*The term *metabolic stroke* refers to a range of mitochondrial disorders that produce stroke through disrupting neuronal cellular metabolism directly rather than via a vascular event.

dissections. Trauma-associated dissections most frequently follow trivial head and neck trauma resulting in small intimal tears. The time from traumatic event until onset of neurologic symptoms is highly variable, with the peak risk period being 1 to 7 days.^{20,21} There is a significant male predominance that cannot be explained by trauma alone, suggesting a sex-linked vascular predisposition. In contrast to adults, children with cerebrovascular dissection rarely present with warning symptoms of headache or neck pain in the absence of neurologic deficit. Hemiparesis at presentation is the most common clinical finding.

In addition to nonspecific prothrombotic states associated with conditions including malignancy and hematologic disorders, an increasing number of specific prothrombotic disorders are being recognized.^{22–24} Several factors predispose to sinovenous thrombosis in the neonatal period. Severe birth asphyxia and maternal preeclampsia are common associations. Prothrombotic abnormalities are said to occur in 20% of neonates with sinovenous thrombosis, although the precise role these conditions play in this disorder is uncertain.²⁵

Causes of sinovenous thrombosis beyond the neonatal period are more relevant to the emergency physician. Head and neck infections and systemic illness with dehydration or bacterial sepsis would remove risk factors. Frequent presentations include headache, papilledema, seizures, sixth nerve palsies, and visual disturbances.

Hemorrhagic Stroke

Arteriovenous malformation is the most common cause of hemorrhagic stroke in childhood beyond the neonatal period.¹⁰ Other frequent causes of nontraumatic intracranial hemorrhage include aneurysms, bleeding into tumors, and coagulopathies, including various causes of thrombocytopenia, hemophilia, and von Willebrand’s disease (see Chapter 45, Brain Tumor; and Chapter 130, Disorders of Coagulation). Previously, about 25% of spontaneous intracranial hemorrhages were idiopathic; however, the utilization of better and more extensive investigation has decreased this number to approximately 10%.^{3,26} Small arteriovenous malformations have a greater risk of hemorrhage than large ones, and preceding warning symptoms are less frequently recognized than in the adult population.

Clinical Presentation

Children with stroke are less likely to present with a well-defined neurologic deficit than adults. Subtle isolated single limb weakness, incoordination, and sensory disturbances are often initially attributed to causes other than stroke in young children. Frequently cited alternative diagnoses include presumed soft tissue injury, normal “clumsiness,” and behavioral problems.⁵ Up to a third of children who have had a stroke will have a history of recent events consistent with transient ischemic attacks.⁹ The younger the child, the more likely gross neurologic deficits will be present at the time of diagnosis and earlier subtler signs and symptoms will have been missed.

To some extent, the presentation of pediatric stroke is age dependent. An understanding of the developmental abilities of children at different ages is quite helpful in evaluating children for stroke. Neonates and young infants frequently present with lethargy, coma, and seizures. Older infants and children more often present with hemiparesis or a gross, focal motor deficit. Subtle signs at presentation are generally only appreciated in older children and adolescents.⁹

Diagnostic tests, including imaging studies, are helpful for narrowing the differential diagnosis, confirming the diagnosis of stroke, differentiating hemorrhagic stroke from ischemic stroke, and guiding the emergency department management. By far the most useful tests for establishing the diagnosis of stroke are imaging studies. Particularly useful for identifying hemorrhagic stroke is computed tomography (CT) scanning of the head. In most emergency departments, CT scanning of these children can be performed promptly, especially with the aid of procedural sedation (see Chapter 159, Procedural Sedation and Analgesia). For ischemic strokes, magnetic resonance imaging (MRI) of the brain is usually indicated when CT scanning does not reveal acute hemorrhage. Further imaging, including standard or magnetic resonance angiography, may be helpful to neurosurgical consultants for their management plans.^{27,28} Once a pediatric stroke has been identified, multiple studies may be helpful for the ongoing inpatient evaluation and management of these children.²³ However, for most cases, the results of these studies will not have an impact on emergency department care.

Important Clinical Features and Considerations

Migraine is a condition that warrants specific consideration. Complicated migraines in which the patient presents with

focal neurologic abnormalities may initially be diagnosed as stroke. A classic history with aura or other migraine-associated symptoms is frequently absent in children with migraine headaches.²⁹ The neurologic deficit may last from hours to days and can vary from subtle abnormalities to dense hemiplegia. In cases in which this is suspected, early neuroimaging is still required to exclude a central nervous system vascular event or other intracranial pathology before expectant management may be safely pursued. Further complicating this entity is the possibility of migraine actually causing an ischemic stroke. While accepted in the adult population,^{30,31} the development of cerebral infarction as a consequence of migraine in childhood has not been definitively described. Several small studies, however, support the concept.^{29,32}

Management

For many children suspected of having a stroke, the initial treatment and resuscitation follow the same basic principles as those for other serious medical conditions (see Chapter 9, Cerebral Resuscitation; Chapter 11, Altered Mental Status/Coma; and Chapter 40, Seizures). For children with sickle cell disease and stroke, exchange transfusion is the treatment of choice (see Chapter 127, Sickle Cell Disease). For arteriovenous malformations and leaking intracranial aneurysms, specific treatments such as coil embolization and aneurysmal clipping are performed by pediatric neurosurgeons.^{33,34} For other children, specific acute stroke interventions have not been adequately studied. The use of antiplatelet agents, heparin, low-molecular-weight heparin, anticoagulants, and thrombolytics is not supported by adequate evidence to make any general recommendations.³⁵⁻³⁷ The small case series that do suggest benefit with these therapies tend to focus on prevention of further stroke rather than acute benefits. The conditions with consensus statements supporting the use of anticoagulation are ischemic stroke secondary to arterial dissection and cerebral venous sinus thrombosis.^{13,20} In the absence of any prospective trials, the decision regarding use of any form of anticoagulation needs to be made on a case-by-case basis.

Summary

The delay in recognition and diagnosis of stroke in children contributes to the significant neurologic deficits that are established by the time of presentation. Although the majority of patients experience some improvement, some permanent disability occurs in 50% to 80% of children who experience strokes.^{8,10} Overall mortality is 5% to 10%. Mortality is as high as 21% in cases of hemorrhagic stroke secondary to arteriovenous malformations.^{8,38} Stroke recurrence occurs in 8% of children with a single risk factor and in up to 42% of those with multiple risk factors.³⁹ For most cases of pediatric stroke, there is no evidence-based treatment.

Brain Tumor

Ann Klasner, MD, MPH

Key Points

Brain tumors are the most common solid tumors of childhood.

The diagnosis of a pediatric brain tumor is often delayed due to the insidious onset of symptoms.

A computed tomographic scan of the head without contrast is a useful screening tool for identifying brain tumors in children presenting to the emergency department.

Prompt and early consultation with a pediatric neurosurgeon is indicated once the diagnosis of a pediatric brain tumor has been made.

Introduction and Background

Brain tumors are the most common solid tumors identified in children.^{1,2} Of all cancers, only leukemia is more common than brain tumors. Unfortunately, the presentation of these tumors is often insidious. This frequently leads to a delay in diagnosis.

Recognition and Approach

Pediatric brain tumors represent 16% to 20% of all childhood cancers. Incidence rates range between 2.8 and 4.3 cases per 100,000 children per year.^{1,2} Brain tumors are classified by histology and location within the cranium. Five major histologic categories represent 80% of all pediatric brain tumors: juvenile pilocytic astrocytoma (20%), diffuse astrocytoma (22%), medulloblastoma/primitive neuroectodermal tumor (23%), ependymoma (8%), and craniopharyngioma (7%).² Notably, nearly half of all pediatric brain tumors are astrocytomas. In general, pediatric brain tumors are nearly evenly divided between infratentorial and supratentorial locations, with a small percentage involving multiple locations within the central nervous system. The location of pediatric brain tumors varies by age. More tumors are located in the supratentorial space in the first year of life and in

children older than 10 years.³⁻⁶ The location of the tumor is helpful in predicting and explaining the signs and symptoms with which a child may present.

Clinical Presentation

The clinical signs and symptoms of pediatric brain tumors are dependent on the age of the child, the location of the tumor, and the size of the tumor. In infants, the signs and symptoms are nonspecific and mimic other disorders. The most common presenting signs and symptoms in infants include irritability, listlessness, vomiting, a bulging fontanelle, increased head circumference, head tilt, and behavioral changes.^{3,4} As children age, the signs and symptoms generally become more specific and localizing. Younger children will have bouts of nausea and vomiting, and may complain of headaches. In school-age children and adolescents, the dominant presenting signs and symptoms include seizures, focal neurologic deficits, and ataxia.^{7,8} Supratentorial tumors may compress adjacent structures and produce signs such as vision changes or abnormal eye movements, personality changes, aphasia, and seizures. Children with infratentorial tumors are likely to display signs such as ataxia, hemiparesis, and neck pain due to cerebellar tonsil herniation. Any intracranial tumor may obstruct cerebrospinal fluid flow and cause increased intracranial pressure. These children are likely to present with headache and vomiting early in the course and depressed mental status as the obstruction progresses (see Chapter 42, Conditions Causing Increased Intracranial Pressure).

Specific syndromes associated with brain tumors have been described. For example, a common presentation of pineal tumors is Parinaud's syndrome.⁹ This syndrome is characterized by paralysis of upward gaze, eyelid retraction, convergence-retraction nystagmus, and pupils reactive to accommodation but not to light directly. Another example seen in infants with suprasellar tumors is diencephalic syndrome characterized by failure to thrive, emaciation, increased appetite, and a euphoric affect.¹⁰ This syndrome may also be referred to as Russell's syndrome.¹¹ Diabetes insipidus may arise from suprasellar and third ventricle tumors.¹²

Adult and pediatric brain tumors have several major differences. Adults are more likely to have intracranial metastases from a distant primary cancer. The histologic types of tumors found in children and adults are different. The most

common primary brain tumors in adults are gliomas and central nervous system lymphoma.¹³ The location of the tumors also differs, with posterior fossa tumors being much more common in children. Children derive greater benefit from resection and have increased survival rates with chemotherapy.⁵

The key to evaluating a child suspected of having a brain tumor is neuroimaging. In the emergency department, a noncontrast computed tomographic scan of the head is helpful in identifying ventricular enlargement suggestive of cerebrospinal fluid obstruction. Mass effect with edema may also be identified even if the tumor itself is poorly visualized on the scan. Although not typically obtained during the emergency department evaluation of children suspected of having a brain tumor, a magnetic resonance image of the brain is indicated early in the hospital course.

Important Clinical Features and Considerations

Given the vague, nonspecific, and varied presentations of pediatric brain tumors, the number of conditions on the initial differential diagnosis for these children is long. These conditions include meningitis, failure to thrive, abusive head injury, the ingestion of drugs or toxins, adverse effects from vaccinations, postviral illness, gastroesophageal reflux, subarachnoid hemorrhage, and vascular headache.^{3,14-18} Only one third of pediatric brain tumors are diagnosed in the first month after the onset of signs and symptoms. On average, there is a 30- to 60-day delay in diagnosis from the onset of symptoms.^{1,7,19,20} Two symptoms that are very confusing are headache and vomiting.

Although children with brain tumors may complain of headaches, headaches are seldom due to brain tumors. One study of pediatric headaches found that 7% of cases harbored a serious neurologic diagnosis, but most of these were cases of viral meningitis.²¹ These researchers did not identify any children with brain tumors. In another study of 104 children younger than 7 years with headaches as their main complaint, no brain tumors were identified.²² It may be the case that headaches with a normal neurologic examination are extremely unlikely to be associated with a brain tumor. In a study of 72 children who had headaches and brain tumors, 69 (96%) exhibited focal neurologic or ocular findings.²³ In the setting of a child with a headache, findings suggestive of a brain tumor include a change in the quality or location of the pain, an abnormal oculomotor examination, and an abnormal neurologic examination.^{8,21,23,24}

Just like headaches, many children with brain tumors will exhibit vomiting, but few vomiting children have brain tumors. At the time of initial presentation, 60% to 80% of children with brain tumors will have a history of vomiting.^{1,7,23,25} Unfortunately, vomiting is common throughout childhood and is a feature in many illnesses, including atypical migraines headaches.²⁵ The signs and symptoms associated with vomiting that raise the likelihood of a brain tumor being present include the absence of fever and diarrhea, lethargy that does not improve or worsens with rehydration, a head tilt, and an abnormal neurologic examination.^{17,23}

Lumbar puncture has no role in the initial diagnosis of pediatric brain tumors. However, prior to the correct diagnosis being made, a lumbar puncture may be performed

during an effort to rule out other diagnoses such as meningitis or a subarachnoid hemorrhage. No definitive information exists regarding the risk of brain herniation in the setting of a lumbar puncture being performed on a child with an undiagnosed brain tumor.^{18,26-29} It may be the case that, for children who are stable and have an abnormal neurologic examination, a noncontrast computed tomographic scan of the head prior to lumbar puncture is indicated.³⁰

Management

There is no specific emergency department treatment for pediatric brain tumors. Critically ill children with brain tumors are managed similarly to other critically ill children (see Chapter 11, Altered Mental Status/Coma; and Chapter 42, Conditions Causing Increased Intracranial Pressure). Consultation with a pediatric neurosurgeon is indicated for all newly identified brain tumors. The urgency of the consultation is related to the severity of the child's overall clinical condition. Awake and stable children may require a phone conversation between the emergency physician and the pediatric neurosurgeon to arrange outpatient follow-up. Obtunded children typically require prompt transport to a tertiary care pediatric facility and emergent consultation.

