, occurring in 20% to 40% of patients after first-time infection, usually within the first 6 months after the initial UTI.^{41–44} Reinfection rates are highest in patients under 1 year of age, especially females. Patients with anatomic abnormality of the urinary tract, such as high-grade vesicoureteral reflux,^{45,46} are at increased risk for reinfection, although recurrences may occur in the setting of normal anatomy.⁴³ Recurrent UTI also significantly increases the risk of renal scarring and sequelae, further emphasizing the importance of accurate diagnosis early in life. Fortunately, renal function is generally preserved with adequate treatment of the UTI and underlying abnormalities.^{47,48}

Management

The majority of infants and children with UTI will not be acutely ill. Nevertheless, because of the nonspecific clinical picture of UTI, infants and young children may present to the emergency department late in their illness, and appear quite ill or toxic from concomitant sepsis or dehydration. Therefore, initial management should focus on stabilization of the “ABCs.” Intravenous fluid resuscitation may be necessary, especially if there is a history of frequent emesis or fluid losses. Once the patient is physiologically stable, attention can be turned to more specific therapies.

Prompt recognition and early treatment of UTI reduces the risk of renal scarring and associated sequelae^{44,49}; its importance cannot be overemphasized. Emergency physicians must maintain a high index of suspicion, and have an astute, systematic approach to identify infants and young children at high risk for UTI. A clinically sensible strategy, using current knowledge of risk factors and performance of available screening tests, is presented in Figure 33–1. This approach identifies patients at high risk for UTI, allowing for empirical therapy with minimal overtreatment. Despite fair sensitivity of screening tests, a urine culture should still be obtained in all cases of suspected UTI.

Antibiotic therapy should be guided by local resistance patterns of known urinary tract pathogens. Fortunately, the majority of known pathogens are sensitive to commonly available antibiotics (Table 33–1). Importantly, despite frequent resistance of urinary pathogens, the kidneys concentrate the majority of antibiotics, resulting in urinary concentration. In the clinical setting, these high concentrations often overcome pathogen resistance. Duration of antibiotic therapy is 10 to 14 days; short-course regimens are not recommended for infants and young children since effectiveness of shorter regimens has not been established in children.⁵⁰

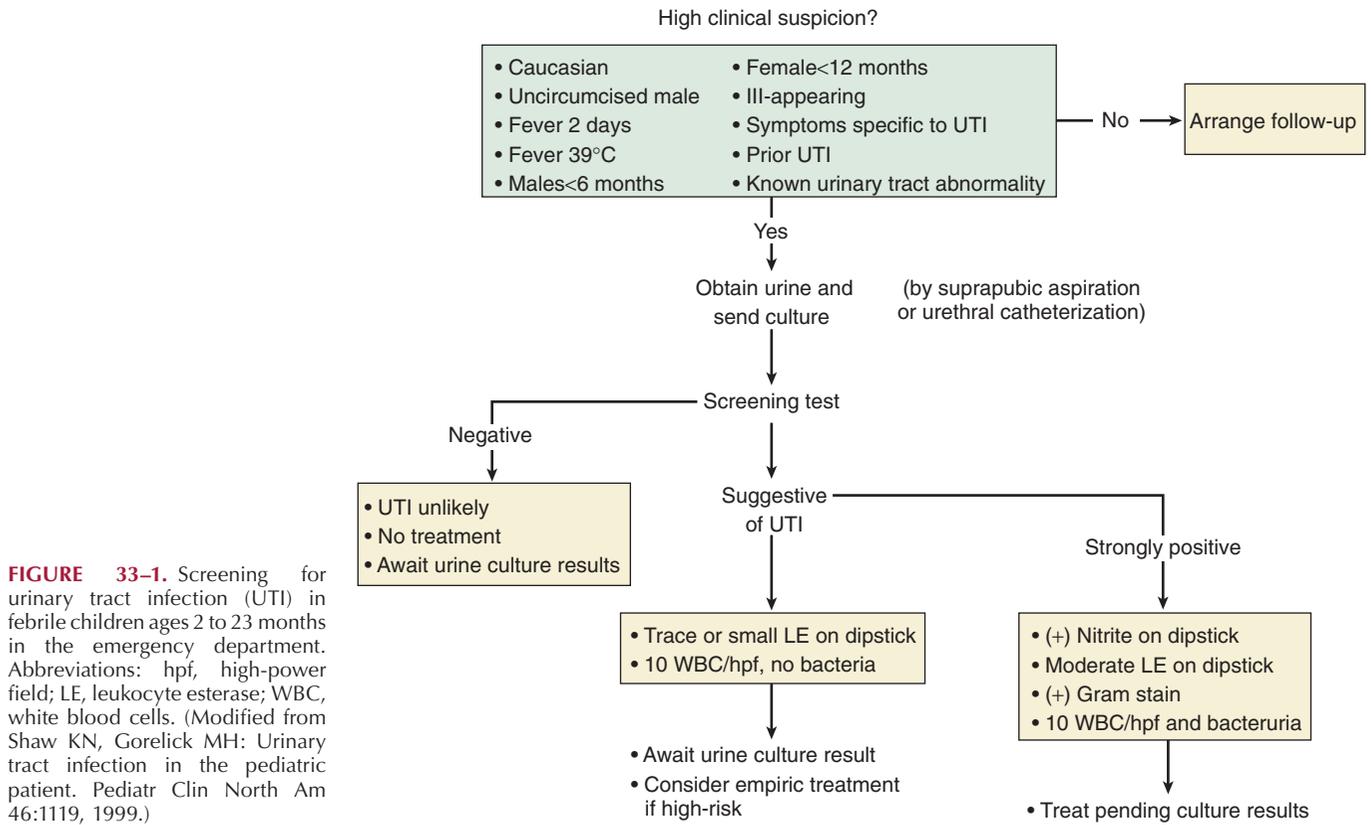

FIGURE 33-1. Screening for urinary tract infection (UTI) in febrile children ages 2 to 23 months in the emergency department. Abbreviations: hpf, high-power field; LE, leukocyte esterase; WBC, white blood cells. (Modified from Shaw KN, Gorelick MH: Urinary tract infection in the pediatric patient. *Pediatr Clin North Am* 46:1119, 1999.)

Table 33-1 Commonly Prescribed Antibiotics for Urinary Tract Infection

Drug	Usual Dosage (per day)
Oral	
cotrimoxazole	8–10 mg/kg of trimethoprim divided bid
nitrofurantoin	5–7 mg/kg divided qid
sulfisoxazole	120–150 mg/kg divided qid
cefixime	8 mg/kg once daily
cefdinir	14 mg/kg once daily
cephalexin	25–50 mg/kg divided qid
Parenteral	
ampicillin	100 mg/kg divided qid
gentamicin	7.5 mg/kg divided tid
ceftriaxone	50–100 mg/kg once daily
cefotaxime	150 mg/kg divided tid

Abbreviations: bid, two times a day; tid, three times a day; qid, four times a day.

From Shaw KN, Gorelick MH: Urinary tract infection in the pediatric patient. *Pediatr Clin North Am* 46:1120, 1999.

The decision to treat infants with pyelonephritis with parenteral antibiotics is debatable. Previously, the most children with pyelonephritis were admitted for intravenous antibiotic therapy. Recent studies using cefixime now suggest that infants over 2 months of age may be safely managed as outpatients, without affecting the natural course of the illness or increasing the risk of recurrence and renal scarring.⁵¹ Inpatient therapy is still recommended for infants under 2

months of age, as there is a paucity of evidence supporting outpatient therapy. Inpatient therapy should be also considered for patients who are ill appearing, dehydrated, vomiting, or unable to tolerate oral antibiotics, have known urologic abnormality, are at risk for poor compliance, or have failed outpatient therapy. Supportive therapy includes hydration, fever control, and pain management. Acetaminophen and/or ibuprofen is adequate for pain and fever in most cases. Phenazopyridine is an effective urinary analgesic; however, its usefulness is limited to older children, since it is only available in tablet form.

Summary

Prognosis

With treatment, the outcome of pediatric UTI is uniformly excellent. UTI generally follows a benign clinical course, with defervescence usually occurring within 24 to 48 hours. The urine usually becomes sterile within 48 hours after onset of treatment, although test of cure is not necessary if the patient is clinically improved.⁵²

The importance of follow-up for infants and children with UTI cannot be understated. During follow-up, those at high risk for future UTI can be identified and appropriately managed, decreasing the potential complications associated with renal scarring. After the emergency department visit, routine follow-up will ensure resolution of symptoms, hydration status, and compliance with therapy. At this time, physicians may elect to perform imaging studies on patients with first-time UTI. In the setting of a detected urinary tract abnormality, many physicians institute antibiotic

prophylaxis until definitive repair is completed, in an effort to decrease the risk of subsequent UTI.

Future Directions

Researchers have made great strides in the clinical management of urinary tract infections. Currently, investigators are focusing on several areas to improve the emergency department management of UTI. The use of ultrasound to improve success rates of urethral catheterization appears to be very promising. Development of screening methods for UTI with improved sensitivity, and possible increased availability of enhanced urinalysis are still necessary. Furthermore, studies are already being conducted to determine the safety of outpatient management of UTI for infants less than 2 months.

Chapter 34

Stridor in Infancy

Antonio E. Muñiz, MD

Key Points

Stridor in infants requires a thorough evaluation to exclude life-threatening conditions.

Glucocorticoids are the mainstay of therapy for croup and can be given orally, parenterally, or as a nebulized medication.

Epiglottitis remains a life-threatening disease for young adults.

Bacterial tracheitis is a life-threatening complication of croup.

Laryngomalacia is the most common cause of stridor in infants.

Introduction and Background

Stridor is an audible harsh, high-pitched musical sound produced by turbulent airflow through a partially obstructed upper airway. During inspiration, areas of the airway that are easily collapsible (e.g., supraglottic region) are “suctioned” closed due to negative intraluminal pressure generated during inspiration. These same areas are forced open during expiration. For this reason, disorders causing supraglottic obstruction (e.g., epiglottitis) cause stridor that is mostly heard on inspiration. The glottic and subglottic airway extends from the vocal cords to the extrathoracic trachea. This part of the airway has firmer cartilaginous support and does not collapse, and its shape does not easily change with inspiration. Stridor that occurs due to glottic (e.g., croup) and tracheal (e.g., tracheitis) disorders is often biphasic or heard during both inspiration and expiration. The intrathoracic airway is composed of the trachea, which lies within the thorax, and the mainstem bronchi. Obstruction at these sites causes stridor that is loudest on expiration since intrathoracic pressure rises on expiration and tends to collapse airway structures.

Important characteristics of airway disorders have been used to differentiate between disorders causing stridor in infants and children.

Age

Congenital disorders (e.g., tracheomalacia, laryngomalacia) present in the first few weeks of life. By 6 months of age, infants begin to explore their environment and place objects in their mouth. The ability to grasp objects improves until a distinct pincer grasp is present in most 1-year-old infants. These developmental aspects contribute to foreign body aspiration that peaks by 2 to 3 years of age. Croup also occurs mostly in infants under the age of 3 years. Retropharyngeal abscesses are most common in those under age 4 since retropharyngeal lymph nodes are present at this age, often disappearing by age 4 to 5 years. Prior to introduction of an effective *Haemophilus influenzae* type b vaccine, epiglottitis generally occurred in children 2 to 7 years old. Since the introduction of this vaccine, the overall incidence of epiglottitis has dropped substantially.

Acuity

An immediate onset of stridor in an appropriately aged child suggests foreign body ingestion or angioedema. Epiglottitis can produce an acute onset of stridor, although children often have a 1- to 2-day prodrome prior to development of airway obstruction.

Infants with stridor due to or preceded by viral infections (croup, tracheitis, retropharyngeal abscess) often have several days to 1 week of cough, congestion, and rhinorrhea prior to development of stridor.

Appearance

Serious bacterial infections (e.g., epiglottitis, airway abscesses, diphtheria, tracheitis) are a likely cause of stridor in infants and children who are toxic appearing, with apprehension, air hunger, and tripodding (holding self up with extended arms). Children with viral infections such as croup are usually not toxic appearing, although airway edema may become severe enough to cause hypoxia and a more toxic appearance.

Associated Symptoms

Serious bacterial infections are associated with the presence of a fever, while foreign bodies and congenital disorders do not cause a temperature elevation. However, temperature alone cannot be used to discriminate between serious and mild infections. Up to 25% of children with epiglottitis and airway abscess are not febrile on initial presentation to a physician, while a significant number of children with croup have an elevated temperature.

Supraglottic obstructions block sounds exiting the glottis and the opening to the esophagus. For this reason, these obstructions (e.g., airway abscess, epiglottitis) can cause a muffled voice and drooling. Hyoid pain and tenderness are present in most cases of epiglottitis. Aspirated foreign bodies are one type of subglottic obstruction that can lead to drooling due to direct compression of the esophagus. Hoarseness is due to inflammation of the vocal cords and is associated with glottic and subglottic disorders. A cough also is associated with glottic and subglottic disorders, while its presence makes epiglottitis less likely.

Acoustics

Stridor during inspiration implicates supraglottic obstruction, biphasic stridor¹ implies glottic or subglottic obstruction, and expiratory stridor is often due to intrathoracic obstruction. Stridor that changes its pattern and timing may be due to an obstruction that is migrating (e.g., foreign body). While some experts state that pitch and frequency are useful in locating the source or cause of stridor, pitch has not been found to be a discriminator.

Air-Shadow Interface—Radiography

Infants and children with stridor who have the potential to develop obstruction of their airway require portable radiography. Alternately, they must be accompanied by appropriate resuscitation equipment (e.g., bag-valve mask) and personnel who can manage an obstructed airway while being transported to the radiology department. An appropriate soft tissue lateral film of the neck requires neck extension during the terminal phase of inspiration. Clinicians must realize that this position can obstruct an already compromised obstructed airway.

Classic plain radiographic findings of epiglottitis include an enlarged epiglottis with the appearance of a thumb, enlarged aryepiglottic folds, and a ballooned hypopharynx. However, these findings are subjective and may not be noted on initial plain films in up to 50% of patients. Objective findings that may be more accurate in diagnosing epiglottitis on lateral radiography include an epiglottic width-to-third cervical vertebral width ratio greater than 0.5, or an aryepiglottic width-to-third cervical vertebral body width ratio greater than 0.35.

Radiographic findings described with retropharyngeal abscesses include a retropharyngeal space greater than 7 mm anterior to the inferior border of the second vertebral body and a retrotracheal space greater than 14 mm anterior to the inferior border of the sixth cervical vertebral body. Other plain radiographic findings include soft tissue air-fluid levels and cervical retroflexion. Computed tomography is more accurate than plain films in identifying abscesses but requires patient stability and the ability to maintain a supine position.

Soft tissue radiography is often used to evaluate children with croup, with up to 50% of pediatricians routinely obtaining plain films in infants and children with this disorder. However, plain films are often misleading or nondiagnostic in this disorder. One study that examined radiologists' interpretations of plain films found that 24% to 28% of children with croup had plain films interpreted as possible epiglottitis, while only 33% to 38% of plain films were called croup.² Thus plain films should not be relied upon to diagnose this disorder.

A final important use for plain films is to detect aspirated foreign bodies. Unfortunately, less than 10% of aspirated foreign bodies are radiopaque. Therefore, the clinician should not rely on normal plain films to exclude an airway foreign body when there is a strong clinical suspicion.

Airway Visualization

In the past, it was taught that direct visualization of the pharynx and use of a tongue blade or mirror to examine the airway were hazardous techniques to be avoided in children with stridor, especially if epiglottitis was a possibility. Laryngospasm involving children with epiglottitis was rare, and only occurred in children who were in extremis and already required immediate airway management.³ Moreover, there has never been a case of laryngospasm in over 1000 adult cases of epiglottitis who underwent direct visualization.⁴ Two series with more than 120 children with epiglottitis showed that no complications occurred during direct laryngoscope visualization with care taken not to touch the epiglottis and hypopharynx.⁵ Importantly, these series indicate that the majority of stable children will tolerate careful laryngoscopy or application of a tongue blade to the middle or anterior tongue. Only clinicians who are skilled with pediatric airway management should perform these techniques. Importantly, it is best to only consider using direct visualization in children with a moderate to low suspicion of epiglottitis who are deemed clinically stable.

Stridor may occur in a wide variety of disease processes (Table 34–1). It is also important to categorize the differential to exclude those that are life-threatening when evaluating any infant who presents with stridor (Table 34–2).

This chapter presents the causes of stridor in infancy and provides a practical approach to their diagnoses and management.

Croup (Laryngotracheobronchitis)

Recognition and Approach

Croup is an acute viral infection characterized by a barklike cough, hoarseness, inspiratory stridor, and respiratory distress that can range from mild to severe respiratory failure. This infection involves primarily the larynx and may extend into the trachea and bronchi. It is the most common etiology for stridor in the febrile infant. Although the disease is most often self-limited, it may lead to severe airway obstruction and death.

Croup typically occurs in children ages 6 months to 3 years, with a mean age of 18 months. There is a male predominance with a ratio of 2 : 1. This syndrome typically occurs in late fall and early winter.

The most common organism causing croup is parainfluenza virus type 1 which is recovered in 60 % of cases.⁶ Mild sporadic cases are caused by parainfluenza type 2 and 3, influenza A, adenoviruses, measles, rhinovirus, echovirus, reovirus, coxsackievirus, respiratory syncytial virus, metapneumovirus, and *micoplasma pneumoniae*.^{7,8} Influenza A has been implicated in children with severe respiratory compromise.

Transmission of the causative virus is by the respiratory route. The initial port of entry is the nose and nasopharynx. The infection spreads to the larynx and trachea, and their

Table 34–1 Differential Diagnoses of Stridor	
Location	Etiology
Nose and Pharynx	
Congenital anomalies	Lingual thyroid, choanal atresia, craniofacial anomalies (Apert's, Down syndrome, Pierre Robin syndrome), cysts (dermoid, thyroglossal)
Inflammatory/infectious	Abscess (peritonsillar, retropharyngeal, parapharyngeal), allergic polyps, diphtheria, uvulitis, infectious mononucleosis
Other	Adenotonsillar hyperplasia, foreign body, decreased muscle coordination from neurologic syndrome
Larynx	
Congenital anomalies	Laryngomalacia, laryngeal web, laryngeal cyst, laryngocele, cartilage dystrophy, subglottic stenosis, cleft larynx, hemangioma
Inflammatory/infectious	Croup, epiglottitis, tracheitis, angioneurotic edema, tuberculosis, diphtheria, sarcoidosis
Vocal cord paralysis	Congenital or traumatic
Neoplasm	Subglottic hemangioma, laryngeal papilloma, cystic hygroma, malignant (rhabdomyosarcoma), neurofibromas
Laryngospasm	Hypocalcemic tetany, irritant, drug effect, spasmodic croup
Foreign body	Laryngeal or upper esophageal
Trauma	Laryngeal fracture or dislocation, hematoma, inhalation injury
Trachea and Bronchi	
Congenital	Vascular anomalies, webs, cysts, tracheal stenosis, tracheoesophageal fistula
Neoplasm	Tracheal, compression from adjacent tumors (thyroid, thymus, esophageal)
Inflammatory/infectious	Bacterial tracheitis
Foreign body	Tracheal or esophageal
Other	
	Psychogenic stridor Hemophilia (hematoma) Cervical spinal trauma Caustic ingestion

Table 34–2 Life-Threatening Causes of Stridor

walls become erythematous and edematous. There is endothelial damage and loss of ciliary function. A fibrinous exudate partially occludes the lumen of the trachea. In addition to luminal narrowing, edema of the vocal cords and subglottic larynx leads to stridor, hoarseness, and the characteristic barklike cough. The edema formation in young children and infants will lead to a significant airway compro-

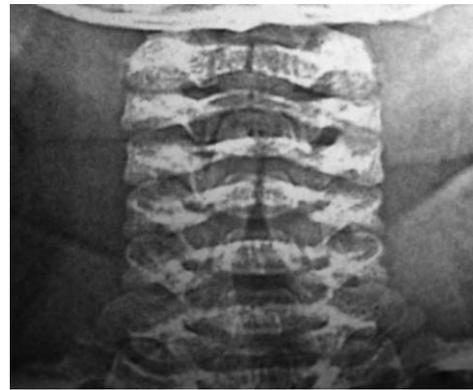

FIGURE 34–1. “Steeple sign” in croup.

mise due to an already narrowed diameter of the airway, especially in the region of the cricoid cartilage. Hypoxemia may occur from progressive luminal narrowing, and impaired alveolar ventilation and ventilation-perfusion mismatch.

Clinical Presentation

The prodrome lasts a few days and consists of a mild upper respiratory infection with fever, coryza, and cough. It is followed by the development of a hoarse voice and harsh, brassy “seal’s bark” cough. Stridor usually develops at night, often awakening the child from sleep and frightening the parents.

The patient’s symptoms range from minimal inspiratory stridor to severe respiratory failure secondary to airway obstruction. In mild cases, respiratory sounds at rest are normal; however, mild expiratory wheezing may be heard. Children with more severe cases have inspiratory and expiratory stridor at rest with suprasternal, intercostal, and subcostal retractions. Air entry may be poor. Lethargy or agitation may be a result of hypoxemia. Other warning signs of severe respiratory disease are tachypnea, tachycardia out of proportion to fever, and hypotonia. Children may be unable to maintain adequate oral intake, which results in dehydration. Cyanosis is often a late ominous sign. In uncomplicated cases the illness lasts 4 to 7 days.

The white blood cell count is generally normal; however, lymphocytosis may occur. In mild cases, transcutaneous oximetry is usually normal, but hypoxemia exists with severe disease. Arterial blood gases are unnecessary and show neither hypoxia nor hypercarbia unless respiratory fatigue ensues.

In typical cases, radiographs are not required for the diagnosis of croup, unless the diagnosis is in question. Lateral soft tissue radiographs of the neck may show subglottic narrowing from soft tissue edema in severe disease, but most are normal or may show overdilatation (ballooning) of the hypopharynx during inspiration. The anteroposterior view of the neck will show narrowing of the laryngeal air column for about 5 to 10 mm below the level of the vocal cord (“steeple sign”) in 50% to 60% of cases⁹ (Fig. 34–1).

Complications in croup occur in only a small minority of patients. The most common is worsening airway obstruction, which is seen in infants or young children. The inflammation may extend into the lower airway, causing wheezing and tachypnea. Pneumonia is uncommon and usually associated with bacterial tracheitis.¹⁰ Other complications include

lymphadenitis and otitis media. Inability to maintain adequate oral intake may lead to dehydration.

Management

Any infant who presents with respiratory complaints must have a good evaluation to ensure the patency of the airway and maintenance of effective oxygenation and ventilation. Infants with severe respiratory distress or compromise require 100% oxygenation with ventilation support using a bag-valve-mask device. If the airway and breathing require continued maintenance, the patient should be intubated with an endotracheal tube.

Most children with croup have no stridor at rest and can be managed as outpatients. Gentle handling and avoidance of unnecessary painful procedures should be the rule since persistent crying increases oxygen demands and respiratory muscle fatigue, and makes the obstruction worse. Careful monitoring of the heart rate, respiratory rate, respiratory mechanics, and pulse oximetry are important to detect early hypoxia. Use of a croup score may aid in management¹¹⁻¹³ (Table 34-3).

Providing high humidity has not been proven clinically to be effective but seems to be beneficial in most children.¹⁴⁻¹⁸ It works by providing water droplets that penetrate the area of inflammation and deliver moisture to the mucosa. Increasing humidity will decrease the viscosity of the secretions in the trachea, which facilitates clearance from the airways. Cool mist may activate mechanoreceptors in the larynx that produce a reflex slowing of respiratory flow rate. Methods used to deliver high humidity include a croup tent, croupettes, masks, and blow-by oxygen. However, methods that separate the child from the parents may increase anxiety, making blow-by oxygen the preferred method. The use of hot steam should be avoided since there are reports of scalds.¹⁹

In children with stridor at rest or more severe symptoms not responding to humidified oxygen, racemic epinephrine (Vaponefrin) has been effective in improving clinical outcome.²⁰⁻²⁴ It is a mixture of the *d*- and *l*-isomers of epinephrine. It works by adrenergic stimulation, which causes constriction of the precapillary arterioles, thereby decreasing capillary hydrostatic pressure. This leads to fluid resorption from the interstitium and improvement in the laryngeal

mucosal edema. Its β_2 -adrenergic activity leads to bronchial smooth muscle relaxation and bronchodilation. The dose ranges from 0.25 to 1 ml of a 2.25% solution in 3 ml saline given via a nebulizer. The dose can be gauged by weight: less than 20 kg, 0.25 ml; 20 to 40 kg, 0.5 ml; and greater than 40 kg, 0.75 ml of a 2.25% solution. Multiple doses may be required for children in severe respiratory distress. It may be repeated at 1- to 2-hour intervals. Its clinical effect last about 2 hours. Previously feared rebound phenomenon appears quite uncommon, although some patients do return to their baseline status after the effect of the drug wears off. Most patients sustain their improvement after racemic epinephrine, particularly if steroids are begun early, and may be safely discharged after at least a 3-hour observation. This period of observation is suggested for all children who receive racemic epinephrine.^{25,26} Those who were initially severely ill, responded incompletely, relapsed during the observation period, or required multiple doses must be hospitalized. *L*-Epinephrine in equal doses of the active *l*-isomer has been shown to have the same beneficial effects as racemic epinephrine.²⁷ This finding is important since racemic epinephrine is not readily available outside of the United States and is less expensive. The dose is 5 ml of a 1:1000 solution diluted in 2 ml of saline.

After several decades of controversy, the use of corticosteroids has been shown to be beneficial in the management of severe, moderate, and even mild croup.²⁸⁻³⁵ Several studies have shown improvement in clinical symptoms and a decrease in return visits for medical care.^{29,32,36-39} Corticosteroids exert their beneficial effect by means of their anti-inflammatory action, whereby laryngeal mucosal edema is decreased. They also decrease the amount of racemic epinephrine needed.^{40,41} A single dose of oral or intramuscular dexamethasone (0.6 mg/kg) has been shown to be useful in reducing the overall severity of croup if given within the first 4 to 24 hours after onset of illness. The long half-life of dexamethasone (54 hours) makes only one injection usually necessary. Dexamethasone 0.15 mg/kg is as effective as 0.3 mg/kg or 0.6 mg/kg in relieving the symptoms of mild to moderate croup.^{30,38,42} In addition, oral dexamethasone (0.6 mg/kg) has been shown to be equally effective when compared to placebo, and as effective as intramuscular administration.^{38,43-49} Oral administration

Table 34-3 Croup Score and Implications

	<i>Croup Score</i>			
	0	1	2	3
Stridor	Normal	Only with agitation	Mild at rest	Severe at rest
Retractions	Normal	Mild	Moderate	Severe
Air entry	Normal	Mild decrease	Moderate decrease	Marked decrease
Color	Normal	Normal	Normal	Cyanotic
LOC	Normal	Restless when disturbed	Restless when disturbed	Lethargic
Management Implications				
Score	Degree	Management		
≤4	Mild	Outpatient; mist therapy		
5-6	Mild to moderate	Outpatient if child improves in ED after mist and steroids, >6 months old, reliable family		
7-8	Moderate	Admit; racemic epinephrine, steroids		
≥9	Severe	Admit; racemic epinephrine, steroids, oxygen, ICU		

Abbreviations: ED, emergency department; ICU, intensive care unit; LOC, level of consciousness.

is easier and cheaper. Recently, a smaller dose of dexamethasone (0.15 mg/kg) and even a single dose of a shorter acting corticosteroid, prednisolone (1 mg/kg) has been shown to be as effective as the higher dose of dexamethasone.^{38,41,50} However, one study did show more returns to the emergency department in children treated with prednisolone.⁵¹ Corticosteroids should not be administered to children with varicella or untreated tuberculosis.

The use of inhaled corticosteroids, especially budesonide, has been shown to be effective.^{43,52} Budesonide is a synthetic glucocorticoid with strong topical anti-inflammatory effects and low systemic activity. Administration of 2 to 4 mg of nebulized budesonide has been shown to decrease the croup score substantially, and to decrease emergency department length of stay and hospitalization, when compared to nebulized saline.⁵³⁻⁵⁷ Nebulized corticosteroids are as effective as oral or intramuscular corticosteroids for croup.⁵² However, they are more expensive than dexamethasone, and one study with oral dexamethasone showed better improvement than with nebulized budesonide.³⁹

Less than 2% of those patients with severe croup will be unresponsive to therapy and will require intubation.^{58,59} Intubation should be accomplished with an endotracheal tube that is 0.5 to 1.0 mm smaller than predicted. Others have used a Heliox (helium 60% to 80%) mixture in order to prevent intubation. Heliox is a metabolically inert, non-toxic gas that is combined with oxygen. It has low viscosity and low specific gravity, which allows for greater laminar airflow through the respiratory tract.⁶⁰ Helium will decrease the force necessary to move the gas through the airways and decrease the mechanical work of respiratory muscles. Heliox has been shown to improve symptoms with severe croup that fails to improve with racemic epinephrine.⁶¹ It has been shown to be equally effective in moderate to severe croup when compared to racemic epinephrine.⁶²

Epiglottitis

Recognition and Approach

Acute epiglottitis is a potentially life-threatening bacterial infection with significant morbidity and mortality. Epiglottitis, or more correctly supraglottitis, is an inflammation of the structures above the site of insertion of the glottis, including the epiglottis, the aryepiglottic folds, the arytenoidal soft tissue, and occasionally the uvula. The upper airway obstruction can evolve rapidly and may lead to respiratory arrest and death.

Fortunately, the prevalence has declined due to the availability of the *H. influenzae* vaccine.⁶³ However, mortality can be as high as 6% to 10% in children without intubation, while mortality is reduced to less than 1% when intubation is performed. Historically, the most common bacterial cause in children was *H. influenzae* type b (>90%). Other bacterial causes include *Streptococcus pneumoniae*, groups A, B, and C streptococcus, and *Staphylococcus aureus*. Unusual causes include *Moraxella catarrhalis*, *Haemophilus parainfluenzae*, *Pseudomonas*, *Neisseria meningitidis*, *Candida albicans*, *Klebsiella pneumoniae*, and *Pasteurella multocida*. Viral agents implicated in epiglottitis have included herpes simplex, parainfluenza, varicella-zoster, and Epstein-Barr viruses. Other

FIGURE 34-2. Epiglottitis.

noninfectious etiologies have included thermal or caustic injuries, traumatic blind finger sweep to remove a pharyngeal foreign body, inhaled foreign bodies, angioneurotic edema, and acute leukemia.⁶⁴⁻⁶⁶

Epiglottitis may be acquired by respiratory transmission from an intimate contact or from bacteria that have colonized the pharynx of normal children. These bacteria may penetrate the mucosal barrier and invade the bloodstream. During the bacteremia, seeding of the epiglottis and surrounding tissues may occur. Other places of potential seeding, especially with *H. influenzae*, include the meninges, facial skin, lung, and joints.

Acute onset of inflammatory edema ensues, beginning on the lingual surface of the epiglottis where the submucosa is loosely attached. The swelling leads to considerable reduction in the aperture of the airway. This swelling progresses rapidly to involve the aryepiglottic folds, the arytenoids, and the entire supraglottic larynx (supraglottitis) (Fig. 34-2). The tightly bound epithelium on the vocal cords halts the spread at this level. Respiratory arrest can occur with aspiration of oropharyngeal secretions or mucous plugging.

Clinical Presentation

Epiglottitis is characterized by an abrupt, explosive onset of symptoms that may progress rapidly to respiratory obstruction and death in a matter of hours in the absence of airway control and medical management. The first symptoms include fever, often reaching 40° C. Shortly afterward, the child develops stridor and labored breathing. Other common signs and symptoms include dysphagia, muffled (guttural) or hoarse voice, refusal to eat, and sore throat. Less commonly occurring symptoms are cough and ear pain.

The child has a toxic appearance, and shock may occur early in the course of the disease. Marked restlessness, irritability, and extreme anxiety are common. The child assumes a sitting position with the chin hyperextended and the body leaning forward (tripod position) in order to maximize air entry past the swollen epiglottis and improve diaphragmatic excursion. The mouth is wide open and the tongue protruding. Frequently the child will drool because of the difficulty or pain in swallowing secretions.

The pulmonary findings include stridor with marked suprasternal, subcostal, and intercostal retractions. The ante-

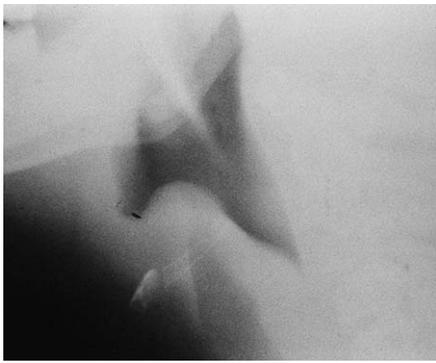

FIGURE 34-3. “Thumbprint sign” of epiglottitis.

rior neck examination may reveal tender adenopathy. An erythematous and swollen epiglottis can often be seen by a careful examination of the oropharynx. Cyanosis is a late finding, indicating poor prognosis.

The laboratory evaluation is nonspecific and should be performed once the airway is secured. The white blood cell count may be elevated from 15,000 to 45,000/mm³ with a predominance of bands occurring. The blood cultures may recover the organism 12% to 90% of the time, especially with *H. influenzae*.^{63,67-69} The epiglottic cultures are positive in half the cases.