Treatment of pediatric brain tumors includes surgical resection, radiation, and chemotherapy. Treatment choices depend on location of tumor, age of the child, and type of tumor. Surgery provides and may also be either palliative or curative depending on the type of tumor. With the advent of stereotactic biopsy and endoscopy, minimally invasive surgery is now possible. The effectiveness of radiation therapy and chemotherapy to treat pediatric brain tumors has dramatically improved in the last decade. Radiation therapy has witnessed improvements in delivery with focal irradiation and lower dosing options. Chemotherapy is playing an increasingly important role in the care of children with brain tumors as it avoids the risk of radiation injury to the developing nervous system. On average, 25% of patients undergo surgical resection alone, 40% require surgery plus radiation, and 30% require surgery, radiation, and chemotherapy.³¹

The emergency physician may see children with brain tumors at nearly any stage in the disease from making the initial diagnosis to managing serious complications near the end of life. The overall 5-year survival rate for all pediatric brain tumors is approximately 70%. However, there is considerable variation depending on the type of tumor, completeness of excision, and patient age.^{32,33} Up to 50% of survivors have long-term sequelae from either the tumor, the treatment, or both. Almost 45% of patients have one or more endocrine issues, including hypothyroidism, growth failure, delayed puberty, and osteoporosis. These children may be on hormone replacement therapy. Late cardiovascular complications are seen in 18% of survivors, including blood clots, strokes, and angina.³³ Whole-brain radiation has been shown to have deleterious effects on cognitive functioning, with younger children being the most profoundly affected.^{4,31,33-35} Steroid use is fairly routine in the perioperative period. Steroids decrease brain edema, which may exacerbate the neurologic impairment resulting from surgical resection or from the presence of the tumor. The most commonly used steroid is dexamethasone^{5,36} (see Chapter 107, The Steroid-Dependent Child). These children may be on antiepileptic

drugs. They may also have a ventriculoperitoneal shunt (see Chapter 42, Conditions Causing Increased Intracranial Pressure).

Summary

Brain tumors are the most common solid tumor in children. The overall 5-year survival rate is 70%, but there is wide variation in survival based type of tumor, completeness of excision, and patient age. Morbidity from pediatric brain tumors is quite high, with half of the survivors having long-term effects from the tumor, the treatment, or both. Early consultation with a pediatric neurosurgeon is indicated in all cases of newly discovered pediatric brain tumors.

Chapter 46

Disorders of Movement

Martin I. Herman, MD and Barry G. Gilmore, MD

Key Points

Disorders of movement can present to the emergency department as new complaints or as an exacerbation of a known condition.

Without a prior diagnosis, the etiologies of movement disorders are difficult to differentiate.

For children with disorders of movement, the gait is often the most revealing part of the physical examination.

The etiologies of movement disorders in children are diverse.

Selected Diagnoses

- Postinfectious acute cerebellar ataxia
- Acute disseminated encephalomyelitis
- Acute dystonia
- Huntington's disease
- Sydenham's chorea
- Tourette's syndrome

Discussion of Individual Diagnoses

Postinfectious Acute Cerebellar Ataxia

Postinfectious acute cerebellar ataxia is the most common cause of acute ataxia in children.¹ Most cases occur in the second year of life.² Seventy-five percent of patients report an antecedent febrile illness within the 3 weeks preceding the onset of ataxia. About half of the patients will have nystagmus. A staggering gait, dysarthria, and truncal ataxia are the characteristic features.² Peripheral white blood cell counts are expected to be normal. Cerebrospinal fluid studies typically yield a mild pleocytosis with normal protein. A computed tomographic scan of the head will typically be normal. In contrast, magnetic resonance imaging of the head typically shows abnormal signal intensity in the cerebellum, cerebral white matter, or globus pallidus.³ The pathophysiology of postinfectious acute cerebellar ataxia is poorly under-

stood. The offending agent may produce the ataxia via direct invasion of the cerebellar tissues or via an autoimmune-mediated effect.⁴ Cerebral and cerebellar antibodies have been found after varicella infections.⁵ Parvovirus B19 has been associated with cerebellar vascular injuries.⁶ Single-photon emission computed tomography of the head may demonstrate reduced regional cerebellar blood flow.⁷

Treatment is controversial and predominantly supportive. For severe or persistent cases, glucocorticoids and intravenous immune globulin have been used with some success.⁴ Fortunately, most children experience a benign course and recover fully.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis, also known as parainfectious encephalitis, is the most common demyelinating condition in children.⁸ This demyelinating disease of childhood has an acute onset, and children with acute disseminated encephalomyelitis typically present with ataxia, abnormal motor control, and altered mental status. This condition is typically considered a self-limited, monophasic disorder that is thought to be immune mediated⁹ (Table 46-1). The incidence of acute disseminated encephalomyelitis is estimated to be as high as 5 in 10,000 hospital admissions. The association with an antecedent viral infection is reported to be between 54% and 77%. However, the true cause-and-effect relationship has not been definitively established due to the high background frequency of viral illnesses in children.^{8,10-12} The average age of onset is 8 years, with a reported age range of 3 months to 18 years of age. A common reported prodrome is headache, fever, nausea, vomiting, and malaise. There are no clinical, laboratory, or computed tomographic findings pathognomonic for acute disseminated encephalomyelitis. The diagnosis is made based on the neurologic examination and the presence of large, multifocal, hyperdense areas in the brain and spinal cord on T2-weighted magnetic resonance imaging. Electroencephalograms typically reveal nonspecific findings and are not diagnostic. Cerebrospinal fluid findings are also nondiagnostic and may reveal mild pleocytosis.

Acute disseminated encephalomyelitis is thought to be due to an immune-mediated process. Treatment is primarily aimed at modulating the immune response and includes the use of glucocorticoids, intravenous immune globulin, and plasmapheresis. To date there have been no clinical trials that compare the effectiveness of these modalities to each other

Table 46–1 Known Causes of Acute Disseminated Encephalomyelitis

Viral	Bacterial	Immunizations
Hepatitis A virus	<i>Clostridium tetani</i>	Influenza (killed)
Herpes simplex virus	β -Hemolytic streptococci	Measles (live)
HIV		Meningococcal
Human herpesvirus 6	<i>Legionella</i>	A and C
Cytomegalovirus	<i>Mycoplasma</i>	Rabies (killed)
Coronavirus	Rickettsiae	Rubella (live)
Mumps virus		
Varicella-zoster virus		

Abbreviation: HIV, human immunodeficiency virus.

Table 46–2 Causes of Dystonia by Rapidity of Symptom Onset

Acute	Gradual
Carbon monoxide	Ataxia-telangiectasia
Cerebral abscess	Brain tumor
Cerebrovascular accidents	Glutaric aciduria type I
Cisapride	Hallervorden-Spatz disease
Dextromethorphan	Leigh disease
Disulfiram	Mitochondrial disorders
Droperidol	Neonatal hypoxia
Encephalitis	Wilson's disease
Hemolytic-uremic syndrome	
Infantile bilateral striatal necrosis	
Methanol	
Metoclopramide	
Postinfectious	
Promethazine	

or to placebo. This is mostly due to the relative rarity of these cases. Treatment recommendations are usually based on small case series.¹⁰ Response to these interventions has been reported to be rapid and dramatic in many cases, with complete recovery in 57% to 81% of patients.⁸ In general, the clinical outcome is good, with complications mainly involving mild cognitive deficits. Unfortunately, relapses may occur in as many as one third of patients.

Acute Dystonia

Dystonic reactions are characterized by opisthotonus, lateral neck flexion, oculogyric spasm, tightening of the extremities, and pain.¹³ Onset of dystonia may occur acutely or gradually, and the causes are heterogeneous (Table 46–2). Because the causes of dystonia are varied, there is not a single overall approach that is appropriate to these children. The evaluation and management is typically guided by the likely cause based on the history and physical examination. Although clinical experience suggests acute dystonia is relatively rare in children, one of the more common causes is exposure to medications. Commonly implicated medications include dextromethorphan, cisapride, and metoclopramide. Treatment for medication-induced acute dystonia is often accomplished by administering 1.25 mg/kg (up to 50 mg) of intravenous or intramuscular diphenhydramine. Unless there are other extenuating circumstances, children who respond well to the diphenhydramine can usually be dis-

charged home from the emergency department after a short period of observation. Continuing oral diphenhydramine at home for a few days is probably prudent. Coordinating the discontinuance of the inciting medication with the prescribing physician is a reasonable courtesy in many cases.

Huntington's Disease

Huntington's disease is an inherited neurodegenerative disorder that is characterized by movement, cognitive, and behavioral problems. Huntington's disease is autosomal dominant and affects 1 in 10,000 people.¹⁴ Huntington's disease is primarily a disease of middle-aged adults; fewer than 10% of cases are diagnosed in children younger than 20 years of age. The term *juvenile Huntington's disease* is sometimes used to designate these early-onset cases. While adults will often have uncontrolled choreic movements, children are much more likely to manifest rigid akinetic symptoms.¹⁵ The initial presentation of juvenile Huntington's disease is often very subtle and nonspecific, making early diagnosis difficult. Common early symptoms include personality changes, school performance problems, rigidity, slowness, stiffness, an awkward gait, clumsiness, speech difficulties, drooling, frequent choking episodes, and seizures.^{16–19}

There is no specific emergency department evaluation for children suspected of having juvenile Huntington's disease. If suspected, the decision to pursue an inpatient or outpatient diagnostic evaluation for children with suspected juvenile Huntington's disease is made on a case-by-case basis. Because Huntington's disease is a progressive disorder, patients may present for a variety of issues over the course of their disease. Seizures, poorly controllable myoclonus, increased rigidity, feeding difficulties, deteriorating mental status, and complications associated with medications are a few of the reasons a child with known Huntington's disease may present to the emergency department. Coordinating care with the family and the child's neurologist is usually prudent.

Sydenham's Chorea

First described by Thomas Sydenham, MD, in 1685, Sydenham's chorea is a hypotonic, hyperkinetic syndrome, characterized by spontaneous involuntary and uncoordinated movements. Other features may include muscular weakness, frequent falls, dysarthria, difficulty concentrating, impaired writing, slurred speech, and emotional lability.^{20,21} In particular, Sydenham's chorea has been shown to be associated with neuropsychiatric disorders.^{20–22} Sydenham's chorea is currently thought to be part of a somewhat controversial grouping of disorders known as "pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections" (PANDAS).^{23,24} The disorders of movement in Sydenham's chorea are usually bilateral, but hemichorea may be seen in as many as 20% of these patients.²¹ There is a clear relationship between Sydenham's chorea and rheumatic fever. The presence of Sydenham's chorea is one of the major criteria used to clinically diagnose rheumatic fever. Sydenham's chorea is seen in as many as 25% of patients diagnosed with rheumatic fever. School-age children are the pediatric group most commonly affected. A single episode of chorea can last 2 to 6 months.^{22,25,26} If performed, magnetic resonance imaging of the brain typically reveals injury to the caudate nucleus.²⁰ The etiology of Sydenham's chorea is unknown, but an immune-mediated process is likely.²⁰

A variety of treatments for Sydenham's chorea have been tried over the years, including haloperidol, barbiturates, chlorpromazine, benzodiazepines, and valproic acid.^{27,28} Immune modulators such as corticosteroids and intravenous immune globulin have also been tried with variable success. Currently, the most promising treatment is valproic acid, which has been shown to be safe and relatively effective.²⁵ Valproic acid has been shown to both control the motor movements and stabilize mood swings.²⁵

Tourette's Syndrome

Tourette's syndrome is the most common and well-known tic disorder.²⁹ The onset is usually between 2 and 28 years of age, with the peak around 11 years. Tourette's syndrome is characterized by repetitive, stereotypical tics that are intermittent and have a compulsive quality to them. The range of symptoms can be divided between vocal, motor, and behavioral. Boys tend to manifest motor and vocal symptoms, while girls tend to manifest more behavioral symptoms. The most well-known and dramatic of the vocal manifestations is coprolalia, the expression of "dirty" words or phrases. Most patients do not demonstrate this feature. Between 5% and 30% of patients with Tourette's syndrome manifest coprolalia. The vocal tics range from simple sounds to complex phrases or speech patterns such as echolalia (repetition of words) or palilalia (rapid repetition of words or phrases). The motor manifestations may be simple, fast, meaningless muscle movements or they may be slower, stereotyped movements that look purposeful. The behavioral symptoms include those labeled attention-deficit/hyperactivity disorder, obsessive-compulsive disorder, self-mutilation, aggression, and various learning disabilities.³⁰⁻³³

There is no specific emergent treatment for the manifestations of Tourette's syndrome. Coordinated care with the child's neurologist is prudent. Most children essentially "outgrow" their tics, but about 10% of children have persistence and worsening symptoms into adulthood.^{29,34,35}

Peripheral Neuromuscular Disorders

Jay Pershad, MD and Kelly L. Kriwanek, MD

Key Points

Patients with acute-onset neuropathic weakness require a prompt assessment and frequent re-evaluations to determine the risk of developing respiratory failure.

Guillain-Barré syndrome is the most commonly acquired peripheral polyneuropathy seen in children.

The most common peripheral mononeuropathy seen in children involves the seventh cranial nerve (e.g., Bell's palsy).

Neuromuscular blocking agents should be avoided in children with muscular dystrophy if possible.

Selected Diagnoses

- Guillain-Barré syndrome
- Myasthenia gravis
- Mitochondrial disorders
- Complications of muscular dystrophy
- Benign paroxysmal vertigo
- Peripheral seventh cranial nerve palsies
- Optic neuritis
- Spinal muscular atrophy
- Channelopathies

Discussion of Individual Diagnoses

Guillain-Barré Syndrome

Guillain-Barré syndrome is an acute inflammatory demyelinating polyneuropathy that typically appears as symmetric ascending flaccid paralysis with loss of deep tendon reflexes and variable sensory changes. Guillain-Barré syndrome affects children of all ages, but is rarely seen in infants. Guillain-Barré syndrome is the most common cause of acute flaccid paralysis in developed countries. The annual

incidence is 0.5 to 1.5 cases per 100,000 persons younger than 18 years.^{1,2} An acute, seemingly minor infection often occurs 1 to 2 weeks before the onset of Guillain-Barré syndrome.^{1,2} Viruses, Mycoplasma, and Campylobacter are some of the most commonly reported organisms associated with Guillain-Barré syndrome.³ The pathophysiology is thought to primarily involve autoimmune-mediated neuronal tissue injury.

Clinical Presentation

There are two primary types of Guillain-Barré syndrome. The first type is generally referred to simply as Guillain-Barré syndrome or "classic" Guillain-Barré syndrome. Children with this syndrome present with ascending, symmetric weakness that begins in the lower extremities and progresses cephalad. The condition of most patients reaches a nadir within 2 to 4 weeks after the onset of symptoms.⁴ Pain and ataxia can be prominent symptoms of childhood Guillain-Barré syndrome.^{2,5} The hallmark of the disease is depressed or absent deep tendon reflexes. The absence of such reflexes helps to identify early Guillain-Barré syndrome, especially in preverbal children whose symptoms can be mistakenly attributed to a musculoskeletal disorder or a primary cerebellar disorder. Paresthesias, dysautonomia, bilateral involvement of facial nerves, and rapid progression to respiratory failure may be observed early in the course of the illness. The second type is generally referred to as the Miller Fisher syndrome, the Fisher syndrome, or the one-and-a-half syndrome. This syndrome is characterized by areflexia, ataxia, and external ophthalmoplegia without motor weakness. In children with this syndrome, the symptoms may begin with the cranial nerves and progress caudally.

Autonomic dysfunction is commonly seen in children with Guillain-Barré syndrome. The typical manifestations of this condition include orthostatic hypotension, urinary retention, paroxysmal hypertension, and arrhythmias. Specific therapeutic intervention is only required for hypertension in the presence of end-organ damage. Respiratory insufficiency requiring airway management may result from three underlying pathophysiologic processes: inadequate inspiratory effort due to weakness of intercostal muscles and the diaphragm; bulbar paralysis; and hypoxemia due to ineffective cough, atelectasis, or poor clearance of secretions

from the airways. Peripheral muscle strength may not correlate with diaphragmatic weakness. If endotracheal intubation is undertaken, dysautonomia and bradyarrhythmias may be encountered during airway manipulation. Hypotension may be exaggerated by the use of conventional sedative-hypnotic agents. Generous application of topical anesthesia, pre-emptive use of vagolytic agents (e.g., atropine) and titration of benzodiazepines may be the most appropriate adjunctive measures to facilitate endotracheal intubation in these children (see Chapter 3, Rapid Sequence Intubation). Judicious use of opiate analgesics for ongoing pain is also beneficial.

The differential diagnosis of rapid ascending peripheral motor weakness includes tick paralysis, food-borne botulism, and ciguatera. Tick paralysis results from inoculation with toxin from a tick's salivary glands during its blood meal. Signs observed during neurologic examination mimic those of Guillain-Barré syndrome, including the progression to respiratory failure. Constitutional symptoms are rare in tick paralysis. Removal of the attached tick results in prompt reversal of the paralysis. Food-borne botulism is commonly characterized by nausea and emesis that precede acute neuropathic weakness. Unlike classic Guillain-Barré syndrome, botulism is associated with oculobulbar weakness, a descending pattern of paralysis, dilated and poorly responsive pupils, and prominent autonomic involvement (e.g., dry mouth, constipation, urinary retention). Mentation is typically normal in cases of botulism. Ciguatera is caused by the consumption of fish containing ciguatoxin in their tissues. Commonly implicated fish include grouper and snapper. Vomiting and diarrhea typically ensue several hours after ingestion of the contaminated fish, and the condition progresses to generalized itching, myalgias, weakness, and dysesthesias of the perioral area and the lower extremities. Ciguatera is a self-limited illness that does not typically lead to respiratory failure. There is no known specific therapy for ciguatera.

The diagnosis of Guillain-Barré syndrome is based on the presence of the typical clinical features of weakness, areflexia, and sensory disturbances. Cerebrospinal fluid studies and electromyography may be helpful in supporting the diagnosis. The cerebrospinal fluid protein concentration is typically elevated in the absence of pleocytosis.

Management

All patients with suspected Guillain-Barré syndrome require hospital admission until the maximum degree of disability has occurred. Dysautonomia and impending or actual respiratory failure warrant intensive care monitoring. There is currently insufficient evidence concerning treatment modalities for childhood Guillain-Barré syndrome to warrant any evidence-based recommendations. Data extrapolated from adult studies suggest that plasma exchange and intravenous immune globulin therapy are effective treatment for severe disease. When initiated within 2 to 4 weeks of symptom onset, intravenous immune globulin therapy and plasma exchange seem to have equivalent efficacy.^{6,7} Corticosteroids do not appear to be effective in treating Guillain-Barré syndrome.⁸

Mortality due to childhood Guillain-Barré syndrome is rare. It is a self-limited illness in which spontaneous recovery usually begins within 3 to 4 weeks after symptom progression ceases. Most children (90% to 95%) achieve a complete functional recovery within 6 to 12 months.² Factors associ-

ated with a poor prognosis include rapid progression of symptoms, the need for ventilatory support, severely reduced action potential of muscle on an electromyogram, recent *Campylobacter jejuni* enteritis, recent cytomegalovirus infection, and poor recovery of motor function at 8 weeks after diagnosis.⁹ There is an increased risk of long-term deficits in children younger than 9 years of age and those who have progression to maximal weakness within 10 days of disease onset.¹⁰

Myasthenia Gravis

Myasthenia gravis is an autoimmune disorder of the neuromuscular junction caused by circulating antibodies directed against the acetylcholine receptor (Table 47-1). This leads to a deficiency of acetylcholine at postsynaptic neuromuscular junctions. The clinical hallmark of myasthenia gravis is fluctuating, painless, asymmetric weakness that most often affects ocular, lower bulbar or proximal limb musculature. Fatigability of voluntary muscles with repetitive motion is essentially diagnostic. Mentation, sensation, pupillary response, and tendon reflexes are characteristically spared. Weakness of neck flexors parallels bulbar and respiratory muscle weakness.

Clinical Presentation

The three forms of myasthenia gravis affecting children are the juvenile form, neonatal form, and congenital form. Juvenile myasthenia gravis accounts for 10% to 15% of all myasthenia gravis cases and is the most common form in children.¹¹ Juvenile myasthenia gravis occurs in children older than 12 months. Unlike the adult form, which more commonly affects women, prepubertal boys and girls are equally affected. The clinical course of juvenile myasthenia gravis is variable

Table 47-1 Anatomic Site of Derangement in Peripheral Neuromuscular Disorders

Anatomic Site	Condition

*May present as rapidly progressive weakness.

[†]Preexisting symptoms or chronic disease.

^{††}Fluctuating weakness.

and is characterized by exacerbations and remissions. As many as 14% to 30% of children diagnosed with myasthenia gravis will experience a spontaneous remission.^{12,13} The younger the child is at the time of diagnosis, the higher the likelihood that complete, lifelong remission will occur. Adolescents are likely to have symptoms continue into adulthood.

Neonatal myasthenia gravis occurs in approximately 20% of infants born to mothers with myasthenia gravis.¹⁴ The pathophysiology is based on passive transfer of maternal antibodies across the placenta. The typical presentation is in the first 72 hours of life, with nonspecific signs and symptoms including hypotonia, poor suck, a weak cry, facial weakness, and respiratory difficulties. Neonatal myasthenia gravis is a self-limited disorder. Weakness usually resolves within the first 2 to 3 weeks of life, but may last as long as 12 weeks.¹¹ Treatment with cholinesterase inhibitors (e.g., pyridostigmine bromide) may be required while awaiting full recovery.

Congenital myasthenia gravis is a heterogeneous group of nonimmune, hereditary illnesses arising from presynaptic, synaptic, and postsynaptic molecular defects. Symptom onset occurs in the neonatal period or early childhood, and symptoms persist throughout life. Common presenting signs are ophthalmoplegia, ptosis, myopathic facies, and mild generalized weakness. Patients with congenital myasthenia gravis do not experience myasthenic crises. Diagnosis is made by a response to cholinesterase inhibitors or a decremental response to repetitive nerve stimulation in limb muscles. It is difficult to differentiate congenital myasthenia gravis from the juvenile form.^{15,16} Children with congenital myasthenia gravis show a more variable response to cholinesterase inhibitors than do children with juvenile myasthenia gravis.

The most dangerous complication of myasthenia gravis is a myasthenic crisis leading to respiratory failure. Precipitating factors include medication changes, infections, surgery, stress, aspiration, hypokalemia, and pregnancy.^{17,18} The most common cause of a myasthenic crisis is a change in medications. Children demonstrating weakness of the bulbar or respiratory muscles require admission to an intensive care unit in anticipation of respiratory failure if it has not occurred already. Differentiating a myasthenic crisis from a cholinergic crisis due to excessive dosing of cholinesterase inhibitors is often difficult. During a myasthenic crisis, it is prudent to discontinue all medications and treat precipitating factors if possible. Certain classes of medications that affect neuromuscular transmission require cautious use in children with myasthenia gravis. These include aminoglycosides, lidocaine, β -blockers, and neuromuscular blocking agents. Increased airway secretions from cholinergic excess may complicate rapid sequence intubation.

The definitive diagnosis of myasthenia gravis is based on the typical clinical features, a positive edrophonium or neostigmine test, repetitive nerve stimulation, single fiber electromyography, and an acetylcholine receptor antibody assay. The edrophonium test is commonly called a “Tensilon test” based on a brand name preparation of edrophonium. In this test, edrophonium, a short-acting cholinesterase inhibitor, is administered intravenously (0.2 mg/kg to a maximum of 10 mg) after a small test dose (0.04 mg/kg). Atropine must be immediately available to treat a potential cholinergic crisis. Muscle strength is evaluated before and after injection. If

weakness is transiently improved, the edrophonium test is considered positive and consistent with the diagnosis of myasthenia gravis.

Management

Treatment of myasthenia gravis is initiated with a cholinesterase inhibitor. Although this treatment will provide symptomatic relief, the course of the disease is not altered. Pyridostigmine is the preferred cholinesterase inhibitor due to its relatively long duration of action and muscarinic side effect profile. Although thymomas are less commonly seen in children compared with adults, thymectomy is widely used as a treatment option for myasthenia gravis. An evidence-based review concluded that thymectomy offers an increased likelihood of remission or improvement.¹⁹ The greatest effect is seen when the thymectomy is performed within the first 2 years of symptom onset.²⁰ Clinical improvement may be delayed for months to years after the surgery. In prepubertal-onset disease, thymectomy is recommended as second-line therapy if cholinesterase inhibitors fail. Other medications that may be used in patients with myasthenia gravis include corticosteroids, azathioprine, cyclophosphamide, cyclosporin A, and mycophenolate mofetil.²¹⁻²³ Immunosuppressive therapy is less frequently used for children with onset of disease before puberty. For adolescents and young adults, corticosteroids induce remissions in 50% to 80% of cases.²¹ Symptom exacerbation is frequently noted after starting treatment with corticosteroids, and this may prompt an emergency department visit. Azathioprine, cyclophosphamide, cyclosporin A, and mycophenolate mofetil have been used as adjunctive, steroid-sparing agents.^{22,23} For short-term therapy in patients with acutely worsening symptoms of myasthenia gravis or refractory myasthenia gravis, or as preoperative preparation, plasma exchange and intravenous immune globulin have been shown to provide improvement within a week. Effects from these treatments may last as long as 2 months. Randomized, controlled trials comparing plasma exchange with intravenous immune globulin demonstrate equal efficacy, but intravenous immune globulin has fewer side effects.^{24,25}

Mitochondrial Disorders

Mitochondrial encephalomyopathies are a group of clinically, genetically, and biochemically heterogeneous disorders caused by a defect in the oxidative phosphorylation pathway of the respiratory chain. In general, organs that consume relatively large amounts of oxygen, such as the skeletal muscle, brain, and heart, are dominantly affected. The worldwide incidence is one case in 10,000 live births.²⁶ Mitochondrial disorders are in the differential diagnosis of encephalopathy, failure to thrive, neurodevelopmental delay, hypotonia, apparent life-threatening events, seizures, unexplained lactic acidosis, and cardiomyopathy. Although the clinical features of mitochondrial disorders vary, their predominant signs are cardiomyopathy and nonspecific encephalopathy.