Radiographic evaluation is not needed in classic cases of epiglottitis; however, it may be needed in certain cases to establish the diagnosis and to exclude other potential causes of acute airway obstruction. Since epiglottitis is a disease of acute deterioration, and since sudden airway obstruction has been described in children with epiglottitis during radiographic manipulation, the child should never be sent to radiology without personnel capable of establishing an airway if such acute deterioration occurs. It is best to have a portable radiograph performed in the emergency department. In addition, the lateral neck radiograph should never delay definitive airway control in children who need it immediately.

The lateral soft tissue radiograph of the neck classically reveals a swollen epiglottis (“thumbprint sign”), thickened aryepiglottic folds, obliteration of the vallecula, and dilation of the hypopharynx (Fig. 34-3). A chest radiograph may reveal a concomitant pneumonia in up to 25% of patients.⁷⁰

Complications associated with a swollen epiglottis and surrounding tissues include airway obstruction, which can lead to respiratory arrest and death from hypoxia. The respiratory arrest that may occur with epiglottitis does not appear to occur because of total airway obstruction, but rather seems to result from fatigue. Other complications may include epiglottic abscess, adenitis, cervical cellulitis, and rarely pulmonary edema. Historically with the bacteremia from *H. influenzae*, other concomitant infectious processes occur, such as meningitis, pneumonia, septicemia, cellulitis, septic arthritis, and rarely pericarditis.⁷¹

Management

Treatment is directed toward relief of the airway obstruction and eradication of the infectious agent. These children generally present to the emergency department in marked respiratory distress and are very anxious. Procedures that are normally performed on infants in acute respiratory distress

Table 34-4 Antimicrobial Agents Effective against Common Epiglottitis Organisms

Antimicrobial	Dose
Ceftriaxone	75–100 mg/kg per day IV/IM once or divided q12h
Cefotaxime	50–75 mg/kg per day IV/IM divided q6–8h
Cefuroxime	50–100 mg/kg per day IV/IM divided q6–8h
Ampicillin	100–400 mg/kg per day IV divided q4–6h

Abbreviations: IM, intramuscularly; IV, intravenously.

may not apply to infants with acute epiglottitis. For example, blood venipunctures and establishing an intravenous access, although appropriate in most cases of acutely ill infants, may heighten the anxiety and precipitate airway compromise in infants with epiglottitis.

As with every acute resuscitation, the airway, breathing, and circulation are the first aspects to evaluate. Providing supplemental oxygen by a nonthreatening and less anxiety-provoking method is the initial step. This is best accomplished easily with blow-by oxygen administered by the parent. Equipment for emergent airway management is placed at the bedside, and the patient remains in the view of the physician at all times. If acute respiratory arrest occurs, the infant should be ventilated with a bag-valve-mask device using 100% supplemental oxygen until arrangements for intubation are made.⁷² In cases in which the appropriate personnel are not available and the infant has a respiratory arrest, attempts to intubate may be performed. Other alternative methods to gain immediate control of the airway include a needle cricothyrotomy. This procedure is a temporizing method used until a more permanent procedure, such as a tracheostomy, can be performed. The use of racemic epinephrine plays little role in the management of infectious or thermal epiglottitis.

The next crucial step is mobilization of the appropriate team to establish an appropriate airway. The patient is taken to the operating room, where equipment for tracheostomy and bronchoscopy are prepared. Laryngoscopy is performed under general anesthesia and an orotracheal tube (0.5 to 1.0 mm smaller than predicted for the child) inserted. After placement of the endotracheal tube, the supraglottic structures are examined by direct laryngoscopy and appropriate surface cultures of the epiglottis are done.

Eradication of the bacterial organism may be accomplished by using antibiotics effective against the more common organisms (Table 34-4). This may include ceftriaxone, cefotaxime, cefuroxime, or ampicillin, and chloramphenicol. It is recommended that chemoprophylaxis with rifampin be given to close contacts in children under 4 years of age. Intravenous hydration should be initiated and the child hospitalized in a pediatric intensive care unit (ICU) setting.

The use of corticosteroids, which has been advocated in the past based on anecdotal reports, remains controversial and has not been shown to be efficacious in the acute setting of epiglottitis.

Bacterial Tracheitis (Membranous Laryngotracheobronchitis, Pseudomembranous Croup)

Recognition and Approach

Bacterial tracheitis is a disease caused by a bacterial infection of the subglottic area that complicates patients with croup. It is more common than epiglottitis but less common than croup. There is a 2 : 1 male : female ratio. A preponderance of infections occur in fall and winter. It may occur at any age, but the average age is 3 years. Mortality has been between 4% and 20%.

Bacterial tracheitis is characterized by subglottic edema and inflammation of the larynx, trachea, bronchi, and sometimes the lung. There are copious purulent secretions and semiadherent mucopurulent pseudomembrane formation in the trachea and bronchi, which increases luminal narrowing and may cause severe respiratory distress.⁷³ Extension of the disease into the bronchi and alveoli is common.

The infection is polymicrobial, but the primary organism responsible for this disease is *S. aureus*. Other organisms include *S. pneumoniae*, *H. influenzae*, α -hemolytic streptococcus, group A β -hemolytic streptococcus, *Klebsiella*, *Pseudomonas* species, *Escherichia coli*, *Moraxella catarrhalis*, *Corynebacterium diphtheriae*, *Bacillus cereus*, parainfluenza and influenza, measles, respiratory syncytial virus, anaerobes (*Peptostreptococcus*, *Bacteroides*, *Prevotella*), and *Aspergillus*.⁷⁴⁻⁷⁸

Clinical Presentation

The illness begins with a prodrome of an upper respiratory illness, lasting 1 to 2 weeks, followed by several days of mild to moderate croup-like illness. Soon afterward, a rapid deterioration occurs over several hours. Once acute respiratory distress occurs, it is indistinguishable from epiglottitis; however, the history of a slower onset will make bacterial tracheitis more likely. At this time there is a high fever and toxicity, and the infant may be quite anxious or may be lethargic. There are obvious signs of severe upper airway obstruction, such as significant stridor, tachypnea, suprasternal retractions, poor air entry, and brassy or barking cough.⁷⁹ Late signs include cyanosis. On occasion there may be evidence of wheezing. The respiratory distress tends to be severe and unresponsive to croup therapy. On radiographs, there is subglottic and tracheal narrowing on the anteroposterior view and there may be a pseudomembrane (auspicated secretion) visible within the tracheal lumen. The supraglottic region is normal in appearance. The chest radiograph may reveal a concomitant pneumonia in 50% of cases. Laryngotracheobronchoscopy is the definitive means of diagnosis, showing the purulent tracheal secretions.

The laboratory evaluation may reveal leukocytosis with a left shift. Positive blood cultures are unusual; however, tracheal cultures are usually positive.

The main complication is the risk of upper and lower airway obstruction, with its attendant risk of hypoxemia, respiratory arrest, and death. Pneumonia often occurs and may progress to acute respiratory distress syndrome (ARDS), and a rare association with toxic shock syndrome exists.⁷³ Other complications include postobstructive pulmonary edema and subglottic stenosis.⁷⁸

Table 34-5 Antimicrobial Agents Effective against Common Bacterial Tracheitis and RPA Organisms

Antimicrobial	Dose
Nafcillin	50–100 mg/kg per day IV/IM divided q6–12h
Cefuroxime	50–100 mg/kg per day IV/IM divided q6–8h
Ceftriaxone	75–100 mg/kg per day IV/IM qd or divided q12h
Cefotaxime	50–75 mg/kg per day IV/IM divided q6–8h
Clindamycin	25–40 mg/kg per day IV/IM divided q6–8h
Piperacillin/tazobactam	240–400 mg/kg per day IV divided q6–8h
Ampicillin/sulbactam	100–400 mg/kg per day IV/IM divided q6h
Ticarcillin/clavulanate	200–300 mg/kg per day IV divided q4–6h
Vancomycin	10–15 mg/kg per day IV divided q8–12h

Abbreviations: IM, intramuscularly; IV, intravenously; RPA, retropharyngeal abscess.

Management

Emergent intubation is usually required. An endotracheal tube 0.5 to 1.0 mm smaller than expected should be used in order to minimize trauma in the inflamed subglottic area. Aggressive pulmonary toilet is quintessential to relieve the obstruction caused by the thick and tenacious secretions. Antibiotic therapy should be initiated with agents effective against the usual organisms (Table 34-5). This may be accomplished with nafcillin and cefuroxime or ceftriaxone or cefotaxime. Clindamycin may be added for anaerobic coverage. Other agents include piperacillin/tazobactam, ampicillin/sulbactam, and ticarcillin/clavulanate. Patients allergic to penicillin may require chloramphenicol and clindamycin. Intravenous hydration should be initiated and the child hospitalized in a pediatric ICU setting.

Retropharyngeal Abscess

Recognition and Approach

Retropharyngeal abscess (RPA) is a deep neck infection filling the potential space between the prevertebral fascia of the cervical vertebrae and the posterior wall of the pharynx. It has the potential for airway compromise.⁸⁰ It occurs most often in young children less than 6 years of age, with a peak at 6 to 12 months of age.

The retropharyngeal space can become infected by either spread of an infection from a contiguous area or direct inoculation of the space secondary to penetrating trauma. Typically an upper respiratory infection spreads to the retropharyngeal lymph nodes. Other sources of infection can include pharyngitis, tonsillitis, adenitis, otitis media, parotitis, sinusitis, and dental infection. Osteomyelitis of the spine can also spread anteriorly from the prevertebral space. Penetrating trauma typically occurs from objects in the mouth forced posteriorly during a fall or from impacted foreign

bodies, such as fish bones or chicken bones.^{81,82} Iatrogenic causes include laryngoscopy, endotracheal intubation, surgery, endoscopy, feeding or nasogastric tube placement, and dental procedures.⁸³ The lymphadenitis can form a cellulitis that then can suppurate as an abscess. The progressive swelling and the relatively higher larynx and narrow airway in infants make airway obstruction a significant early complication.

Usual organisms include group A β -hemolytic streptococcus, *S. aureus*, viridans streptococci, *S. epidermis*, and occasionally *E. coli*, *H. influenzae*, *Neisseria*, *Klebsiella*, *Salmonella*, *Eikenella*, corynebacterium, anaerobes (*Bacteroides*, Peptostreptococcus, *Fusobacterium*), *Mycobacterium tuberculosis*, *Blastomyces*, and *Coccidioides*.⁸⁴⁻⁸⁷

Clinical Presentation

Presentation is similar to epiglottitis, but onset is less abrupt. A prodrome of nasopharyngitis or pharyngitis occurs. It is followed by abrupt onset of high fever, chills, toxic appearance, pain with neck movement, stridor, drooling, odynophagia, trismus, sore throat, dysphagia, refusal to eat, anorexia, torticollis, and muffled (“hot potato”) voice or voice that sounds like a duck quack (*cri du canard*).⁸⁸⁻⁹⁰ There is usually unilateral cervical lymphadenopathy. A “tracheal rock sign” occurs when pain is elicited while gently moving the larynx and trachea from side to side. Meningismus may be present from irritation of the paravertebral ligaments. RPA must be considered in an infant with nuchal rigidity but no pleocytosis in cerebrospinal fluid. Rarely, the examination shows an obvious midline swelling of the pharynx.

The laboratory evaluation is nonspecific, with leukocytosis and a left shift. The lateral neck radiograph may show an increase in width of the soft tissues anterior to the vertebrae, and on occasion an air-fluid level may be noted (Fig. 34-4). A plain radiograph, however, may miss up to 30% of RPAs. Ultrasound can be used to visualize an abscess. Dynamic fluoroscopy may show widening of the retropharyngeal space. However, computed tomography scan of the neck is the imaging modality of choice and has been used to assess the extent of the infection.^{89,91} It may not, however, be as accurate in differentiating cellulites from abscess.⁹²

Complications are due to mass effect, rupture of abscess, or spread of infection. These include airway compromise, aspiration pneumonia, sepsis, ARDS, spontaneous perforation, reformation of retropharyngeal abscess, mediastinitis, purulent pericarditis, tamponade, pyopneumothorax, pleuritis, empyema, bronchial erosion, osteomyelitis of the spinal column, necrotizing fasciitis, carotid artery rupture, jugular vein thrombosis, or atlanto-occipital dislocation.⁹¹

Management

As with any infection that can compromise the airway, a thorough assessment of the patency of the airway and adequacy of oxygenation and ventilation must be performed. Less than a third of infants will require endotracheal intubation. Eradication of the bacterial organism may be accomplished by using antibiotics effective against the more common organisms.^{86,93} This may be accomplished with nafcillin and cefuroxime or ceftriaxone or cefotaxime. Clindamycin may be added for anaerobic coverage. Other agents include piperacillin/tazobactam, ampicillin/sulbactam, and ticarcillin/clavulanate. Patients allergic to penicillin may require chloramphenicol and clindamycin. Intravenous

FIGURE 34-4. Widening of the retropharyngeal space.

hydration should be initiated and the child hospitalized in a pediatric ICU setting.

Treatment without surgical drainage can be successful in a select group of infants.⁷⁶ Failure of medical management or the presence of a large abscess requires drainage, and the intraoral route is preferred.⁷⁷

Congenital Anomalies

The onset of stridor shortly after birth is most likely caused by a structural defect. This type of stridor tends to worsen slowly and is severe only when the infant is stressed, such as during crying or a respiratory illness. The causes of congenital stridor are shown in Tables 34-6 and 34-7.⁹⁴⁻¹⁰²

Foreign Body Aspiration

Recognition and Approach

Foreign body aspiration can cause stridor in infants. Through play, oral curiosity, or normal daily activities, infants are likely to place foreign bodies just about anywhere. In addition, the lack of fully developed dentition and oral protective reflexes places the infant at increased risk for the object to lodge in the respiratory tree.

Aspirated foreign bodies can be found in any segment of the respiratory tree. The size and shape of the object and the forcefulness of inspiration determine where in the airway a foreign body lodges. Most are in the mainstem bronchi or distal trachea near the carina, though smaller objects can

Table 34–6 Laryngeal Causes of Congenital Stridor

Laryngomalacia	Most common cause of congenital stridor (75%). It may be caused by an enlarged epiglottis that prolapses posteriorly on inspiration, short aryepiglottic folds, or bulky arytenoid cartilage that prolapses anteriorly over the larynx on inspiration. Symptoms are present at birth or within the first 4–6 weeks. Infants typically have high-pitched inspiratory stridor that increases with crying and when supine. Stridor is positional and is relieved by placing the infant in the prone position with head extended. It rarely interferes with feeding or is associated with dyspnea. Radiographic evaluation may show downward and inferior displacement and bowing of aryepiglottic folds. Diagnosis is by laryngoscopy. It usually resolves on its own by 12–24 months of age. Infants with respiratory distress, cor pulmonale, apnea, or failure to thrive may require epiglottoplasty, laryngoplasty, and/or tracheotomy. ^{94,95}
Vocal cord paralysis	The second most common cause of neonatal stridor. ⁹⁶ Most cases are diagnosed within first 12 hours of life. Neonates usually have a weak or absent cry, respiratory distress (bilateral vocal cord paralysis), and difficulty feeding. The stridor is biphasic. If unilateral, it improves with lying down on the affected side. Unilateral vocal cord paralysis can be congenital or due to trauma at birth or at the time of cardiac or intrathoracic surgery. Unilateral vocal cord paralysis may improve spontaneously or with vocal cord reinnervation procedures. ⁹⁷ Bilateral vocal cord paralysis has been associated with malformations of the central nervous system, such as Arnold-Chiari malformation. ⁹⁸ Bilateral paralysis is a life-threatening emergency. These neonates present with a high-pitched biphasic stridor that may progress to severe respiratory distress. Treatment is tracheostomy.
Subglottic stenosis	Can be congenital or acquired. Congenital types occur from an incomplete canalization of the subglottic and cricoid ring causing a narrowing of the subglottic lumen. Acquired form arises from prolonged endotracheal intubation or infections (diphtheria, tuberculosis). Infants present with stridor, cough, and recurrent croup. Stridor is usually biphasic or inspiratory. If not present at birth, it may be mistaken for asthma. Tracheostomy, laryngeal dilation, endoscopic scar excision, or laryngeal reconstruction may be required. ⁹⁹
Laryngeal web	Caused by incomplete recanalization of the laryngeal lumen during embryogenesis. Most are in the glottic area. Infants present with a weak cry and biphasic stridor. Treatment is surgical.
Laryngeal cyst	Found in the supraglottic region in the epiglottic folds. Infants present with stridor, cough, hoarse voice, or aphonia. ¹⁰⁰ If the cyst is large, it may cause respiratory obstruction and require surgical excision.
Laryngeal hemangioma	Approximately 50% of cases are accompanied by hemangiomas in the head and neck region. Infants have inspiratory or biphasic stridor that worsens as the hemangioma enlarges. Hemangioma usually regresses by 12–18 months of age. May require surgical resection or laser therapy if respiratory symptoms occur. Medical management may include oral corticosteroids or intralesional corticosteroids.
Laryngeal papilloma	Most common laryngeal tumor. Occurs from vertical transmission of the human papilloma virus in maternal condylomata or infected vaginal cells to the larynx or pharynx of the infant during delivery. Infants present with stridor and hoarseness. Treatment requires recurrent surgical excisions.

Table 34–7 Tracheal Causes of Congenital Stridor

Extrinsic compression	Anomalies that may lead to stridor include double aortic arch, right aortic arch, innominate artery compression, aberrant right subclavian vein, and pulmonary artery sling. ¹⁰¹
Bronchogenic cysts	Can cause extrinsic compression of the trachea and require surgical excision.
Tracheomalacia	The most common cause of expiratory stridor. It is caused by a defect in the cartilage resulting in loss of rigidity necessary to maintain the tracheal lumen patent or by extrinsic compression of the trachea (vascular ring or sling). It leads to tracheal collapse on inspiration. It can be primary or secondary to vascular abnormalities, tracheoesophageal fistula, relapsing polychondritis, or Ehlers-Danlos syndrome, or acquired after intubation or tracheotomy. It may occur with laryngomalacia and gastroesophageal reflux. It has been mistaken for asthma or prolonged bronchiolitis. Symptoms usually subside by the age of 3 years. Definitive diagnosis is with bronchoscopy. Infants with respiratory distress or failure to thrive may require a tracheostomy. ¹⁰²
Tracheal stenosis	Can be congenital or due to extrinsic compression. Congenital stenosis is usually related to complete tracheal rings, is characterized by persistent stridor, and requires surgery based on severity of symptoms. The most common extrinsic causes include vascular rings, slings, and a double aortic arch that encircles the trachea and esophagus. Infants present during the first year of life with noisy breathing, intercostal retractions, and a prolonged expiratory phase. Treatment is with dilation or surgical correction.

lodge more peripherally. The most serious sequela of foreign body airway aspiration is complete obstruction of the airway. In such cases, the foreign body becomes lodged in the larynx or trachea, leaving little room peripherally for air exchange. If the object lodges in the glottis and stimulates spasm, the infant may die before aid is available. Fortunately, the foreign body more often passes into the bronchi, resulting in unilateral obstructive emphysema.

Clinical Presentation

An accurate history and a strong suspicion are of paramount importance in diagnosing foreign body aspiration in infants, because in 33% to 64% of cases nothing in the initial history

indicates aspiration.^{103,104} Certainly, new-onset bronchopulmonary symptoms in an otherwise healthy infant must alert the physician to the possibility of airway foreign body aspiration. When an infant has unexplained, recurrent, or persistent respiratory illness that does not respond to adequate medical therapy, aspiration, as well as atypical asthma, should be part of the differential diagnosis. Foreign body aspiration can mimic other disease processes, leading to a misdiagnosis of croup, pneumonia, bronchiolitis, or asthma.

Physical examination may reveal wheezing, stridor, crackles, dyspnea, retractions, decreased air entry, tachypnea, rhonchi, hoarseness, cyanosis, fever, and apnea.^{103–105} One fourth of infants may be asymptomatic at the time of presen-

tation, and 39% may have no helpful physical examination findings.¹⁰⁶ The complete triad of coughing, wheezing, and decreased breath sounds is present in only 40% of cases.¹⁰⁶

Specific manifestations of aspirated foreign bodies depend on whether the object is located in the trachea or bronchi and on the size of the object, which relates to the degree of obstruction. Although most patients are seen within a day of aspiration, some have symptoms that last weeks or months before the proper diagnosis is made.^{103,105} Signs and symptoms associated with foreign body aspiration occur in three stages. In the initial stage, there is a history of a choking episode, followed by violent paroxysms of coughing, gagging, and occasionally complete airway obstruction. An asymptomatic interval generally follows the aspiration, during which the foreign body becomes lodged, the reflexes become fatigued, and the immediate irritating symptoms subside. This stage is the most treacherous and accounts for a large percentage of delayed diagnoses or overlooked foreign bodies. The third stage is characterized by symptoms of complications caused by the foreign body, such as obstruction, erosion, or infection. Chronic cough, hemoptysis, pneumonia, lung abscess, unexplained fever, and malaise are common presentations of chronic airway foreign bodies.

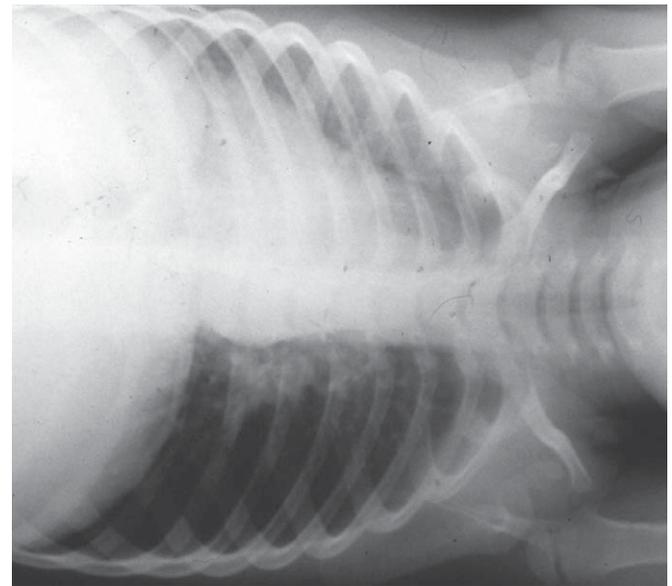

Although only 6% to 17% of aspirated foreign bodies are radiopaque, the lung abnormalities caused by aspirated objects are generally detectable.¹⁰⁷⁻¹⁰⁹ Radiographic evaluation should start with anteroposterior and lateral views of the chest and neck. Lateral soft tissue radiographs may reveal the foreign object in the hypopharynx, glottis, subglottis, or cervical esophagus or embedded in the posterior pharyngeal wall. Ballooning of the hypopharynx may indicate subglottic obstruction. Widening of the retropharyngeal soft tissues or air in the soft tissues, or both, are signs of perforation with abscess formation. Coins lodged in the trachea generally appear to be aligned in the sagittal plane on an anteroposterior or posteroanterior chest radiograph.

The effect of an airway foreign body on the lung depends on the object's location and how it obstructs the flow of air. The intrathoracic airways tend to dilate on inspiration and contract on expiration, causing most bronchial foreign bodies to act as check valves. During inspiration, air can bypass the foreign body, but during expiration the bronchus narrows and is occluded, causing obstructive emphysema and sometimes pneumothorax or pneumomediastinum.

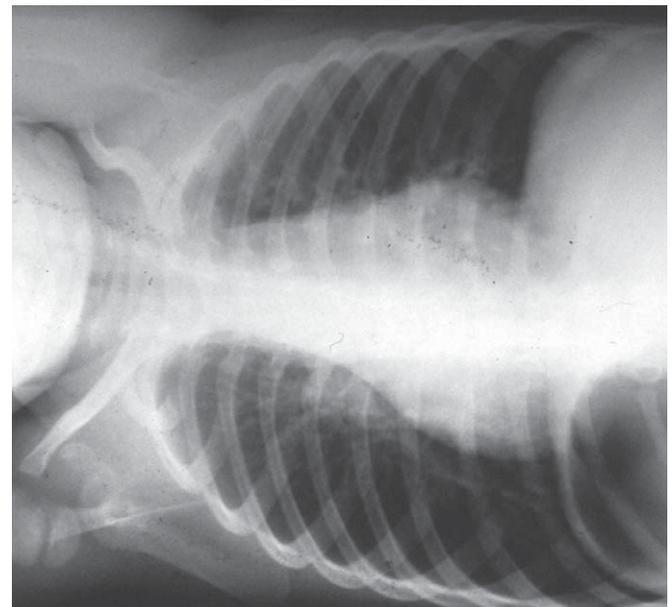

Routine radiographs are normal in 25% of children who have aspirated foreign bodies, especially when the object is not radiopaque and is located in the trachea. When the object is in the bronchus, radiographic findings include hyperlucency or obstructive emphysema (38% to 52%), atelectasis (10% to 20%), pneumonia (16% to 27%), opaque foreign body (4% to 19%), pneumomediastinum (6%), consolidation (5%), effusion (2%), pneumothorax (1%), abscess (<1%), and bronchiectasis (<1%).¹⁰²⁻¹⁰⁵ Foreign bodies may

completely occlude the airway as a result of edema and granulation tissue, acting as a stop valve. Air beyond the obstruction is resorbed, resulting in atelectasis of the affected lobe.

Radiographs often detect hyperaeration of the affected lung or lobe. Differential inflation and deflation of the affected lung may be documented by fluoroscopy, lateral decubitus radiographs, or an assisted expiratory film when suspicion persists despite normal routine radiographs¹⁰⁴⁻¹⁰⁷ (Fig. 34-5). In a recent review, decubitus radiographs had

A

B

FIGURE 34-5. A, Left decubitus film showing normal deflation of the left lung. B, Right decubitus film showing hyperaeration of the right lung with a foreign body suspected in the right bronchus.

only a sensitivity of 27% for children with foreign body aspiration.¹¹⁰ Aluminum and plastic foreign bodies may sometimes be seen when radiographs are exposed with more than the usual amount of x-ray energy (overpenetrated views). Recently, low-dose multidetector computed tomography (MDCT) and virtual bronchoscopy has been shown to be accurate in detecting suspected foreign body aspiration.¹¹¹

Management

Initial management must focus on establishment of adequate oxygenation and ventilation. Recognition of the infant whose airway is completely obstructed is critical to the success of first aid efforts. If an infant can cough or talk, obstruction is not yet complete, and the infant should be allowed to cough without interference. Delivering first aid to such an infant is unnecessary and potentially dangerous. Complete airway obstruction in the conscious infant may be recognized by sudden respiratory distress, followed by an inability to speak or cough. When the airway is completely obstructed, first aid must be delivered promptly. This consists of delivering a sequence of back blows and chest thrusts until the object is dislodged. Emergency strategies may also include direct laryngoscopy, which may permit visualization of the foreign body, allowing for removal with McGill forceps.¹¹² If the object is in the subglottic trachea, orotracheal intubation may be life saving, dislodging the object into a mainstem bronchus and converting a complete obstruction to a partial obstruction. If the foreign body cannot be removed and endotracheal intubation cannot be achieved, needle cricothyrotomy can bypass the obstruction and deliver oxygen to the patient. In stable children, removal of the foreign body can be performed with rigid bronchoscopy or flexible bronchoscopy.^{111,112}

Summary

Stridor in infants can occur from a variety of causes, such as inflammatory or infectious diseases, congenital anomalies, and trauma. After excluding a life-threatening etiology or a treatable abnormality, infants can be discharged with appropriate otolaryngologic or pulmonary follow-up.

Vomiting, Spitting Up, and Feeding Disorders

Barbara E. McDevitt, MD

Key Points

The significance of vomiting encompasses a spectrum of problems ranging from the trivial (mild gastroesophageal reflux) to the catastrophic (small bowel obstruction).¹

Acute vomiting of an underlying critical nature must be distinguished from regurgitation or spitting up.

Regurgitation is the passive, nonforceful expulsion of gastric contents up the esophagus, and commonly into the oropharynx, during and between feeds.

Bilious vomiting etiologies must be distinguished from those entities associated with nonbilious etiologies, such as esophageal atresia, tracheoesophageal fistula, pyloric stenosis, and gastroenteritis.

Contributing to feeding disorders may be a wide range of psychosocial and behavioral problems. These may be exacerbated by the current mobility of our society, frequently leaving young parents with a limited family support system.⁴⁻⁶

Introduction and Background

Emergency department (ED) visits for vomiting and feeding complaints are common in infancy. The differential diagnosis is quite extensive. These visits to the ED may be precipitated by a wide spectrum of symptoms, including crying, recurrent emesis, inadequate nutritional intake, and the parental perception of inadequate intake.¹⁻⁷ The vast majority of children with vomiting who visit the ED will have self-limited gastroenteritis or simple reflux. The clinician must be able to differentiate serious life-threatening disorders from simple spit-ups in an emergent yet thorough manner.

Recognition and Approach

The evaluation of the infant with vomiting begins by obtaining a history from the caregiver. Many caregivers consider feeding to be the primary means of assessing their ability to appropriately care for their child.⁸ They may be concerned that the newborn's intake is inadequate, as reflected by crying or irritability. In today's society, fewer parents/caregivers have extended family to provide experience and reassurance. In addition, it is now the norm to discharge both mother and infant within 48 hours of delivery.⁹ This may leave parents unprepared to recognize what is or is not normal behavior for a neonate.^{7,10}

Neonatal conditions that in the past would have been recognized prior to discharge may not present until the newborn is at home, unsupervised by medical personnel. For example, infants lose up to 10% of their birth weight in the first week of life. They then regain their birth weight by 2 weeks. After the first 2 weeks, expected weight gain is approximately $\frac{1}{2}$ to 1 ounce a week.¹⁰ Thus, obtaining the birth weight and present weight in the ED is valuable in recognizing an infant with an underlying disorder.⁷

Approximately 85% of all infants will have some vomiting or "spitting up" in the first 9 months of life and, in particular, during their first weeks at home. This generally resolves by the age of 1 year. Between birth and 3 months of age, 40% to 65% will vomit at least an ounce daily.^{10,11} Combined, these normal patterns of feeding and reflux may create great anxiety, especially among new parents.

Infants differ from adults in that they have a short, narrow esophagus that allows passive regurgitation of stomach contents into the esophagus and then into the oropharynx. Contributing factors also include delayed gastric emptying, relaxed lower esophageal sphincter tone, overfeeding, or poor positioning of an infant after feeds.^{11,12}

Pathogenic gastroesophageal reflux disease is distinguished by the number and severity of the reflux episodes and the presence of complications, including esophagitis, weight loss or inadequate weight gain, and respiratory problems. Secondary aspiration, pneumonia, and wheezing with recurrent cough are currently believed to play a significant role in apparent life-threatening events.^{11,13}

Vomiting is the forceful expulsion of gastric contents through the mouth and nose. It is caused by coordinated diaphragmatic and abdominal contractions in conjunction with the relaxation of the gastroesophageal sphincter.² An infant with true forceful recurrent vomiting requires an expedient and thorough evaluation to rule out a potentially lethal disorder.¹

Less emergent are the infants who present to the ED with a wide range of disorders such as congenital heart disease, neurologic impairments, or congenital syndromes. These infants have difficulty coordinating their suck-gag reflex,⁴ which places them at risk for aspiration. They may chronically aspirate both their formula and their own secretions. They may also have impairments secondary to the technology they depend on for nutrition.¹⁴

Clinical Presentation

The clinical presentations of vomiting may be grouped by the age of the patient, by medical or surgical etiology, or by the nature of the emesis.^{15,16} Biliious and forceful vomiting are of particular concern as they suggest an obstruction beyond the part of the duodenum where the ampulla of Vater connects.¹⁷⁻¹⁹ This is a significant symptom in young babies as it may indicate malrotation, volvulus, duodenal atresia, or meconium ileus.^{7,20} Many other conditions associated with the gastrointestinal (GI) tract in infants also require urgent recognition and intervention due to their potentially catastrophic outcome if not diagnosed promptly.

Two of the most common causes of vomiting in infants are overfeeding and physiologic gastroesophageal reflux (GER).¹¹ However, vomiting can also be a symptom of more systemic entities, including metabolic disorders, infectious disease, intracranial pathology, and renal disease and, in current times, it may be seen in association with neonatal narcotic withdrawal secondary to maternal addiction. Table 35-1 lists common causes of pediatric vomiting.

The history should ascertain whether the infant is in pain, the amount and the frequency of the emesis, the timing of the emesis with respect to recent feeding or coughing paroxysm, recent bowel movements, and fever.¹⁹ The family history should cover any relatives with metabolic disorders, trisomy 21, cystic fibrosis, or Hirschsprung's disease.^{21,22}

Table 35-1 Important Causes of Vomiting in Infancy

Feeding problems, including overfeeding/gastroesophageal reflux
Infection—including otitis media, pneumonia, sepsis, urinary tract infections, meningitis, enteritis, and pertussis
Gastrointestinal tract obstructions—including esophageal atresia, duodenal atresia, malrotation/volvulus, Hirschsprung's disease
Neurologic—raised intracranial pressure or brain subdural hematoma, hydrocephalus, meningitis
Incarcerated hernia
Metabolic—congenital adrenal hyperplasia, hypothyroidism, phenylketonuria
Cow's milk intolerance or malabsorption
Narcotic withdrawal due to maternal addiction

Formula Issues

Overfeeding and Underfeeding

Full-term, healthy neonates typically require 105 to 115 cal/kg per day of nutrition. Most formulas contain 20 calories per ounce (30 ml) unless they are fortified with extra calories. Using these numbers, clinicians can determine if formula-fed neonates and young infants are receiving inadequate nutrition or if they are being overfed. Moreover, infants who are overfed (e.g., >150 cal/kg per day) have more frequent stools and may have more frequent regurgitation, spitting up, and vomiting. These symptoms typically occur soon after feeding and are exacerbated when infants are placed in a recumbent position. If any of these symptoms occur in an overfed young infant, decreasing the amount of feeds, decreasing the volume of each feed, and increasing the frequency of feeding may decrease vomiting.