Classic phenotypic syndromes associated with mitochondrial DNA mutation have been described but are uncommon in pediatric mitochondrial diseases. Most pediatric mitochondrial diseases fall outside of these well-described syndromes. These syndromes are best known by their abbreviations and include MELAS (*mitochondrial encephalopathy*

with lactic acidosis and stroke-like episodes); MERRF (*myoclonic epilepsy with ragged red fibers*); LIMD (*lethal infantile mitochondrial disease*); NARP (*neuropathy, ataxia, and retinitis pigmentosa*); and MNGIE (*mitochondrial neurogastrointestinal encephalomyopathy*). Other named mitochondrial disorders emergency physicians may encounter include Leber's hereditary optic neuropathy, Kearns-Sayre syndrome, necrotizing subacute encephalomyelopathy (Leigh disease), and Pearson's syndrome. Definitive diagnosis requires an integrated approach incorporating clinical, pathologic, enzymatic, molecular, and metabolic criteria.²⁷ Life expectancy for most patients with a classic mitochondrial syndrome is 5 years or less. Patients with noncardiac phenotypes have somewhat better survival rates.²⁸

Complications of Muscular Dystrophy

Muscular dystrophies are a group of chronic, progressive, genetically determined disorders characterized by cellular degeneration of muscle. These disorders are characterized by muscle atrophy without nervous system derangements. There are a number of muscular dystrophies, including Duchenne's muscular dystrophy, Becker's muscular dystrophy, Emery-Dreifuss muscular dystrophy, limb-girdle muscular dystrophy, facioscapulohumeral muscular dystrophy, myotonic dystrophy, oculopharyngeal dystrophy, distal muscular dystrophy, and congenital muscular dystrophy. These disorders differ in the age of onset, the order in which muscle groups are affected, the degree to which cardiac involvement is expected, the rate of symptom progression, and life expectancy.

There are four major clinical "pearls" associated with the emergency department management of children with muscular dystrophy. First, glucocorticoids are used to treat children with muscular dystrophy. For those children on chronic steroid treatment, adrenal suppression and an overall immunocompromised state should be assumed (see Chapter 107, The Steroid-Dependent Child). Second, when respiratory failure occurs, the use of neuromuscular blocking (i.e., paralytic) agents should be avoided. If used, prolonged neuromuscular blockade may occur. Succinylcholine, in particular, should be avoided in these children due to the increased risk of malignant hyperthermia.²⁹ Third, rhabdomyolysis with myoglobinuria may be present and suggests an intercurrent infection or excessive physical exertion.³⁰ Fourth, cardiomyopathies are associated with many of the muscular dystrophies. Cardiomyopathy associated with tachyarrhythmias, congestive heart failure, and cardiomegaly occurs in 50% to 80% of these children at some time during their disease course.³¹ Supportive care in an intensive care setting is indicated. The overall clinical course of the muscular dystrophies is generally slow but progressive. The cause of death in these children is often intractable congestive heart failure or an overwhelming infection.

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo typically develops in children between 1 and 3 years of age. This disorder is characterized by a sudden onset of unsteadiness, pallor, and anxiety. These may manifest as the child falling or refusing to walk or sit. The verbal child may describe a spinning sensation. Throughout the episode, consciousness is preserved. The physical examination often reveals no abnormalities except the horizontal nystagmus that occurs during an attack of vertigo.

Episodes are brief, typically lasting between 1 and 5 minutes.³² Symptoms are expected to recur and may occur daily or monthly, but typically resolve within 2 years of the onset of symptoms. Between episodes, these children are asymptomatic. Benign paroxysmal vertigo is thought to be a migraine equivalent³³ (see Chapter 41, Headaches). Many children with benign paroxysmal vertigo have a family history of migraine headaches and are thought to be at high risk for migraine headaches later in life. Benign paroxysmal vertigo is a diagnosis of exclusion and has a benign, self-limited course. Treatment is supportive.

Peripheral Seventh Cranial Nerve Palsies

Peripheral cranial nerve VII palsies are caused by lesions in the facial nerve nucleus in the brainstem or in the extra-axial portion of the nerve. The result is partial or complete paralysis of the forehead and lower facial musculature. Because of this innervation, cranial nerve VII is also known as the facial nerve. Peripheral cranial nerve VII palsies can be clinically differentiated from a cortical lesion in the brain by the weakness or paralysis in the forehead. A brain lesion would spare the forehead. The first step in the emergency department evaluation of a child with a suspected peripheral cranial nerve VII palsy is to evaluate the motor function of the forehead. If the forehead musculature is weak or paralyzed, peripheral nerve palsy is confirmed. If the forehead musculature appears normal, a central process is likely and the child should be evaluated for stroke (see Chapter 44, Central Nervous System Vascular Disorders).

The facial nerve has motor, sensory, and autonomic components. The motor component controls the muscles involved in facial expression and the stapedius muscle (which protects the middle ear from damage due to loud noises). The sensory branches provide cutaneous sensation to the auricular canal. The autonomic component consists of the parasympathetic afferents that innervate the lacrimal and salivary glands and the efferent fibers that innervate the anterior two thirds of the tongue. Depending on the portion of the facial nerve that is affected, varying degrees of sound sensitivity and dysfunction in lacrimation, salivation, or taste may be noted. The most common type of isolated peripheral mononeuropathy of cranial nerve VII is idiopathic and is commonly referred to as "Bell's palsy" named after Sir Charles Bell who first described this clinical entity in the early 19th century. The incidence of Bell's palsy is 2.7 cases per 100,000 in children younger than 10 years and 10.1 cases per 100,000 in children who are 10 to 20 years old.³⁴

The history and physical examination should focus on assessing the risk of a secondary cause for the nerve palsy. Unfortunately, high-quality pediatric-specific epidemiologic data are not available regarding Bell's palsy. Some general features are applicable in the study of all age groups who experience Bell's palsy. Although classic Bell's palsy is a mononeuropathy, one third of patients have associated involvement of cranial nerves V, IX, or XII. Systemic illnesses and infections that can cause facial palsy include acute otitis media, mastoiditis, cholesteatoma, Epstein-Barr viral infection, herpes simplex viral infection, Lyme disease, herpes zoster (Ramsay Hunt syndrome), mycoplasma infection, tuberculosis, Guillain-Barré syndrome, myasthenia gravis, lymphoma, leukemia, hypertension, diabetes, and sarcoidosis. In rare circumstances, Bell's palsy can be bilateral,

although one side is usually more involved than the other. The utility of additional testing in cases of an uncomplicated mononeuropathy is probably very limited. Additional testing such as nerve conduction studies and cranial magnetic resonance imaging should be reserved for atypical cases or those in which recovery is not achieved within 4 to 6 weeks of diagnosis. Urgent imaging is probably indicated for those children who have a recent history of head trauma, a systemic illness, recurrent palsies, hypertension, acute otitis media, a parotid mass, bilateral facial nerve weakness, and multiple cranial nerves involved. Recurrent unilateral facial paralysis suggests the presence of a vascular malformation, neoplasia, or Melkersson-Rosenthal syndrome (a rare genetic syndrome occurring in patients younger than 16 years of age and characterized by a fissured tongue and recurrent orofacial edema).

The treatment of Bell's palsy in children is, for the most part, controversial. The least controversial component of care is the associated eye care. Incomplete lid closure can predispose patients to desiccant keratitis, corneal abrasions, and an ectropion (an everted eyelid). The use of artificial tears during the day and the application of a moisturizing ophthalmic ointment in conjunction with eye patching at bedtime are considered helpful in preventing ophthalmologic complications. If eye redness or irritation occurs, ophthalmologic consultation is prudent. In one trial conducted exclusively in children 2 to 6 years old, no benefit from corticosteroid therapy was noted.³⁵ In trials that enrolled adults and children, steroids were effective when treatment was initiated during the first 2 weeks of symptoms.³⁶ Recent data suggest a possible benefit when antiviral drugs (e.g., acyclovir, valacyclovir) are combined with prednisone.³⁷ There are insufficient data about the effectiveness of surgical facial nerve decompression therapy in treating typical Bell's palsy. The prognosis of Bell's palsy in children is thought to be good, as most patients fully recover within 6 months to a year from the onset of symptoms.³⁸

Optic Neuritis

Optic neuritis in childhood presents as an acute loss of central visual acuity, an afferent pupillary defect, and a fundoscopic appearance that resembles papilledema and hemorrhage. Some patients have headache and pain that are associated with extraocular movement. Optic neuritis is bilateral in 60% of pediatric patients. Prior to widespread routine immunizations, optic neuritis was seen following acute infections including mumps, measles, or varicella. The visual prognosis of pediatric patients with optic neuritis is better than that of adults with the same type of neuritis.³⁹ The mean age of children at the time of onset is 9.4 years, with a reported age range of 2.5 to 16 years. Multiple sclerosis may eventually be diagnosed in up to one third of patients with uncomplicated optic neuritis.⁴⁰ Ancillary diagnostic tests include visual evoked response testing and magnetic resonance imaging. Most patients with bilateral disease recover complete visual function. The role of corticosteroid therapy is controversial because it is unknown whether this treatment alters the natural course of optic neuritis.⁴¹

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive disorder caused by degeneration of anterior horn cells in the

spinal cord and brainstem. SMA is the second most common neuromuscular disease of childhood, with an incidence of 1 in 10,000 live births.⁴² The clinical features of SMA include progressive, symmetric weakness and atrophy affecting the proximal muscle groups more than the distal groups, loss of deep tendon reflexes, preservation of sensation, and normal intelligence. Fasciculations, especially of the tongue, are frequently seen. SMA is classified into three types according to age of onset and clinical severity. Type I SMA (Werdnig-Hoffmann disease) is the most severe form and presents within the first 6 months of life with profound generalized muscle weakness, hypotonia, and areflexia. Most patients die within the first 2 years of life from respiratory failure. Type II SMA is the intermediate form, with disease onset before 18 months of age. With supportive care, patients can survive into adulthood. Type III (Kugelberg-Welander syndrome) is the juvenile form of the disease, with onset of symptoms after 18 months of age. These patients may have a near-normal life expectancy. Confirmatory diagnosis requires genetic testing. Electromyography, nerve conduction studies, and muscle biopsy are also helpful for confirming the diagnosis. There is no known cure for SMA. Treatment is supportive. In severe cases, life span may be prolonged with the aid of noninvasive respiratory support or tracheostomy⁴³ (see Chapter 164, Tracheostomy Tubes; and Chapter 165, Noninvasive and Mechanical Ventilation).

Channelopathies

The channelopathies are a heterogeneous group of disorders involving specific ion channel dysfunctions. Many of these disorders occur episodically and affect otherwise healthy, active people.⁴⁴ Diverse clinical entities including migraine headaches, some forms of epilepsy, and cardiac conduction disturbances, such as seen in cases of a prolonged QT interval, are thought to be due, at least in part, to channelopathies.⁴⁴ A subset of these disorders, primarily those involving potassium channels, clinically manifest with episodes of profound muscle weakness followed by complete resolution.⁴⁵

Hypokalemic periodic paralysis is the most common periodic paralysis, having a prevalence of about 1 in 100,000.⁴⁶ The first clinical symptoms typically occur in the first 2 decades of life and are characterized by the onset of muscular weakness usually sparing the facial and respiratory muscles.⁴⁶ Symptoms typically last several hours and resolve gradually. Precipitating factors include prolonged rest after vigorous exercise, ingestion of a carbohydrate-rich meal the day prior to the onset of symptoms, fatigue, stress, and intercurrent viral illnesses.⁴⁶ Medications known to precipitate symptoms include β -agonists, corticosteroids, and insulin.⁴⁶ A low serum potassium level is characteristically identified during periods of weakness. Aggressive intravenous potassium replacement should be avoided in these patients as marked hyperkalemia may develop as the attack resolves. Oral replacement of potassium in the emergency department is often effective in normalizing the patient's serum potassium which, in turn, leads to symptom resolution.⁴⁶

Less common is hyperkalemic periodic paralysis. These children typically develop symptoms earlier in life and may exhibit muscle stiffness or weakness. These children more commonly have facial involvement and may develop respiratory compromise. The continuance of mild activity, the

ingestion of sweets, and the use of inhaled β -agonists may minimize the effects of attacks in these children.⁴⁶

Eye Disorders

Michael C. Bachman, MD, MBA and Neil Schamban, MD

Key Points

Evaluation of the patient with a red eye requires a thorough history and physical examination, including lid eversion and slit-lamp examination when age appropriate.

The physician must differentiate between orbital and preseptal cellulitis by presence of proptosis, limited range of extraocular movements, chemosis, and decreased visual acuity.

Age of patient and presenting symptoms will help determine the etiology of conjunctivitis.

Immediate irrigation is the cornerstone of the management of chemical eye injuries.

Selected Diagnoses

- The red eye
- Iritis
- Lacrimal duct pathology
- Periorbital and orbital cellulitis
- Hordeolum (stye) and chalazion
- Conjunctivitis
- Chemical injury
- Contact lens complications
- Traumatic eye injuries

Discussion of Individual Diagnoses

The Red Eye

In evaluating a patient with a red eye, a detailed history must be taken, including the onset, presence of pain, photophobia, visual changes, presence of discharge, history of trauma, prior episodes and ophthalmologic history, whether symptoms are unilateral or bilateral, and the use of contact lenses. The physical examination must include testing of visual acuity; extraocular movements; pupil size, shape, and reactivity; presence of photophobia; slit-lamp examination (age appropriate); eyelid inspection with lid eversion; and intra-

ocular pressure measurement. The differential diagnosis of the red eye is summarized in Table 48–1.

Iritis

Inflammation of the iris can occur as a result of blunt trauma to the eye. Nontraumatic iritis is associated with certain diseases, such as ankylosing spondylitis, Reiter's syndrome, sarcoidosis, inflammatory bowel disease, and psoriasis. Infectious causes may include Lyme disease, tuberculosis, toxoplasmosis, syphilis, and herpes simplex and herpes zoster viruses. Iritis has a rapid onset and typically affects only one eye. Signs and symptoms of iritis include pain in the eye, photophobia, tearing, and blurred vision.

Diagnosis is based on slit-lamp examination findings of keratic precipitates (white blood cells on the endothelium) and detection of an increase in the protein content of the aqueous humor evident by flare.¹ Treatment includes cycloplegic drops and ophthalmology consultation.

Lacrimal Duct Pathology

Lacrimal duct inflammation, known as canaliculitis, is uncommon in children. Canaliculitis usually presents with induration and erythema in the medial eyelid and is often coupled with discharge from the involved puncta. The cause is often *Actinomyces israelii*, and the condition may result in stone formation within the lacrimal ducts. In cases without dacryoliths, topical or systemic antibiotics may be adequate treatment. In cases in which stones have formed, punctal dilation, canaliculoplasty, curettage, and antibiotic irrigation become necessary to cure the disease.²

Dacryocystitis results from the obstruction of the flow of tears from the eye through the nasolacrimal duct. Lack of tear drainage results in stasis and accumulation of bacteria and toxins, thus promoting more inflammation. The nasolacrimal system becomes more stenotic, and an abscess forms in the nasolacrimal sac. The mainstay of treatment for dacryoadenitis is application of warm compresses for 15 minutes four times per day to promote drainage and prevent the spread of infection. If the condition does not improve with conservative management, the patient should be referred to an ophthalmologist for incision and drainage.

Periorbital Cellulitis

Periorbital or preseptal cellulitis is an infection of the eyelid and periorbital soft tissues anterior to the orbital septum, a fibrous tissue that arises from the periosteum of the skull and

Table 48–1 Differential Diagnosis of the Red Eye

Diagnosis	Clinical Findings
Blepharitis	Eyelid margin inflammation with erythema, crusting, or scaling. Symptoms include irritation, burning, and itching. Usually bilateral. Two main types are staphylococcal and seborrheic.
Canaliculitis	Mild red eye, usually unilateral. Discharge can be expressed from the canaliculus.
Conjunctivitis	Presence of vascular dilation, cellular infiltration, and exudation. May be allergic, viral, bacterial, or chemical.
Corneal inflammation	May have decreased visual acuity and photophobia, severe eye pain. Fluorescein staining may detect an epithelial defect.
Dacrocystitis	Inflammation of the lacrimal duct resulting in localized pain, edema, and erythema.
Episcleritis	Inflammation tends to be limited to an isolated patch.
Foreign body	Detect abrasions with fluorescein, exclude globe injury by slit lamp, and always evert eyelids to exclude retained foreign body.
Iritis	Presence of perilimbal flush, cells, and flare noted in the anterior chamber during slit-lamp examination; may be decreased visual acuity and photophobia. Usually is unilateral.
Hordeolum	Infection of glands of the lid; can be internal or external.
Subconjunctival hemorrhage	Bright or dark red patches in the bulbar conjunctiva, secondary to injury or inflammation.

continues into the eyelids. Periorbital cellulitis can be secondary to spread from adjacent infectious sinusitis and upper respiratory tract infections (usually children < 5 years of age) or local spread from adjacent facial infections (usually children ≥ 5 years of age), or can result from primary bacteremia (usually children < 1 year of age). *Streptococcus pneumoniae* is currently the primary causative agent of bacteremia resulting in periorbital cellulitis. Other organisms responsible include *Staphylococcus aureus*, *Staphylococcus epidermidis*, and group A streptococcus.³

The patient typically presents with erythema, edema, induration, and tenderness or warmth of the periorbital tissues, but often shows no signs of systemic illness such as fever or leukocytosis. A break in the skin or an insect bite may be noted. It is important to rule out conditions that can simulate periorbital cellulitis, including allergic reactions, severe conjunctivitis, and orbital cellulitis. While preseptal cellulitis is confined to the tissues anterior to the septum, the infection may spread beyond the septum to the subperiosteal tissue and create an intraorbital infection.

Well-appearing children beyond infancy with no systemic signs and mild periorbital cellulitis can be treated with oral antibiotics against gram-positive bacteria (cephalexin, dicloxacillin, clindamycin).⁴ Clinical improvement should be seen within 24 to 48 hours. If the patient deteriorates, orbital cellulitis must be ruled out.

Orbital Cellulitis

Orbital cellulitis is an infection of the orbit itself. Orbital cellulitis occurs

1. As a complication of sinusitis with extension of the infection to the orbit
2. Secondary to penetrating trauma
3. As an extension of a nearby facial infection

Infectious agents include *S. pneumoniae*, nontypeable *Haemophilus influenzae*, *Moraxella catarrhalis*, group A streptococcus, *S. aureus*, and anaerobes. Patients present with signs of periorbital cellulitis and decreased eye movement, proptosis, chemosis, decreased visual acuity, and papilledema. Local complications include abscess formation, optic neuritis, retinal vein thrombosis, and panophthalmitis. Resulting septic thrombophlebitis can lead to meningitis, epidural and subdural abscesses and cavernous sinus thrombosis.

If orbital cellulitis is suspected, a computed tomography (CT) scan of the orbit is indicated. Signs of orbital cellulitis

on CT scan include proptosis, inflammation of the ocular muscles, subperiosteal abscess, or frank orbital abscess (Fig. 48–1). Ophthalmologic consultation is indicated for suspected orbital cellulitis, and an otorhinolaryngology consultation may be necessary when associated with sinusitis.

Patients with orbital cellulitis must receive prompt treatment with intravenous antibiotics. Third-generation cephalosporins and ampicillin/sulbactam are the antibiotics of choice. If the child is penicillin allergic, vancomycin is an appropriate choice.⁵ Inpatient admission is required for frequent monitoring and observation for progression of the infection. When an abscess is present, surgical drainage is indicated.⁶

Hordeolum (Stye) and Chalazion

An external hordeolum or stye is an infection involving the gland of Zeis at the base of the cilia on the eyelid. Patients present with localized lid edema, erythema, and tenderness, and purulent drainage may be noted along the lid margin (Fig. 48–2). A chalazion is an internal hordeolum that results in a chronic granulomatous inflammation of the meibomian glands within the tarsal plate. Patients present with painful swelling and erythema in the body of the eyelid. The chalazion may rupture to the conjunctival surface (Fig. 48–3) or externally to the skin, or become chronic and develop into a nontender, noninflamed mass in the eyelid body. It is essential to perform a thorough eye examination to rule out a foreign body under eyelid.

Management of both styes and chalazions consists of eyelash scrubs with baby shampoo once or twice daily and warm compresses applied for 15 minutes four times daily.⁷ The use of topical antibiotics remains controversial and is not recommended by the American Academy of Ophthalmology.⁸ If a chalazion has not resolved after 4 weeks, ophthalmologic consultation should be sought.

Conjunctivitis

Inflammation of the conjunctiva can be due to various etiologies. The age at presentation and type of symptoms can help in differentiating between the various etiologies (Table 48–2). Special attention must be paid to the presence and quality of eye discharge and the presence of pruritis and pain. The physical examination should include a complete eye examination, visual acuity testing, fluorescein staining, and, if indicated, slit-lamp examination and tonometry. Conjunc-

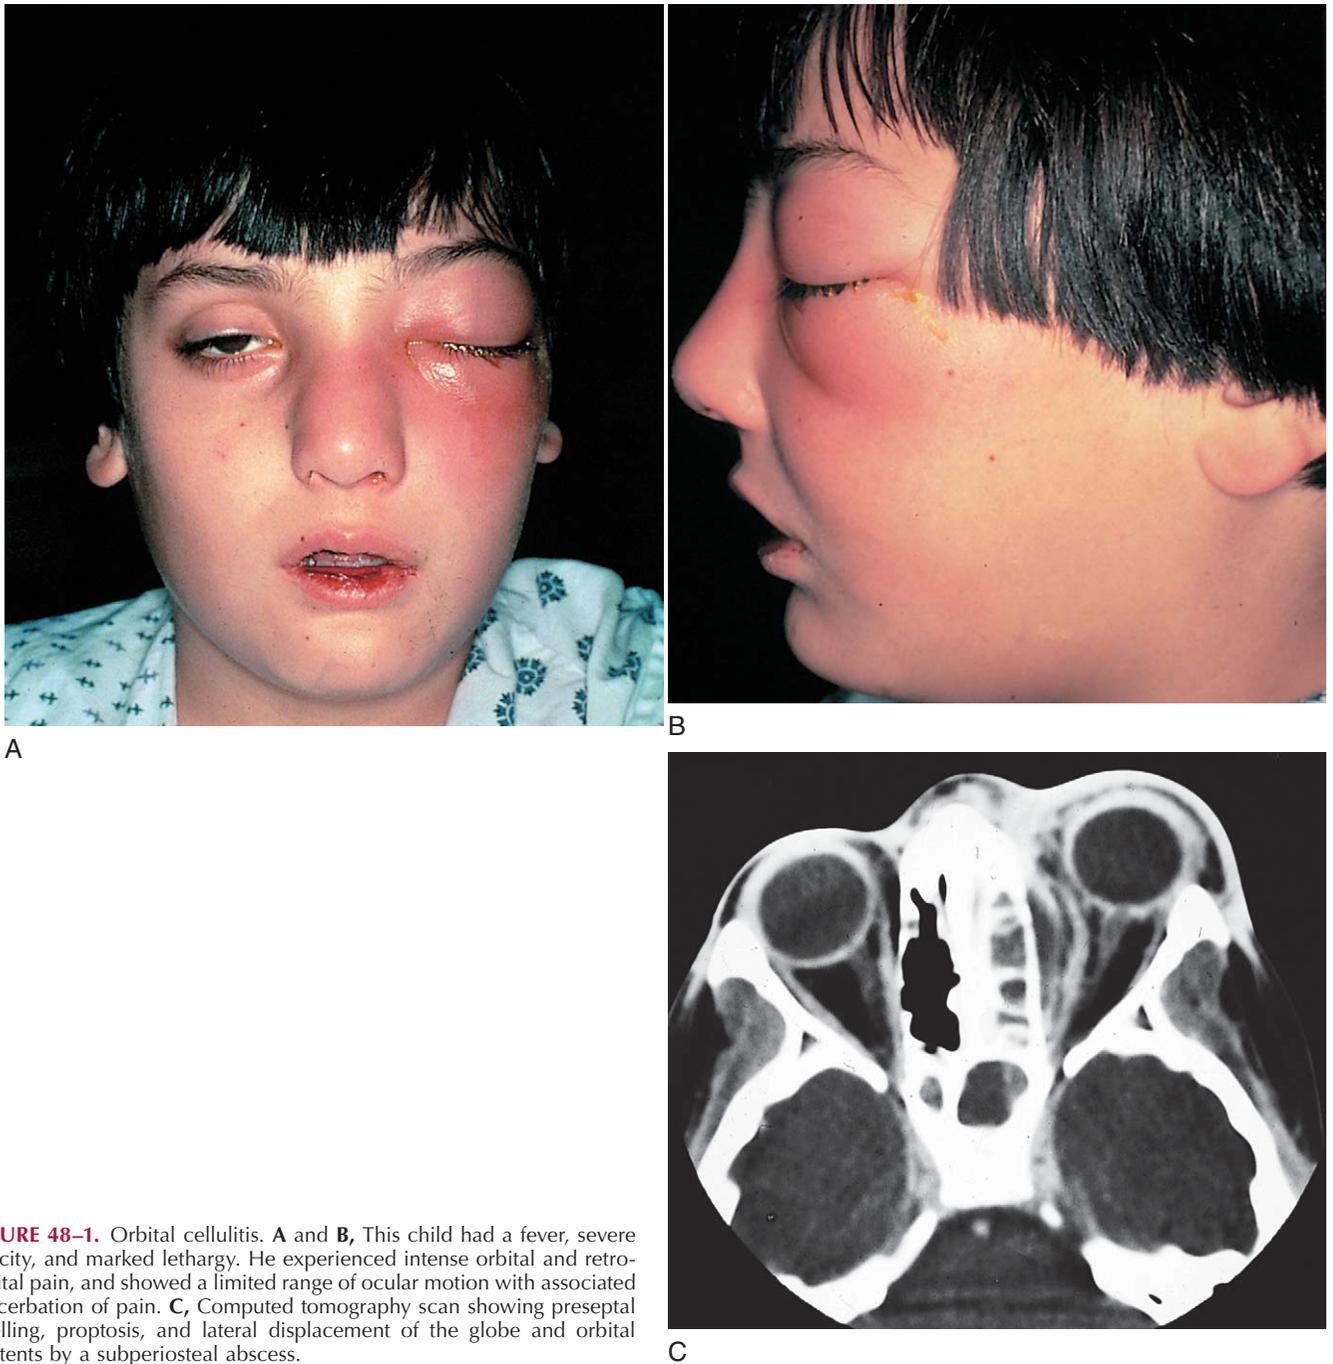

FIGURE 48-1. Orbital cellulitis. **A** and **B**, This child had a fever, severe toxicity, and marked lethargy. He experienced intense orbital and retro-orbital pain, and showed a limited range of ocular motion with associated exacerbation of pain. **C**, Computed tomography scan showing preseptal swelling, proptosis, and lateral displacement of the globe and orbital contents by a subperiosteal abscess.

tivitis is usually diagnosed clinically by history and physical examination. Culture and Gram stain are indicated for those patients with persistent symptoms despite treatment, in all neonates, and when gonorrheal infection is suspected. Chlamydial etiology can be proven with immunofluorescent antibody testing of conjunctival discharge.^{9,10} Treatment is based on etiology of the inflammation¹¹ (see Table 48-2).