Inappropriate Feeding

A gradual introduction of solid foods (e.g., cereals) to an infant's diet should not occur until the age of 4 to 6 months. Too early use of solid foods may lead to increased regurgitation or spitting up.

Formula Intolerance and Allergy

Infants may develop intolerance or allergy to components of formula. Nearly 3% of infants are allergic to cow's milk protein, while over 1% have soy protein allergies. Reactions to these proteins are often immunoglobulin E mediated, with prominent GI symptoms (vomiting, diarrhea [often heme positive], chronic constipation, and colic). Respiratory symptoms (wheezing, rhinitis) and cutaneous manifestations (atopy, urticaria, angioedema) may also occur. Laboratory testing occasionally reveals an eosinophilia. Infants with true formula intolerance may benefit from use of hypoallergenic formulas (e.g., extensively hydrolyzed or free amino acids). For infants above the age of 6 months who have cow's milk intolerance, a soy formula may also be tried.

Breast Milk Issues

Breast-feeding is recommended by the American Academy of Pediatrics, the World Health Organization, and UNICEF as the ideal route for providing nutrition to neonates and young infants.²³ In general, breast-fed infants have less constipation and colic and fewer GI symptoms than bottle-fed infants.^{23,24} However, an altered maternal diet or maternal medication or drug ingestion may lead to GI symptoms, including vomiting and spitting up. Maternal ingestion of illicit drugs (e.g., heroin, cocaine) can lead to vomiting and spitting up, in addition to multiple other toxic effects. Additionally, prenatal maternal ingestion of heroin or narcotics may cause severe withdrawal symptoms in neonates, including seizures, jitteriness, vomiting, and diarrhea. While maternal ingestion of medications is often safe for breast-fed infants, the list of drugs that might be responsible for GI symptoms or other more toxic effects is extensive.²⁵ Clinicians should consult authoritative references to determine the possible impact of maternal medications on symptoms in breast-fed infants. For most herbal supplements, levels within human milk and effects on breast-fed infants have not been studied. For this reason, they should be avoided by breast-feeding mothers.²⁴

Although a food allergy is uncommon in breast-fed infants compared to formula-fed infants, rare cases of anaphylaxis to cow's milk proteins have been reported in breast-fed infants, as well as more frequent cases of cow's milk-induced proctocolitis. Importantly, immunologically recognizable proteins from the maternal diet can be found in breast milk. Elimination of cow's milk, eggs, fish, peanuts and tree nuts, and other foods from the maternal diet may lead to resolution of allergic symptoms in the nursing infant.²⁶ Gastrointestinal complaints other than allergy (e.g., spitting up, gas, diarrhea) can be due to ingestion by the mother of specific foods (e.g., onions, cruciferous vegetables such as cabbage, tomatoes, berries, chocolate, and spices).²⁶ If a reaction to any of these foods is highly suspected, the mother consider removing them from her diet.

Gastroesophageal Reflux

GER is defined as the passive movement of gastric contents into the esophagus and higher. Relaxation of the lower esophageal sphincter is the most common cause. Other important causes include increased intra-abdominal pressure, excessive crying (with air swallowing), delayed gastric emptying, and sluggish esophageal motility. Neonates who are premature or stressed (especially due to respiratory illness) are most at risk for developing GER. Importantly, GER is not always a benign disorder. When a fluid comes into contact with the mucosal surface, nerve endings are stimulated, resulting in a laryngeal chemoreflex.²⁷ These receptors mediate several aspiration preventive reflex responses, which include swallowing, airway constriction or closure, and coughing. Cessation of breathing or apnea also may occur.²⁷

Symptoms of GER include postprandial spitting up and coughing or choking during feeding. Aspiration may cause recurrent pneumonitis, laryngospasm, and bronchospasm. Esophageal irritation may lead to food aversion, weight loss, and failure to thrive.

Management consists of decreasing the volume of each feed while increasing the frequency of feeding. For formula-fed infants, thickening of formula (1 tablespoon of cereal for each 1 to 2 ounces of formula) may decrease regurgitation. Parents should be instructed to maintain infants in an upright position for at least 15 to 20 minutes after feeding. The seated position should be avoided as this may increase abdominal pressure and worsen regurgitation. If cow's milk or soy protein allergy is a possibility, the parents should consider changing to a hypoallergenic formula.

Medications that may be useful include histamine₂-receptor antagonists (cimetidine, famotidine, nizatidine, and ranitidine), and proton pump inhibitors (omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole) to decrease acidity of stomach contents and lessen esophageal and laryngeal symptoms. Prokinetic agents (e.g., metoclopramide, bethanecol, erythromycin) increase lower esophageal sphincter pressure and may increase the clearance of esophageal and gastric contents. As a final resort, surgical procedures can be used to decrease or eliminate regurgitation via the esophagus.

Infants with severe symptoms (e.g., apnea, aspiration pneumonitis, failure to thrive) require admission, inpatient confirmation of diagnosis, monitoring, and initiation of therapy.

Mild Systemic Illness

Neonates are obligate nose breathers until they reach the age of 4 to 6 months. The presence of upper respiratory infections may lead to difficulty with feeding and breathing. Excess air may be swallowed as young infants attempt to feed, leading to abdominal distention and vomiting. Vomiting may be a symptom of minor illness, minor upper respiratory infection, or gastroenteritis. With this in mind, it is important to exclude major systemic illness and surgical disorders as a cause of vomiting in neonates and infants.

Major Systemic Illness

Metabolic disorders may cause vomiting, but many are now detected during newborn screenings.^{1,9} However, though rare, urea cycle defects may present early after discharge from the nursery with vomiting and elevated ammonia levels.²⁸ The adrenogenital syndrome commonly presents with vomiting as the presenting event in males. Symptoms begin at the 7th to 10th day, or earlier if the infant is stressed. Diagnosis is easier in girls as virilization of the external genitalia may have been noticed at birth. Diagnosis is supported by the finding of hyperkalemia, hyponatremia, and hypoglycemia and by an infant who may then rapidly progress into shock^{1,28} (see Chapter 29, Inborn Errors of Metabolism; and Chapter 108, Addisonian Crisis).

Neurologic disorders typically lead to vomiting associated with an altered mental status or abnormal neurologic examination. Any suspicion for intracranial disease requires a cranial computed tomography (CT) scan. This is necessary to rule out a subdural hemorrhage secondary to accidental trauma or abuse, an intracranial tumor, or increased intracerebral pressure secondary to congenital hydrocephalus.^{1,28}

Infants who have had shunts placed at birth for congenital hydrocephalus or status post intraventricular hemorrhage or meningitis may develop vomiting as the first symptom of increasing hydrocephalus from a malfunctioning shunt. In addition, the shunt's tubing, which empties into the peritoneal cavity, may in itself cause a volvulus or form adhesions. Finally, the lumen itself may become blocked by debris and stop draining spinal fluid in an appropriate manner, leading to hydrocephalus.²⁹

Serious bacterial and viral infections must be considered and excluded in neonates and infants with vomiting. Findings on examination are particularly subtle at younger ages, and fever is often absent in the setting of a serious bacterial infection. Simple viral enteritis may present with vomiting and fever. However due to the low reserves for hydration and limited glucose storage in neonates and very young infants, a lower threshold for intravenous rehydration should be established, and clinicians should consider and exclude congenital, metabolic, and surgical disorders.¹⁰ An infant with meningitis may present with vomiting, but fever, altered mental status, and sepsis will predominate.^{1,10}

Emesis may be the presenting symptom in an infant with otitis media or a urinary tract infection. A practitioner may be fooled by erythematous tympanic membranes, which are often associated with fever and crying in the young infant. This can lead to the inadvertently attribution of all the infant's symptoms to an ear infection. Therefore, a urinalysis and culture of a specimen obtained by catheterization should always be included in an ED evaluation.¹

Pertussis is having a resurgence in this country due to parental resistance to immunizations. Parents may bring their infant to the ED because of their concern about the post-tussive emesis associated with the disease's paroxysms of coughing.²

Renal stones or ureteropelvic junction obstruction may manifest through cyclic vomiting. Vomiting associated with colicky pain and hematuria is suggestive of this diagnosis.^{30,31}

Narcotic withdrawal in an infant may be manifested by vomiting or irritability. This diagnosis will involve urine tests, as well as skillful questioning of the mother.^{1,10}

Surgical Disorders

Esophageal Atresia and Tracheoesophageal Fistula

Infants with esophageal atresia may be diagnosed in utero, or when they fail to tolerate their first feed or are unable to swallow their own secretions. A history of maternal polyhydramnios and prematurity is common.²² A plain radiograph will show a soft nasogastric tube passed into the esophagus coiling back on itself, unable to pass into the stomach. Further confirmation can be obtained by injecting a small quantity of air down this catheter; this will distend the proximal esophageal pouch. Contrast material should not be used as it could lead to aspiration.²²

Esophageal atresia is associated with a tracheoesophageal fistula (TEF) in 85% of the cases, and 64% of infants with esophageal atresia had associated anomalies, including vertebral, renal, and anal anomalies as well as duodenal atresia and congenital heart disease.^{32,33} If a TEF is present, the radiograph will show gas in the intestine. The abdomen is gasless in those infants without a fistula.³⁴ An infant with isolated TEF may present to the ED in respiratory distress due to recurrent aspiration, or with a history of choking and coughing with all feeds.^{32,35}

Proximal Gastrointestinal Surgical Disorders

PYLORIC STENOSIS

Pyloric stenosis is the most common pediatric surgical condition that causes emesis (nonbilious) in young infants. It is the most common condition requiring surgery in the first few months of life. Pyloric stenosis is an idiopathic hypertrophy of the pyloric muscle whose etiology is not well understood. It is characterized by elongation and narrowing of the pyloric lumen, secondary gastritis, and mucosal edema that will eventually result in almost complete obstruction.³⁶

Infants with pyloric stenosis are usually healthy the first few weeks of life. They have successfully established their feeding regimen and regained their birth weight.⁷ By the third to fourth week of life, these infants typically will begin to vomit intermittently with feeds, with progressively increasing force, volume, and frequency. Throughout the progression of these symptoms, these infants are hungry, eager to take the breast or bottle, but then vomit within 30 minutes of feeding.^{36,37} The emesis will not contain bile but may be blood-tinged from associated esophagitis/gastritis.

If symptoms have been present for several days, the infant will present with dehydration, projectile nonbilious vomiting, and a hypochloremic, hypokalemic metabolic alkalosis. This metabolic state is unique to infants with pyloric steno-

sis. That is because the gastric fluid loss from these infants is associated with the loss of H⁺ and Cl⁻, unlike fluid losses in conditions caused by vomiting with an open pylorus, which involves loss of gastric, pancreatic, biliary, and/or intestinal fluids.^{38,39}

On physical examination, these infants may have a palpable "olive" mass, as well as peristaltic waves across the abdomen, though in reality neither is commonly palpated.³⁷ A radiograph of the abdomen may show a large gastric bubble secondary to gastric outlet obstruction.³⁶ Ultrasound is the diagnostic modality of choice. It is both highly sensitive and specific for pyloric stenosis,⁴⁰ and clearly demonstrates hypertrophied muscle whose length and thickness can be measured to confirm the diagnosis. Pyloric stenosis is present if the muscle thickness exceeds 4 mm.^{39,41} In cases in which ultrasound is inconclusive, an upper GI series may be done to evaluate for possible GER, duodenal atresia, or malrotation^{39,42} (see Chapter 76, Pyloric Stenosis).

DUODENAL ATRESIA

Duodenal atresia, duodenal webs, and duodenal stenosis can lead to intestinal narrowing or to a complete blockage of the intestinal lumen. The blockage may also be secondary to extrinsic causes, including an annular pancreas or a midgut volvulus with Ladd bands.³² The etiology of duodenal atresia is unknown. It may be secondary to a failure of recanalization of the duodenal lumen during the early gestational stage of the embryo.³²

The primary symptom of duodenal atresia is vomiting, which may or may not be bilious depending on the level of the obstruction. In 85% of the infants, the obstruction is distal to the ampulla of Vater. Therefore, the papilla of Vater opens into the proximal duodenum, accounting for the bilious nature of the emesis.^{22,32} If the obstruction is proximal to the ampulla, then the infant may vomit clear material. If it is only a partial stenosis, the diagnosis may not be made until well beyond the newborn period. At that time, the infant may present with dehydration, weight loss, and constipation in addition to intermittent vomiting.

In atresia, the classic diagnostic sign is the double bubble sign on abdominal radiography. The double bubble sign is two air-filled structures in the upper abdomen with little or no air distally.³⁴ The proximal left-sided bubble is the air- and fluid-filled stomach. The proximal duodenum represents the second bubble to the right of the midline. When there is gas distal to the dilated proximal duodenum, malrotation must be distinguished from duodenal stenosis by ultrasound or an upper GI study.^{15,43} However, even in the neonate with the classic appearance of a "double bubble" without distal air, intrinsic causes of obstruction, especially malrotation, must be considered.¹⁹ If surgical intervention is delayed or if there are additional symptoms on physical examination suggestive of acute obstruction, further radiologic investigation is mandatory.²⁰ A neonate with bilious vomiting has malrotation with midgut volvulus until proven otherwise.²²

MALROTATION WITH MIDGUT VOLVULUS

Malrotation with midgut volvulus occurs when there is failure of the developing bowel to undergo the usual counterclockwise rotation during embryogenesis. Peritoneal bands (which normally attach the bowel to the abdominal wall) can compress the duodenum, partially obstructing it.⁴¹

Additionally, as the mesentery is not well attached, patients are at risk for developing a midgut volvulus. Volvulus refers to the complete twisting of a loop of bowel around its mesenteric attachment, leading to intestinal obstruction. The superior mesenteric artery can be compressed, leading to ischemia of the small bowel from the duodenal-jejunal junction to the midtransverse colon.^{17,20}

Unless recognized and treated promptly, bowel ischemia progresses to infarction and necrosis, fever, peritonitis, abdominal distention, hypovolemia, and septic shock. This anomaly may be a difficult diagnostic problem. Clinical presentations may include intermittent vomiting, distention, and constipation that may become more constant, or progress to full-blown obstruction with peritonitis. The hallmark symptom of bilious emesis is present in 75% to 100% of the cases of midgut volvulus.⁴⁴

In a review of 22 patients undergoing surgery for malrotation, 50% had normal abdominal examinations and 32% had abnormal distention without tenderness.⁴⁵ The obstruction on midgut volvulus is usually high, and abdominal distention may not be present. The newborn may only present with crying and bilious vomiting and then rapidly progress to abdominal distention. As midgut ischemia progresses, the infant may rapidly dehydrate and develop metabolic acidosis.^{17,39}

Infants with bilious vomiting require emergent imaging. Plain abdominal films may show a distended stomach and a proximal duodenal bulb with little or no intestinal air, and ultrasound may detect an abnormal relationship between the superior mesenteric artery and vein, also referred to as the whirlpool sign.³⁹ The definitive study is the upper GI series with small bowel follow-through. It can conclusively differentiate a midgut volvulus from duodenal atresia/stenosis.^{31,46} The barium enema is now less frequently used due to frequent false-negative studies.

Laboratory analyses are of little benefit in early presentation, but as bowel compromise progresses, they will reflect increasing hypovolemia and the beginning of extensive ischemic bowel and intestinal necrosis.³⁹ All bilious vomiting in the neonate should be considered a malrotation with midgut volvulus until proven otherwise. An emergency upper GI series must be performed as the patient is being evaluated.^{18,19} All patients require aggressive fluid resuscitation, placement of a nasogastric tube, parenteral antibiotics effective against enteric organisms, and surgical consultation (see Chapter 83, Malrotation and Midgut Volvulus).

Distal Surgical Disorders

JEJUNAL ATRESIA

Jejunal atresia is classified into four types, but the symptoms and signs are identical regardless of the type of lesion. It is more common than duodenal atresia, occurring in 1 in 1500 births, and is also associated with polyhydramnios and premature birth.⁴⁷ It is not associated with chromosomal anomalies or with anomalies of systems outside of the GI tract.³² Infants may present with a varied complex of symptoms including bilious vomiting, abdominal distention, and failure to pass meconium.³² The acuteness of the symptoms may also vary. Vomiting may be only bile stained, abdominal distention may be minimal, and small amounts of meconium may be passed. Five percent of the lesions may involve only partial obstruction or stenosis caused by incomplete intraluminal

occlusion.¹⁹ Diagnosis may be aided by obtaining an obstructive radiographic series, which would show multiple dilated loops of intestine with air-fluid levels.¹⁸ The small bowel close to the atresia may become grossly distended.^{18,19,31,32,48}

MECONIUM ILEUS

Meconium ileus is actually a mechanical obstruction. As a result of pancreatic enzyme deficiency, the distal ileum is plugged by thick meconium, leading to a functional obstruction. Ninety percent to 95% of these infants have cystic fibrosis, and thus a deficit of pancreatic enzymes in the intestines.³⁶ Fifteen percent of infants with cystic fibrosis are born with meconium ileus.⁴⁵ This entity should be detected in the neonatal period prior to discharge from the hospital. In approximately 50% of the patients the bowel is intact and its continuity preserved. However, the emergency physician should be aware that an ileus can reoccur at any time in a patient with cystic fibrosis.

Infants with a meconium ileus will present with bilious vomiting and a distended, tender abdomen with palpable thickened loops of bowel. Plain abdominal films show distended loops of intestine with thickened bowel walls. Meconium mixed with swallowed air will give a characteristic ground-glass appearance without air-fluid levels. Treatment of meconium ileus involves evacuation of the meconium, preferably by nonsurgical management. Contrast enemas (using Gastrografin) may be used with careful ongoing hydration and observation of the patient, as the risk of perforation reportedly is 3% to 10%.^{19,32} A meconium ileus may lead to peritonitis if a volvulus or perforation of the bowel occurs. Calcifications, free air, or very large air-fluid levels are consistent with bowel perforation, which require urgent surgical intervention.²²

MECONIUM PLUG SYNDROME

Meconium plug syndrome occurs when plugs of meconium obstruct the colon. It is associated with conditions that predispose to dysmotility of the neonatal bowel. Conditions predisposing to meconium plugs are prematurity and or low birth weight in the neonate. Also at risk are infants born to mothers with hypothyroidism or diabetes or those whose mothers received magnesium sulfate during delivery.¹⁹ While it is not associated with cystic fibrosis, a small percentage of these infants have associated Hirschsprung's disease. Infants may not develop symptoms until several days after birth.

Infants may present with bilious vomiting, abdominal distention, and no passage of meconium.³² Usually the abdomen is nontender early in presentation. This disorder can resemble small bowel obstruction. In this condition, the colon is believed to be normally innervated but functionally immature. The radiograph may be consistent with low small bowel obstruction or large bowel obstruction.^{31,39,41} A simple rectal examination may allow the plug to pass. A water-contrast enema is usually both diagnostic and curative, with passage of the plug. The GI tract is decompressed and normal GI function established. However, 10% to 15% of these infants may have aganglionsis of the colon and need close follow-up to rule out Hirschsprung's disease.^{32,49}

COLONIC ATRESIA

Colonic atresia is rare. It accounts for less than 15% of all distal intestinal atresias.⁴⁹ Patients present with abdominal

distention, failure to pass stool, and vomiting. It may occur in conjunction with small bowel atresia or Hirschsprung's disease. It is diagnosed via a contrast enema to distinguish it from distal ileal atresia and Hirschsprung's disease.^{19,29}

HIRSCHSPRUNG'S DISEASE

Hirschsprung's disease is a common form of distal bowel obstruction in the newborn. It is defined by the absence of ganglion cells in a variable length of distal bowel (in 80% cases it involves only the rectosigmoid colon). It affects 1 in 5000 infants, and is increased in cases of trisomy 21.^{22,39} A lack of ganglion cells in the colon leads to a failure of parasympathetic-mediated relaxation in the involved segment. An aganglionic colon cannot maintain normal peristalsis, the internal sphincter does not relax, and a functional intestinal obstruction occurs.¹⁹

Clinical manifestations in the neonate include bilious vomiting, failure to pass meconium, abdominal distention, constipation, anorexia, and no stool in the rectum on digital examination.²² Vomiting may be bilious or feculent due to the distal site of obstruction. Although most infants present in the first month of life with bowel obstruction, a minority of infants present later with chronic constipation. A plain film may show distended bowel loops, air-fluid levels, and stool in the proximal colon, making this condition difficult to distinguish from a small bowel obstruction.^{22,39} In Hirschsprung's disease a barium enema will, 80% of the time, show a transitional zone at the junction between the aganglionic and ganglionic intestine.⁴⁹ Diagnosis is confirmed by rectal biopsy^{16,49} (see Chapter 77, Constipation).

Hirschsprung's enterocolitis may occur when the diagnosis of Hirschsprung's disease is delayed or when an extremely large length of aganglionic segment is involved. Symptoms include abdominal distention, vomiting, explosive diarrhea, and sepsis. This is believed to occur when the mucosal integrity of the massively dilated proximal colon is compromised, allowing for the bacterial invasion of the epithelium with impaired mucosal or neuronal immunity.¹⁹ The physical examination will be consistent with peritonitis and sepsis. Radiographs may show distended loops of bowel along the left flank with an abrupt termination in the pelvis (intestinal cutoff sign).²² These infants will require rapid and aggressive intervention, including volume resuscitation, antibiotics, and possibly urgent colonic decompression or a colostomy.

ANORECTAL MALFORMATIONS

Anorectal malformations range from a slight anterior displacement of the anal opening to a completely imperforate anus. All of these should be picked up on neonatal examination, but low lesions with perineal fistulas or an anterior ectopic anus may be difficult to discern.⁵⁰ Infants with imperforate anus may have several associated problems: vertebral anomalies, anal atresia, cardiac anomalies (tetralogy of Fallot, ventricular septal defects), TEF, and various renal, urologic, and GI anomalies. The morbidity and mortality in these infants may be related to the severity of their associated lesions. Therefore, an initial evaluation plan should include a chest radiograph, electrocardiogram, echocardiogram, and appropriate urologic and orthopedic studies as indicated.⁵⁰

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis is commonly associated with premature infants, but also with full-term infants who had a hypoxic insult at birth.^{51,52} It is a rapidly progressive disease producing hemorrhagic necrosis of the intestines, leading to peritonitis and sepsis. Its etiology is unknown but is believed to be related to the inability of the immature GI tract and an infant's immune system to deal with postnatal stresses, especially perinatal hypoxia.⁵³ It may affect any part of the GI tract but has a predilection for the ileocecal region.⁵² It will usually present in the immediate newborn period, but some infants do not manifest symptoms until 10 to 12 days of age.⁵²

The infant may present to the ED with bilious vomiting, bloody stools, abdominal distention, and ileus. More insidiously, the infant's symptoms may be very nonspecific, including lethargy, apnea, anorexia, and full-blown sepsis and shock. The kidney-ureter-bladder film may be pathognomonic for necrotizing enterocolitis, with pneumatosis intestinalis or gas within the bowel wall, as well as air in the portal vein; free air will be noted with perforation. Sequential films that show fixed loops of bowel and/or an ileus may indicate bowel ischemia.²² Laboratory values consistent with sepsis and shock, especially thrombocytopenia, indicate the need for urgent surgical intervention along with ongoing resuscitation and stabilization.^{18,52}

INCARCERATED INGUINAL HERNIAS

Incarcerated inguinal hernias are an important and easily overlooked cause of bowel obstruction in infants. A hernia is defined as the protrusion of a portion of tissue through the wall normally containing it. Inguinal hernias result from the incomplete obliteration of a small diverticulum of the peritoneal sac, the processus vaginalis, in the lower abdomen. This can lead to the development of hernia that may also involve the testes in the male or the ovaries in the female. There is a 6:1 male:female predominance, but females have higher rate of incarceration.⁵⁴ Its incidence increases with premature birth as well as with conditions associated with increased intra-abdominal pressure. These include, among other less common causes, ventriculoperitoneal shunts, peritoneal dialysis, or ascites.⁵⁵ Most infants are asymptomatic unless incarceration develops. Incarceration is defined as the inability to reduce the contents of the hernia back into the inguinal cavity. Fifty percent of incarcerations present at less than 6 months of age. These are almost always indirect inguinal hernias.⁵⁵

Parents commonly bring their infants to the ED because of a swelling or bulge noted in the inguinal or umbilical area. Other symptoms may include vomiting, constipation, abdominal distention, and poor feeding.^{55,56} Nearly 95% of these inguinal hernias can be reduced by constant, gentle upward pressure on the hernia sac.³⁶ Undescended testes can appear to be hernias. The physician should be sure to palpate both testicles in the scrotum prior to diagnosing an inguinal hernia.

It is appropriate as well as therapeutic to first treat the infant with an agent to reduce pain and anxiety before attempting reduction. If the infant's hernia is easily and successfully reduced, the infant may be referred to a pediatric surgeon for close follow-up and further evaluation.²¹ However,

infants may also present with a toxic appearance secondary to strangulation of the bowel. These infants may present with an erythematous, firm, immobile mass, and manual reduction should not be attempted. Intestinal obstruction due to strangulation of the bowel may present with bilious vomiting, abdominal distention and tenderness, bloody stools, and a hypovolemic state.^{36,55} These symptoms necessitate emergent intervention, including fluid resuscitation, placement of a nasogastric tube, laboratory assessments for sepsis and degree of hypovolemia, the initiation of appropriate antibiotics, and immediate surgical consultation. Plain films are generally not necessary and would simply confirm bowel obstruction^{22,56} (see Chapter 84, Abdominal Hernias).

APPENDICITIS

Appendicitis is rare in infancy. If it occurs, the diagnosis is usually delayed. Almost all cases are perforated upon presentation, and the typical symptom duration prior to diagnosis is more than 3 days. Vomiting is present in nearly all infants. Common symptoms include abdominal pain, fever, and diarrhea. Nonspecific symptoms include irritability, difficulty breathing or grunting, and right hip stiffness or pain. Nearly all infants have diffuse abdominal tenderness, while localized right lower quadrant tenderness is noted in only a few cases. Other described features include lethargy due to sepsis, abdominal rigidity or distention, and an abdominal or rectal mass due to abscess formation^{2,36,57} (see Chapter 73, Appendicitis).

INTUSSUSCEPTION

Intussusception can lead to vomiting in infancy.^{28,58} The incidence of this disorder peaks at 10 months of age, with a range of 3 months to 2 years, although 10% of children are older than 2 years at the time of presentation.^{36,59} In this entity, a segment of bowel telescopes into the lumen of the portion of intestine just distal to it. This occurs most commonly at the ileocolic junction. As the distal ileum invaginates and advances into the ascending colon, the prolapsed segment compresses mesenteric vessels, thereby limiting blood flow, leading to obstruction, strangulation, and, if unrecognized and allowed to progress, bowel necrosis.⁵⁹

The classic textbook triad of colicky abdominal pain, vomiting and bloody stools with mucus (“currant jelly stools”) is seen in less than one third of cases.⁵⁹ More commonly infants present with the sudden onset of cramping, intermittent abdominal pain (83% to 92% of patients) that recurs at frequent intervals, accompanied by crying and frequently flexing of the legs as the child attempts to find a position of relief. Nonbilious vomiting occurs in 85% of cases, but the vomitus may eventually become bile stained as the obstruction progresses.^{58,59} Hematochezia is both a late, as well as an infrequent, sign (<8% of infants) associated with high morbidity and mortality.⁵⁶ A more recently recognized set of behavioral symptoms in infants has been well documented in association with intussusception, though their exact etiology has yet to be delineated. An infant with an altered mental status, or lethargy, on presentation to the ED must have intussusception included prominently in the differential diagnosis.³⁶ A right upper quadrant mass may be palpated and, when combined with a schaphoid right lower quadrant (Dance’s sign), is highly suggestive of intussusception.

Diagnosis is primarily by history and observation of the child. Radiographs may rarely show “target signs,” or a paucity of gas in the distal colon. Ultrasound is very sensitive (98% to 100%), though less specific than an enema. Water, contrast, or air enema may be diagnostic as well as curative, allowing for nonoperative intervention.^{60,61} However, prior to attempting reduction, the infant’s metabolic and volume status must be stabilized and pediatric surgery must be readily available in anticipation of possible perforation of the bowel during the attempted reduction. Absolute contraindications for nonoperative reduction are peritonitis, high-grade bowel obstruction, and perforation. Rates of perforation associated with barium enema are estimated to be 0.7%, and those with an air enema, 2.8%.⁵⁸ Any infant who presents with signs of peritonitis, pneumoperitoneum, or associated shock is a candidate for surgical reduction only after stabilization. There is a 5% to 8% recurrence rate, regardless of the method of reduction⁶² (see Chapter 74, Intussusception).

Nonaccidental Trauma

Nonaccidental trauma can be an important cause of vomiting in infants with intracranial and abdominal injuries. The recognition of nonaccidental abdominal injury may be difficult because of subtle abdominal findings or minimal histories.

Risk factors include the caregiver’s delay in seeking treatment for prolonged vomiting or for emesis stained by blood or bile. There may also be inconsistencies in the history and duration of the infant’s symptoms, as given by the family members.^{46,63} Infants with duodenal hematomas may present initially with emesis, consistent with a viral gastroenteritis. As the hematoma causes increasing obstruction or even rupture of the viscus, symptoms of peritonitis or septic or hypovolemic shock may develop. Trauma must always be part of the differential diagnosis of the young infant with emesis that is bilious or blood tinged or suggestive in any way of an abdominal injury.

Abdominal CT is the diagnostic modality of choice and, if positive, should be followed by a complete evaluation for evidence of abuse.^{64,65}

Important Clinical Features and Considerations

Vomiting is a common presenting complaint among young infants presenting to the ED. Its etiologies range from the manifestation of a systemic illness to a congenital anatomic or metabolic anomaly, to an infectious entity or simple overfeeding. As it is a common presenting symptom in childhood, the majority of infants do not require any imaging.⁴¹

The diagnosis of disorders that cause vomiting must center on a careful history and physical examination, as well as a period of observation with repeat examinations in the ED.^{7,10} Surgically correctable causes of vomiting in the young infant are less common than medical ones. As etiologies that can be treated by surgical intervention are rarely seen in the ED, the physician must always be aware of the symptoms and signs of bowel obstruction. Importantly, clinicians must realize that plain abdominal radiographs are normal in half of all infants with surgical abdominal disorders.⁶⁶ They must be aware of appropriate diagnostic techniques for each disease.

Rapid diagnosis of an anatomic anomaly of the GI tract can mean the difference between complete recovery and the catastrophic loss of bowel, with its associated morbidity and mortality.

Bilious vomiting in an infant indicates obstruction beyond the level of the second part of the duodenum.¹⁹ This is of great significance in a newborn as it may indicate malrotation and possible volvulus. The infant may also present with hypovolemic shock and appear septic. Stabilizing a potentially septic infant, who also has symptoms suggestive of a bowel obstruction, should not preclude his or her management as having a malrotation and possible volvulus until proven otherwise. A surgical consultant should be involved in the infant's care immediately, with appropriate imaging (a rapid ultrasound or a definitive upper GI series with bowel follow-through) ordered simultaneously. However, bowel obstruction may present with more subtle symptoms, including nonbilious vomiting or a distended abdomen. Diarrhea may also be present.

The infant with intussusception may be inconsolable secondary to pain or may be lethargic.^{21,59} The "classic" three findings of vomiting, intermittent abdominal pain, and currant jelly stools actually occur concomitantly in less than 10% of all cases. The presence of blood and mucus in the stool is suggestive of an intussusception that has already led to bowel necrosis.⁵⁹

Management

Management of infants with vomiting and spitting up requires an initial determination of hydration, cardiopulmonary status, and likelihood of serious medical or surgical disorders. If symptoms suggest the presence of intestinal obstruction (bilious vomiting, abdominal distention or tenderness, bloody stool, a hypovolemic state or an altered mental status lacking a clear neurologic basis), the physician should proceed aggressively with preparation for surgical intervention.³⁶ A nasogastric tube is placed if bowel obstruction or perforation is present, and any drainage is replaced with appropriate isotonic intravenous fluids.^{21,38,53} Hypoglycemia and electrolyte abnormalities should be corrected during hydration. Appropriate imaging studies, if time allows, should be ordered. Intravenous access should be established for rapid isotonic fluid resuscitation. Cardiopulmonary monitoring is required, with frequent reassessment of volume status, vital signs, and mental status.

Infants with gastroenteritis or minor illness and mild to moderate dehydration potentially can be orally dehydrated. For infants, a rehydration solution is used that contains 50 mEq of sodium and 25 g/L of glucose (e.g., Pedialyte). The infant is given 1 to 2 teaspoons every 5 to 15 minutes over the first hour, and the hydration status is reassessed. The volume is doubled every hour afterward until the infant tolerates 2 ounces every 20 minutes. If the infant looks well, he or she can be discharged home with instructions on how to advance the diet. If the infant vomits at home, the caregiver should wait an hour and repeat the process of introducing rehydration solution at 1 teaspoon every 15 minutes. If the infant vomits again, he or she must be brought back to the ED for reassessment.⁶² Once the infant can tolerate oral rehydration liquids, the caregiver should give breast milk or full-strength formula. A clear liquid diet should not be continued

for more than 24 hours. Breast-feeding may be attempted throughout the hydration process.