Chemical Injury

A chemical injury to the eye is an ophthalmic emergency and must be treated promptly to prevent permanent damage. The severity of the injury is based on the pH of the chemical, the duration of the exposure, and the concentration of the chem-

ical in the involved solution. It is of utmost importance to differentiate between acid and alkali burns. Acid burns tend to be less severe and cause conjunctival erythema, edema, and small hemorrhages. Alkalis, including lime, lye, and ammonia, cause more severe injury than acids. They can destroy the conjunctiva and penetrate the cornea, anterior chamber, and retina. Due to their rapid penetration of the ocular tissue, damage continues long after the injury. A chemical conjunctivitis may also be caused by smoke from house fires. Other common irritants that can cause discomfort include household detergents and pepper spray.¹²

Patients with a chemical eye injury may present with pain, erythema, tearing, difficulty keeping the eye open, a

FIGURE 48-2. Acute hordeolum of the eyelid (pointing externally) with swelling, induration, and purulent contents.

FIGURE 48-3. Chalazion of the left lower lid pointed internally. A pyogenic granuloma consisting of a vascularized mound of conjunctival tissue has developed over the chalazion because of spontaneous rupture under the palpebral conjunctiva.

Table 48-2 Age-Based Etiology of Conjunctivitis		
Etiology	Clinical Findings	Treatment
Neonates		
Silver nitrate	6–12 hours after birth. Erythema, chemosis, eyelid edema, and purulent exudates.	Spontaneous resolution by 24–48 hr
<i>Neisseria gonorrhoeae</i>	2–5 days of life. Thick mucopurulent drainage, tense lid edema.	Ceftriaxone 25–50 mg/kg IV given once; frequent eye irrigation until discharge is eliminated
<i>Chlamydia</i>	5–14 days of life. Mild inflammation to severe swelling with purulent exudates.	Oral erythromycin 50 mg/kg per day in 4 divided doses for 14 days
Herpesvirus	5–15 days of life. Diffuse hyperemia, watery drainage.	Steroids are contraindicated. Immediate ophthalmology consultation for further examination and treatment.
Children		
Viral	Acute or subacute. Thin, seropurulent discharge; marked conjunctival injection. Pruritis is common.	Self-limited but highly contagious. No treatment necessary. Artificial tears may alleviate symptoms.
Bacterial	Acute onset. Minimal pain; thick, purulent discharge. Staphylococcal and streptococcal are most common.	Ointment is better for infants and young children. Choices include bacitracin/polymyxin B, trimethoprim, erythromycin, and ofloxacin.
Chlamydia	Chronic with exacerbations and remissions. History of STD. Minimal discharge and moderate conjunctival injection.	Doxycycline 100 mg twice a day for 10 days or azithromycin 1 g in a single dose.
Gonococcal	Copious mucopurulent drainage.	Ceftriaxone 50 mg/kg (maximum 1 g) IM in a single dose.
Allergic	Acute or subacute. Painless, with moderate injection, clear watery drainage, and significant pruritis.	Cool compresses, lubricants, decongestants (naphazoline), and mast cell stabilizers (cromolyn).
Abbreviations: IM, intramuscularly; IV, intravenously; STD, sexually transmitted disease.		

sensation of something in the eye, eyelid edema, and blurred vision. Immediate irrigation is the cornerstone of the management of chemical eye injuries. Irrigation should commence immediately after a patient has been triaged with a steady stream of eye irrigation solution, normal saline, or lactated Ringer's solution for 15 to 20 minutes. If readily available, topical anesthetic drops should be used prior to and during irrigation. Conjunctival pH should be checked periodically with litmus paper, and irrigation continued until the pH normalizes to 7.0. After completing irrigation, patients should be referred to an ophthalmologist for evaluation and ongoing treatment.¹³

Contact Lens Complications

Contact lens wearers can experience complications affecting the lids, conjunctiva, and cornea. The most prevalent complication is a hypersensitivity reaction to the contact lens solution. This can cause corneal staining and conjunctival injection. Treatment involves removal of the lens, cold compresses, and follow-up with an ophthalmologist. Contact lens wearers can also develop giant papillary conjunctivitis and present with conjunctival injection, mucoid discharge, itching, and blurred vision. Corneal abrasions are common among contact lens wearers. A severe infectious complication in contact lens wearers is bacterial infectious keratitis. Patients

present acutely with pain, photophobia, tearing, purulent discharge, and blurry vision. The most common causative agents are *Pseudomonas aeruginosa*, *S. aureus*, and *S. epidermidis*. Prompt treatment with topical antibiotics is indicated. Use of disposable contact lenses and reduced wearing time have decreased the incidence of these complications.¹⁴

Traumatic Eye Injuries

Conjunctival and Corneal Foreign Bodies

Conjunctival and corneal foreign bodies must be removed. Local anesthetics are useful for detecting the foreign body during a thorough eye examination and allows for removal of the foreign body. However, they should never be given to the patients to use themselves because they slow healing, and the patients may cause further damage rubbing the anesthetized eye.

Small, loose conjunctival foreign bodies can be removed with a cotton-wool bud or irrigated with saline. It is important to evert the upper lid to exclude a subtarsal foreign body, especially if the patient reports the sensation that a foreign body is still present. Lid eversion should not be performed if a penetrating injury is suspected.¹⁵ Corneal foreign bodies may be more difficult to remove. If they are metallic, they may have formed a rust ring that may permanently stain the cornea. They should be removed with a needle tip or rotary drill.¹⁶ These procedures require meticulous care, and these patients should be evaluated by an ophthalmologist.

Corneal Abrasions and Corneal Ulcers

Corneal abrasion, the most common eye injury in children, occurs because of a disruption in the integrity of the corneal epithelium.¹⁷ While corneal epithelial abrasions usually will heal without serious sequelae, deeper corneal involvement may result in epithelial facet formation or stromal scar formation. Symptoms range from mild foreign body sensation with small abrasions to severe pain with larger abrasions. Pain typically starts immediately after the trauma and can last for days, and may be accompanied by photophobia and excessive tearing. Typically conjunctival injection and occasionally eyelid swelling are present. In cases of a significant abrasion, slit-lamp examination reveals a defect in the corneal epithelium. This defect can be confirmed by placing a drop of fluorescein in the inferior fornix. The defect takes up the fluorescein and appears to glow under the blue cobalt light of the slit lamp.

Topical antibiotics are recommended for all corneal abrasion as prophylaxis from developing a bacterial corneal ulcer. Topical fluoroquinolones, ciprofloxacin drops, polymyxin B/trimethoprim drops, erythromycin ointment, bacitracin ointment, and bacitracin/polymyxin B ointment are appropriate choices. Close follow-up care of corneal abrasions is

necessary because of possible progression to an ulcer.¹² Patients with abrasions should receive follow-up care until healing is complete and no staining with fluorescein occurs. Patching has not been found to increase the rate of healing and is not routinely recommended for use in children.¹⁸

Subconjunctival Hemorrhage

Generally, this condition is painless. Vision is not affected. The eye will have a red spot of blood on the sclera (the white part of the eye). This occurs when there is a rupture of a small blood vessel on the surface of the eye. The area of redness may be fairly large, and its appearance is sometimes alarming. It is not dangerous and generally goes away slowly with no treatment.

Chapter 49

Epistaxis

Kenneth B. Briskin, MD

Key Points

Blood supply to the septum is from both the internal and external carotid systems, which affects the approach to management.

Most episodes of epistaxis are anterior and can be controlled with 5 to 10 minutes of direct pressure.

Management of epistaxis in children needs to proceed in a stepwise, organized fashion from local measures to packing to surgical intervention.

Control of significant bleeding should take precedence over a lengthy history.

Universal precautions must be observed at all times, with protective eyewear, gowns, mask, and gloves for all caregivers.

Introduction and Background

Epistaxis is an anxiety-provoking occurrence that affects both patients and parents. Children with acute hemorrhage from the nasal cavity or nasopharynx present with varying degrees of blood loss.¹ Patients may present with intermittent blood streaking or life-threatening hemorrhage. Fortunately, severe epistaxis is rare in children, and in most cases only simple measures are necessary to control the bleeding.² The emergency physician must be ready to quickly evaluate and treat these children in an orderly fashion. He or she needs knowledge of the procedures to control epistaxis and when a referral to an otolaryngologist is indicated. Having an organized, systematic approach will allay the fears of the patient and parents.

Recognition and Approach

Epistaxis can occur at almost any age, but generally first appears at about 3 years of age. Its frequency increases from ages 2 to 10 years and levels off by adolescence.¹ Epistaxis most commonly occurs from the nasal septum, where superficial vessels can become easily exposed with minimal trauma.

The nasal mucosa is adherent to the periosteum and perichondrium on the inside of the nose and provides little support and protection to the overlying plexus of vessels. The most common site of bleeding is in Little's area in the superior area of the anterior septum. Bleeding occurs here in a confluence of richly supplied vessels known as Kiesselbach's plexus.

Epistaxis in children can be very different than in adults. Both children and parents are generally very anxious, making diagnosis and treatment difficult. It is more difficult in children to gauge the amount of blood loss, which tends to be exaggerated. The significantly smaller nasal airway in children makes identification of the bleeding site much more difficult.^{2,3}

Clinical Presentation

Patients with epistaxis present with varying degrees of acuity. Most patients present to the emergency department with active bleeding that does not stop quickly at home. Patients who present early on do so most commonly with anterior, unilateral bleeding. These patients are otherwise normal in appearance, with normal vital signs and laboratory values. Bleeding is most commonly unilateral from the Kiesselbach plexus area of the anterior septum.⁴

Late presentation can include changes in mental status, color, and vital signs.^{3,4} Bleeding from a posterior site must be considered in these cases. Fortunately, posterior epistaxis is rare in children. If bleeding is seen bilaterally, a posterior bleed must be considered. This could be coming from a nasopharyngeal mass, such as a juvenile nasopharyngeal angiofibroma, seen most commonly in adolescent males.⁴ If the patient has a septal perforation, bilateral bleeding may also be present.

Patients with posterior bleeding may present with little anterior bleeding from the nares. There may be significant blood loss that is swallowed, and these patients may only present to the emergency department after vomiting a large amount of blood. A posterior source of bleeding is likely in these cases, and the oropharynx must be examined for blood streaming down from above.^{4,5}

Children most commonly present with a history of local irritation.⁴ This may come from digital trauma. A recent upper respiratory infection or exacerbation of allergic symptoms can cause vasodilation of the nasal mucosa, making this more susceptible to bleeding.

Table 49–1 Etiology of Epistaxis**Local Factors**

Trauma, picking
 Local inflammation: allergic rhinitis, viral upper respiratory infection, mononucleosis, measles, furuncle
 Foreign body
 Rhinitis sicca

Masses

Polyps
 Juvenile nasopharyngeal angiofibroma
 Malignant neoplasms (rare)

Systemic Factors

Platelet disorders: leukemia, idiopathic thrombocytopenic purpura, von Willebrand's disease, uremia
 Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome)
 Hepatic disease
 Vitamin K deficiency
 AIDS
 Drugs: aspirin, NSAIDs, warfarin
 Hypertension

Abbreviations: AIDS, acquired immunodeficiency syndrome; NSAIDs, nonsteroidal anti-inflammatory drugs.

Laboratory studies in cases of epistaxis are dependent on the history and presentation. Often a recent onset of mild acute bleeding requires no blood work at all. However, a history of persistent, intermittent bleeding warrants a complete blood count with platelets and type and screen. If there is any suspicion of bleeding disorders through a history of other unusual bleeding or bruising, tests for coagulopathies and platelet disorders should be included. Initial studies include prothrombin time, partial thromboplastin time, international normalized ratio, and platelet function analyzer (PFA). Radiologic studies are rarely necessary unless a neoplasm is suspected^{1,4-6} (see Chapter 129, Acute Childhood Immune Thrombocytopenic Purpura and Related Platelet Disorders; and Chapter 130, Disorders of Coagulation).

There are many causes of nose bleeds (Table 49–1). Local causes (e.g., nose picking) are the most common. Other causes include facial trauma, neoplasms, foreign bodies, chemical irritants, and inhalation of dry air. Local infections and inflammation (i.e., rhinitis, sinusitis) can lead to epistaxis, but generally only lead to blood-tinged mucus. Foreign bodies can cause unilateral bleeding with a foul-smelling discharge. Iatrogenic causes include nasogastric and nasotracheal tubes.

Episodes of epistaxis can be associated with systemic causes. Coagulopathies, platelet disorders, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), and renal disease are possible causes. Neoplasms associated with epistaxis include intranasal arteriovenous malformations. Juvenile nasopharyngeal angiofibromas are benign neoplasms seen in adolescent males and must be considered in this population.^{7,8}

Many medications can cause epistaxis. Nonsteroidal anti-inflammatory agents, aspirin, and warfarin are commonly associated with epistaxis. Allergy medications, including antihistamines, can dry mucosa, and topical nasal decongestants can irritate mucosa, inducing bleeding. Topical nasal steroid sprays can cause irritation from the medication as well as trauma to the septum from the tip of the dispenser.⁴

Table 49–2 Management of Epistaxis**Local Measures**

Pressure for 5–10 min to lower third of nose
 Anesthetic-vasoconstrictor placed into nasal cavity
 Cauterization with silver nitrate

Packing

Anterior packing
 Self-expanding packs
 Petrolatum-soaked gauze
 Posterior packing
 Nasal balloons
 Posterior gauze/Foley balloon catheter

Surgical Intervention

Nasal endoscopy with electrocauterization
 Endoscopic ligation of sphenopalatine artery
 Transantral ligation of internal maxillary artery
 Ligation of ethmoid arteries

Interventional Radiology

Embolization of external carotid system

Important Clinical Features and Considerations

Patients presenting with epistaxis are very anxious, as are their parents. Many parents have already tried to stop the bleeding with pressure or ice. Parents often try home methods unsuccessfully or put pressure on an ineffective area, such as over the nasal bones. Patients frequently position their heads with the neck extended, swallowing a great deal of blood. Patients will be more comfortable sitting up with their head forward to avoid more blood going down the back of their throat. It is unlikely that a dangerous amount of blood has been lost in an acute bleed; however, hypovolemia must be a concern if the history of when the bleeding started is unclear.

Management

Management of epistaxis should be approached in an orderly fashion (Table 49–2). The initial assessment and physical examination should be performed as described earlier. Immediate management involves positioning the patient in an upright position and providing gauze pads and possible suction for the oral cavity. The obvious initial treatment maneuver is local compression. The thumb and index finger are used to compress the lower third of the nose for 5 to 10 minutes. This will likely slow and possibly stop the bleeding, allowing formation of a hemostatic plug over the bleeding vessel. It also allows the physician time to set up for the next step in management^{9,10} (see Chapter 174, Epistaxis Control).

Cauterization is the next step if bleeding is not controlled or if the bleeding has been recurrent. Topical anesthetic with 2% lidocaine can be combined with a local vasoconstrictor. Cotton pledgets can be soaked in this solution and placed into the nose for 5 minutes. Accurate identification of the bleeding site and a good head light are necessary to successfully control epistaxis by cauterization. Silver nitrate sticks are used to control the bleeding sites. Pressure is applied to the bleeding site with the stick for 10 to 15 seconds. Following this, further pressure can be held on the site with

a cotton-tipped applicator. If silver nitrate gets on the patient's skin, it will leave a black mark that will remain for 2 to 3 days.

When bleeding continues following cauterization, nasal packing is needed. Packing can be very uncomfortable; therefore, topical anesthetic with lidocaine and intravenous sedation may be necessary prior to placement. Many different materials for anterior packing are currently available. They include synthetic sponges that expand when moist and balloons that are filled with saline, putting pressure on the bleeding point. These are quick and easy to insert and can be used for bilateral epistaxis if necessary. The success rate of these packs is over 90% regardless of the extent of experience of the physician.¹¹ A more traditional type of packing is with petrolatum-soaked gauze. Placement of this packing is technically more difficult, but it can provide more pressure than the sponges. After placement of this packing, the oropharynx should be examined for blood trickling down from the nasopharynx. If this occurs, either the packing is inadequate or the bleeding is posterior.

Posterior epistaxis in pediatric patients, fortunately, is uncommon. Packing in the posterior aspect of the nasal cavity can fall into the nasopharynx. Therefore, a pack must be placed against the nasopharynx in such a manner that it will not unravel. Alternatively, balloon catheters are inserted into the nasopharynx via the nostril and filled with saline. Posterior packing is an unpleasant experience for the patient while in place. These patients require admission with cardiopulmonary monitoring and sedation. Packing should be left in place 48 to 72 hours.

Complications with nasal packing exist, but can be easily avoided if anticipated. Infection and toxic shock syndrome are uncommon in the pediatric population, but antibiotics should be used when the packing is in place. The packing can become dislodged or aspirated. Septal perforation and alar necrosis can occur. Nasal-vagal response has been reported with bradycardia, hypotension, hypoxia, and apnea. Therefore, sedation should be kept to a minimum.¹¹

When packing is ineffective, an otolaryngologist should be consulted for surgical intervention. Initial surgical intervention includes nasal endoscopy with direct visualization of bleeding and electrocautery. This is extremely effective in controlling bleeding and can also help when packing is removed, especially in patients with recurrent epistaxis. The sphenopalatine artery can also be identified endoscopically and clipped, controlling most bleeding.¹² More traditional surgical interventions, such as transantral ligation of the internal maxillary artery and clipping of the ethmoid artery, are also possible but rarely necessary.

Interventional radiology has a growing role in the control of persistent epistaxis. The external carotid artery branches can be embolized. This technique, however, is currently used in adults who are at high risk for general anesthesia. The success rate is high, and the procedure can avoid the need for posterior packing.^{13,14}

Summary

Epistaxis is a common clinical problem. Management of nosebleeds in an organized fashion has a high success rate. With proper treatment, the prognosis for these patients is excellent. Patients discharged with packing in place should see an otolaryngologist for removal in 48 to 72 hours. Patients need to be aware that the greatest risk is recurrent bleeding. These cases should be referred to an otolaryngologist for a complete nasal and nasopharyngeal examination.

Rhinosinusitis

Robert Acosta, MD

Key Points

Rhinosinusitis remains a clinical diagnosis.

When used appropriately, antibiotics can reduce the number of symptom days.

Any abnormal neurologic finding in a child with rhinosinusitis warrants a brain imaging study.

Introduction and Background

Sinusitis is the inflammation of one or more of the paranasal sinuses, which include the ethmoid, maxillary, sphenoid, and frontal sinuses. This inflammation can be due to infection, allergy, or anatomic obstruction. The obstruction of the sinus ostia, whether due to infection, allergy, or anatomic malformations (Fig. 50–1), is the common pathway leading to the symptoms and pathology of sinusitis.^{1,2} The term *rhinosinusitis* is considered by many experts to be a more accurate term since the nasal mucosa is almost always involved in sinus infections.³ Rhinosinusitis, based on the duration of symptoms, is further subdivided into acute rhinosinusitis, chronic rhinosinusitis, and recurrent rhinosinusitis.^{1,2} It has been estimated that between 5% and 10% of children with an upper respiratory infection will go on to develop rhinosinusitis.^{2,4}

The etiology of rhinosinusitis can be divided into the following categories: infectious and allergic. Among infectious etiologies, viral causes of rhinosinusitis include rhinovirus, influenza virus, and coronavirus.³ Viral infections cause local inflammation and blockage of the sinus ostia. Additionally, they can disrupt the ciliary function of the sinuses, leading to stasis and subsequent bacterial colonization. Cultures obtained from individuals presenting to an outpatient clinic with signs and symptoms consistent with acute bacterial rhinosinusitis revealed a number of organisms, as reported by the Respiratory Surveillance Program.⁴ The most common bacterial organisms causing rhinosinusitis are listed in Table 50–1.

There is a strong association between rhinosinusitis and allergy. Children with a family history of allergy are at a

higher risk of developing rhinosinusitis.¹ Some authors have considered whether rhinosinusitis and asthma are variations of the same disease.⁵ When an allergen is identified and exposure to that allergen reduced or eliminated, there is a marked decrease in rhinosinusitis symptoms.^{5,6}

Recognition and Approach

The maxillary and ethmoid sinuses form in utero and are present at birth. The sphenoid sinus forms at approximately 5 years of age and the frontal sinuses at 7 to 8 years. This timeline becomes important when considering the clinical symptoms and complications that accompany rhinosinusitis at various ages. Maxillary sinusitis, for example, is more common in younger children than sphenoid or frontal sinusitis.

Clinical Presentation

Acute Bacterial Rhinosinusitis

According to the American Academy of Pediatrics clinical practice guideline on sinusitis, acute bacterial sinusitis is defined as a bacterial infection of the paranasal sinuses that persists less than 30 days.¹ Goldsmith and Rosenfeld defined acute rhinosinusitis as an upper respiratory infection that persists beyond 10 days.³ Ueda and Yoto used the same definition for rhinosinusitis in his study group and was able to demonstrate radiographic proof of sinusitis in 92.5% of patients.⁷ Acute bacterial sinusitis can also be further divided by the severity of the presenting symptoms. Severe symptoms include illness duration of more than 10 to 14 days, fever $\geq 102^\circ$ F, and purulent nasal discharge in an ill-appearing child.¹

The symptoms of an acute rhinosinusitis include nasal discharge, cough, fever, and halitosis. Nasal discharge can be clear or mucopurulent and does not correlate with the severity of disease. Cough is the most common complaint and is classically worse at night. The cough is described as persistent and may be dry or accompanied by copious nasal secretions. Fever is more indicative of a bacterial rhinosinusitis infection, especially when it lasts longer than 3 days and accompanies the rhinitis.³ Children with maxillary sinusitis can present with pain to the upper posterior teeth. Rhinosinusitis can be differentiated from an upper respiratory tract infection (URI) by the worsening of symptoms

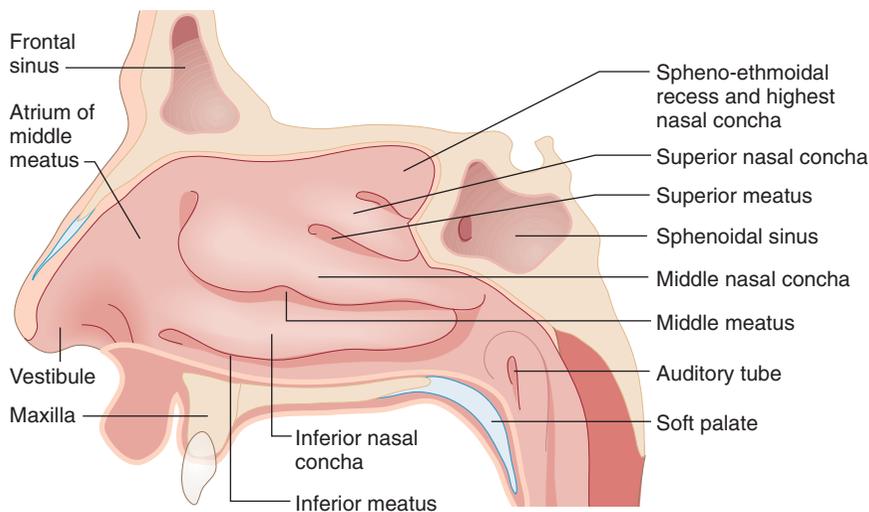

FIGURE 50-1. Lateral view of the nasal passages. (From Williams PL, Warwick R: *Gray's Anatomy*, 36th ed. London: Churchill Livingstone, 1980.)

Table 50-1 Frequency of Organisms in Acute Pediatric Sinusitis	
	Frequency (%)

over time. URI symptoms will usually improve after a week. Most viral URIs have a fever that peaks early in the disease.^{1,3,8}

The physical examination often is of limited value because the clinical findings mimic those of a viral URI. The use of an otoscope to examine the nose is recommended.³ The nasal mucosa should be examined for edematous turbinates, polyps, and foreign bodies. Reproducible facial tenderness on percussion or pressure over the sinuses may be indicative of sinusitis, although complaints of facial pain are not consistent in children.¹

Chronic Bacterial Rhinosinusitis

Chronic bacterial rhinosinusitis is described as an infection of the sinuses that lasts more than 90 days. Symptoms include persistent nasal congestion, cough, nasal discharge, and halitosis. Headache is a more common symptom in chronic rhinosinusitis, and a history of behavioral changes may also be present.³

Important Clinical Features and Considerations

Children with asthma who continue to have persistent symptoms of cough and rhinorrhea despite appropriate asthma therapy may benefit from antibiotic treatment for rhinosi-

nusitis. Resolution of rhinosinusitis in these patients may decrease the number of asthma exacerbations.^{5,6}

Intubated patients or patients with a recent history of intubation are at a higher risk of developing rhinosinusitis. Antimicrobial therapy should be aimed at treating *Pseudomonas aeruginosa*, *Acinetobacter* species, *Escherichia* species, *Enterobacter* species, *Streptococcus* species, and *Staphylococcus aureus*.⁹

Differential Diagnosis

The differential diagnosis for rhinosinusitis includes URI, allergic rhinitis, pneumonia, asthma, nasal foreign bodies and tumors, and immune deficiency (common with human immunodeficiency virus).

Complications

- Frontal sinusitis can result in several complications, including osteomyelitis, intracranial abscesses, meningitis, orbital complications, and dural sinus thrombophlebitis.¹⁰
- Maxillary sinusitis complications include intracranial abscesses, meningitis, and oral abscesses.
- Sphenoid sinusitis may cause complications as a result of compression or bacterial infiltration and involve the internal carotid artery, cavernous sinus, cranial nerve palsy, ocular disease, intracranial abscess, and meningitis.¹¹
- Ethmoid sinusitis has been reported to cause intracranial abscesses, orbital cellulitis, and osteomyelitis.

Imaging Studies

Although rare, children with severe acute and chronic rhinosinusitis are at risk for intracranial pathology. Any child presenting with an abnormal neurologic examination should undergo brain imaging with computed tomography (CT) or magnetic resonance imaging (MRI).¹⁰⁻¹²

Plain Radiography/Sinus Series

These studies have a poor correlation with CT scanning; as many as 75% of them either underestimate or overestimate

disease. Plain radiography is a fairly inaccurate screening method for maxillary sinus disease. Inaccuracies are compounded by mucosal tears, asymmetric facial or sinus development, overlying soft tissue, multiple septal walls, sinus overlap, improper exposure, and head rotation.

Computed Tomography

Thin-cut axial and coronal images of the paranasal sinuses are optimal. A limited number of coronal images alone are used by some as a screening method. Contrast is not necessary for routine sinus evaluation, but it is necessary when a complication such as orbital or intracranial abscess is suspected. The best images for chronic sinusitis are taken at the point of maximal wellness, usually during the last week of a 4-week course of maximal medical therapy. Maximal medical therapy includes appropriate antibiotics and possibly nasal saline irrigations, topical nasal steroids, or decongestants.

A 45% occurrence of incidental sinusitis/opacification has been found on pediatric facial CT scans taken for other reasons. In an asymptomatic patient, no treatment or further workup is necessary. In children younger than 12 years, mucosal thickening or sinus opacification is associated with only a 50% chance of actual sinusitis. During an acute viral URI, the sinuses are routinely opacified on CT scan. In the early stages, URIs do not require treatment with antibiotics.

Anatomic abnormalities, hypoplastic maxillary sinuses, concha bullosa, and changes consistent with cystic fibrosis (e.g., medial displacement of the lateral nasal wall) should be noted on review of CT scans. A thinning of the surrounding bone with wispy areas of calcium density may be observed in patients with allergic fungal sinusitis.