The use of antiemetics in infants remains controversial. In a 1996 position statement, the American Academy of Pediatrics recommended that the use of antiemetics be avoided because of questionable side effects.⁶⁷ There is also the potential of masking a more serious condition. Promethazine has recently received a black box from the Food and Drug Administration (FDA), secondary to its association with respiratory failure in infants less than 2 years of age. The FDA also recommended using caution in children above age 2 with this agent due to multiple potential side effects. However, many EDs are now using 5-hydroxytryptamine₃ antagonists in dehydrated children. Two recent studies have shown that oral and intravenous ondansetron therapy is safe in children and reduces hospital admission rates.^{68,69} However, much larger evidence-based studies are still needed to demonstrate their efficacy, and their use in infants younger than 6 months may obscure a more potentially serious underlying cause for these infants' emesis.

Summary

Vomiting in infancy is quite common. Determining which infants have serious medical and surgical disorders can be difficult. The practitioner must be able to distinguish between benign, non-life-threatening conditions and true surgical emergencies. Knowledge of presenting features, typical and atypical signs and symptoms, and appropriate diagnostic adjuncts will aid in diagnosing serious disorders in a timely manner. For infants who are not ill, caregivers must be comforted and instructed in how to rehydrate their infant at home and when they should bring the infant back to the emergency department for further evaluation.

Chapter 36

Failure to Thrive

Todd A. Mastrovitch, MD

Key Points

Knowledge of normal growth and development patterns is necessary to evaluate a patient with failure to thrive.

Failure to thrive is a multifactorial process.

The differential diagnosis must include both organic and nonorganic causes of failure to thrive.

Introduction and Background

The evaluation of failure to thrive presents a unique challenge for the emergency practitioner. Weight loss in an infant or child presenting to the emergency department (ED) is an infrequent chief complaint but one for which there are many causes. The term *failure to thrive* is a description for a process in an infant or child whose weight and growth has been interrupted by an organic or nonorganic process. Numerous conditions have been described that lead an infant or child to begin and continue to lose weight. Diseases of medical, nutritional, psychological, behavioral, and environmental origin have all been implicated in leading to failure to thrive.

Recognition and Approach

Normal Pediatric Growth, Development, and Feeding

It is important for practitioners in the ED to have an understanding of normal infant and childhood growth in order to determine which children are failing to thrive. For healthy term newborn infants, a loss of 5% to 10% from their birth weight is seen initially. Infants should have regained their birth weight by 2 weeks of age. Infants should then double their birth weight by 4 to 5 months and triple their birth weight by 1 year of age.

During the first 3 months of life, an infant should have a steady gain of 30 g (1 ounce) per day. The amount gained will decrease to 20 g/day at 3 to 6 months, 12 g/day at 6 to 12 months, and 8 g/day at 12 to 18 months. The child's height should double within the first 4 years of life. As a general rule,

exclusively breast-fed infants are smaller than comparable formula-fed infants at 1 year of age.¹

The American Academy of Pediatrics suggests exclusive breast-feeding as the feeding of choice for the infant under 1 year of age. Questions must be asked of the caregiver regarding the type, frequency, volume, and tolerance of the breast or formula feedings to help determine the nutritional adequacy provided.² Infants do not require water supplementation under normal circumstances. Excessive fruit juice consumption is associated with failure to thrive and should be limited in older infants. Solid foods are usually started between 4 and 6 months, when the infant's oral-motor and gastrointestinal mechanisms have matured.³

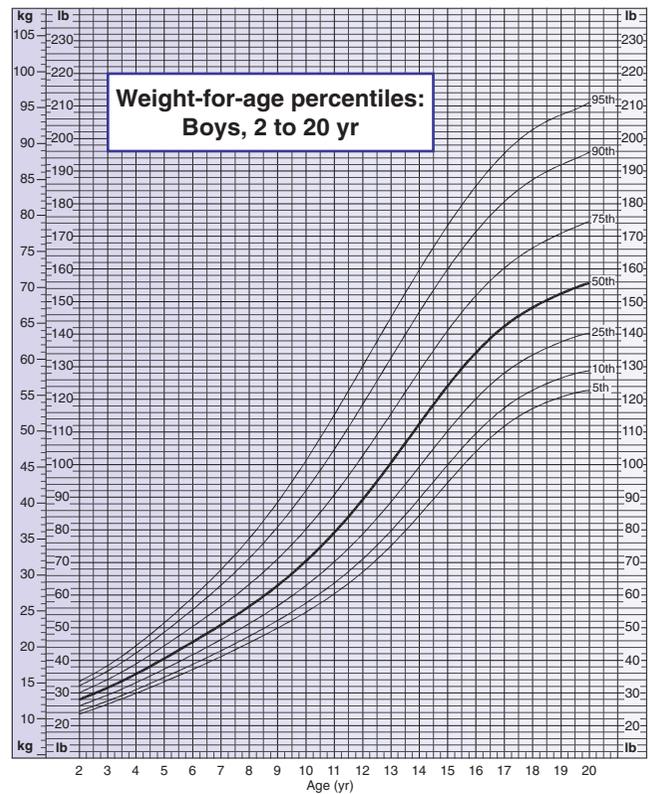

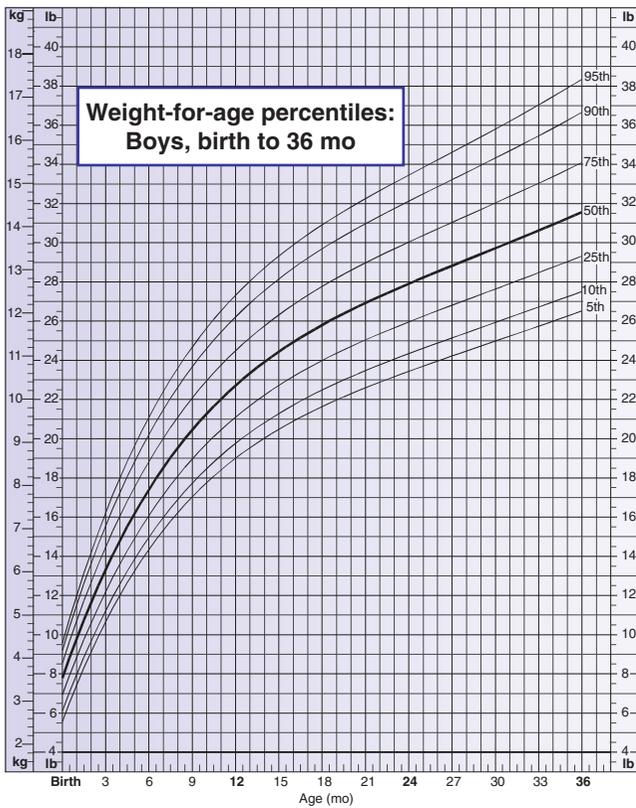

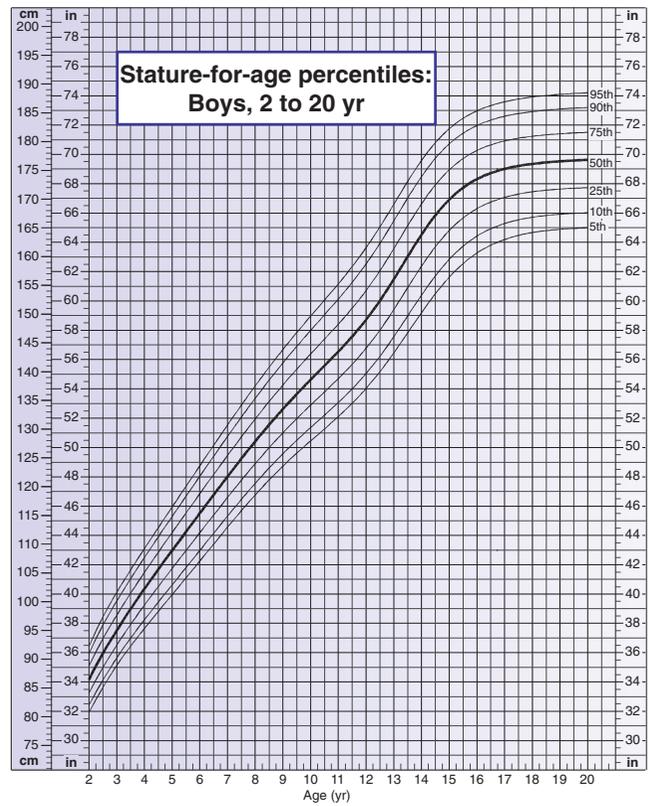

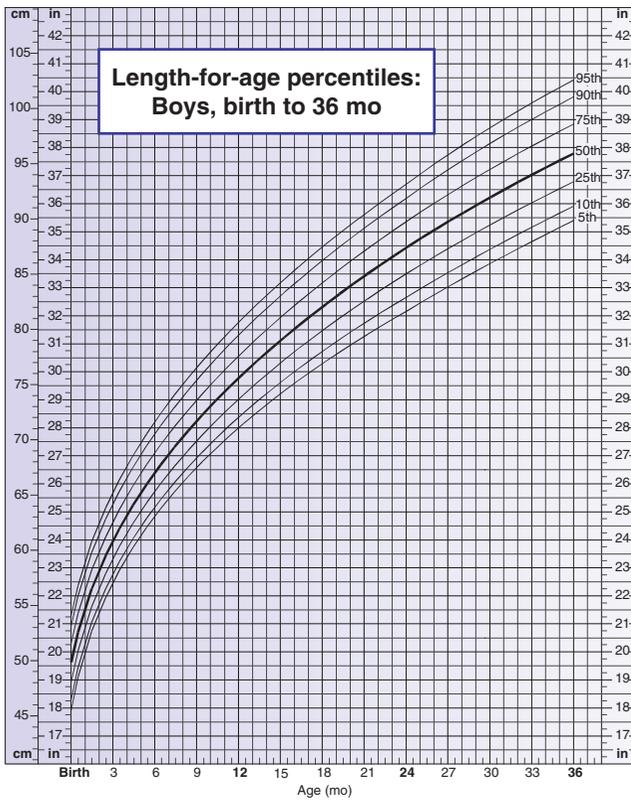

The standard method of evaluating growth in a child is by plotting serial weight, height, and head circumference measurements on the revised growth charts for children published by the Centers for Disease Control and Prevention. These growth charts take into account different sexes, ethnicities, and feeding types. It is important in the ED to contact the patient's primary care practitioner to obtain more data points in time to evaluate a child's true growth. Failure to thrive should be considered if the weight of the infant is less than the 3rd percentile or the infant's weight drops and crosses over two percentile lines in a few months' time (usually less than 6 months) (Figs. 36–1 and 36–2).

Clinical Presentation

Causes of failure to thrive can be divided into two categories: organic and nonorganic (Table 36–1). Organic causes affect the infant's ability to intake, absorb, and utilize the nutrition provided for growth. Nonorganic causes disrupt the normal psychosocial/behavioral elements of feeding between the infant and caregiver, which then results in malnutrition of the infant.^{3,4}

By gathering historical data during the interview of the caregivers, the clinician may begin to piece together the reasons for the infant's growth failure (Table 36–2). The infant's history usually provides key reasons for growth disturbance. Reasons such as inadequate breast-feeding or formula intake, increased vomiting with feedings, or absorption problems with frequent diarrhea may be found to be causing the growth difficulty.⁵ It is essential that, during the physical examination, the infant or child is carefully weighed and the length and head circumference are measured. The

Table 36–1 Conditions Associated with Failure to Thrive**Organic Causes**

Cardiopulmonary	Congenital heart disease, cystic fibrosis, bronchopulmonary dysplasia, severe reactive airway disease, chronic inflammation of tonsils and adenoids
Congenital	Chromosomal abnormalities (e.g., Noonan's, Turner's, Williams syndromes), cleft palate
Endocrinologic	Diabetes, Addison's disease, hyperthyroidism, hypothyroidism, congenital adrenal hyperplasia, growth hormone deficiency
Gastrointestinal	Oral/esophageal anatomic abnormalities, pyloric stenosis, gastroesophageal reflux, parasites/chronic enteric infections, biliary disease, pancreatic insufficiency, liver disease, celiac disease, milk allergy
Hematologic	Lead toxicity, iron deficiency anemia
Immunologic	Chronic immunodeficiency, HIV/AIDS, TB, chronic UTI, recurrent infection, malignancy, rheumatologic disease
Metabolic	Inborn errors of metabolism
Neurologic	Cerebral palsy, developmental disabilities, CNS neuromuscular/esophageal motility problems, anosmia, blindness
Nutritional	Insufficient lactation in mother
Perinatal factors	Prematurity, very-low-birth-weight infants, intrauterine growth retardation
Renal	Renal insufficiency, renal tubular acidosis, Bartter's syndrome

Nonorganic Causes

Inappropriate feeding technique
 Disturbed mother-child relationship (e.g., bonding and feeding difficulty)
 Socioeconomic factors
 Psychosocial factors/apathy
 Insufficient family support/family discord
 Chronic disease states with increased support needs by the caregivers
 Child abuse/neglect

Abbreviations: CNS, central nervous system; HIV/AIDS, human immunodeficiency virus/acquired immunodeficiency syndrome; TB, tuberculosis; UTI, urinary tract infection.

scale used for weighing should be frequently zeroed and calibrated, and attention should be paid to the way in which the infant was weighed last (e.g., clothed/un clothed, diaper/no diaper), with the standard being a completely undressed/undiapered infant or child. These data points should then be plotted on the standardized growth charts, hopefully with a previous growth point for comparison. If head circumference, weight, and length are all decreased compared to normal percentiles, genetic and prenatal disorders should be suspected. If weight and height growth are delayed and head circumference is normal, endocrine disorders and constitutional delay are possible causes. Children with normal head circumference and low weight relative to height often have inadequate nutrition as the cause. In cases of nonorganic failure to thrive, the only physical finding is usually growth failure (e.g., a thin, cachectic appearing infant or child with minimal subcutaneous tissue).⁶ Typically a child with an organic failure to thrive will have a specific finding (e.g., metabolic or renal abnormality)⁷ that helps guide the practitioner in the diagnosis.

Table 36–2 Historical Considerations**History of Present Illness**

Was the pregnancy, delivery, or newborn period difficult?
 Do the parents note a problem with the infant?
 Exactly what is the infant/child being fed?
 Any cultural factors affecting the child's intake?
 What support system is in place for the caregivers of the infant?

Family History

History of the parents' growth as an infant
 Any fetal losses or infantile deaths in the family?
 What are the parents' and siblings' height, weight, and head circumferences?
 Any family history of mental illness, abuse, neglect, extreme dieting, or eating disorders?

Social History

Evaluation of maternal coping mechanisms/maternal depression
 Adequacy of financial support for food
 Who makes up the infant's/child's support system?
 What are the major events in the child's life? (e.g., frequent moves, recent homelessness, family instability)

Breast-Fed Infants

What are the length and frequency of the feeds?
 How is the infant's suck mechanism?
 What are the maternal attitudes toward breast-feeding?
 Is there adequate milk production and let-down?
 Is there spitting up, vomiting, or coughing during feeding?

Bottle-Fed Infants

How is the formula prepared?
 How many ounces are taken per feed or per day?
 Who feeds the infant?
 Is there spitting up, vomiting, or coughing during feeding?

Toddlers

How many meals per day?
 What is a normal meal composed of for the child?
 Who feeds the child?
 How long do mealtimes last?

Initial routine laboratory testing of electrolyte levels, blood urea nitrogen and creatinine, calcium, complete blood count, liver function tests with protein and albumin, urinalysis and urine culture, chest radiograph, and Mantoux tuberculin testing is appropriate. Further testing and radiographic and imaging studies may be indicated on the basis of the clinical examination.

Management

In patients who are less severely growth impaired, not ill appearing, and clinically and psychologically stable, a trial of outpatient management is instituted, with close monitoring by the primary care provider.

In cases in which the clinical and psychological status of the patient is more severely affected, hospitalization plays a key role in helping to improve the patient's nutritional status. Hospitalization is also helpful for those patients who need correction of fluid and electrolyte imbalance. While in the hospital, more information is gathered over time as to how the infant feeds, the interaction between the infant and caregiver, and the daily physiologic functions of the child (i.e., stools, sleep/wake periods, general disposition). By examining this information, the medical team will then be able to help the family unit understand and treat the causes of failure

to thrive.⁸ The desired result of hospitalization for the growth-impaired infant is weight gain and improvement in social interaction with caregivers.

Infants and children who have physical findings of systemic disease or who fail to gain weight while under care in the hospital setting should be further evaluated for organic causes of failure to thrive. More extensive testing and consultation with pediatric subspecialists in gastroenterology, endocrinology, infectious diseases, neurology, or psychiatry may be necessary to elucidate a cause for the growth failure. It is also often helpful to seek the assistance of social workers, nutritionists, physical/occupational therapists, and behavioral pediatricians due to the multifactorial nature of this disease process.¹⁰ In working together, the treatment team often will be able to identify the issues leading to the infant's or child's poor growth status.¹¹

Summary

Failure to thrive is a multifactorial disorder resulting from malnutrition in infants and children. Medical, psychological, nutritional, behavioral, abusive, environmental, and congenital factors have been implicated. The emergency physician must be able to begin to sort out the organic versus the non-organic causes of failure to thrive, and to identify those patients who require hospitalization in order to stabilize their clinical status. Diagnosing failure to thrive and identifying which patients need laboratory and/or radiologic testing depends on the key findings in the history and physical examination. To treat failure to thrive, the emergency physician must focus on the correction of the underlying causes and

enlistment of the multidisciplinary team to improve the nutritional and psychological status of the patient.

Minor Infant Problems

Jonathan H. Valente, MD

Key Points

The term *breath-holding spells* is a misnomer as these episodes occur involuntarily and during the exhalation phase.

The excessively crying infant should be evaluated for the presence of a hair-thread tourniquet.

The successful treatment of oral thrush involves cleansing the infant's pacifier and bottle nipples. For breast-fed infants, the mother may need to be treated with a topical or oral antifungal agent.

Vaginal bleeding in the first week of life is most likely benign and due to the withdrawal of maternal hormones.

Selected Diagnoses

- Breath-holding spells
- Hair-thread tourniquets
- Congenital muscular torticollis
- Oral thrush
- Neonatal vaginal bleeding

Discussion of Individual Diagnoses

Breath-holding Spells

The use of the term *breath-holding spell* is actually a misnomer as these episodes occur involuntarily and during the exhalation phase. The typical spell begins after an event that is frightening, startling, painful, or upsetting to a child. This is followed by a brief period of crying that leads to a stage of apnea and silent, noiseless expiration. During this period, the child's skin may become either pale or cyanotic. This has led to the classic description and classification of these episodes as being either pallid or cyanotic spells. In mild spells, the episode resolves without loss of motor tone or syncope. This is followed by a loud inspiratory response and a fairly prompt return to normal activity. However, in more severe spells, the child may experience loss of motor tone or syncope as well as other symptoms such as loss of consciousness, myoclonic

jerks, incontinence, or stiffness. Drowsiness is common following a more severe spell, but a return to normal consciousness is usually fairly prompt. The typical breath holding spell lasts from a few seconds to a few minutes depending upon the severity of the episode.¹ Pallid spells are thought to result from a vagally mediated cardiac inhibitory pathway, whereas cyanotic spells are believed to result from a more complex mechanism involving a hyperventilatory-Valsalva pathway.² In some cases, breath-holding spells defy classification as either pallid or cyanotic and are classified as "mixed." Approximately 60% are cyanotic, 20% are pallid, and 20% are mixed.¹

Recognition and Approach

Breath-holding spells are relatively common. Severe spells occur in 0.1% to 4.6% of healthy children. Simple spells occur in up to 27% of healthy children.^{1,3,4} The age at onset is as follows: neonatal in 5%, in the first 6 months of life in 12%, in the first year in 66%, and in the first 2 years in 94%.^{1,3,5} Virtually all children who will manifest breath-holding spells will have their first spell before their third birthday.

The frequency with which infants and young children have breath-holding spells is quite variable. Spells may occur as a weekly or even daily event in more severe cases. The peak frequency typically occurs at about 18 months of age. In more severe cases, up to one third of these children have more than one spell each day at the age of peak frequency.⁵ Children outgrow breath-holding spells. By age 4 years, about half of children experiencing breath-holding spells will stop having them. By age 6 years, 90% have stopped having breath-holding spells. Nearly all children stop having breath-holding spells by age 8 years.^{1,3,6}

Clinical Presentation

A detailed description of the event is the key to making the diagnosis. For example, a breath-holding spell never occurs in the sleeping child. The differential diagnosis for similar events includes seizures, cardiac disturbances, orthostasis, brain tumors, and developmental disorders. Unlike many of these other diagnoses, breath-holding spells are almost always immediately preceded by a painful or emotionally provocative event. In addition, the cyanosis or pallor presents *prior* to the loss of motor tone or syncope. Family history may be helpful as 20% to 30% of children with severe breath-holding spells will have a family history of breath-holding spells.^{1,7}

Management

The evaluation of a child suspected of having had a breath-holding spell does not involve extensive testing or imaging. The physical examination is focused on the cardiac and neurologic status of the child. An electrocardiogram (ECG) may be performed to look for abnormalities such as prolonged QT syndrome. A bedside hemoglobin may be obtained to identify anemia.⁸ In cases in which the diagnosis is not clearly a breath-holding spell, ECG monitoring during an ocular compression test may elicit episodes of asystole consistent with pallid breath-holding spells.⁹ Although rarely indicated, an electroencephalogram may help rule out seizures.^{2,9}

Medications to treat breath-holding spells are seldom, if ever, indicated in the emergency department. On occasion, a child who is being treated for repeated episodes of breath-holding spells will present to the emergency department. Such children may be taking oral atropine, oral theophylline, iron supplements, or have a transdermal scopolamine patch.^{1,8,10-15} A prospective double-blind study showed that iron therapy was beneficial in the treatment of breath-holding spells. More than 50% of the treatment group showed a complete response to therapy with iron compared with none in the placebo group.¹¹ Other researchers have reported similar outcomes with iron therapy and even studied blood transfusion therapy in children with breath-holding spells.^{8,12-15} For severe refractory cases, permanent pacemaker therapy has been utilized and been shown to have some efficacy in these rare instances.^{16,17}

Parental reassurance is an important feature in successfully treating children with breath-holding spells. Recurrent breath-holding spells cause a significant amount of stress in the mothers of these children—twice as much as in mothers of children with a seizure disorder.¹⁸ Breath-holding spells are benign. In otherwise healthy children, there is no evidence to suggest any increased risk of epilepsy or serious long-term sequelae except, perhaps, a slightly increased risk of syncope later in life.³ Parents should be careful not to succumb to their child's every wish just to avert a breath-holding spell. Doing so may lead to behavioral problems and parental manipulation by the child. Parents should be instructed to simply observe the child and take measures to protect him or her from injury during a breath-holding spell. Children diagnosed with breath-holding spells may be discharged home from the emergency department with primary care follow-up.

Hair-Thread Tourniquets

The hair-thread tourniquet syndrome is caused by a hair or thread encircling a finger, toe, penis, clitoris, or uvula (Fig. 37-1).¹⁹⁻²¹ The circumferential strangulation of the digit leads to decreased venous and lymphatic drainage with the subsequent formation of edema distal to the tourniquet. Arterial insufficiency may follow due to inflammation and edema. In more prolonged or severe cases, the surrounding tissues may even epithelialize over the hair or thread, making visualization extremely difficult or impossible. Ultimately, tissue necrosis may develop and lead to autoamputation or the need for surgical amputation.²² A physical property of human hair is that it stretches when wet and shrinks when dried. This most likely contributes to the constrictive phenomenon observed with this syndrome.²¹ The time course to recogni-

FIGURE 37-1. Toe hair tourniquet. (Photo courtesy of Robert Acosta, MD, Jacobi Medical Center, Bronx, NY.)

tion and presentation has been reported to range from hours to months following the initial constriction.²³

Clinical Presentation

The majority of toe and genital tourniquets are caused by hair, while most finger tourniquets are caused by strings or thread (e.g., from mittens). Infants at highest risk for hair tourniquets are typically younger than 6 months of age and infants of mothers with long hair. This coincides with the period of greatest maternal hair loss following delivery. This period of postpartum hair loss is termed *telogen effluvium* and affects up to 90% of otherwise healthy mothers.²⁴ In a review of 66 cases of hair and thread tourniquets, 43% involved toes, 24% involved fingers, and 33% involved the genitalia. The hair-thread tourniquet syndrome may involve multiple digits, but more often involves only one. On the hand, the middle finger and index fingers are reported to be at higher risk for strangulation. Similarly, on the foot, the middle and second toes are most frequently involved.²⁵

The hair-thread tourniquet syndrome is a cause of excessive crying (see Chapter 31, Excessive Crying). The syndrome is most frequently accidental and not due to abuse.²⁶ In the rare cases in which it has been associated with child abuse, the genitals are often involved (e.g., tourniquets created by

caregivers to prevent nocturnal enuresis).²⁶⁻²⁸ Poor public and clinician awareness that this syndrome is not often associated with abuse has been highlighted by a 1994 survey by Biehler et al.²⁹ In this study, more than half of the respondents claimed that they would report a classic case of the toe tourniquet syndrome to the child protective service. The group that responded included 42 physicians, 19 child welfare workers, and 23 nurses.²⁹

Management

The most effective treatment is expedient removal of the tourniquet. Often the tourniquet can be removed by using a probe to lift up the fiber and then cut the fiber with scissors or a scalpel blade. Another technique is to use a short, deep dorsal longitudinal incision over the area of strangulation in toes.³⁰ The incision is made down to the bone. The retrospective study supporting this technique suggested that this approach may decrease the risk of injury to the digital nerves and vascular structures. However, injury to the extensor tendon is possible, and there are no prospective studies evaluating the potential complication rates or long-term functional deficits associated with this technique. If this technique is used, splinting of the digit is prudent to promote healing of the extensor tendon. Other well-documented surgical techniques involve longitudinal incisions made at the lateral and medial aspects (3-o'clock and 9-o'clock positions) of the toe or finger. These incision locations are selected to avoid neurovascular and tendon structures.³¹ For tourniquets involving the genitals, emergent urologic consultation is generally indicated for surgical removal, unless the tourniquet is superficial. The use of depilatory agents has been suggested, but this chemical approach may lead to tissue toxicity, since the epithelium and soft tissues are already damaged, and would be ineffective for tourniquets made of material other than hair.³¹ Following removal of the thread or hair, patients should be followed on a regular basis for at least 1 month to evaluate for retention of tourniquet remnants or epithelialized fibrous connective tissue bands.²³ Surgical exploration under magnification may ultimately be needed when doubt exists as to the complete removal of the hair or thread.

Anticipatory guidance for parents, especially in the first few months of life, may help to better recognize this clinical entity. Careful inspection of the baby's fingers, toes, and genitalia are important aspects of routine care. Washing clothing turned inside out and turning clothing inside out to look for and remove loose hairs or threads also may be helpful in preventing this syndrome.²⁴

Congenital Muscular Torticollis

Congenital muscular torticollis is a term used to describe a painless clinical condition of neonates and young infants manifested by unilateral tightening or shortening of a sternocleidomastoid muscle.³² Related terms include *neonatal torticollis*, *pseudotumor of infancy*, *sternocleidomastoid tumor of infancy*, and *fibromatosis colli*.³²⁻³⁵ Due to definitional problems, it is not clear if these are different names for the same conditions, names for findings along the clinical spectrum of a single condition, or distinct clinical entities. There is no predilection for gender or sidedness.³⁶ Bilateral torticollis is extremely rare.³⁷ Congenital muscular torticollis is the most common cause of infantile torticollis, with an incidence of 0.3% to 1.9%.^{32,34,35}

Clinical Presentation

Patients present within the first few weeks of life with their heads tilted to the side of the affected sternocleidomastoid muscle and their chins turned toward the contralateral side.^{34,35} This clinical presentation has been referred to as a "cock robin" or "wryneck" deformity.³⁸ These infants exhibit a limited range of motion of their necks. Some infants may have a palpable, firm, fibrous mass within the sternocleidomastoid muscle.^{32,38}

There are many theories regarding the cause of congenital muscular torticollis, but the true etiology remains unknown. Some theories include birth trauma to the sternocleidomastoid muscle with hematoma formation leading to localized fibrous scar formation, ischemia due to venous occlusion, intrauterine malposition, hereditary factors, neurogenic causes, infections, and a form of compartment syndrome during the intrauterine period.³⁵ Infants with congenital muscular torticollis have a higher incidence of difficult births, breech presentations, and congenital hip dysplasia than other infants.^{34,38} Long-term complications associated with this disorder include possible functional and cosmetic abnormalities such as facial asymmetry, plagiocephaly (i.e., a parallelogram-shaped head or a flattened area on one side of the head), and scoliosis.^{32,39,40}

In most cases, the diagnosis is evident based on the history and physical examination. Testing and radiography are reserved for those cases in which initial therapy fails or the infant's condition changes to suggest an alternative diagnosis. Other categories of disorders that may cause torticollis in infants include traumatic, ocular, gastrointestinal (e.g., Sandifer's syndrome), aplastic, infectious, neoplastic, inflammatory, or congenital osseous conditions (e.g., cervical vertebral abnormalities).^{38,41} Of note, most neurologic causes of torticollis will present after infancy.³⁸ Potentially useful diagnostic studies include fine-needle biopsy, radiographs, ultrasound, computed tomograph, and magnetic resonance imaging.^{33,34,40}

Management

Significant controversy surrounds the optimal treatment for congenital muscular torticollis. About 95% of these infants will respond to conservative therapy such as exercise and stretching performed by the parents at home, manual stretching by a therapist, and observation.^{39,42,43} Patients with a palpable mass, an initial head rotation deficit of greater than 15 degrees, and a delay of initial treatment to after the first birthday tend to have worse outcomes and may require surgical intervention.³⁹ The optimal age for surgical intervention is between 1 and 4 years.⁴⁴ Other treatment options include simple observation, orthotic devices, and botulinum toxin.^{38,44}

Oral Thrush

Thrush, also known as oral mucocandidiasis, is most frequently caused by *Candida albicans*. Thrush presents with discrete whitish plaques on an erythematous background on the buccal mucosa, tongue, and gingiva (Fig. 37-2). Lesions may also present on the tonsils and palate. These plaques are quite adherent and a little bleeding may occur if they are scraped with a tongue blade. Infants may have a history of irritability and poor feeding or be asymptomatic.

There is a high prevalence of oral colonization in infants due in part to the direct contact of the infant's mouth with

FIGURE 37–2. Oral thrush. (Photo courtesy of Deirdre Fearon, MD, Hasbro Children’s Hospital, Providence, RI.)

the birth canal. During pregnancy, the prevalence of vaginal *Candida* increases up to 40% compared to about 15% in nonpregnant, asymptomatic women.^{45,46} Both breast-fed and bottle-fed infants may develop thrush, but bottle-fed infants are at increased risk.^{46–49} Risk factors for developing thrush include pacifier use, being admitted to a special care unit in a hospital, and maternal symptomatic vaginal candidiasis around the time of delivery.^{46,47,50–52}

Nystatin is the standard topical drug of choice to treat infantile thrush due to its low cost and high safety profile. Nystatin is used topically on the lesions four times per day for 10 to 14 days. However, its use has been associated with high recurrence rates attributed to limited duration of contact of the medicine with the thrush and the difficulty in administration leading to poor compliance.⁵³ A recent study reported only a 54% clinical cure rate at day 12 in healthy infants treated with nystatin suspension as compared with a 99% cure rate in infants treated with miconazole gel. Relapse rates were similar between the two groups.⁵⁴ However, a miconazole gel formulation is currently not available in the United States. One small pilot study of 47 infants showed superior efficacy of oral fluconazole compared with nystatin for the treatment of infants ages 1 to 12 months.⁵³ Clinical cure rates were 29% for nystatin at day 10 and 100% for fluconazole at day 7. Patients in this study received a dose of fluconazole of 3 mg/kg per day for 7 days.⁵³ However, in the healthy host, thrush is not a life-threatening disease and the added cost and potential side effects with systemic therapy may outweigh the risk of treatment failure.

Maternal Nipple Candidiasis

In breast-fed infants, recurrence is especially common in mothers who develop nipple candidiasis. A clear correlation has been established between nipple candidiasis and vaginal candidiasis, previous antibiotic use, and nipple trauma.⁵⁵ In such cases, both maternal and infant treatment is advised. Fluconazole can be used to treat maternal nipple candidiasis.

It is excreted in small amounts in the breast milk and there are limited safety data regarding its use in the breast-feeding infant. However, the amount excreted in the breast milk is less than the normal infant dose if the infant were to be treated systemically with oral fluconazole for thrush. A recent survey of 312 members of the Academy for Breastfeeding Medicine evaluating the treatment of thrush in the breast-feeding infant showed that the majority recommended treatment of the infant and mother, even if the mother was asymptomatic.⁵⁶ Of those surveyed, 47% recommended the use of oral nystatin for the infant and nystatin cream for the mother, 3% recommended oral nystatin for the infant and oral fluconazole for the mother, and 2% recommended oral fluconazole for both as the initial therapy. In cases with symptomatic maternal nipple candidiasis and oral infantile thrush, 56% recommended oral nystatin for the infant and cream for the mother, 13% recommended oral nystatin for the infant and oral fluconazole for the mother, and 4% recommended oral fluconazole for both as initial therapy. Of those surveyed, oral fluconazole for both the infant and the mother was recommended by 21% in recurrent cases and by 33% in persistent cases. Alternatively, miconazole cream may also be applied to the affected nipples four times per day. The cream will need to be applied until 48 hours after the resolution of symptoms. The cream is applied after breast-feeding, and the nipples should be cleaned prior to the next feeding. When administering antifungals or other medications, medication droppers or spoons should not be reused without boiling or sterilizing. Alternatively, application of the antifungal can be via disposable cotton-tip swabs. Breast pumps, bottles, and toys will require thorough cleaning and sterilization. Strict hand washing may prevent reexposure.⁵⁷

Neonatal Vaginal Bleeding

Vaginal bleeding in neonates may occur within the first few weeks of life and is usually due to the withdrawal of maternal estrogen. Bleeding may last a few days. No treatment is necessary for such cases. Reassurance is very important as this can be a very worrisome experience for caregivers.⁵⁸ Other causes of vaginal bleeding in the neonate should be considered in the atypical cases with prolonged or excessive bleeding, an abnormal external genital examination, or an unusual history. The differential diagnosis includes but is not limited to abuse, vaginitis, urethral prolapse, and tumor.

Literature regarding neonatal vaginal bleeding is very limited. A study published in 1978 covering 15 years of experience at one institution reported on 51 girls being evaluated for vaginal bleeding.⁵⁹ This study included a neonate ultimately diagnosed with McCune-Albright syndrome and a 1-month-old with cyclical vaginal bleeding who, at 3-year follow-up, appeared to be developing normally and had no secondary sexual characteristics. About 80% of children with urethral prolapse will present with bleeding as a complaint. However, most of these children will be toddlers and young school-age girls. In a study of 192 cases of urethral prolapse, the mean age was 5.4 years and the range of ages at presentation was 1.5 months to 16 years.⁶⁰ In another study of 55 girls under the age of 10 years evaluated for vaginal bleeding, hormonal withdrawal bleeding in the neonate accounted for 6 cases (11%).⁵⁸ Aside from withdrawal bleeding in the neonate, other causes of vaginal bleeding in the neonate are uncommon.

Chapter 38

Jaundice

Niranjan Kissoon, MD

Key Points

Neonatal jaundice is common, but acute bilirubin encephalopathy and kernicterus are rare.

Estimates of total serum bilirubin based solely on clinical examination are not reliable.

Phototherapy is the initial treatment of choice for most cases of neonatal hyperbilirubinemia.

Jaundiced infants exhibiting signs and symptoms suggestive of a concurrent serious illness require more extensive diagnostic testing and empirical treatment.

Introduction and Background

Jaundice is a yellowish pigmentation of the skin, tissues, and body fluids caused by the deposition of bile pigments. In most cases in which the infant is born at term, newborn jaundice arising during the first few days of life is of little clinical significance.¹ However, severe jaundice is associated with permanent brain damage.¹⁻⁴ Managing neonates with jaundice may be challenging for emergency physicians as these cases are relatively uncommon in most emergency departments and yet are occasionally fatal.⁵

Brain injury is the predominant factor in the morbidity and mortality directly attributable to neonatal jaundice.^{1,6-9} Since the early 20th century, the term *kernicterus* has been somewhat loosely used to describe any brain injuries associated with severe hyperbilirubinemia.^{6,10,11} In the last few years, organizations such as the American Academy of Pediatrics Subcommittee on Hyperbilirubinemia have proposed language to describe neurologic damage associated with neonatal jaundice more precisely.¹² The term *kernicterus* is used for cases of “chronic and permanent clinical sequelae of bilirubin toxicity.”¹² The term *acute bilirubin encephalopathy* is used for the acute manifestations of bilirubin toxicity seen in the first few weeks of life. Acute bilirubin encephalopathy has also been referred to as “early bilirubin toxicity.”¹³

Recognition and Approach

While jaundice is common, acute bilirubin encephalopathy and kernicterus are not. Approximately 60% of the 3.5 million healthy infants born each year in the United States will develop jaundice during the first week of life.¹⁴ Of jaundiced newborns, approximately 25% will develop “severe hyperbilirubinemia,” which corresponds to a total serum bilirubin level above the 95th percentile based on age (in hours).¹⁴ For low-risk, full-term neonates, the 95th percentile corresponds to a total serum bilirubin level of approximately 17 mg/dl (291 μ mol/L).¹⁵ Extreme elevations of total serum bilirubin are rare. For example, for total serum bilirubin levels greater than 20, 25, and 30 mg/dl (342, 428, and 513 μ mol/L), the corresponding incidences are approximately 2%, 0.2%, and 0.02% respectively.¹⁶ While jaundice is common, demonstrable brain injury due to severe hyperbilirubinemia is not. There is no mandatory reporting mechanism for cases of kernicterus. This results in incomplete epidemiologic data. However, by one estimate approximately 125 cases of kernicterus were identified in the United States from 1984 to 2002.¹⁷ This represents fewer than 10 cases per year in the United States.

Neonatal hyperbilirubinemia results from a buildup of bilirubin in newborn infants who have a limited ability to excrete it.¹⁸ Neonates and young infants have high rates of bilirubin production due to rapid turnover of their red blood cells.¹⁹ The strongest predictors of hyperbilirubinemia or early jaundice are a family history of jaundice in a newborn, exclusive breast-feeding with some difficulties encountered, bruising or cephalohematoma development during delivery, Asian race, maternal age greater than 25 years, and lower gestational age at birth^{20,21} (Table 38–1).

Clinical Presentation

There are two main presentations of jaundice during early infancy. Infants may be brought to the emergency department primarily for a chief complaint of jaundice. These infants are typically robust and doing well. At times, however, infants may be brought to the emergency department for complaints in addition to jaundice. In the context of other potentially serious signs and symptoms, an evaluation for the underlying etiology is indicated^{21,22} (Table 38–2) (see Chapter 7, The Critically Ill Neonate).

History

Several historical features can assist in risk-stratifying jaundiced neonates (see Table 38–1). In particular, gestational age is an important risk factor for hyperbilirubinemia.²³ In most circumstances, there is little difference in the home care or medical management of healthy-appearing, appropriate-weight neonates born between 35 and 40 weeks' gestation. There is, however, an inverse relationship between gestational age and risk for severe hyperbilirubinemia.^{12,23} Full-term neonates are at much lower risk for developing severe hyperbilirubinemia than those born preterm. Knowing whether the infant is breast-fed, bottle-fed, or both is helpful. Particularly if the mother and her neonate are having difficulties with feedings, exclusively breast-fed infants are at increased risk for severe hyperbilirubinemia.¹² Exclusive bottle feeding decreases the risk.¹²

Infants whose jaundice is due to hemolytic disease are at a higher risk for acute bilirubin encephalopathy. Historical factors suggestive of hemolytic disease include a family history of significant hemolytic disease, the onset of jaundice within the first 24 hours of life, a mother who is Rh negative (especially if the mother has not received Rh immune globulin), and a complaint of pallor.²⁰ On occasion, a prior bilirubin level will be available either from testing in the newborn nursery or from a check in the doctor's office. If this informa-

tion is available, a rise in total serum bilirubin by more than 0.5 mg/dl per hour is also suggestive of hemolytic disease.²⁰

Occasionally a neonate or young infant will present with a history consistent with cholestatic jaundice. These infants may have biliary atresia or other serious causes of cholestasis. In particular, a history of dark urine or dark urine stains in the diaper and very light-colored stools is suggestive of cholestatic jaundice. A history of prolonged jaundice, particularly if lasting more than 3 weeks, is suggestive of cholestatic jaundice. If infants with cholestatic jaundice have had bilirubin testing from another hospital or doctor's office prior to presentation in the emergency department, these infants will have an elevation of direct bilirubin that may prompt the visit.

For several decades, clinicians have recognized that the timing of the onset of jaundice appears to risk-stratify infants for severe hyperbilirubinemia and identify infants at risk for underlying comorbid illnesses.²⁴ Clinical experience supports this concept, although no evaluation of this framework has been performed using contemporary methodology. It is clear that jaundice with an onset within the first 24 hours of life is likely to be associated with a serious underlying illness.^{12,20} Unless the child is the product of a home delivery, it is unlikely these infants will be discharged from the newborn nursery prior to the jaundice being recognized and addressed. Therefore, these infants are unlikely to present to the emergency department. Benign jaundice typically becomes evident during the second or third day of life, peaks at the fifth day and resolves by day 10.²⁵ A later onset of jaundice raises the likelihood of a comorbid illness, particularly sepsis.

Physical Examination

Fortunately, discoloration of the dermis and body fluids is fairly obvious to the naked eye. Some cases of jaundice are obvious to the mother, the triage nurse, and the physician. In more subtle cases, appreciating jaundice can be enhanced by blanching the skin with digital pressure to reveal the underlying color of the skin and subcutaneous tissue. Dermal icterus is first seen in the face and progresses caudally to the trunk and extremities.²⁶ As the total serum bilirubin level rises, the extent of cephalocaudal color progression parallels the degree of jaundice.²⁷ Unfortunately, estimating the total serum bilirubin based solely on the physical examination is not reliable.¹² After the identification of jaundice, the next step in the evaluation of these neonates is to determine their risk for severe hyperbilirubinemia and concurrent illnesses.

Besides the presence of jaundice, some physical examination findings are helpful in identifying infants at increased risk for severe hyperbilirubinemia. In particular, the presence of pallor and hepatosplenomegaly suggests hemolytic disease and a higher risk for severe hyperbilirubinemia. Excessive weight loss in the setting of exclusive breast-feeding places the infant at higher risk for severe hyperbilirubinemia. Determining if weight loss is excessive during the first week or two of life may be challenging if few infants are seen in an emergency physician's usual practice. It is assumed that infants will lose some weight during the first week of life. An appropriate weight loss for most infants is probably less than 10% of the birth weight. After the first week, a neonate is expected to gain about 1 ounce per day throughout the first month or two of life. By about 4 months of age, the infant should weigh approximately twice the birth weight.

So, excessive weight loss during the first week of life would be the loss of more than approximately 10% of the birth weight. Comparing birth weight, which is usually verbally provided by the parents, with a weight measured in the emergency department is inherently inaccurate, but is the only information typically available and provides a rough estimate of weight change. Physical examination findings suggestive of a serious underlying comorbid illness include poor tone, a weak suck, irritability, lethargy, temperature instability or fever, a distended abdomen, respiratory distress, ill appearance, a sunken fontanelle, and delayed capillary refill (see Chapter 7, The Critically Ill Neonate). Neonates who harbor comorbid illnesses have clinical features similar to neonates experiencing acute bilirubin encephalopathy, with severe jaundice, lethargy, and hypotonia with a poor suck.¹²

Diagnostic Tests

Laboratory testing is fundamental in risk-stratifying neonates for severe hyperbilirubinemia. Fortunately, the initial evaluation of hyperbilirubinemia requires tests readily available in emergency departments (Table 38–3). The measurements of total and direct serum bilirubin are the foundation of this evaluation.²⁸ Treatment recommendations are typically based on the assumption that a neonate has an unconjugated hyperbilirubinemia. Unfortunately, there is not a universally accepted definition of what constitutes an “unconjugated” or a “conjugated” hyperbilirubinemia. In general, a conjugated hyperbilirubinemia is present when the direct serum bilirubin level is greater than 20% of the total serum bilirubin level.²⁹ In the future, measurement of free bilirubin (i.e., bilirubin not bound to proteins) may play an important role in risk-stratifying jaundiced neonates.¹³

In addition to measuring bilirubin levels, one goal of laboratory testing is to assess the neonate for hemolysis. Test results suggestive of hemolysis include a positive Coombs’ test, a peripheral blood smear revealing red cell destruction, and ABO or Rh incompatibility between the neonate and the mother (see Table 38–3). A serum albumin below 3 g/dl (30 g/L) is a risk factor for severe hyperbilirubinemia. Urine reducing substances may be helpful in identifying inborn errors of metabolism, which, if present, place the neonate at increased risk for severe hyperbilirubinemia and comorbid

illnesses (see Chapter 29 Inborn Errors of Metabolism). Additional testing is indicated if the neonate demonstrates signs or symptoms consistent with a comorbid illness (see Table 38–2).

Important Clinical Features and Considerations

One promising technology is the use of transcutaneous bilirubin measurement devices,^{26,27,30,31} which noninvasively measure total serum bilirubin.¹² The use of these devices in the emergency department has not been evaluated. The quality of the output is sufficiently accurate that the American Academy of Pediatrics recommends against ordering a confirmatory serum bilirubin measurement before starting treatment.¹²

One concern in the emergency department is intravenous access in neonates (see Chapter 161, Vascular Access). If there is concern over obtaining intravenous access or performing a successful venipuncture, capillary blood from a heel stick is an acceptable specimen for the measurement of bilirubin, pH, hematocrit, hemoglobin, sodium, calcium, glucose, serum bicarbonate, and lactate.^{28,32} Capillary specimens are not accurate for the measurement of serum potassium.³²

Exhaled carbon monoxide has been shown to be effective in accurately identifying infants who are experiencing hemolysis.³³ The measurement most often cited is the end-tidal carbon monoxide level corrected for ambient carbon monoxide (ETCO_c).¹² The ETCO_c has been shown to have better test characteristics than the Coombs’ test.³⁴ However, the ETCO_c is not currently used in emergency departments.

Management

In 1994 and again in 2004, the American Academy of Pediatrics published recommendations for the identification, evaluation, and treatment of hyperbilirubinemia.^{12,20} In general, these recommendations are evidence based. Not all of the recommendations are relevant to emergency department care. Distilling the relevant information from these documents is challenging as multiple caveats for each recommendation and algorithms containing as many as 27 text boxes are presented. In general, young gestational age is the greatest risk factor for severe hyperbilirubinemia. Infants younger than 36 weeks’ gestation are considered to be at much higher risk than those who were born at ≥ 38 weeks’ gestation. Second, the traditional treatment threshold of 20 mg/dl (342 μ mol/L) has been replaced with treatment thresholds based on the age of the neonate in hours^{6,11,12} (Table 38–4). For healthy neonates born after 38 weeks’ gestation who are at least 96 hours old, the treatment threshold remains 20 mg/dl (342 μ mol). The three basic management plans for hyperbilirubinemia are observation and monitoring, phototherapy, and exchange transfusion.

Observation and Monitoring

Observation and monitoring is appropriate for neonates who do not meet treatment thresholds, but may develop further increases in serum bilirubin. The most common scenario is a jaundiced neonate who presents to the emergency department, does not demonstrate signs or symptoms of a serious comorbid illness, does not have a conjugated hyperbilirubi-

nemia, does not demonstrate historical, examination, or laboratory evidence of hemolysis, lacks high risk factors (see Table 38–1) and has a total serum bilirubin level below the treatment threshold (see Table 38–4). If the neonate has reliable caregivers, it is reasonable to discharge these children home from the emergency department and arrange a recheck of the total serum bilirubin as an outpatient. There is no evidence upon which to base the decision as to when follow-up should occur. Factors impacting this decision include availability of the neonate's primary care physician, the distance the family must travel to receive care, reliability of the parents, how close the total serum bilirubin level is to the treatment threshold, and the presence of vague complaints such as "just a little fussy," which may represent an early manifestation of a serious comorbid illness but probably does not. For many of these neonates, a conservative plan would be to have them return to the emergency department or their doctor's office in 12 hours for a repeat physical examination and total serum bilirubin measurement. Of course, the neonate should return to the emergency department sooner if worrisome signs or symptoms arise in the interim. For the neonate being discharged from the emergency department, there are no evidence-based guidelines regarding the continuance of breast-feeding. For infants unlikely to cross the threshold for phototherapy, continuing breast-feeding is probably reasonable. For infants at higher risk, decisions will need to be made on an individual basis.

Phototherapy

Phototherapy is the most commonly performed treatment specifically designed for hyperbilirubinemia. Phototherapy is generally safe and inexpensive. Phototherapy was introduced into clinical practice in 1958, but did not play a significant role in the treatment of jaundiced neonates until the late 1960s and 1970s.³⁵ Clinical experience suggests that phototherapy is very rarely initiated in the emergency department and, when it is, it is a temporary situation arising because of hospital overcrowding. Initiating phototherapy is based on the neonate's risk of severe hyperbilirubinemia, the age of the infant (in hours), and the total serum bilirubin level (see Tables 38–1 and 38–4). Coordinating care with the patient's primary care physician, the on-call pediatrician, or a neonatologist at a hospital to which the infant may be transferred is indicated.

ologist at a hospital to which the infant may be transferred is indicated.

Exchange Transfusion

For more than 50 years, exchange transfusion has been recognized as a treatment for hyperbilirubinemia.^{36,37} Exchange transfusion was originally developed to treat severe hemolytic hyperbilirubinemia from Rhesus isoimmunization.³⁸ Prior to the introduction and acceptance of phototherapy, exchange transfusion was the treatment of choice for neonates with severe hyperbilirubinemia.¹¹ Now, exchange transfusion is primarily used in very high-risk situations and when phototherapy fails.¹²

Pharmacologic Therapy

In the future, pharmacologic treatment for severe hyperbilirubinemia may play a substantial role in the management of these neonates. In particular, laboratory experiments and case reports suggest the metalloporphyrins, particularly tin mesoporphyrin, are effective in dramatically lowering serum bilirubin levels.³⁹ Tin mesoporphyrin is appealing as a potential treatment in the emergency department because it is administered subcutaneously.³⁹ Currently, the metalloporphyrins have no role in the emergency department management of hyperbilirubinemia and have not been approved by the Food and Drug Administration.

Fluid Administration

The administration of intravenous normal saline is common in the management of jaundiced neonates seen in the emergency department. In general, exclusively breast-fed neonates who have jaundice also have dehydration. Treating this dehydration is prudent. The results of a small randomized, controlled trial suggested that both oral and intravenous rehydration may be effective.⁴⁰ Continuing feeds with a milk-based formula will inhibit enterohepatic circulation of bilirubin.¹² Clinical experience suggests that, if intravenous access has been established, an initial fluid bolus of 20 ml/kg of normal saline is reasonable during the initial evaluation and management of jaundiced neonates seen in the emergency department. Excessive hydration is not recommended.¹²

Summary

In most cases the healthy neonate with jaundice has a very good outcome.^{41–43} However, hyperbilirubinemia in apparently healthy infants continues to hold the potential threat of acute bilirubin encephalopathy and kernicterus. Admission to the hospital is necessary if the phototherapy treatment threshold is approached or surpassed. Phototherapy is the treatment of choice for most cases of severe hyperbilirubinemia. Neonates who exhibit signs and symptoms of comorbid illnesses or cholestasis require approaches different from standard hyperbilirubinemia treatment pathways.

Neonatal Skin Disorders

Antonio E. Muñiz, MD

Key Points

Most neonatal rashes are benign in nature.

Erythema toxicum neonatorum must be differentiated from pustules that result from bacterial infections or sepsis.

Omphalitis is a serious infection that requires antibiotics and occasionally surgical débridement

Selected Diagnoses

- Milia
- Miliaria rubra
- Sebaceous gland hyperplasia
- Cutis marmorata
- Erythema toxicum neonatorum
- Transient neonatal pustular melanosis
- Acne neonatorum
- Omphalitis

Introduction and Background

Skin lesions appearing in the first month of life usually prompt parents to seek medical advice. The skin of the neonate differs from that of an adult in that it is thinner, has less hair and weaker intercellular attachments, and produces fewer sweat and sebaceous gland secretions. The normal full-term newborn's skin feels soft and smooth. The skin of a postmature neonate often appears dry and cracked because the stratum corneum, which has accumulated in utero, has not yet been shed. Fissures and bleeding may be seen on the ankles and wrists.

The skin at birth usually has a purplish red hue that is most pronounced over the extremities, known as acrocyanosis. This occurs because of increased tone of the peripheral arterioles, which creates vasospasm, secondary dilation, and pooling of blood in the venous plexuses, and results in cyanosis of the distal extremities. Skin care should involve gentle cleansing with a nontoxic, nonabrasive neutral material, and moisturizers should be applied frequently to hydrate the skin.¹

Discussion of Individual Diagnoses

Milia

Milia are benign, keratin-filled cysts that occur in 40% to 50% of newborns. They usually appear 1 to 2 days after birth, but on occasion develop weeks after birth.² Milia result from retention of keratin and sebaceous material within the pilosebaceous apparatus of the newborn. The skin lesions consist of multiple, pearly white or yellow papules, 1 to 2 mm in diameter, located over the forehead, cheeks, nose, and chin (Fig. 39–1). Occasionally they may occur on the upper trunk, limbs, penis, or mucous membranes. These cystic spheres rupture onto the skin surface and exfoliate their contents within weeks of birth.

A discrete round, pearly white or yellow, freely movable mass, 2 to 3 mm in diameter, on the midline of the hard palate (Epstein's pearl) or gum margins (Bohn's nodule) is the counterpart of facial milia.

Lesions that may mimic milia include molluscum contagiosum, sebaceous gland hyperplasia, erythema toxicum neonatorum (ETN), herpes simplex virus (HSV) infection, transient neonatal pustular melanosis, and neonatal acne.

No treatment is necessary for this rash. It usually disappears during the first 3 to 4 weeks of life but occasionally may persist until 3 months of age. Milia is a benign disorder that should not be confused with other more serious rashes, such as HSV infection.

Miliaria Rubra

Miliaria rubra is characterized by an erythematous papular or vesicular eruption in areas of skinfolds. It is seen more commonly in conditions of high heat and humidity that lead to excessive sweating.³ Lesions are exacerbated by wearing tightly fitted clothes. Miliaria rubra is caused by blockage of eccrine ducts by keratinous plugs at the level of the stratum corneum. Maceration of the ducts and escape of eccrine sweat into the dermis creates a localized inflammatory response resulting in the skin eruption.⁴

It rarely is present at birth and usually develops during the first week of life, especially in association with warming of the infant by an incubator, occlusive clothing or dressings, or fever.

Lesions are small, discrete, erythematous papules, vesicles, or papulovesicles surrounded by a thin, erythematous rim (Fig. 39–2). They occur in the neck, groin, and axilla and may be pruritic. The diagnosis is based upon clinical features.

FIGURE 39-1. Milia.

FIGURE 39-3. Sebaceous gland hyperplasia.

FIGURE 39-2. Miliaria rubra.

FIGURE 39-4. Cutis marmorata.

Sparse squamous cells and lymphocytes are seen on Wright-stained smear of the vesicular content. Differential diagnosis includes cutaneous candidiasis, varicella, ETN, folliculitis, HSV infection, and neonatal acne.

Treatment is directed toward avoidance of excessive heat and humidity. Lightweight clothing, cool baths, and air conditioning are useful in ameliorating the lesions.

Sebaceous Gland Hyperplasia

Sebaceous gland hyperplasia occurs in about 50% of newborns.² Maternal androgenic stimulation is responsible for the increase in sebaceous gland volume and size. Lesions consist of multiple small, yellow to flesh-colored macules or papules, 1 mm in diameter, that are seen at the opening of each pilosebaceous follicle over the nose, upper lips, and cheeks (Fig. 39-3). The lesions of sebaceous gland hyperplasia can be easily confused with milia.

There is no treatment for these lesions, and they usually resolve spontaneously within 1 week of life, but occasionally may persist up to 4 to 6 months of age. If treatment is deemed necessary, cryotherapy, cauterization, topical chemicals, or surgical excision may be tried. The major disadvantage of these therapeutic strategies is a considerable risk of posttraumatic scarring or dyspigmentation. Recently, pulsed dye laser has been shown to be effective without scarring.⁵

Cutis Marmorata (Mottling)

Cutis marmorata is a normal, reticulated, bluish mottling of the skin seen in the trunk and extremities caused by exposure to a cold ambient environment.⁶ It is caused by the immature nature of the autonomic control of the dermal plexus with constriction of the deeper plexus and vasodilation of the superficial plexus. It occurs in response to hypothermia and disappears as the infant is rewarmed.

The skin exhibits a lacelike pattern of dusky erythema over the extremities and trunk when the neonate is exposed to cold ambient temperature (Fig. 39-4). In some neonates, cutis marmorata may recur until early childhood or remain persistent, as in cases of Down syndrome, trisomy 18, and Cornelia de Lange's syndrome. Mottling that persists beyond 6 months of age may be a sign of hypothyroidism, vascular malformation, or cutis marmorata telangiectasia congenita, all of which can be associated with musculoskeletal or vascular abnormalities.⁷ Other mimickers may include livedo reticularis, which is seen in neonatal lupus erythematosus.

No treatment is required except rewarming the infant and maintaining a normal skin temperature.

Erythema Toxicum Neonatorum

ETN is a benign, self-limited, transient rash characterized by vesicles or pustules that are surrounded by blotchy, red macules. The eruption occurs by day 3 or 4 day of life, but may be seen at birth or may be noted as late as 2 weeks after birth.^{8,9} It occurs in about 30% to 50% of full-term infants and in only 5% of preterm infants.^{10,11}

ETN is of unknown etiology but may be due to an allergic reaction to substances passed transplacentally or a result of

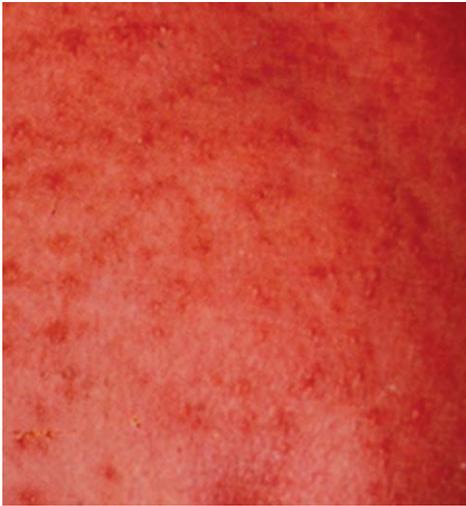

FIGURE 39-5. Erythema toxicum neonatorum.

an acute graft-versus-host reaction induced by the maternal-fetal transfer of lymphocytes before or during delivery.¹²

The lesions begin as blotchy, erythematous macules, 2 to 3 cm in diameter, with small (1- to 4-mm) vesicles or pustules in the center of the macules (“flea-bitten” appearance).¹³ They occur on the chest, back, face, and proximal extremities, sparing the palms and soles, and may vary from a few to several hundred lesions¹⁴ (Fig. 39-5). The individual lesions clear in 4 to 5 days, and new lesions may appear up to the second week of life.

A smear of the fluid from the vesicle or pustule will reveal numerous eosinophils on Wright- or Giemsa-stained preparations. A peripheral blood eosinophilia may also occur.¹⁵ The differential diagnosis may include HSV infection, impetigo, varicella, neonatal sepsis, miliaria rubra, folliculitis, milia, transient neonatal pustular melanosis, and cutaneous candidiasis.

ETN is a benign disorder requiring no treatment, but is extremely important to distinguish from other conditions with a worse prognosis, such as bacterial infection or sepsis, in which systemic symptoms are usually present.

Transient Neonatal Pustular Melanosis

Transient neonatal pustular melanosis is a benign, self-limited disorder of unknown etiology characterized by vesiculopustular lesions that rupture easily and evolve into evanescent hyperpigmented macules.¹⁶ Seen in 0.2% to 4% of neonates, it is more common in African Americans.^{17,18}

The lesions occur at birth as vesicles, pustules, or ruptured vesicles or pustules with a collarette of surrounding fine white scales¹⁹ (Fig. 39-6). The lesions are located on the chin, forehead, neck, lower back, and shins, and occasionally can be found on the cheeks, trunk, and extremities. Intact vesicles and pustules rupture and leave behind brown, hyperpigmented macules (Fig. 39-7).²⁰

Smears of the fluid in the vesicles or pustules show numerous neutrophils and occasionally eosinophils on Wright-stained preparations, while Gram staining reveals no organisms. Transient neonatal pustular melanosis may be misdiagnosed as ETN, HSV infection, milia, miliaria rubra, or acropustulosis of infancy.

FIGURE 39-6. Transient neonatal pustular melanosis.

FIGURE 39-7. Hyperpigmented macules in transient neonatal pustular melanosis.

There is no recommended treatment for this disorder. The vesicles and macules disappear by day 5 of life, while the brown hyperpigmented macules resolve over 3 weeks to 3 months.²¹ The most important entity to exclude is bacterial infection or sepsis, which also may manifest a pustular eruption. Bacterial infection and sepsis are often associated with other signs of illness or a history of prolonged rupture of amniotic membranes; infants with transient neonatal pustular melanosis are well appearing.

Acne Neonatorum

Neonatal acne is characterized by a facial eruption of inflammatory and noninflammatory lesions. It rarely presents at birth and generally appears after the second week of life. It may persist up to the eighth month of life. It occurs in up to 20% of neonates and is more common in males.²²

This condition appears to develop as a result of androgen hormonal stimulation of sebaceous glands.²² Multiple, discrete papules on the face, chest, back, and groin are characteristic. Papules evolve into pustules after a few weeks (Fig. 39-8). Closed comedones are more common, but open comedones as well as inflammatory lesions, such as papules and pustules, may be seen.²³ The differential diagnosis includes neonatal pustules from sepsis, ETN, transient neonatal pustular melanosis, cutaneous candidiasis, infantile acropustulosis, nevus comedonicus, psoriasis, and sebaceous gland hyperplasia.

FIGURE 39-8. Acne neonatorum.

Acne neonatorum usually resolves spontaneously without treatment within 4 months, with therapy required only for cosmetic improvement. In mild cases, daily cleansing with soap and water may help. For comedonal acne neonatorum, azelaic acid (20%) topical or mild tretinoin preparation (0.025% to 0.05%) may be used.²⁴ Topical salicylic acid (1%) is another alternative.²⁴ For inflammatory lesions, topical erythromycin (2%) or benzoyl peroxide (2.5%) gel can be applied.^{24,25}

Omphalitis

Omphalitis, or umbilical sepsis, is a bacterial infection of the umbilical stump and surrounding tissues. Widespread aseptic umbilical cord care has greatly reduced its occurrence.^{26,27} Risk factors for the development of omphalitis include low birth weight (<2500 g), prior umbilical catheterization, and premature rupture or prolonged rupture of amniotic membranes.²⁸

A bacterial infection through an open wound of the umbilical cord or surrounding tissue is the usual cause, although primary bacteremia with seeding of the umbilical stump can occur. Most infections are polymicrobial. The primary organisms responsible for omphalitis include *Staphylococcus aureus*, group A streptococcus, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, and anaerobes such as *Bacteroides fragilis* and *Clostridium perfringens*.²⁹⁻³¹

Initial findings include a purulent discharge from the umbilical stump, followed by periumbilical erythema, edema, induration, and tenderness (Fig. 39-9). Late in the course of infection, neonates manifest signs of sepsis, including lethargy, irritability, and hypothermia or hyperthermia. If the infection is left untreated, it can progress to superficial abscess, necrotizing fasciitis, myonecrosis, portal vein thrombosis, peritonitis, bowel evisceration, hepatic abscess, endocarditis, sepsis, and death.³²⁻³⁴ An irritant dermatitis produced by treatment of the umbilicus may mimic omphalitis.

Omphalitis is treated with antibiotics directed toward the more common causative organisms. These may include nafcillin and cefotaxime. Metronidazole can be added for anaerobic coverage, especially if necrotizing fasciitis or myonecrosis is suspected. Surgical débridement may be required for

FIGURE 39-9. Omphalitis.

complications.³⁵⁻³⁷ Omphalitis is a potentially life-threatening infection.

Seizures

Jonathan Marr, MD and Pamela J. Okada, MD

Key Points

Febrile seizures are unique to young children, commonly lead to an emergency department visit, and are generally managed the same way as fever without a seizure.

Neonatal seizures may have subtle manifestations and require a different approach than seizures in older infants and children.

Benzodiazepines are the first-line pharmacologic agents for treating ongoing seizures.

Stable doses of anticonvulsants in growing children will tend to become subtherapeutic over time.

There are quite a few conditions that share some presenting features with seizures, but are not seizures.

Introduction and Background

Shaking, odd behaviors, unusual movements, or eye rolling commonly leads to pediatric visits in the emergency department. These events may be called “fits,” “spells,” “convulsions,” or “seizures” by the family. Clinical experience suggests it is common for families to want to know if their child actually had a seizure. One accepted definition of a seizure is a sudden change in behavior due to unregulated electrical activity in the brain.¹ Unfortunately, definitions such as this are not helpful when evaluating children presenting to the emergency department because the electrical activity of the brain is not routinely evaluated in our clinical setting. Over the last few decades, multiple categorization schemes have been developed for pediatric seizures.²⁻⁶ Although these categorization schemes may be useful in the development of standardized research, they have limited utility in the emergency department as they tend not to guide acute management. However, several relatively simple clinical features are helpful in the emergency department evaluation of these children. These include the age of the child

(Table 40–1), the presence or absence of fever, whether the body movements were generalized or focal, whether the child has a known past history of seizures, whether the postseizure neurologic examination is normal or not, and whether the child is continuing to seize or not. One additional feature that is important to elicit is whether known trauma was associated with the seizure (see Chapter 17, Head Trauma). With these simple clinical features used as a basic framework, emergency physicians can develop a rational approach to managing these children in the emergency department.

Recognition and Approach

In the United States, approximately 120,000 children per year seek medical attention for a newly recognized seizure.⁷ Some of these children will go on to have lifelong seizures, while others will have either a single event or a small number of seizures during a limited time in their lives.

Given the complexity of the human nervous system, there are nearly limitless ways in which seizures and seizure-like events may present to the emergency department. Fortunately, there are a few broad categories into which many of these events fit. To at least some extent, each of these categories has been defined and studied. This structure allows for the development of some evidence upon which to base diagnostic and management decisions. These categories include status epilepticus, febrile seizures, first-time afebrile seizures, neonatal seizures, seizures occurring in children with known seizure disorders, and seizure-like events.

Status Epilepticus

Status epilepticus can be defined as “a continuous series of generalized tonic-clonic seizures without return to consciousness” or “any prolonged series of similar seizures without return to full consciousness between them.”⁸ Clinical research on status epilepticus typically includes the caveat that the combination of seizures and abnormal consciousness has lasted at least 30 minutes.^{6,9-11} Based on data from the North London Status Epilepticus in Childhood Surveillance Study, the incidence of status epilepticus is estimated to be 20 episodes per 100,000 children per year.¹⁰ In this population-based study, more than half of the children were neurologically healthy before experiencing their first episode of status epilepticus. Of these previously neurologically healthy children, half were febrile on presentation, 10% were diagnosed with bacterial meningitis, and 3% died.¹⁰

Febrile Seizures

The term *febrile seizure* has a specific meaning to clinicians. A commonly accepted formal definition is a seizure occurring in a child between 6 months and 5 years of age who has a temperature greater than 38° C (100.4° F) or a history of recent fever, without a prior history of seizures or other neurologic disorders.^{12,13} Febrile seizures are very common, occurring in as many as 5% of all children.¹² Since the mid-1970s, febrile seizures have been subclassified as either simple or complex.¹⁴ Simple febrile seizures are defined as generalized seizures lasting less than 15 minutes and occurring only once within a 24-hour period.¹² Simple febrile seizures are common, benign events. Complex febrile seizures include any combination of being focal, lasting longer than 15 minutes, or recurring within 24 hours. A subset of children with complex febrile seizures harbors serious diseases, including bacterial meningitis.^{10,11} Clinical experience suggests two important points about febrile seizures. First, regardless of the formal definition, in the vernacular used among pediatricians and emergency physicians, the term *febrile seizure* is synonymous with “simple febrile seizure.” Second, there is a wide spectrum of disorders that fall within the formal definition of a “complex febrile seizure.” This spectrum ranges from a well-appearing, febrile toddler who has experienced two 30-second seizures within 24 hours to a

critically ill febrile young child in status epilepticus. This heterogeneity makes generalizations about complex febrile seizures problematic.

A term coined in 1997, febrile seizures plus, has appeared in the literature and may lead to confusion. Febrile seizures plus refers to “children suffering febrile seizures extending beyond 6 years, with or without associated afebrile generalized tonic-clonic seizures, who do not have one of the recognized [seizure] syndromes.”¹⁵ Most emergency physicians would categorize these children as simply having a known seizure disorder whether or not this disorder has an official name. These children do not fit the common use of the term *febrile seizure*.

First-Time Afebrile Seizures

Each year in the United States, approximately 30,000 previously neurologically healthy children older than 1 month of age experience their first afebrile seizure.¹⁶ Although such cases are not as common as febrile seizures, these children commonly present to emergency departments for evaluation.

Neonatal Seizures

It is difficult to determine the epidemiology of neonatal seizures relevant to the practice of emergency medicine. This is because much of the literature and study involve neonates in intensive care units and may include electroencephalographic data in the definitions and classification schemes. About 65% of clinically apparent neonatal “seizures” are not associated with electroencephalographic seizure activity.¹⁷ Prematurity is a risk factor for clinically defined seizures. Preterm infants are more than 40 times more likely to have clinically evident seizures than term infants.¹⁸ Since many preterm infants will be diagnosed with seizures prior to their initial discharge from the hospital, these infants are typically considered to have a known seizure disorder by the time they present to an emergency department. In addition, the presentation of a seizure in neonates may be subtle and includes staring episodes, rhythmic blinking, eyes rolling back, or lip smacking.¹⁹ Alternatively, the initial clinical picture may be best classified as an apparent life-threatening event (ALTE) rather than as a seizure²⁰ (see Chapter 28, Apparently Life-Threatening Events). Approximately 10% of infants presenting to the emergency department with ALTEs are ultimately diagnosed with a seizure as the cause.²⁰

Children with a Known Seizure Disorder

Although these are perhaps the most commonly seen seizure presentations in the emergency department, there are no epidemiologic data on these children. The wide variability in causes, presentations, chronic medications prescribed, and ages makes generalized statements about this diverse group of children problematic.

Seizure-like Events

There are quite a few conditions that can mimic or be mistaken for seizures (Table 40–2). Familiarity with these conditions may lead to a correct, alternative diagnosis. Benign conditions such as breath-holding spells, if mistaken for a seizure, may lead to unnecessary diagnostic testing and worry in the parents (see Chapter 37, Minor Infant Problems).

Table 40–2 Conditions That Share Clinical Features with Seizures

Benign paroxysmal vertigo
 Breath-holding spell
 Cataplexy*
 Chills
 Choreoathetosis
 Dystonia
 Infantile torticollis
 Masturbation
 Migraine
 Narcolepsy
 Night terrors
 Pseudoseizures
 Rage attacks
 Sandifer's syndrome†
 Shuddering attacks
 Sleepwalking
 Spasmus nutans‡
 Syncope
 Tics

*Cataplexy is characterized by abrupt attacks of weakness and decreased tone associated with strong emotions.

†Sandifer's syndrome is characterized by intermittent torticollis due to gastroesophageal reflux.

‡Spasmus nutans is characterized by nodding of the head accompanied by nystagmus.

Clinical Presentation

A few features are particularly helpful in developing a diagnostic and management plan for children who present to the emergency department for evaluation of one or more seizures.

Age

The age of the child determines the initial differential diagnosis (see Table 40–1). For example, simple febrile seizures only occur in children between the ages of 6 months and 5 years.

Fever

The presence of fever also modifies the differential diagnosis. Outside the age group for simple febrile seizures, infectious etiologies increase in likelihood if a fever is present. These infections may include relatively benign conditions such as viral meningitis or life-threatening conditions such as bacterial meningitis or encephalitis (see Chapter 43, Central Nervous System Infections). Fever in a child with a known seizure disorder may suggest an acute infection that has lowered that child's seizure threshold and led to either an increase in seizure frequency or a seizure after a fairly long seizure-free period.

Generalized or Focal Body Movements

Focal refers to a seizure whose initial symptomatology indicates initial activation of only part of one cerebral hemisphere. An example of a focal seizure would be a child who shakes only one arm during the first part of a seizure. In some instances, the seizure may then generalize. *Generalized* refers to a seizure whose initial symptomatology indicates involvement of both cerebral hemispheres. Typically, generalized seizures start with whole body stiffening or shaking. In one study of 500 children with a first-time seizure, those who

were younger than 33 months and had a focal seizure were more likely to have an abnormal finding on neuroimaging than other children.²¹

Known Prior History of Seizures

Clinical experience suggests that children with known prior seizures are the most common presenters to the emergency department with a chief complaint of seizure. These children have frequently already had neuroimaging and undergone electroencephalographic studies. They frequently have a pediatric neurologist who either coordinates their seizure care with a primary care pediatrician or manages their seizure disorder primarily. Most of these children are expected to have occasional seizures without apparent provocation. Assessing them for an acute infection may reveal a suspected viral or bacterial infection that has lowered the seizure threshold. One situation unique to these children is “outgrowing” their antiepileptic medications. Eliciting a history that the child has been on the same dose of an anti-epileptic drug for a prolonged period during which the child grew can be very helpful. During this time, although the same dose of medication was administered the same way, the child is now larger and heavier. This leads to a smaller dose based on milligrams per kilogram since the kilograms are now greater. These children may also have a ventriculoperitoneal shunt for hydrocephalus that may impact on decision making (see Chapter 42, Conditions Causing Increased Intracranial Pressure). These children may also have vagal nerve stimulators in place. They are often selected for vagal nerve stimulation when they have an exceedingly large number of seizures each day that are not adequately controlled with medications.²² Vagal nerve stimulators are implanted devices that allow for electrical stimulation of the left vagus nerve. Coordinated care with a pediatric neurologist or pediatric neurosurgeon is typically indicated when these children have uncontrolled seizures.

Postseizure Examination

Physical examination findings may be suggestive of syndromes with increased risk for seizures. A facial vascular nevus (port-wine stain) involving the cutaneous distribution of the ophthalmic division of the trigeminal nerve suggests Sturge-Weber syndrome. Hypomelanotic macules with irregular borders (ash-leaf spots) at birth or erythematous papules distributed over the nose and malar region of the face (adenoma sebaceum) of a child are characteristic of tuberous sclerosis. Multiple hyperpigmented skin macules (café-au-lait spots) becoming prominent at puberty, axillary or inguinal freckling, skin fibromas, and iris hamartomas (Lisch nodules) suggests neurofibromatosis. Iris colobomas in infant girls are suggestive of Acardi's syndrome. A young infant with bruising may have sustained nonaccidental head trauma (see Chapter 119, Physical Abuse and Child Neglect).

If the child awakens following a postictal period and has an abnormal neurologic examination, the likelihood of a benign cause for the seizure decreases. For children with an unremarkable prior neurologic history, the differential diagnosis includes rupture of an intracranial arteriovenous malformation, a stroke, a brain tumor, meningitis, and encephalitis (see Chapter 43, Central Nervous System Infections; Chapter 44, Central Nervous System Vascular Disorders; and Chapter 45, Brain Tumor). In particular, a

simple febrile seizure is ruled out by an abnormal postseizure physical examination.

Continuing Seizure Activity

A child in status epilepticus may have frequent seizures without a lucid interval between them or continuous seizure activity. Although making a specific diagnosis is desirable, and a preliminary differential diagnosis guides diagnostic and management decisions, the primary goal during episodes of status epilepticus is to stop the seizure activity.

Important Clinical Features and Considerations

A long and diverse list of diagnoses can mimic seizures in children (see Table 40–2). Breath-holding is a common event occurring in young children (see Chapter 37, Minor Infant Problems). Stiffness may occur as part of an ALTE (see Chapter 28, Apparent Life-Threatening Events). Syncope and the resultant transient ischemia of the brain cortex may lead to brief twitching or stiffening that can be mistaken for a seizure (see Chapter 61, Syncope). Night terrors, events typically occurring in younger children in the middle of the night, manifest as a sudden awakening with screaming, diaphoresis, hyperventilation, dilated pupils, and irrational speech.²³ Depending on the characteristics exhibited by a particular child, parents or prehospital care providers may suspect a seizure as the cause of these events.²⁴ Sleepwalking may be confused with a complex partial seizure since the child appears to walk around in a trancelike state.²³ Tics are stereotyped, patterned sequences involving nonrhythmic movement of multiple muscles and may be mistaken for seizures.²⁴ Spasmus nutans affects children between the ages of 4 and 12 months; the characteristic symptoms include a head tilt, head nodding, and asymmetric nystagmus. This condition may be initially assumed to be a seizure, but is a self-limited condition that typically resolves in later childhood. It is exceedingly unlikely that this diagnosis will be made during an emergency department visit.^{25,26} Chills associated with fever may be mistaken for seizures. Sandifer's syndrome or gastroesophageal reflux may be confused with tonic seizures since tonic posturing occurs with these conditions.²⁷

Pseudoseizures are nonepileptic events resembling epileptic seizures as they both present with paroxysmal, involuntary, time-limited alteration in behavior, motor activity, autonomic function, consciousness, and sensation.²⁸ Other names that have been used in the past include hysterical epilepsy, hysterical seizures, psychogenic seizures, factitious seizures, functional seizures, conversion fits, pseudo-attacks, paroxysmal somatoform disorder, and pseudo-status epilepticus.²⁹ There is no epileptogenic pathology or epileptiform electroencephalographic ictal pattern in cases of pseudoseizure. Clinically, children with pseudoseizures have bizarre postures, verbalizations, thrashing movements, reactive pupils, and rigid-appearing posture with “waxy” flexibility, and they lack cyanosis, tongue biting, or injury during the attack, and do not occur during sleep.²⁴

Management

There is no standard approach to all pediatric seizures. For many children, particularly those with known seizure disor-

ders or who have experienced an event that is unlikely to be a seizure, care will necessarily need to be individualized. Factors impacting these decisions include a description of the event prompting the emergency department visit, family dynamics, availability of prompt follow-up, and the child's physical examination in the emergency department. Fortunately, management follows the few broad categories into which many of these events fit.

Status Epilepticus

Status epilepticus encompasses a fairly wide range of events, from a single seizure lasting just a bit longer than 30 minutes that has resolved upon presentation to the emergency department to continuous seizure activity in the emergency department. The most concerning are those children who have ongoing seizure activity on presentation, since neurologic morbidity is directly related to the duration of the seizure activity.^{30,31} A bedside glucose check may reveal hypoglycemia requiring treatment (see Chapter 106, Hypoglycemia). If hypoglycemia is not the cause of the seizure activity, the administration of a benzodiazepine is the accepted first-line therapy. While intravenous administration is probably best, vascular access is particularly difficult in continuously shaking children. If initial attempts at peripheral venous access are unsuccessful, options include administering rectal diazepam or lorazepam^{32,33} (Table 40–3) or obtaining intraosseous access³⁴ (see Chapter 161, Vascular Access). The intramuscular route is notorious for its variability in absorption and pharmacokinetics and may account for the paucity of prospective studies. The intramuscular route, however, may have a role in the prehospital setting for children with difficult intravenous access, as one study has found that intramuscularly administered midazolam results in more rapid cessation of seizures when compared to intravenous diazepam.³⁵ Midazolam is also an accepted benzodiazepine for the treatment of status epilepticus.³⁶ Midazolam has the advantages of a short half-life, faster clearance, and fewer venous complications than seen with other benzodiazepines.³⁷ A small number of subjects have been studied evaluating the delivery of midazolam through buccal and nasal mucosa for pharmacologic control of seizures in children, and the results have been generally favorable.^{38–40} Before widespread use of these routes, more research is probably needed. Adverse effects of benzodiazepines include respiratory depression, hypotension, and impaired consciousness. If successive doses of benzodiazepines are required to stop the seizure activity, it is prudent for the emergency physician to be prepared to promptly manage apnea in these children (see Chapter 3, Rapid Sequence Intubation).

If successive doses of benzodiazepines are ineffective, a second-line agent is indicated.⁹ Choices typically include phenytoin and phenobarbital (see Table 40–3). Phenytoin is an efficacious, long-acting agent that has been widely used for more than 30 years in the acute and chronic treatment of seizures in children.⁴¹ It has been used as initial therapy for the termination of status epilepticus and when benzodiazepines fail.⁴² Side effects of phenytoin include hypotension, arrhythmias, asystole, and renal and hepatic damage.⁴¹ The manner in which phenytoin is prepared leads to the administration of propylene glycol along with the phenytoin. Because of this, phenytoin should be given no faster than 1 mg/kg per minute (up to 50 mg/min) to avoid cardiac

Table 40–3 Selected Antiepileptic Drugs Used to Treat Pediatric Seizures in the Emergency Department

Drug	Route	Initial Dose	Repeat Dose	Frequency	Maximum Single Dose
Lorazepam	IV	Neonate: 0.05 mg/kg Child: 0.1 mg/kg Adolescent: 0.07 mg/kg	Same 0.05 mg/kg	10–15 min	4 mg
Diazepam	IV	Child: 0.05–0.3 mg/kg	Same 0.05 mg/kg	15–30 min	5 mg (<5 yr old) 10 mg (>5 yr old)
	PR	Child > 2 yr: 0.5 mg/kg	Same	4–12 hr	Round to nearest 2.5, 5, 10, 15, or 20 mg per dose
Phenytoin	IV	Child 6–11 yr: 0.3 mg/kg >12 yr: 0.2 mg/kg Neonate: 15–20 mg/kg loading dose Child: 15–18 mg/kg loading dose	None	Once	
Fosphenytoin	IV/IM	Child: 10–20 mg/kg of Phenytoin Equivalents	10 mg/kg	Once	
Phenobarbital	IV	Neonate: 15–20 mg/kg Child: 15–18 mg/kg	5 mg/kg	Twice	30 mg/kg

Abbreviations: IM, intramuscularly; IV, intravenously; PR, per rectum.

complications. Phenytoin should not be given intramuscularly as the drug is poorly absorbed and causes hemorrhagic necrosis of the soft tissues at the injection site. Fosphenytoin is a water-soluble prodrug of phenytoin that is rapidly converted to phenytoin by serum phosphatases. Dosages are expressed as phenytoin equivalents, which are the amounts of phenytoin released from the prodrug. The advantages of fosphenytoin include predictable pharmacokinetics via the intramuscular route and faster delivery to therapeutic concentrations without the cardiovascular complications seen with phenytoin, as well as less common phlebitis and soft tissue damage.^{34,42} The cost of fosphenytoin compared with phenytoin remains the main disadvantage.⁴³

Phenobarbital is a long-acting, potent antiepileptic agent that is typically used to treat status epilepticus after benzodiazepines fail to control the seizures. Phenobarbital has potent respiratory depressant and sedative properties, especially when administered after a benzodiazepine. Phenobarbital remains the standard for the treatment of persistent neonatal seizures after failure of benzodiazepines.⁴⁴ Studies have demonstrated that phenobarbital and phenytoin are equivalent but incompletely effective in controlling neonatal seizures.^{45,46}

If seizure activity continues despite the administration of a benzodiazepine, phenytoin (or fosphenytoin), and phenobarbital, transfer to a pediatric intensive care unit should be anticipated. For most of these children, endotracheal intubation will be indicated at this point if it has not occurred earlier in the management. A short-acting muscle relaxant or “paralytic” (e.g., succinylcholine) is recommended to allow for the continued monitoring of the patient for seizure activity when electroencephalographic monitoring has not yet been established. Further history may reveal specific toxicologic agents responsible for the ongoing seizures. For example, an inappropriate ingestion of isoniazid may require the administration of pyridoxine to stop the seizure activity. Transfer to a setting in which ongoing electroencephalographic monitoring can be accomplished while the patient is given pentobarbital to the point of suppression of all brain electrical activity (i.e., a “pentobarbital coma”) is indicated. Children who reach this point in management typically have a poor neurologic outcome.⁴⁷

Approaches currently under study include the use of propofol and intravenous valproic acid.^{34,42,48–50} Further research is needed before these agents can be recommended in the routine management of status epilepticus.

Simple Febrile Seizures

In 1996, the American Academy of Pediatrics created practice parameters for the evaluation of children with simple febrile seizures.¹² Recommendations include that a lumbar puncture be “strongly considered” for the first febrile seizure in infants younger than 12 months, and that a lumbar puncture should be “considered” for infants between 12 and 18 months of age. The American College of Emergency Physicians refined this concept in 2003 and suggested that a lumbar puncture be “strongly considered” in a child younger than 18 months of age who has had a febrile seizure with any of the following features: a history of irritability, decreased feeding, or lethargy; an abnormal appearance or mental status on observation after the postictal period; any physical signs of meningitis, such as a bulging fontanelle; any complex features; a slow postictal recovery of mentation; or pretreatment with antibiotics.¹³ If these factors are absent, a lumbar puncture can be safely deferred.¹³ In general, a child with a simple febrile seizure is treated no differently than a child of the same age and gender who presents with fever without having had a seizure (see Chapter 33, Urinary Tract Infection). Blood tests and neuroimaging are not indicated for well-appearing children.

First-Time Afebrile Seizures

For children with a normal postictal neurologic examination, the management of a single afebrile seizure in a young child is rather straightforward. In 2000, the American Academy of Neurology, the Child Neurology Society, and the American Epilepsy Society published a practice parameter for first afebrile seizures in children.¹⁶ In general, the ordering of tests should be made on a case-by-case basis. This includes the option of ordering of laboratory tests if dehydration is present. Lumbar puncture should be reserved for those instances in which there is a concern for possible meningitis or encephalitis based on criteria other than a single seizure (see Chapter 43, Central Nervous System Infections).

Toxicologic screening is indicated if an ingestion is suspected. Emergent neuroimaging is only indicated if the postictal physical examination reveals a focal deficit or the child does not return to baseline within several hours after the seizure. The recommended study is magnetic resonance imaging of the brain. Subsequent research supports this selective approach in emergent neuroimaging.²¹ The only standard test required is an electroencephalogram, which can be obtained on an outpatient basis.¹⁶

Neonatal Seizures

The approach to neonatal seizures is similar to that of the approach to a critically ill neonate or an ALTE (see Chapter 7, The Critically Ill Neonate; and Chapter 28, Apparent Life-Threatening Events). If the infant is not in status epilepticus, a “septic workup,” including a lumbar puncture with cerebrospinal fluid studies, is indicated (see Chapter 171, Lumbar Puncture). One condition of particular concern is encephalitis due to herpes simplex virus. It is currently controversial whether the administration of intravenous acyclovir should be standard therapy for neonates who undergo a “septic workup.” The most effective test for herpes simplex virus is the polymerase chain reaction study performed on cerebrospinal fluid.

Children with a Known Seizure Disorder

These children typically require individualized care. Assessing these children for common infections, including urinary tract infections in those not toilet trained and pneumonia in those who are ventilator dependent, is usually prudent. Taking guidance from experienced parents is a key to successfully managing these cases. If the dosages of the child’s antiepileptic medications can be adjusted to achieve therapeutic levels in a reasonable time frame, it is usually prudent to obtain these levels. Adjusting medications in coordination with the child’s primary care physician or neurologist may be all that is needed in some instances.

Seizure-like Events

If the event can be confidently diagnosed as something other than a seizure, management is guided by this alternative diagnosis. Well-appearing, active, playful children who have experienced a brief event can often be discharged home with prompt follow-up. An outpatient electroencephalogram may be indicated and can be arranged by the primary care physician.

Summary

Seizures are a common occurrence in pediatrics, with diverse etiologies, multiple diagnostic decisions, and assorted treatment modalities. Determining disposition can be challenging for both physicians and families, particularly when the event does not readily fall into one of the known broad categories of seizures. Factors such as test results, physician judgment, family reliability, and proximity and access to health services are all integral components to the disposition decision. Discharge criteria include return to baseline neurologic status, no focus of serious infection, therapeutic drug levels, and family comfort with caring for the child at home. Close follow-up with the child’s pediatrician or neurologist is prudent in many of these cases.

Chapter 41

Headaches

Tommy Y. Kim, MD and Tonya M. Thompson, MD

Key Points

Pediatric headaches are often a part of a constellation of symptoms and are usually benign.

The key to the diagnosis of migraine headaches is the presence of associated disability.

Loss of previously acquired developmental milestones is concerning for a secondary cause of pediatric headaches.

Laboratory and imaging studies are rarely needed in the emergency department evaluation of pediatric headaches.

Most headaches are managed with nonsteroidal anti-inflammatory medications.

Introduction and Background

Headache is a common complaint encountered in the pediatric emergency department, accounting for approximately 1% of all visits.^{1,2} The emergency medicine physician's role in the management of pediatric headaches is to rule out organic causes of headache, manage headache symptoms, and, when appropriate, give reassurance. It is helpful to categorize headaches according to standardized terminology. This permits clearer communication between the emergency physician and the child's neurologist or primary care pediatrician. Appropriate classification allows for the selection of treatment with the highest likelihood of success. Fortunately, most children with headaches who present to the emergency department harbor benign conditions, and their headaches are a part of a constellation of symptoms associated with minor viral illnesses.^{1,2}

Recognition and Approach

Confusingly, there are two overlapping categorization schemes for headaches. One scheme is based on whether or not there is an identifiable cause for the headache. In this scheme, headaches for which a "cause" cannot be identified

are termed *primary*. An example of a primary headache would be a classic migraine headache. Headaches for which a "cause" can be identified are termed *secondary*. Examples of secondary headaches include those due to brain tumors, meningitis, a subdural hematoma, or fever. A key task for emergency physicians is identifying secondary headaches. The other classification scheme is based on the temporal pattern of the headaches. This scheme consists of five general types of headaches: acute, acute recurrent, chronic progressive, chronic nonprogressive, and mixed. The overlap in these two schemes leads to dual designations applying to a single child. Primary headaches are usually either acute recurrent or chronic nonprogressive headaches. New-onset acute headaches are usually secondary headaches. Accurate classification of pediatric headaches can be difficult or impossible in a single emergency department visit.

Clinical Presentation

Acute Headaches

Acute headaches are usually a manifestation of a secondary illness (Table 41-1). The causes are diverse. The evaluation is guided by the dominant clinical features.

Acute Recurrent Headaches

The most common acute recurrent headaches are migraine headaches, migraine variants, tension headaches, and cluster headaches.

Migraine Headaches

Migraines and migraine variants are increasingly recognized as conditions of childhood.³ Migraine headaches can be further subdivided into those without aura and those with aura (Table 41-2). Migraine headaches without auras are probably underdiagnosed and underappreciated in children. The prevalence of migraine headaches increases with age.^{4,5} At a younger age, migraines are more prevalent in boys, but in adolescence girls are more likely to suffer from migraine headaches. Girls are less likely to have auras than boys. Children younger than 15 years do not usually have associated aura. Headache attacks in children can be variable, and attacks can last less than an hour.⁶ Without appropriate treatment, central sensitization may occur and lead to chronic daily headaches. Migraine headaches with auras can be associated with transient focal deficits prior to or during the onset of the headache. Transient focal deficits can be visual, motor,

or sensory. Visual deficits can consist of scotomas, fortification, visual field deficits, and photopsia. Motor deficits can consist of weakness and ataxia, and sensory deficits can consist of paresthesias.

There are three specific types of migraine headaches with characteristic and dramatic features: hemiplegic, basilar-type, and confusional migraines. Hemiplegic migraines have an initial phase of transient focal deficits, including hemisensory deficits, visual field deficits, and speech disturbances.⁷ Deficits usually precede the headaches but may continue even after the onset of headache. Hemiplegic migraines may have a genetic basis.⁸ Basilar-type migraines are present in about 15% of all migraines, and the age of onset is usually 7 years. There is usually an associated dizziness and vertigo that lasts from 5 to 60 minutes and is followed by an occipital headache. Other initial symptoms can include nausea, vomiting, ataxia, tinnitus, diplopia, weakness, confusion, and visual defects. It is advisable to obtain magnetic resonance imaging (MRI) of the brain and magnetic resonance angiography to rule out a posterior fossa tumor or compromise of the basilar circulation. Confusional migraines are associated with acute confusional or delirium states and also with transient global amnesia of childhood. Agitation, disorientation, dysarthria, and dysphasia are common during an attack, but the headache phase may be mild. Confusional migraines are often triggered by trauma, so a computed tomographic (CT) scanning of the head is indicated (see Chapter 17, Head Trauma).

Migraine Variants

Other childhood syndromes associated with headaches include benign paroxysmal vertigo, cyclic vomiting syndrome, and abdominal migraine. These syndromes are usually a diagnosis of exclusion. Benign paroxysmal vertigo typically occurs in toddlers.⁹ This form of vertigo is characterized by abrupt attacks of ataxia and vomiting without a loss of consciousness. The spells last minutes and can occur in clusters. The differential diagnosis includes epilepsy, posterior fossa tumors, Meniere's disease, positional vertigo, and vestibular neuronitis.

Table 41–2 International Headache Society Diagnostic Criteria for Migraines

Migraine Without Aura	Migraine With Aura
At least 5 attacks of headache lasting 4–72 hr*	At least 2 attacks of headache
PLUS	PLUS
At least 2 of the following:	Aura consisting of at least 1 of the following:
Unilateral location	Fully reversible visual symptoms
Pulsating quality	Fully reversible sensory symptoms
Moderate or severe pain intensity	Fully reversible dysphasic disturbance
Aggravation by or causing avoidance of routine physical activity	AND
AND	At least 2 of the following:
During headache at least 1 of the following:	Homonymous visual symptoms and/or unilateral symptoms
Nausea and/or vomiting	Aura symptom develops over ≥ 5 min
Photophobia and phonophobia (may be inferred from behavior)	Each symptom last ≥ 5 min and ≤ 60 min
	AND
	Headache fulfilling criteria for migraine without aura that begins during the aura or follows within 60 min

*Attacks in children last from 1 to 72 hours.

Adapted from the Headache Classification Committee of the International Headache Society.⁴⁸

Cyclic vomiting syndrome is associated with recurrent episodes of intense but otherwise unexplained nausea and vomiting.³ These episodes can last 1 hour to 5 days in children. Vomiting occurs at least 4 times in an hour, but can be as high as 13 times per hour. The age of onset of symptoms is around 5 years, and most children have resolution of symptoms by 10 years of age. Only 40% of children with cyclic vomiting syndrome will complain of headaches. Since vomiting is common in childhood, these children may undergo extensive gastrointestinal testing prior to the diagnosis being made.

Abdominal migraines were first described by Symon and Russell in 1986.¹⁰ Abdominal migraines are estimated to have a prevalence of approximately 4% in children.¹¹ The abdominal pain is severe enough to interfere with normal daily activities and can last from 1 to 72 hours. The pain is usually described as midline, periumbilical, dull, and colicky. The diagnosis of abdominal migraine requires at least two of the following four symptoms: anorexia, nausea, vomiting, and pallor. Between attacks of abdominal pain, there is complete resolution of symptoms. There is no requirement for headache to make the diagnosis of abdominal migraine.

Tension Headaches

Tension headaches are characterized by their intermittent nature and the absence of nausea or vomiting. Episodic tension headaches are further divided into frequent and infrequent types (Table 41–3). Tension headaches are the most frequent type of headache encountered. Most data regarding tension headaches are extrapolated from the adult literature. Tension headaches can have an onset during adolescence with a slight female predominance. Unlike migraines (which are based on positive features), the diagnosis of tension headaches is predominantly based on the absence of certain clinical features. To appropriately make the diagnosis, the headache must lack photophobia, phonophobia, nausea, and vomiting, and must not worsen with activity. The pain is often described as vicelike or a squeezing steady pain and is often associated with neck or upper back pain.

Tension headaches are more common during the week and usually begin during the daytime, with gradual progression through the course of the day. The headaches may be precipitated by stress, lack of sleep, poor posture, or “stress let-down” (e.g., following an important examination in school).

Cluster Headaches

Cluster headaches are very rare in children (Table 41–4). Although the peak age of onset is 20 to 50 years, cluster headaches may occur during adolescence. These headaches affect less than 1% of the population and have a male predominance. The pain is unilateral, severe, and located either retro-orbitally, periorbitally, or frontally. The intensity peaks about 5 minutes after the onset of pain. The key to the diagnosis is the presence of associated unilateral autonomic features such as lacrimation, nasal congestion, and conjunctival injection that occur in a predictable time cycle. Because the headache is most likely to occur during periods of relaxation rather than intense activity, most patients prefer to be moving during the headache episode and may pace the examination room. The headache episodes may be clustered into time blocks lasting from 6 to 8 weeks in duration and are more common during the spring and fall. The headaches may regularly awaken the patient at the same time each night.

Chronic Progressive Headaches

Chronic progressive headaches usually have an organic etiology. The most common causes of chronic progressive headaches include idiopathic intracranial hypertension (formerly known as pseudotumor cerebri), tumors, masses, and intracranial abscesses. Idiopathic intracranial hypertension presents with a chronic, progressive headache with or without associated vomiting. The headache can manifest with transient visual obscuration and palsy of the sixth cranial nerve. There is a slight female predominance, with risk factors including obesity, hyperthyroidism, hypoparathyroidism, hypervitaminosis A, and tetracycline use. The exact cause is unknown, but etiologic factors could include cerebral edema, high cerebral fluid outflow resistance, and high cerebral venous pressure.

Tumors, masses, and abscesses have a more insidious onset and are frequently associated with vomiting. Neurologic

Table 41–3 International Headache Society Diagnostic Criteria for Tension Headaches

Infrequent episodic—at least 10 episodes occurring on <1 day/mo on average (<12 days/yr)

OR

Frequent episodic—at least 10 episodes occurring on ≥ 1 but <15 days/mo for at least 3 mo (≥ 12 and < 180 days/yr)

PLUS

Headache lasting from 30 min to 7 days

AND

At least 2 of the following characteristics:

- Bilateral location
- Pressing or tightening quality
- Mild or moderate intensity
- Not aggravated by routine physical activity

AND

Both of the following:

- No nausea or vomiting
- No more than one of photophobia or phonophobia

Adapted from the Headache Classification Committee of the International Headache Society.⁴⁸

Table 41–4 International Headache Society Diagnostic Criteria for Cluster Headaches

At least 5 attacks with a frequency of one every other day to 8/day

PLUS

Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15–180 min if untreated

AND

Headache accompanied by at least one of the following:

- Ipsilateral conjunctival injection and/or lacrimation
- Ipsilateral nasal congestion and/or rhinorrhea
- Ipsilateral eyelid edema
- Ipsilateral forehead and facial sweating
- Ipsilateral miosis and/or ptosis
- A sense of restlessness or agitation

Adapted from the Headache Classification Committee of the International Headache Society.⁴⁸

signs and symptoms may include gait abnormalities, vision changes, and behavioral problems. The headaches may initially be rather mild, but progressively worsen. A history of polydipsia and polyuria suggests a craniopharyngioma. The physical examination may be normal in the early phase of the illness. Classically, a mass above the tentorium is associated with a frontal headache, a mass below the tentorium is associated with a neck or occipital headache, and with a chiasmal mass the pain is referred to the vertex. The location of the headache correlates with the tumor site only about one third of the time.

Chronic Nonprogressive Headaches

Chronic nonprogressive headaches occur daily to almost daily without associated neurologic symptoms. These can be difficult and frustrating to manage. The headache generally lasts approximately 4 hours and occurs greater than 15 days per month. Comorbidities include depression, anxiety, panic disorders, and psychopathologic sleep disturbances.

Characteristic chronic nonprogressive headaches include medication rebound headaches and caffeine-induced headaches. Rebound headaches occur in patients with preexisting headaches.^{12,13} These are self-sustaining and predictable. Eighty percent of patients are using acute agents daily.¹⁴ Refractory headaches are, by definition, refractory to otherwise appropriate symptomatic and preventative treatments. Medication withdrawal results in escalation of headache intensity. Another type of recurrent nonprogressive headache is caffeine-induced headaches. Caffeine has been used to treat headaches and is included in over-the-counter migraine preparations, but the overconsumption of caffeine can lead to chronic headaches. Consumption of cola drinks is a prominent and common risk factor. In a study of 36 children and adolescents with caffeine-induced headaches, the average consumption of caffeine was found to be 1.5 L of cola drinks per day. With the gradual withdrawal of caffeine, sustained resolution of the headaches is likely.¹⁵

Mixed Headaches

Mixed headaches exhibit features of more than one type of headache. The heterogeneity of these cases makes research very difficult and leaves us without a generalizable evaluation and management plan for these children. Coordinated care with the patient's primary physician or pediatric neurologist is prudent.

Emergency Department Evaluation

The first and most important step in the evaluation of headaches is obtaining an appropriately directed history and physical examination. Family history of headaches or a previous history of similar headache suggests a primary headache disorder. A history of recent trauma alters the differential diagnosis and increases the likelihood of an intracranial injury being present. The location, quality, intensity, duration, and associated symptoms help classify headaches. Provoking and relieving factors, including response to medications, are useful for assessing the severity of the child's condition. A loss of previously acquired milestones or failure to achieve developmental milestones is concerning for a secondary cause of headache.

The physical examination provides further clues to the etiology of headaches. Identifying fever supports a secondary cause for the headache. Unless the child has known confusional migraines, abnormal mental status suggests a secondary cause. A focused and detailed neurologic examination has a high sensitivity for intracranial pathology. In children with brain tumors, up to 98% of neurologic abnormalities are found on a focused examination of mental status, coordination, deep tendon reflexes, sensation, motor function, and examination of the eyes.¹⁶ The skin may reveal characteristic findings such as petechiae associated with meningococemia, café-au-lait spots associated with neurofibromatosis I, or ash-leaf spots associated with tuberous sclerosis.

No standard set of laboratory tests is indicated when a child presents to the emergency department complaining of headache. In general, laboratory tests are selected to confirm or rule out suspected diagnoses in cases of secondary headaches. No routine laboratory tests have been shown to be of clinical use in the evaluation of headache.^{17,18}

Most children with headaches do not require neuroimaging during their emergency department visit. The indications for neuroimaging are few (Table 41–5). In the limited studies in children with headaches, there is a low incidence of positive findings on neuroimaging in those children who had a normal physical examination.^{19–24} In an acute situation, CT scanning of the head is the preferred imaging modality to evaluate for intracranial bleeds or brain edema. Brain MRI is preferred for the evaluation of a brain tumor or if an abnormality in the posterior fossa or brainstem is suspected.

Lumbar puncture (LP) is useful for the evaluation of suspected meningitis, subarachnoid hemorrhage, or idiopathic intracranial hypertension (see Chapter 171, Lumbar Puncture). Previously, for children with a closed anterior fontanelle, a head CT prior to LP was recommended. It is currently thought that the physical examination is more sensitive in detecting impending herniation than a CT scan.²⁵ The American College of Emergency Physicians has recommended that a head CT be performed prior to LP only if papilledema, altered mental status, a focal finding on neurologic examination, or a clinical impression of impending herniation is present.²⁶ Although relatively rare in children, a post-LP headache may arise. This risk can be minimized by using the smallest needle possible, inserting the needle such that the bevel is perpendicular to the longitudinal fibers of the dura,

Table 41–5 Criteria for Ordering Neuroimaging in Evaluation of Pediatric Headaches

Suspicion of intracranial hemorrhage or infarct
Stroke evolution

Abbreviation: ICP, intracranial pressure.

and replacing the stylet before withdrawing the needle from the patient.¹⁹ Prophylactic bed rest following LP is of no benefit.²⁷

Important Clinical Features and Considerations

A potential pitfall to avoid in the emergency department is confusing a tension headache with a tumor, pseudotumor cerebri, or hydrocephalus. Certain “red flags,” if present, may alert the emergency physician to a higher likelihood of a serious secondary cause being present (Table 41–6). In particular, headaches occurring upon awakening in the morning are associated with brain tumors (see Chapter 45, Brain Tumor). Headaches that occur simultaneously in multiple family members suggest carbon monoxide exposure.

Management

Most headaches in children are treated symptomatically by parents and primary caregivers, usually with acetaminophen or ibuprofen. By the time the child presents to the emergency department, most outpatient therapies have failed and parents have a fear of a more serious underlying disorder. Once secondary causes of the headache have been excluded, the role of the emergency physician is to provide reassurance about the benign nature of the headache and to treat the acute attack.

The first-line therapy in pharmacologic management of migraine headaches is oral analgesics. Acetaminophen, ibuprofen, naproxen, and ketorolac are the most commonly used oral analgesics. Appropriate doses of ibuprofen (10 mg/kg) or acetaminophen (15 mg/kg) have been found to be more effective in relieving migraine headaches in children when compared to placebo, and ibuprofen was twice as likely to abort migraines compared to acetaminophen.²⁸ In the presence of nausea and vomiting, ketorolac (Toradol), a nonsteroidal

anti-inflammatory agent, is available for use either intramuscularly or intravenously (IV).

The antiemetics prochlorperazine, droperidol, and metoclopramide have also been recommended for use in the management of migraine headaches due to their dopaminergic effects. These agents not only provide relief of nausea and vomiting but also have been found to provide headache relief.^{29–31} Unfortunately, the side effect profile includes the potential for extrapyramidal reactions.

Most data on the pediatric emergency management of headaches are largely based on adult studies. The only study to evaluate the emergency department management of pediatric migraine compares the use of IV ketorolac with IV prochlorperazine.³² After 60 minutes, 55% of those receiving ketorolac and 85% of those receiving prochlorperazine had improvement of their headaches, as shown by a reduction in a Nine Faces Pain Scale score. Both treatment groups were discharged with naproxen, and both groups had an approximately 30% recurrence rate at telephone follow-up.

Other drugs, such as butalbital and isometheptene, have limited use in the management of childhood migraines. Butalbital (Fiorinal, Fioricet, and Esgic) are very addictive and have the potential for analgesic rebound. No single trial indicates that these are effective in treating migraine headaches,³³ and some feel that it should be banned.³⁴ There is also no evidence that isometheptene (Midrin) has use in the management of childhood migraines.

Triptans (serotonin receptor agonists) are gaining increased use in the management of pediatric migraines. Oral sumatriptan has been shown to be effective in the treatment of adult migraines,³⁵ but has not been shown to be useful in children.³⁶ However, sumatriptan nasal spray has been shown to be effective in treating migraine headaches in adolescents and children and has been used by pediatric neurologists down to the age of 5 years with no reported morbidity or mortality.^{37–40} Subcutaneous sumatriptan showed a reduction in headache severity in 78% of pediatric patients from a pediatric neurology clinic.⁴¹ Other oral triptans, including zolmitriptan, naratriptan, rizatriptan, and almotriptan, are not currently approved by the Food and Drug Administration for use in children. Studies on rizatriptan have not shown any significant improvement compared to placebo in adolescents.⁴²

The side effects of triptans are usually transient and consist of flushing, chest tightness or pain, tingling, abdominal discomfort, neck pain, metallic taste in the mouth, and a feeling of heaviness. These side effects are often better tolerated in children than adults. Although there is a fear of rare cardiac complications, no cardiac events have been reported in children. Patients develop a tolerance to the side effects with time. The use of triptans should be avoided with hemiplegic migraines, basilar artery migraine, hypertension, congenital heart disease, or pregnancy. Multiple types and routes are available and are chosen based on the side effect profile.

Narcotics are indicated when abortive treatment fails. It is important to avoid narcotics in the presence of chronic abuse, and they are contraindicated with pregnancy, breastfeeding, or allergy. When using narcotics for rescue, it is best to use long-acting agents with appropriate dosing. The key for any analgesic use is to give the maximum allowable

Table 41–6 Red Flags and Comfort Signs in Evaluation of Headaches

Red Flags in Headache	Comfort Signs in Headache
New severe headache	Stable pattern
First or worse headache ever	Long-standing headache history
Headache when less than 5 yr of age	Family history of similar headaches
Fundamental change in headache pattern	Normal physical examination
Headache with fever or stiff neck	Consistently triggered by Hormonal cycles Specific foods Specific sensory inputs Lights/glare, odors, or weather changes
Headache with neurologic signs or symptoms	
Headache with nocturnal awakening	
Worsening headache over time	
History of trauma	
History of cancer or immunosuppression	

dose, give it early (within 30 minutes), make prescriptions available for school use, and save narcotics for use as a last resort.

Prophylaxis is not the purview of emergency medicine, but clinicians should keep the following in mind. It is generally recommended in the presence of more than three headaches a month. Less than 30% of patients with headaches need daily prophylactic medications.⁴³ Prophylaxis demonstrates an improvement in headache frequency and severity in up to 89% of patients.⁴⁴ Commonly used agents are pericetin and tricyclic antidepressants in children less than 12 years of age. The most common tricyclic antidepressant used is amitriptyline. Adolescents are given propranolol, calcium channel blockers, anticonvulsants (e.g., valproate, topiramate, gabapentin), or selective serotonin reuptake inhibitors. The majority of young headache patients, including those with migraines, are managed with as-needed analgesics plus or minus antiemetics.²

Cluster headaches and tension headaches are managed similarly to migraine headaches. With cluster headaches, oral therapy is not indicated due to the rapidity of the headache. Intramuscular sumatriptan and inhaled high-flow oxygen are given for the acute management of cluster headaches. Tension headaches usually respond well to first-line oral analgesics as described for the treatment of migraines. With chronic tension headaches, it is helpful to identify “stressors” and make lifestyle changes as needed. For refractory tension headaches, treatment can include central-acting muscle relaxants or benzodiazepines.

Nonpharmacologic strategies for management of chronic headaches include behavioral therapy,⁴⁵ such as stress management, relaxation programs,⁴⁶ cognitive control, and biofeedback. These measures have been shown to reduce headache frequency by as much as 80% to 85%.⁴⁷ If children are missing more than 15 days of school because of headaches, psychological evaluation for stress, social, or psychological disorders should be considered.

Education for the family is paramount at the disposition of the child from the emergency department. It is important to keep a headache diary, follow a regular schedule, not skip meals (especially breakfast), avoid caffeinated beverages, and get 8 hours of sleep a night. Patients should have good follow-up with their primary care physician when dealing with chronic headaches. The parents should initiate nonpharmacologic strategies and give the maximum allowable dosage of medication at the earliest sign of headaches. They should be advised to limit the use of over-the-counter medications to no more than 2 days per week. If there is more frequent use, then prophylaxis should be considered with the primary care physician or a subspecialist.

Summary

Most headaches in children are benign unless red flags are involved. Most are quick in onset and short in duration. Most headaches respond to analgesics with or without antiemetics. If a child can get to sleep, most benign headaches are relieved. Pediatric migraine is real and often underdiagnosed. Treatment includes using medications quickly and using the maximum allowable dosage based on the patient’s age and weight. Nonpharmacologic measures should be employed in conjunction with medications whenever possible. The emer-

gency physician should refer the patient or involve subspecialists in nonresponders or in red flag cases.

Conditions Causing Increased Intracranial Pressure

Gail M. Stewart, DO, Tommy Y. Kim, MD, and Alexander Zouros, MD

Key Points

The number of children who require intracranial shunting for hydrocephalus has increased in recent decades.

Early signs and symptoms of increased intracranial pressure are nonspecific and can be subtle, overlapping with those of other, more common childhood illnesses.

A missed or delayed diagnosis of increased intracranial pressure can result in permanent neurologic damage or death.

When shunt malfunction is suspected, early consultation with a neurosurgeon experienced in the management of pediatric shunts can be life saving.

Introduction and Background

Increased intracranial pressure in children is often due to hydrocephalus, which is not rare. The prevalence of children with hydrocephalus is rising because of improved treatments leading to improved survival. Prior to the mid-20th century, there were no successful treatments for hydrocephalus, and many of these children died in infancy or early childhood. Now, with the use of intracranial shunting, many of these children are surviving and thriving. There are multiple causes of increased intracranial pressure in children (see Chapter 9, Cerebral Resuscitation; Chapter 17, Head Trauma; Chapter 43, Central Nervous System Infections; Chapter 44, Central Nervous System Vascular Disorders; and Chapter 45, Brain Tumor). Some of these conditions are associated with hydrocephalus and others are not. This chapter focuses on conditions associated with hydrocephalus (Table 42–1) and intracranial shunt complications, including shunt malfunction.

Recognition and Approach

Hydrocephalus is caused by impeded cerebrospinal fluid flow or resorption. Cerebrospinal fluid is produced primarily in

the choroid plexus of the lateral third and fourth ventricles at a rate of approximately 20 ml/hr in adults. Cerebrospinal fluid can freely flow into the third ventricle, pass through the aqueduct of Sylvius into the fourth ventricle, and circulate in the subarachnoid spaces of the brain, spinal nerve roots, and cranial basal cisterns (Fig. 42–1). Cerebrospinal fluid is resorbed into the venous circulation at these sites through active transport as well as pressure gradient–driven flow. Impairment of cerebrospinal fluid resorption at the interface with the venous circulation is termed *communicating hydrocephalus*. Impairment of cerebrospinal fluid flow through the ventricular system or subarachnoid spaces is termed *obstructive hydrocephalus*. The net accumulation of intracranial cerebrospinal fluid results in expansion of the ventricles (i.e., ventriculomegaly). If the volume of cerebrospinal fluid increases to the point that the brain's compliance is exceeded, intracranial pressure will rise.¹

Intracranial shunts were developed in the mid-20th century to divert the excess accumulation of cerebrospinal fluid and avert or reverse the development of hydrocephalus. Shunts are composed of proximal tubing, which is placed into the ventricle; a one-way valve; and a distal tube that drains fluid to an extracranial location (see Chapter 167, Ventriculoperitoneal and Other Intracranial Shunts). The most common extracranial location is the peritoneal cavity, but others include the right atrium, pleural cavity, gallbladder, urinary bladder, ureter, stomach, fallopian tube, bone marrow, mastoid, and thoracic duct.^{1,2}

Although life saving, intracranial shunts are prone to malfunction and failure. Of the approximately 18,000 shunts placed annually in the United States, up to 25% to 40% will fail in the first year after placement.^{3–8} Fifty-six percent to 80% of patients will experience at least one episode of malfunction in the 10 years following insertion, and the annual rate of shunt malfunction is estimated to be 2% to 5%.^{1,8} The mortality from a shunt malfunction is as high as 1% to 2%.^{3,7,8} The number of children requiring intracranial shunts has increased more in the past decade than previously. This is due to the improved survival of the smallest premature infants. Hydrocephalus develops from intraventricular hemorrhages in these neonates.⁹ Once shunted, these neonates are at a higher risk for shunt malfunction than children who were not born prematurely.^{9–11}

The most common causes for malfunction are obstruction, overdrainage, loculation, and infection.⁴ Less common causes include disconnection and migration. Some causes of malfunction are relatively specific to the extracranial location to which the shunt drains (Table 42–2). Obstruction is the most common cause of malfunction and can occur anywhere along the shunt tubing. The proximal catheter can become wedged against the ventricular walls, embedded in the brain parenchyma, or occluded with choroid plexus.¹² Failure of the distal catheter seems to be time dependent. As the distal catheter ages, it can calcify and become fibrotic. It can also accumulate intraluminal debris, leading to fracture, occlusion, or degradation.^{13,14} Overdrainage occurs when too much cerebrospinal fluid is siphoned from the ventricles, leading to intracranial hypotension. With overdrainage, brain shrinking away from the dura can tear the bridging vessels and cause a subdural hematoma.¹ Loculation occurs when the proximal tube is trapped in a small pocket within a ventricle, thereby failing to communicate with the rest of the ventricular system. This leads to a buildup of cerebrospinal fluid in all locations outside of the small loculated area.

Shunt infections most often result from contamination at the time of surgery. Ninety percent of shunt infections are diagnosed within 6 months of initial shunt placement or revision.^{1,12} Shunts can also become secondarily infected in the presence of septicemia or abdominal infections such as appendicitis or abscess. Disconnection occurs when the shunt tubing disconnects from the valve. Migration occurs when the distal tubing finds its way into unintended anatomic locations. Shunts have been reported to perforate the intestine and extrude through the anus, migrate through the fallopian tube and out the vagina, coil up in the scrotal sac, perforate the gallbladder, and protrude through the nipple, neck, umbilicus, knee, or other sites.^{15–22}

Clinical Presentation

The clinical presentation of a shunt malfunction is varied and dependent on multiple factors, including the presumed

Table 42–1	Conditions Associated with Hydrocephalus
	Aqueductal stenosis
	Arnold-Chiari malformation
	Bacterial meningitis
	Congenital hydrocephalus
	Craniosynostosis
	Cyst
	Dandy-Walker malformation
	Developmental skull anomalies
	Encephalocele
	Intraventricular hemorrhage

Weakness
Worsening school performance

*Identified as statistically associated with shunt malfunction in a population of children presenting to an emergency department. From Kim TY, Stewart G, Voth M, et al: Signs and symptoms of cerebrospinal fluid shunt malfunction in the pediatric emergency department. *Pediatr Emerg Care* 22:28–34, 2006.

rate in the rise in intracranial pressure, age of the child, timing of the most recent shunt placement or revision, location of the distal tip of the tubing, and underlying comorbid conditions. The progression of shunt malfunction may be slow. In these cases, the initial signs and symptoms are often nonspecific, vague, and subtle (Table 42–3). These children are easily misdiagnosed as having common childhood illnesses due to the substantial overlap in presentation of early shunt malfunction with these illnesses. Some of these children are sent to the emergency department from the pediatrician's office for the evaluation of increasing head circumference, loss of developmental milestones, or increasing difficulty in school. If shunt malfunction is identified under these circumstances, these children are often deemed to have "chronic" shunt malfunction. In other cases, the shunt malfunction is more acute. In these cases, signs and symptoms will have a shorter duration before presentation and are likely to appear more serious. Finally, if the child either has a very rapid rise in intracranial pressure or has a delayed diagnosis, the presentation may be hyperacute. These children are typically critically ill appearing and may be unresponsive with dilated pupils, papilledema, respiratory failure, posturing, hypertension, and bradycardia. Interestingly, clinical experience suggests parents whose children have had

prior shunt malfunctions seem to be adept at identifying subsequent episodes of shunt malfunction. In the single study available evaluating the signs and symptoms associated with shunt malfunction in a population of children presenting to the emergency department, only lethargy and shunt site swelling were statistically significantly associated with shunt malfunction.²³

The age of the child also impacts on the presenting signs and symptoms. Neonates and young infants might present with a bulging fontanelle, widened cranial sutures, prominent scalp veins, poor head control, or an upward gaze palsy. These findings are relatively specific to this age group. Unfortunately, neonates and young infants with early and slowly progressing hydrocephalus may also present with nonspecific signs and symptoms similar to other illnesses in this age group (see Chapter 7, The Critically Ill Neonate). In addition, children younger than 1 year are at a higher risk for shunt infections than are older children.

The timing of the most recent shunt placement or revision helps risk-stratify these children for shunt infections. Shunt infection is the second most common cause of shunt-related complications. The epidemiologic data regarding shunt malfunction suggest wide variability, with reported rates of infection ranging from 2% to 30%.² A shunt infection can occur on the equipment itself, at the wound site, in the cerebrospinal fluid, or at the site of the distal tube. The most common pathogens causing shunt infection are *Staphylococcus epidermidis* and *Staphylococcus aureus*.^{1,2,12,24} The clinical presentation for shunt infection is variable. Children might present with low-grade temperature elevations and nonspecific complaints or with irritability and meningeal signs. If the surgical wound becomes infected, erythema, swelling, cellulitis, or purulent discharge is likely to be seen. When the infection site is primarily in the cerebrospinal fluid, the classic signs of meningitis may be absent. Fever is present in most patients with shunt infection but is an unreliable predictor. Approximately 50% of infected shunts will become obstructed with bacteria and inflammatory cells, so these children may also present with signs and symptoms of shunt malfunction.²

One way to categorize shunts is by the initial location of the tip of the distal tubing. There are certain clinical syndromes and conditions associated with each type of shunt (see Table 42–2). For example, children with ventriculopleural shunts may develop chest pain, shortness of breath, or respiratory failure if excess fluid accumulates in the pleural cavity. A child with a ventriculoatrial shunt may present with complaints of chest pain or shortness of breath due to a pulmonary embolus or cardiac arrhythmia. Patients with ventriculoatrial shunts who develop shunt nephritis will have persistent low-grade fevers, proteinuria, and hematuria.¹²

The presence of comorbid illnesses also impacts on the presentation of shunt malfunction. The presentation of shunt malfunction in children with spina bifida or myelodysplasia can be insidious. Staring spells are a common presentation in these patients, as well as neck pain, lower cranial nerve palsy, and myelopathy. These signs may be due to an associated type II Chiari's malformation and worsening brainstem compression. This association puts patients with spina bifida at a particularly high risk for rapid and critical deterioration with shunt malfunctions. For patients with myelomeningocele, the clinical signs of a urinary tract infection, including

lethargy, headache, and abdominal pain, might mimic shunt malfunction. Children with myelomeningocele may also be more susceptible to bowel perforation from the distal catheter due to insufficient innervation causing weakness of the bowel wall.²⁵⁻²⁷

The ability to diagnose a malfunction by assessing the shunt pumping mechanism is unreliable. It is intuitively appealing to think that if the valve depresses easily, the distal tube is patent. Similarly, if the valve refills quickly after being depressed, the proximal tube should be functional. Unfortunately, the sensitivity for predicting shunt malfunction by this method is only 19%.¹

The primary imaging studies for evaluating children with possible shunt malfunction are a computed tomographic scan of the head and a series of plain radiographs covering the entire course of the shunt tubing (i.e., a shunt series). Children who have undergone shunting often have abnormal underlying brain architecture and will likely have abnormally large ventricles even after successful shunting. Therefore, obtaining images from prior, relatively recent computed tomographic scans of the head is very valuable for determining if ventricular enlargement is present for that particular child. If they are available, it is important to know whether the prior images were obtained during a prior episode of shunt malfunction or during an asymptomatic period. Unfortunately, computed tomographic scanning of the brain is known to produce a substantial number of false-negative scans. In approximately 11% to 16% of shunt failures, the imaging demonstrates small to normal-sized ventricles.^{28,29} A shunt series may reveal disruption, fracture, migration, or kinking of the tubing.

The definitive test for diagnosing a shunt infection is analysis of the cerebrospinal fluid. The fluid is usually obtained by “tapping” the shunt rather than by performing a standard lumbar puncture. Whether the emergency physician taps the shunt or defers to a neurosurgeon depends on factors such as the geographic location of the hospital, the urgency with which the fluid needs to be obtained, and the availability of a neurosurgeon. Nonetheless, performing a shunt tap in consultation with a neurosurgeon seems prudent. Once obtained, cerebrospinal fluid is typically analyzed for cell count, Gram stain, cultures, glucose, and protein levels²⁴ (see Chapter 171, Lumbar Puncture). Cerebrospinal fluid results consistent with infection include a positive Gram stain, pleocytosis, low glucose, high protein, or a positive culture. There appears to be an association of cerebrospinal fluid eosinophilia and shunt complications, including infections and malfunctions.³⁰

Important Clinical Features and Considerations

Slit Ventricle Syndrome

Children with slit ventricle syndrome typically present with a constellation of findings consistent with shunt malfunction despite having small ventricles on computed tomographic scanning of the head. The etiology of slit ventricle syndrome is unknown. The peak occurrence is 5 to 10 years after the initial insertion of the shunt.³¹ Intermittent proximal catheter obstruction is a common problem for children with slit ventricle syndrome.²⁵ Patients with slit ventricle syndrome

may present with chronic, cyclic headaches, nausea and vomiting, or acutely with signs of increased intracranial pressure. Some children have postural headaches. Overdrainage occurs in the upright position, causing a headache that is relieved by lying down and allowing the ventricle to re-expand.²⁵ Treatment options for slit ventricle syndrome include medications commonly used to treat migraines and neurosurgical procedures, including shunt revision.^{2,32}

Management

Management of infants and children suspected of having shunt malfunction is typically directed by a neurosurgeon familiar with the management of pediatric shunts. The available management options include tapping the shunt, inserting an intracranial pressure monitor, observing the child for progression of symptoms in a pediatric intensive care unit, invasive shunt patency studies, or operative shunt revision. If shunt infection is confirmed or strongly suspected, the best treatment is operative removal of the shunt and placement of an external ventricular drain.³³ In general, intravenous antibiotics are administered postoperatively rather than empirically in the emergency department.

Treatment of the patient presenting in extremis from shunt failure is similar to managing other critically ill children (see Chapter 1, Approach to Resuscitation and Advanced Life Support for Infants and Children). The single unique aspect of such a resuscitation is the performance of an emergently performed shunt tap. This procedure is not without risk of complications, but may be life saving. If the emergency physician determines that the child’s condition is such that death is likely to occur before the arrival of a neurosurgeon or before a child can be transferred to an appropriate tertiary care facility, the emergency physician should proceed with the shunt tap.² By removing cerebrospinal fluid, the decrease in intracranial pressure may be sufficient to stabilize a child until a more definitive neurosurgical evaluation and intervention can be performed. Potential complications associated with a emergent shunt tapping include damage to the shunt tubing or valve, persistent cerebrospinal fluid leakage, infection, and intracranial bleeding if cerebrospinal fluid is removed too rapidly.¹²

Summary

Shunt-related complications are not negligible and can result in neurologic impairment or death. Studies show that patients who experience one shunt failure are at risk for subsequent failures. The incidence of epilepsy increases significantly following each shunt revision.⁸ Furthermore, each revision carries a 5% risk of infection.³ The morbidity of shunt infection is significant. Studies have documented a marked decline in children’s IQ scores following shunt infection, reflecting its devastating effect on a maturing central nervous system.⁷ Mortality rates of 1% to 2% have been observed with shunt failure.^{3,7,8} Approximately 20% of children treated with shunts die from causes related to the original disease or its treatment. Most deaths occur during the first 2 years after shunt placement and are due to complications of the surgery or progression of the underlying disease.⁷ The most common causes of shunt-related mortality are obstruction, infection, and pulmonary embolism.⁷ Children with suspected or

confirmed shunt complications are typically admitted to a neurosurgeon familiar with the management of pediatric shunts at a hospital that has a pediatric intensive care unit.

In addition, there is no way to measure the considerable psychological impact on families of shunted children, who must remain ever watchful for subtle signs of malfunction. Oftentimes numerous, and time-consuming, trips to the office or emergency department are required to evaluate for shunt malfunction. Understanding the difficulties these families face is helpful in coordinating care with them.

Despite ongoing research and exploration of alternative methods for the treatment of hydrocephalus, the shunting system is likely to remain the principle means of cerebrospinal fluid diversion for the near future. Even with their associated problems and complications, shunts have saved many children with hydrocephalus.

Chapter 43

Central Nervous System Infections

James A. Wilde, MD

Key Points

Bacterial meningitis is relatively rare in the United States outside of the neonatal period.

Viral meningitis due to enteroviruses is the most common central nervous system infection in the pediatric emergency department setting.

Bacterial and viral meningitis are different diseases with overlapping signs and symptoms.

While infection with West Nile virus is now common in the United States, overt encephalitis with severe neurologic sequelae due to West Nile virus is not.

Brain abscess should be considered in febrile patients who present with new focal neurologic abnormalities.

Introduction and Background

Emergency physicians manage many infectious diseases in the course of their duties. One study in an academic pediatric emergency department estimated that 50% to 60% of these diseases were self-limited viral infections primarily affecting the respiratory or gastrointestinal tract, and another 30% were minor bacterial infections such as acute otitis media or sinusitis.¹ Less than 5% of children had a serious bacterial infection. An even smaller subset of febrile illnesses target the central nervous system (CNS), but they have the potential to cause severe morbidity and mortality. For this reason, emergency physicians must be vigilant when managing a child with fever so that these more dangerous CNS infections may be diagnosed in a timely fashion. Unfortunately, the signs and symptoms of these infections can be quite subtle, making early recognition difficult despite the best efforts of clinicians.

One of the most feared CNS infections among clinicians is bacterial meningitis. In some cases, the course of the illness from symptom onset to death may be less than 24 hours, particularly if the infection is due to *Neisseria meningitidis*, also known as meningococcus. Fortunately, bacterial meningitis has become a rare diagnosis in the United States since

the introduction of conjugate vaccines for *Haemophilus influenzae* type b (Hib) in 1991 and *Streptococcus pneumoniae* in 2000. As a result of the Hib vaccine alone, cases of bacterial meningitis dropped by 87% nationwide.² A smaller but still significant drop can be expected after use of the pneumococcal vaccine becomes widespread.^{3,4} Just prior to the introduction of the pneumococcal vaccine, total bacterial meningitis cases in children under 18 years of age in the United States were estimated to be less than 2800 per year, or approximately one case for every 22,000 children.² The incidence is higher in younger children, particularly neonates, for whom effective vaccines have not yet been developed (Table 43–1). The most common causative organisms vary by age: in neonates, group B streptococcus and *Listeria monocytogenes* predominate, although gram-negative enteric organisms such as *Escherichia coli*, Klebsiella, and Enterobacter species also play a role; in children between 1 and 23 months, *S. pneumoniae* and *N. meningitidis* cause most cases; and in children 2 to 18 years, *N. meningitidis*, *S. pneumoniae*, and *H. influenzae* type b predominate.

Viral meningitis is a related disease that is quite common in the United States, causing more than 75,000 symptomatic infections per year.⁵ The ratio of viral meningitis to bacterial meningitis in U.S. children is at least 20 : 1. The causative organism in all but a small percentage of cases is Enterovirus, a group of viruses that circulate primarily in the warm months of the year from April to September. Over 70 distinct serotypes of Enterovirus have been described, most classified as either echoviruses or coxsackieviruses. Many different serotypes of ECHO and Coxsackie have been implicated in outbreaks of meningitis. Viral meningitis tends to be most common in children, who account for up to 96% of cases in some reports.⁶ Unlike bacterial meningitis, viral meningitis due to Enterovirus rarely causes significant sequelae in children, and death is rare.⁷

Encephalitis is an infection that includes direct brain parenchymal invasion, whereas meningitis is an infection of the cerebrospinal fluid (CSF) and tissues that surround the brain. Many cases of enteroviral meningitis actually represent a combination of both, a syndrome referred to as meningoencephalitis. Prior to 1999, herpes simplex virus (HSV) was the most common cause of nonepidemic, acute focal encephalitis in the United States.⁸ The most common cause of encephalitis in the United States in 2005 is West Nile virus, a newly imported infectious agent that has spread throughout the country with amazing rapidity since the first case was

documented in New York in 1999. In 2003, there were 9000 cases reported in the United States, with 220 deaths.⁹ West Nile virus is a flavivirus spread by mosquitoes; birds are the primary reservoir. Other less common causes of encephalitis in the United States include arboviruses such as the La Crosse strain of California encephalitis virus, St. Louis encephalitis virus, western equine encephalomyelitis virus, and eastern equine encephalomyelitis virus. Infections due to arboviruses generally occur during the warm months of the year and tend to parallel mosquito activity. HSV encephalitis can occur during any time of the year and at any age, although the most severe form tends to occur in neonates in the first 2 to 3 weeks of life.

Brain abscess is rare in children. Even with prompt diagnosis and treatment, the mortality rate is 25% or more. Aerobic and anaerobic streptococci cause about half of all brain abscesses in children, followed by staphylococci (10% to 30%) and enteric bacteria such as Enterobacteriaceae (10% to 25%). Mixed infections are found in 30%.¹⁰

Recognition and Approach

Any child who develops a fever and headache may have a CNS infection, but most do not. Due to the subtlety of the symptoms, it can be very difficult to detect all CNS infections on the initial presentation. In addition, some patients may be at the beginning stage of a series of events that will lead eventually to CNS infection, such as patients with bacteremia (Fig. 43–1). This series of events may occur over several hours or several days. In the clinical setting, it is not possible to precisely determine the point at which CNS invasion has occurred. Several authors have suggested guidelines to identify children with occult bacteremia in an effort to interrupt the progression to meningitis.¹¹ Even with the use of laboratory screens as suggested in these guidelines, more than one third of children with occult bacteremia will not be identified, and a small proportion of them will go on to develop meningitis (see Chapter 68, Bacteremia). Thus it is inevitable that some febrile children without meningitis who are seen early in the course of their illness will develop bacterial meningitis later in the illness despite the best efforts of physicians to detect the disease.

Two different presentations for bacterial meningitis have been described. These include a fulminant form and an insidious form. Patients with fulminant meningitis have rapid progression of their disease with obvious signs and

symptoms pointing to the severity of their illness, such as altered mental status, shock, and nuchal rigidity. Recognition of fulminant meningitis is relatively easy early in the course if these signs and symptoms are present. The insidious form develops more slowly, often over several days, and recognition early in the course is difficult since the more specific signs and symptoms develop later. Despite potential delay in making the diagnosis in the case of the insidious form, patients are generally not as ill at the point of diagnosis, and the outcome is better than in patients with fulminant meningitis.^{12–14} Given the pathophysiology of bacterial meningitis, one explanation for these differences is that, in those with the insidious course, bacterial invasion of the CNS is a late event. For example, patients who present with the insidious form may not have had meningitis at all if evaluated for fever 2 days before meningitis is eventually recognized. The reason for this delayed invasion is unclear; it may be related to the virulence of the organism,¹⁵ or it may be related to variations in host response to infection. This helps explain an apparent paradox in patients with meningococcal infections, in whom the presence of meningitis at the time of diagnosis is actually associated with a better outcome.¹⁶ Highly virulent meningococcal strains may be so lethal that progression to sepsis and multiorgan failure occurs before significant invasion of the CNS can occur. Less virulent strains have more time to invade the CNS and produce typical symptoms of meningitis. Conversely, recent data indicate that the systemic response to infection shows profound genetic variation and that patients with variations in cytokine production may be at increased risk for morbidity and mortality due to bacterial pathogens such as *N. meningitidis*.^{17,18} In these patients, the outcome may depend more on the patient's own innate immune response than on the invading organism.

One fourth of all brain abscesses are diagnosed in children under 15 years of age.¹⁰ The most common predisposing conditions are cyanotic congenital heart disease, usually with hematogenous spread of bacteria, or direct invasion from a contiguous site such as infected sinuses or middle ear infection. Immunosuppression has also emerged as a leading predisposing factor over the last 25 years, as has premature birth.¹⁹ Brain abscess is an unusual complication of bacterial meningitis. Brain abscess after head trauma also is unusual, and tends to lag well behind the initial injury. Physicians should have a heightened level of suspicion for brain abscess if a child with one of these risk factors develops symptoms suggestive of CNS infection, particularly if new neurologic deficits are noted.

Up to 80% of infections with West Nile virus are asymptomatic, and less than 1% of infected patients develop severe neurologic illness such as meningitis, encephalitis, or flaccid paralysis.⁹ Viral encephalitis should be considered in the differential diagnosis of patients who present with these neurologic manifestations during the summer months. West Nile virus infection is 10 times more common in patients over age 50 than in children, and illness in children tends to be milder. *West Nile fever* is the term given to patients who are asymptomatic with West Nile infection but who have no neurologic disease.²⁰ Patients with West Nile fever have an acute febrile illness lasting 3 to 6 days in addition to headache, vomiting, myalgia, and rash. The most severe form of viral encephalitis in the United States is eastern equine encephalitis. Encephalitis due to other arboviruses in the United States have much

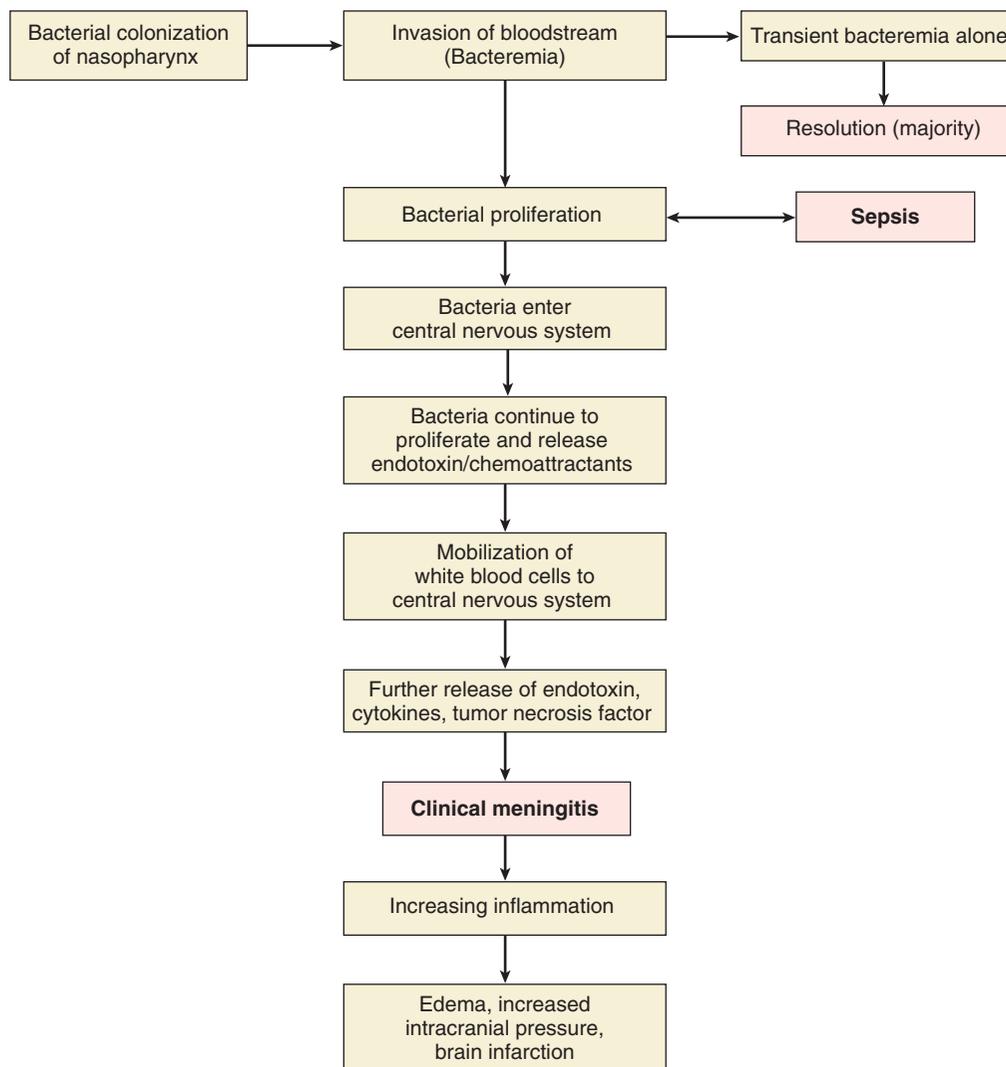

FIGURE 43-1. Steps in the development of bacterial meningitis.

lower rates of morbidity and mortality, and many infections remain subclinical. Arboviruses are maintained in nature through a cycle involving transmission from mosquitoes to birds and small mammals. Humans are considered “dead-end hosts” for arboviruses such as West Nile due to low levels of viremia; person-to-person spread does not occur.

Clinical Presentation

Nonspecific signs and symptoms that are generally present with CNS infections include fever, headache, and vomiting. In the absence of more specific signs or symptoms, further workup outside the newborn period is generally not warranted and symptomatic therapy alone is appropriate, since the overwhelming majority of these patients will not have a CNS infection. Inflammation of the meninges may lead to more specific signs or symptoms such as increased pain on flexion of the neck, stiff neck (nuchal rigidity), photophobia, altered mental status, or irritability. Seizures, focal neurologic abnormalities, petechial or purpuric rash, and hypoten-

sion may suggest meningitis, encephalitis, or brain abscess. Patients who present with fever, headache, and vomiting in addition to one or more of these other signs and symptoms, and patients with unusually severe symptoms, generally require further evaluation for meningitis. Patients with risk factors for CNS infection, such as those with ventriculoperitoneal shunts, cyanotic congenital heart disease, recent CNS surgery or head trauma, or immunocompromised states, may also require a more aggressive workup even in the absence of these additional signs and symptoms.

Another subset of patients that requires more aggressive evaluation is the newly born, in whom specific signs and symptoms often do not develop until very late in the course of their CNS infection. In this population, clinical signs and symptoms of meningitis may be very subtle, including poor oral intake, increased sleep, irritability, respiratory distress, or jaundice. Many neonates with meningitis are afebrile at presentation,²¹ and most have no meningeal signs.²²

One of the most important signs of bacterial meningitis is a change in the child’s affect or state of alertness. In one

study, 36% to 60% of children older than 3 months with this diagnosis were described as toxic or moribund, and 73% to 100% were described as lethargic or comatose.²² Physicians should be careful to document the presence of lethargy based on clinical findings rather than on a parent's report. Children who are febrile for any reason tend to show decreased activity and an increased desire for sleep. This does not necessarily indicate that they are lethargic. "Lethargy" in the medical sense refers to an inappropriately decreased response to external stimuli. For example, children can be expected to cry and resist attempts at examination by medical personnel, particularly in the younger age groups. They should react similarly to venipuncture and other painful procedures. Children who do not respond vigorously to these stimuli may be truly lethargic. Lethargy is an ominous finding that should prompt further investigation. On the other hand, most patients with fever and headache who are active, alert, playful, or smiling are unlikely to have a serious CNS infection in the absence of more specific signs or symptoms.

Up to 30% of children with acute bacterial meningitis have seizures on initial presentation.²³ Most of these children are profoundly ill at presentation. A study focusing on seizures as the initial presenting symptom in bacterial meningitis revealed that almost all of these children have marked alterations in their sensorium; over 90% were either comatose or semicomatose.²⁴ It is important to note that most children who have seizures and fever do not have acute bacterial meningitis. Children who meet the case definition for a simple febrile seizure and who return to a normal level of alertness shortly thereafter are at low risk for bacterial meningitis; except in those under 12 months of age, further laboratory investigation for meningitis is not recommended.²⁵

Meningismus is a term that refers to irritation of the meninges, usually from bacterial or viral meningitis. Meningismus can be assessed in a number of ways. The prime method is to examine the patient for nuchal rigidity, or a stiff neck. Flexing the neck causes the meninges to stretch, so the neck muscles tend to resist flexion as an involuntary protective mechanism in the presence of inflamed meninges. Many medical students are taught to test for nuchal rigidity by pulling up on the back of the supine patient's head. This method may be less helpful in very young children, who tend to resist examination and manipulation of any sort. A simpler method that can be used in any age group is to assess the patient from a sitting position, asking the child to look down toward his or her umbilicus. In younger children, the physician may simply place something of interest such as a toy or light in the region of the umbilicus. A child who readily looks down by flexing the neck so that the chin touches the chest does not have nuchal rigidity. Two other helpful signs to assess for meningismus are Kernig's and Brudzinski's signs. Kernig's sign is positive if the patient actively flexes the neck in response to a maneuver that includes passive flexion at the hip followed by passive extension at the knee. Brudzinski's sign is positive if passive flexion of the neck by the examiner causes an involuntary active flexion at the hip. Meningismus is almost always present in children who present with bacterial meningitis beyond 13 months of age, but it is usually absent in children under 6 months.²²

Children with brain abscess usually present with headache, fever, and vomiting, but the classic triad of headache,

fever, and focal deficits occurs in less than one third. Up to half will have seizures, altered mental status, or focal neurologic signs, but more than half have none of these additional signs or symptoms.

Patients who present with signs and symptoms that suggest acute CNS infection warrant further evaluation. This includes all children with meningismus or photophobia, even if the child presents with a nontoxic appearance that suggests viral meningitis. Central to that evaluation is an examination of CSF after performance of a lumbar puncture (LP)²⁶ (see Chapter 171, Lumbar Puncture). In uncomplicated bacterial meningitis, LP can be performed safely without a prior head computed tomography (CT) scan. The practice of routinely ordering a head CT scan before the LP is performed in these patients can lead to unnecessary delays in administration of antibiotics and should be discouraged.^{27,28}

It may be appropriate to delay the LP in some patients with suspected CNS infection. For instance, CSF findings are non-specific in patients with brain abscesses, and bacteria are rarely isolated from culture. Thus for patients in whom brain abscess is suspected, LP is of marginal value. It may be more appropriate to first order a head CT scan to determine if an abscess is present. If an abscess is found, LP is not required. If no abscess is found, the LP can be done to search for evidence of meningitis. Due to the risk of cerebral herniation, LP should also be delayed in patients with focal neurologic abnormalities or focal neurologic symptoms that suggest a CNS mass lesion. LP in patients with papilledema or a limited neurologic examination due to a decreased level of consciousness should also be delayed for the same reason. In each of these cases, CT of the head should be ordered first to assess for a space-occupying lesion. If a space-occupying lesion is not present, LP can be performed in the absence of any other contraindications. Other reasons to delay performance of an LP include the presence of thrombocytopenia or uncorrected coagulopathy; cellulitis overlying the lumbar vertebra; or an unstable patient who would be at risk for acute clinical deterioration from the procedure itself. If the LP is to be delayed for any reason, blood should be collected for bacterial culture prior to administration of antibiotics. Bacterial pathogens can be isolated from blood culture in up to 80% of patients with bacterial meningitis.^{29,30}

Examination of the CSF can provide clues to the presence or absence of inflammation. Normal CSF in the neonatal period contains less than 26 white blood cells (WBCs)/mm³. Beyond the neonatal period, there should be fewer than 7 WBCs/mm³.³¹ Pleocytosis is present if the number of WBCs in the CSF is above those limits. CSF pleocytosis is indirect evidence for inflammation. An elevated level of CSF protein or a decreased level of CSF glucose also indicates the presence of inflammation. The results of these three tests provide useful clues about the underlying diagnosis (Table 43–2). However, there is a considerable degree of variability in these tests. For example, up to 10% of children with viral meningitis have been reported to have CSF WBC counts greater than 1000/mm³,⁵ and 1% of children with bacterial meningitis have a normal CSF WBC count on initial examination.³²

The rapid test that is most helpful and practical in assessing for the presence of bacterial meningitis is the CSF Gram stain. The Gram stain will reveal bacteria in up to 90% of patients with bacterial meningitis.^{33,34} It is important to note also that appropriate antibiotic therapy does little to

Table 43–2 Typical Cerebrospinal Fluid Characteristics in Central Nervous System Infections

	Bacterial Meningitis	Viral Meningitis	Encephalitis	Brain Abscess
WBC/mm ³	>1000	<500	<200	Variable
Protein	Markedly elevated	Normal	Elevated	Variable
Glucose	Markedly decreased	Normal	Normal	Variable
Gram stain	Bacteria	No bacteria	No bacteria	Bacteria rarely present
	Polymorphonuclear cells	Mononuclear cells and polymorphonuclear cells	Mononuclear cells	

Abbreviation: WBC, white blood cells.

diminish the inflammatory response in the first few days of treatment. It is not unusual to find an increased degree of pleocytosis 1 to 2 days after starting antibiotic therapy, and CSF pleocytosis persists for at least 7 to 10 days.³⁵

Important Clinical Features and Considerations

The diagnosis of bacterial meningitis does not depend on the measurement of a peripheral WBC count. Even in clinically apparent meningitis, the WBC count often is not elevated significantly; more than 50% of patients with meningitis due to *N. meningitidis* have WBC counts under 15,000/mm³.³⁶ The diagnosis of bacterial meningitis is based on clinical criteria, examination of CSF for evidence of inflammation, and isolation of bacteria from CSF. Patients outside of the neonatal period who do not have specific signs or symptoms pointing to meningitis are highly unlikely to have the disease. Physicians who choose to use the peripheral WBC count as a screen to detect occult bacteremia in an effort to “prevent” a case of meningitis, or as a means to diagnose clinically inapparent bacterial meningitis, should be aware of the significant limitations and pitfalls of that strategy.

A particularly vexing problem for clinicians is how to distinguish viral meningitis from the early stage of bacterial meningitis, when the degree of CSF pleocytosis may still be mild. Although viral meningitis typically is associated with mononuclear cell predominance in the CSF, early in the course of infection polymorphonuclear cells often predominate. Some authors have devised a clinical “scoring system” to determine which patients with CSF pleocytosis are likely to have viral meningitis and which are likely to have bacterial meningitis.^{37,38} The only validated prediction model in the era after the Hib vaccine was introduced was found to have a high sensitivity for detecting a case of bacterial meningitis as well as a high negative predictive value for this diagnosis.³⁸ The authors concluded that patients who had a bacterial meningitis score of zero were highly unlikely to have bacterial meningitis and may be managed as outpatients (Table 43–3). A subsequent multicenter retrospective validation study showed that the risk of bacterial meningitis is less than 0.1% in patients with a score of zero.³⁹

Another dilemma for clinicians is how to decide who requires an LP and who does not. Some physicians take the approach that any child with possible meningitis requires an LP, without regard to whether viral or bacterial meningitis is suspected. Viral meningitis and bacterial meningitis are two different diseases, with different pathophysiology, management, and prognosis. If a patient’s symptoms include meningismus or photophobia, an LP should be performed even in

Table 43–3 Predictors for Bacterial versus Viral Meningitis

- Positive Gram stain
- CSF protein \geq 80 mg/dL
- Peripheral ANC \geq 10,000 cells/mm³ (10×10^9 cells/L)
- Seizure at or before presentation
- CSF ANC \geq 1000 cells/mm³ (1×10^9 cells/L)

Scoring: Two points for positive Gram stain, one point for all other items.

All negative: likely viral meningitis; negative predictive value for bacterial meningitis 97%–100%

Positive Gram stain or any two other items positive: likely bacterial meningitis; sensitivity 87%

Abbreviations: ANC, absolute neutrophil count; CSF, cerebrospinal fluid.

Adapted from Nigrovic LE, Kuppermann N, Malley R: Development and validation of a multivariable predictive model to distinguish bacterial from aseptic meningitis in the post-*Haemophilus influenzae* era. *Pediatrics* 110:712–719, 2002.

the nontoxic patient. However, physicians in the United States should keep in mind that it is not imperative to search for evidence of viral meningitis in a patient if symptoms are not severe, since virtually all patients recover without specific therapy. It is imperative to search for evidence of bacterial meningitis, since appropriate antibiotic therapy can be life saving. Thus, a nontoxic child who presents with fever and headache in the absence of meningismus or photophobia does not *require* an LP even if a sibling was diagnosed with viral meningitis 3 days earlier.

In light of the fact that bacteria are rarely isolated from the CSF in patients with brain abscess, the CSF profile in these patients may be similar to that seen in viral meningitis or encephalitis. Once again, a high level of suspicion for this infection should be maintained for children at increased risk for brain abscess since many of them do not present with seizures or new focal neurologic deficits on physical examination.¹⁹

The hallmark of viral encephalitis is CNS dysfunction. This dysfunction may be manifested by an altered level of consciousness, focal neurologic abnormalities, seizures, or unprovoked emotional outbursts. Encephalitis should be considered in patients with headache and fever who present with these additional features.

Management

Expedient diagnostic studies and therapeutic interventions are important in patients with signs and symptoms of CNS infection who present to the emergency department (Table

Table 43–4 Suggested Steps in the Management of Bacterial Meningitis in the Emergency Department

Rapid evaluation to include:

- Head computed tomography in selected cases
- Blood culture *before* administration of antibiotics
- Serum chemistry panel
- Lumbar puncture (in the absence of contraindications)
- Cerebrospinal fluid culture and Gram stain
- Cerebrospinal fluid protein and glucose
- Cerebrospinal fluid cell count and differential

Rapid administration of antibiotics targeted against suspected pathogens

Fluid resuscitation to maintain adequate blood pressure (fluid restriction is **not** recommended)

Vasopressor agents as needed if blood pressure does not improve with fluid boluses

Dexamethasone as adjunctive therapy if infection due to *Haemophilus influenzae* type b is suspected

Transfer to a pediatric intensive care unit for definitive care

Antibiotic prophylaxis for selected close contacts if disease due to *H. influenzae* type b or *Neisseria meningitidis* is suspected

43–4). All of these emergency department evaluations should include blood culture, most should include LP, and some may include head CT scan. If the patient is likely to have bacterial meningitis or brain abscess, antibiotics should be administered quickly. Dogmatic pronouncements that the antibiotics must be given within a specified time frame, such as within 30 minutes of the patient's arrival in the emergency department, should be avoided. These time intervals are based more on opinion than on solid evidence; there are no data that conclusively show a better outcome if antibiotics are administered within the first 30 minutes compared with 1 or 2 hours.¹³ In addition, a 30-minute time interval may be impractical for many cases, particularly if the diagnosis is not obvious. One retrospective study of bacterial meningitis in a general emergency department showed that the average duration from arrival in the emergency department to administration of antibiotics was more than 2 hours.⁴⁰ The authors of this study correctly pointed out that, since the standard of care is based on the actual practice in the community, this is a more realistic "standard." Since randomized studies examining various intervals between presentation and treatment of established bacterial meningitis would be unethical, it may not be possible to prove that one interval provides a better outcome than another. If bacterial meningitis is likely, a reasonable recommendation is to administer the antibiotics immediately after collecting blood for culture, or immediately after completion of the LP if there is no delay in performing the procedure. The yield for CSF culture declines within 1 to 2 hours of third-generation cephalosporin administration in patients with meningococcal meningitis, within 4 hours with pneumococcal meningitis, and within 8 hours with meningitis due to group B streptococcus.³⁰

The proper antibiotic choice for bacterial meningitis in the United States depends on the age of the patient, the presence or absence of risk factors for unusual organisms, and information gained from the Gram stain. A patient with CNS hardware such as a ventriculoperitoneal shunt, a history of recent CNS surgery, or recent head trauma is at higher risk for staphylococcus or streptococcus species than is a patient

Table 43–5 Suggested Empirical Antibiotic Regimen for Bacterial Meningitis

Age	Suggested Antibiotic Regimen
<1 mo	Gentamicin 2.5 mg/kg OR cefotaxime 50 mg/kg Plus Ampicillin 50 mg/kg Use vancomycin if staphylococcus species or <i>Pneumococcus</i> is suspected
>1 mo	Ceftriaxone 75 mg/kg OR cefotaxime 100 mg/kg Plus Vancomycin 10–15 mg/kg

without these conditions. If either *Staphylococcus aureus* or *Staphylococcus epidermidis* is likely, the antibiotic regimen should include vancomycin. A patient with sickle cell disease and gram-negative rods on Gram stain should be given an antibiotic that targets salmonella, such as a third-generation cephalosporin. A patient over the age of 1 month with an unremarkable past medical history and gram-positive organisms on Gram stain should be given antibiotics that are active against *S. pneumoniae*, such as third-generation cephalosporins. Given the current rate of penicillin-resistant pneumococcus in the United States, empirical therapy with ampicillin or penicillin should no longer be considered adequate therapy, although penicillin is still the drug of choice if the isolate is determined to be sensitive to penicillin. Some authors have shown equivalent benefit from carbapenems such as meropenem when compared with cephalosporins; these agents should be considered in the cephalosporin-allergic patient.⁴¹ In light of recent trends toward increased levels of penicillin resistance among pneumococci, the addition of vancomycin to any regimen chosen is now recommended if this pathogen is suspected⁴² (Table 43–5).

The adjunctive use of dexamethasone in bacterial meningitis is controversial.^{42,43} Early studies examining the use of dexamethasone showed no clear benefit. However, these studies focused on mortality as the outcome measure. More recent studies that evaluated the effect of dexamethasone on both mortality and morbidity appeared to show less hearing loss in the group treated with dexamethasone.⁴⁴ Upon closer inspection, the benefit appeared to be confined to patients with meningitis due to *H. influenzae* type b. Multiple studies have been undertaken since then to determine if that benefit extends to patients with meningitis due to *S. pneumoniae* or *N. meningitidis*. Unfortunately, the data for these pathogens have been less clear. One meta-analysis performed in 1989 showed benefit only for *H. influenzae* type b.⁴⁵ Another meta-analysis performed in 1997 concluded that there is benefit in patients with *H. influenzae* type b, and possible benefit in patients with *S. pneumoniae*.⁴⁶ The definitive answer to this question may never be known. Most of the data from these two meta-analyses relied on studies done before vancomycin and third-generation cephalosporins were recommended in combination as the initial antibiotic regimen. In light of the fact that vancomycin appears to provide a synergistic effect against these pathogens, the question today should ideally be answered using study designs including both antibiotics.⁴³ Only two such studies have been performed, and they came to conflicting conclusions. In an era in which meningitis due to *S. pneumoniae* has become

increasingly rare due to vaccination, randomized studies designed to settle the issue will be difficult to perform. Dexamethasone has not been shown to reduce hearing loss in meningococcal meningitis.

The Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) stated that the use of adjunctive dexamethasone “may be beneficial” in patients over the age of 2 months if they are suspected to have meningitis due to *H influenzae* type b.⁴⁷ This panel of experts suggested only that dexamethasone be “considered” for bacterial meningitis due to pneumococcus because “data are not sufficient to demonstrate a clear benefit in children.”⁴⁸ Given the available literature and this recommendation from the AAP panel, the use of dexamethasone should not be considered the standard of care in the management of bacterial meningitis in children; physicians may reasonably decide not to use dexamethasone in the early management of this infection. If dexamethasone is to be used, it should be given in a dosage of 0.15 mg/kg per dose intravenously before or concurrently with the first dose of an antimicrobial agent. Dexamethasone should not be used in aseptic meningitis or in children with bacterial meningitis who are less than 6 weeks of age.⁴³

For many years clinicians were advised to restrict fluids to two thirds of maintenance requirements in patients with bacterial meningitis. The reason given was that the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) commonly occurred during the acute stages of bacterial meningitis, and too much fluid during a period of SIADH could potentially cause increased brain edema with concomitant increased intracranial pressure. However, recent studies have shown that SIADH may actually provide a protective effect during early meningitis by maintaining a blood pressure sufficient to overcome some of the impedance to cerebral perfusion brought about by brain edema.⁴⁹⁻⁵¹ The gathering consensus among experts is that fluid restriction is no longer warranted in the treatment of bacterial meningitis. Fluids should be provided as needed to support blood pressure and cover maintenance requirements.

Invasive infections due to *H. influenzae* type b and *N. meningitidis* pose a risk to some close contacts of the index patient.^{47,52} For this reason, prophylaxis of some close contacts is recommended to prevent further spread of the infection. However, care must be taken to avoid alarm in hospital staff, families, and the community in general. The risk is significant only for close contacts, but even in those cases the risk is not as high as anxious hospital personnel and families might imagine. For disease due to *H. influenzae* type b, the risk is primarily confined to unimmunized children under 4 years of age; hospital personnel are not at risk. For *H. influenzae* type b prophylaxis, rifampin is given orally once daily for 4 days at a dose of 20 mg/kg (maximum dose 600 mg). For disease due to meningococcus, while the risk for secondary meningococcal infection among household contacts is at least 1000-fold greater than for the public at large, secondary infections occur in less than 5% of cases.⁵³ Prophylaxis against *H. influenzae* type b and meningococcus should be offered to family contacts and close social contacts such as day care or school classmates, but extending the “net” of prophylaxis beyond that point is rarely indicated. Among hospital personnel, prophylaxis against meningococcus should be offered to health care workers involved in direct contact with the index patient, particularly if the contact

involved tracheal intubation, deep suctioning of the airway, or other direct exposure to the patient’s oral secretions.⁵¹ Recommended regimens include rifampin 600 mg every 12 hours for 2 days (5 mg/kg for children < 1 month), a single 500-mg dose of ciprofloxacin, or a single 250-mg dose of intramuscular ceftriaxone (125 mg for children < 15 years). Prophylaxis is not warranted for health care personnel without direct contact with oral secretions. Consultation with public health authorities or an infectious disease expert is recommended to coordinate decisions regarding prophylaxis.

If clinical findings and laboratory data suggest viral meningitis as the diagnosis, further management will depend primarily on the severity of the symptoms. Enterovirus can be isolated in viral culture from CSF in 50% to 70% of patients, but in most cases has little impact on patient management.⁵⁴ Polymerase chain reaction has also been described for definitive diagnosis.⁵⁵ This diagnostic technique may have more impact on patient management since it can be performed more rapidly. Admission of a patient who is suspected to have viral meningitis is not mandatory. Patients who have mild to moderate symptoms and who are not dehydrated may be candidates for discharge from the emergency department and supportive care at home. Children who are under 1 year of age, children whose diagnosis is uncertain, and children with severe symptoms should be managed as inpatients until preliminary culture data are available. The decision to administer antibiotics to a child with suspected viral meningitis depends on the clinical situation and the likelihood of the diagnosis. If there is significant doubt about the diagnosis, antibiotic therapy should be begun. For particularly severe meningoencephalitis due to Enterovirus, recent studies have shown some benefit from the antiviral agent pleconaril, although it is not yet widely available.⁵⁶

Patients with suspected encephalitis should always be managed as inpatients. Even with optimal management, significant morbidity and mortality do occur, particularly with infections due to eastern equine encephalomyelitis virus and HSV encephalitis. Neurodiagnostic tests such as head CT scanning, magnetic resonance imaging (MRI), and electroencephalography may be helpful in the evaluation of a patient with suspected encephalitis, particularly if the infection is due to HSV.⁸ HSV can be isolated from CSF in 50% of cases of neonatal HSV encephalitis but is rarely isolated from older children or adults.⁵⁴ Arboviruses are rarely isolated in culture; arboviral encephalitis is diagnosed on the basis of arbovirus-specific immunoglobulin M in spinal fluid. Acyclovir has been shown to improve survival in patients with HSV encephalitis. For this reason, intravenous acyclovir should be considered in patients with a clinical syndrome suggestive of encephalitis. For most cases of encephalitis due to arboviruses, specific antiviral therapy has not been shown to be beneficial, although in vitro data suggest a possible role for ribavirin in West Nile encephalitis and interferon- α in both West Nile and St. Louis encephalitis.⁹

Evaluation for brain abscess should include CT or MRI with contrast, which typically shows a ring-enhancing hypodense lesion. Surgical drainage is required in most cases, so neurosurgical consultation should be sought as soon as the diagnosis is confirmed.¹⁹ For brain abscesses associated with sinusitis, otitis media, or cyanotic congenital heart disease, the recommended antibiotic regimen is a third-

generation cephalosporin plus metronidazole. Alternatives include meropenem and ampicillin/sulbactam. Vancomycin should be added in cases associated with penetrating head trauma, ventriculoperitoneal shunts, endocarditis, and meningitis.¹⁰

Summary

Children with bacterial meningitis, encephalitis, and brain abscess should all be admitted, preferably to a tertiary care pediatric hospital that can manage complications. Selected patients with viral meningitis may be candidates for outpatient management, but close follow-up should be arranged within 24 hours. Most CNS infections can be diagnosed on the patient's initial presentation. Some, however, present with nonspecific signs and symptoms due to an early stage of disease evolution. In the latter category, "missed" diagnoses are inevitable no matter how astute the physician may be. Physicians can protect themselves from allegations of substandard care in these cases by careful documentation of the visit and by providing thorough discharge instructions.

Central Nervous System Vascular Disorders

Stuart Lewena, MBBS and Franz E. Babl, MD, MPH

Key Points

Failure to recognize the signs and symptoms of strokes in children leads to a delay in diagnosis.

The disease and conditions predisposing children to strokes are numerous and diverse.

For most cases of pediatric stroke, there is no evidence-based treatment.

Introduction and Background

A stroke is “a condition with sudden onset caused by acute vascular lesions of the brain.”¹ These brain lesions can be broadly classified as either ischemic or hemorrhagic. While the vast majority of strokes in adults are ischemic and due to atherosclerosis,² strokes in children are more evenly divided between ischemic and hemorrhagic types and are due to a wide range of causes.^{3,4} Unfortunately, due to the relative rarity of strokes in children and clinical presentations that frequently differ from those of most adults with stroke, the diagnosis is often delayed in children.⁵ Increased awareness and understanding of pediatric strokes could lead to more prompt diagnoses and improved emergency department care.

Recognition and Approach

The overall incidence of pediatric stroke is between 2 and 8 cases per 100,000 population per year.^{3,4,6-8} Neonates and infants account for about one third of all pediatric strokes.^{8,9} There are specific risk factors that place children at risk for strokes (Table 44-1).

Ischemic Strokes

Risk factors that place infants and children at risk for ischemic stroke include congenital cardiac diseases, sickle cell disease, arteriopathies, traumatic arterial dissections, and prothrombotic disorders. Approximately 20% to 30% of children with ischemic stroke have a congenital cardiac

disease.⁸⁻¹⁰ Complex cardiac anomalies constitute the greatest risk, but almost any lesion may be implicated. The nature of the lesion is usually known prior to the diagnosis of stroke. Children rarely present with stroke due to previously undiagnosed congenital heart disease. Cardiogenic emboli and polycythemia of cyanotic heart disease predispose to both embolic and thrombotic strokes.

Sickle cell disease is an extremely common cause of pediatric stroke in communities where this condition is prevalent, accounting for up to one third of cases in some studies.¹¹ Approximately 10% of children with sickle cell disease will suffer a stroke at some time before 20 years of age.¹² While the exact pathophysiology remains unclear, anemia, microvascular occlusion, and endothelial damage from sickled cells are all likely to play a role. There is much interest in identifying which children with sickle cell disease are most at risk. The Childhood Arterial Stroke Guideline,¹³ developed by the British Paediatric Neurology Association, recommends annual screening from the age of 3 years for changes in internal carotid artery or middle cerebral artery flow velocity. Approximately 8% of children with sickle cell disease have velocities greater than 200 cm/sec, and children in this group have only a 60% probability of remaining stroke free over the next 40 months.¹⁴ Other risk factors in sickle cell disease are thought to include nocturnal hypoxemia and depressed protein C and protein S levels^{15,16} (see Chapter 127, Sickle Cell Disease).

An increasing number of children with ischemic stroke are identified as having preexisting vascular disease on the basis of conventional or magnetic angiographic studies.^{17,18} In one study of arterial stroke using contrast angiography, 53% of children had arteriopathies.¹⁹ These arteriopathies included arterial dissections and progressive vasculopathies, including moyamoya disease, and a significant number were classified as idiopathic intracranial arterial disease. An episode of preceding cerebral vasculitis is thought to explain some of these cases. It is through this mechanism that varicella-zoster virus is thought to predispose to stroke in the year following chickenpox infection.

Approximately 10% of ischemic strokes in children can be attributed to arterial dissection and subsequent thromboembolism. Intracranial and extracranial vessels may be affected, with trauma more likely to be implicated in extracranial

Table 44–1 Underlying Conditions That Place Children at Increased Risk for Stroke**Cardiac Disorders**

Congenital heart disease
Endocarditis
Cardiomyopathies
Arrhythmias

Central Nervous System Vasculopathies

Congenital lesions
Vasculitis
Traumatic vascular injuries
Idiopathic

Hematologic Conditions

Sickle cell disease
Leukemia
Platelet disorders
Hemophilia
Factor V Leiden
Protein C deficiency
Protein S deficiency
Activated protein C resistance
Prothrombin disorders
Increased lipoprotein (a)
Hypercholesterolemia syndromes

Infectious Diseases