Management

Antimicrobial therapy continues to be the mainstay of the treatment of rhinosinusitis. Because of increasing resistance of bacteria to antibiotics, it is important that treating physicians understand the local resistance patterns in their communities. When used judiciously, antibiotics can decrease the number of symptom days in rhinosinusitis.¹³ First-line drugs for acute bacterial rhinosinusitis are listed in Table 50–2. The duration of treatment is from 10 to 14 days or for 7 days after symptoms resolve.^{1,3,13}

Adjunctive therapy, such as antihistamines, decongestants, and steroids, is controversial, and there are no definitive data concerning their use. Saline drops may help clear the nasal passages and give some comfort to the patient but do not hasten clinical cure.

Overall, imaging has no role in the diagnosis of uncomplicated acute bacterial rhinosinusitis. It may be useful in cases of chronic rhinosinusitis and in those patients who failed medical therapy and for whom surgery is a possibility (Figs. 50–2 and 50–3). Proper positioning of children for radiographs is difficult, and some children may require sedation for CT or MRI.

All patients require re-evaluation after 72 hours to ensure that the antimicrobial therapy is adequate, and that there is no worsening in the patient's condition. Any deterioration in the patient's condition may necessitate a change in the antibiotic regimen.

Table 50–2 First-Line Drugs for Acute Bacterial Rhinosinusitis

Mild to Moderate Rhinosinusitis	Severe Rhinosinusitis or Nonresponder to Initial Antibiotic Treatment
First Line	
Amoxicillin 45 mg/kg <i>or</i>	Amoxicillin/clavulanate 90 mg/kg (amoxicillin component) divided bid
Amoxicillin 90 mg/kg divided bid	
Amoxicillin Allergy	
Cefdinir 7 mg/kg q12h <i>or</i> 14 mg/kg daily	Consider ceftriaxone for those patients unable to tolerate drug by mouth.
Cefuroxime 30 mg/kg divided bid	
Cefpodoxime 5 mg/kg q12h	
Severe Amoxicillin Allergy	
Azithromycin	If hospitalized, the patient should have a computed tomography scan of the sinuses. Obtain otorhinolaryngology consult and consider starting the patient on vancomycin.
Clarithromycin	
Clindomycin	

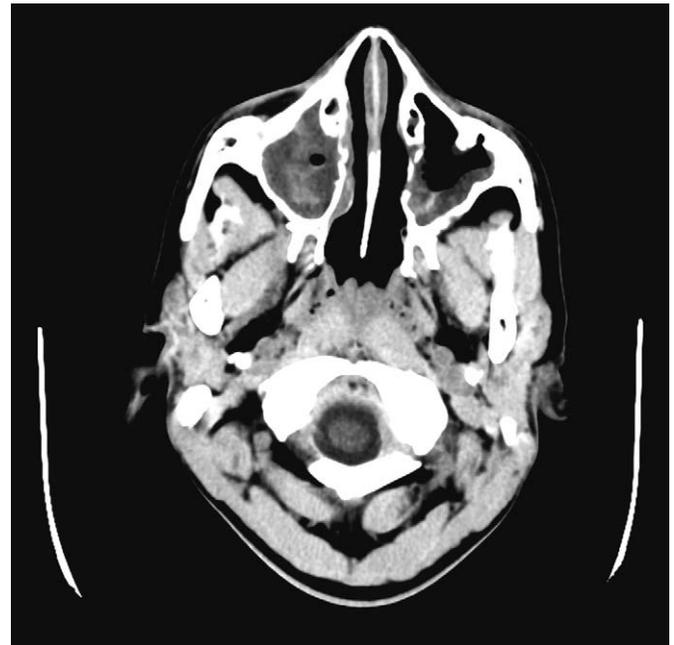

FIGURE 50–2. Computed tomography scan demonstrating maxillary sinusitis (opacified right maxillary sinus).

Summary

Rhinosinusitis affects a large number of children every year. As a result, it is important that clinical criteria be used to decide who has the disease and when to treat. This will decrease the unnecessary use of radiographs and CT scans and allow the appropriate use of antibiotics.

FIGURE 50-3. Computed tomography scan of a child with frontal sinusitis (opacified frontal sinus).

Ear Diseases

Irene Tien, MD, MSc and Miriam Aschkenasy, MD, MPH

Key Points

A healthy child age 6 months to 2 years with a mild illness (fever $< 39^{\circ}$ C, mild otalgia) and an unclear diagnosis, or a child over the age of 2 without severe symptoms or with an uncertain diagnosis, can be observed for 48 to 72 hours without antibiotic therapy.

Otitis externa is generally a localized disease that responds well to appropriate outpatient, topical antibiotic therapy.

The most common causes of vertigo in children are migraine and benign paroxysmal vertigo. Treatment should be directed at the underlying cause.

Facial palsy associated with a vesicular eruption on the ear is diagnostic of Ramsay Hunt syndrome. Treatment with acyclovir is recommended to improve prognosis.

Selected Diagnoses

- Acute otitis media
- Acute mastoiditis
- Cholesteatoma
- Otitis externa
- Vertigo
- Ramsay Hunt syndrome
- Other ear disorders
 - Impacted cerumen
 - Cauliflower ear
 - Barotrauma
 - Complications of ear piercings

Discussion of Individual Diagnoses

Acute Otitis Media

Approximately 90% of children have had acute otitis media (AOM) by the age of 7.¹ Peak incidence occurs during the first 24 months of life, and the prevalence of infection as well as recurrent infection are increasing.²⁻⁴ AOM is an infection of the middle ear that leads to an acute inflammatory response

that may extend to include the tympanic membrane (myringitis). The most common pathogens are viruses, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae* non-type b.^{5,6}

Clinical Presentation

Symptoms can vary slightly with different pathogens but are not predictive of a bacterial versus a viral cause.⁵ In general, older children will complain of ear pain and possibly fever and hearing loss. Vertigo, fullness in the ear, or symptoms of an upper respiratory tract infection may also be associated. Symptoms in young children can be vague, including irritability, inability to sleep, crying, feeding problems, ear pulling, eye discharge, vomiting, diarrhea, and upper respiratory tract symptoms. In infants less than 2 months of age, the most common presenting symptoms are fever, conjunctivitis, and upper respiratory tract symptoms.⁷

Risk factors for AOM include a preceding upper respiratory tract infection or exposure to tobacco smoke; day care exposure, sibling history or history of adenoidectomy for children 6 to 24 months old; history of tonsillectomy if the child is 12 to 24 months old; history of tympanostomy tubes, or if the first attack of AOM occurred at less than 1 year of age.⁸ Findings upon examination of the ear can be variable depending on the age of the child and the course of the infection. The hallmark finding is that of a red, bulging, nonmoving tympanic membrane (TM). In an early infection the only sign may be a red eardrum. The light reflex of the anterior inferior quadrant may disappear, and exudate may be visible behind the TM. Late infection may reveal a ruptured eardrum with draining exudate.

Management

The current management of AOM is controversial.⁹⁻¹² A meta-analysis of the natural history of AOM found that 70% of children had complete resolution of symptoms in 7 to 14 days, with no significant change in the rate of suppurative complications.¹¹ Management of AOM must balance considerations for antibiotic resistance with optimal treatment. The American Academy of Pediatrics (AAP) and American Academy of Family Physicians (AAFP) published clinical practice guidelines that suggest that a healthy child aged 6 months to 2 years with mild illness (fever $< 39^{\circ}$ C, mild otalgia) and an unclear diagnosis, or a child over the age of 2 without severe symptoms or with an uncertain diagnosis, can be observed for 48 to 72 hours without antibiotic

Table 51-1 Treatment Options for Acute Otitis Media (AOM)

Clinical AOM Scenario	Treatment Options
No systemic symptoms, healthy child, and no recurrence in last 30 days Systemic symptoms (e.g., fever)	Observation for 48 hr Amoxicillin <ul style="list-style-type: none"> • low dose (40–45 mg/kg/day divided tid) if low local resistance rates • high dose (80–90 mg/kg/day divided tid) if unknown or high local resistance rates
Severe illness Systemic symptoms, amoxicillin allergic	Amoxicillin/clavulanate (90/6.4 mg/kg/day divided bid) Azithromycin (10 mg/kg/day on day 1 then 5 mg/kg/d × 4 days) Cefdinir (14 mg/kg/day divided qd or bid), cefpodoxime (10 mg/kg/day qd), or cefuroxime (30 mg/kg/day divided bid); if more severe illness, consider ceftriaxone 50 mg/kg/day qd for 1–3 days.
Treatment failure (no improvement after 48–72 hr of antibiotics)	Amoxicillin/clavulanate (90/6.4 mg/kg/day divided bid), ceftriaxone (50 mg/kg/day divided qd), or clindamycin Consider tympanocentesis
Tympanostomy tubes Cochlear implants Otitis media with effusion without symptoms of AOM	Topical 0.3% ciprofloxacin/0.1% dexamethasone otic suspension (4 drops bid for 7 days) No special considerations Watchful waiting, close follow-up, early referral

therapy.¹² If this option is chosen, the child should be re-evaluated within 48 to 72 hours so that antibiotic therapy may begin if needed.¹²

If management with antibiotics is chosen, AAP/AAFP guidelines recommend amoxicillin at 45 or 90 mg/kg per day as first-line therapy in the majority of cases. However, recent studies have shown that local prevalence of nonsusceptible *S. pneumoniae* can help to dictate therapy. Standard-dose amoxicillin is sufficient to treat the majority of cases of AOM.¹³ In cases of high fever (39° C or higher), in which more broad-spectrum coverage is desired, high-dose amoxicillin/clavulanate can be used (Table 51-1).¹²

Therapy for AOM should include pain management. Options include topical anesthetics containing benzocaine or antipyrine or oral agents such as acetaminophen, ibuprofen, or even narcotic analgesia in moderate to severe cases. There is no role for antihistamine or corticosteroid use in the treatment of AOM. Both of these classes of drugs have been shown to increase the duration of middle ear effusion and should be avoided.¹⁴ Children with AOM can be selectively referred for otolaryngology follow-up if they have persistent symptoms or infections or if they are at high risk for recurrence (age < 15 months, prior history of failure of AOM treatment, family history).¹⁵

Important Clinical Features and Considerations

AOM IN THE PRESENCE OF TYMPANOSTOMY TUBES

Children with AOM may present differently if they have tympanostomy tubes in place. The TM is not intact, and the hallmark of infection is usually an acute purulent otorrhea rather than fever, otalgia, or hearing loss. Pathogens also differ in this patient subset, with *Pseudomonas aeruginosa* and *Staphylococcus aureus* becoming more common. Topical ciprofloxacin with dexamethasone otic suspension (4 drops of 0.3% ciprofloxacin with 0.1% dexamethasone twice daily for 7 days) is an effective therapy for AOM in patients with tympanostomy tubes. This approach has been demonstrated to have better cure rates than oral antibiotics or topical ofloxacin alone.¹⁶⁻¹⁹

AOM WITH COCHLEAR IMPLANT

Children with cochlear implants are not at higher risk for AOM, nor do these patients have more severe infections or higher complication rates. Conventional antibiotic therapy has been shown to be effective in these patients.²⁰

SEROUS OM WITH EFFUSION

It can be difficult to distinguish AOM from serous otitis media with effusion (OME). “Otitis media with effusion” refers to a presence of fluid in the middle ear without signs or symptoms of an acute infection. OME can be persistent and result in short- and long-term hearing loss due to decreased movement of the TM and conduction delay.

Diagnosis of OME is best made with pneumatic otoscopy. A cloudy TM with impaired mobility and possibly an air-fluid level in the middle ear, without a history of acute inflammatory symptoms, is suggestive of OME. Redness of the TM alone is not enough to distinguish between AOM and OME.

OME tends to be self-limited and should be watched without intervention for 3 months. Spontaneous resolution is the most likely outcome. OME in children at risk for learning or speech difficulties should receive early referral for evaluation and intervention. There is no role for antihistamines, decongestants, or corticosteroids in the treatment of OME.^{21,22}

Acute Mastoiditis

Acute mastoiditis (AM) is an infectious and inflammatory process of the posterior portion of the temporal bone that can result in osteolysis of the bony trabeculae. This process is often preceded by AOM. The use of sulfa antibiotics decreased the incidence of AM from 0.4% in 1959 to 0.0004% in the 1980s.^{23,24} Because of a recent decline in the use of antibiotics for AOM, there is now evidence of a small rise in the incidence of AM.^{25,26}

AM has presenting symptoms similar to those of AOM, the most common being pain, irritability, and fever. Signs include an abnormal TM, retroauricular tenderness and swelling, protrusion of the auricle, and retroauricular erythema. The

organisms commonly involved in AM are *S. pneumoniae*, *S. aureus*, and *Streptococcus pyogenes*, with *P. aeruginosa* being the most common cause of chronic mastoiditis.^{26,27} Diagnosis can be made with clinical findings and computed tomography demonstrating coalescence of mastoid air cells, subperiosteal abscess, osteitis, or clouding of the mastoid.

Management includes hospital admission and administration of an intravenous cephalosporin (ceftriaxone, cefuroxime, or cefotaxime). Myringotomy, tympanostomy tube placement, and simple or radical mastoidectomy are possible treatment options for complicated cases. Complications from AM can include osteomyelitis, subperiosteal abscess, sinus thrombosis, bacteremia, meningitis, epidural and intracerebral abscesses, cholesteatoma formation, and facial nerve palsy.

Cholesteatoma

The term *cholesteatoma* refers to a sac of stratified squamous epithelium that is filled with exfoliated keratin. This sac grows in the middle ear space and can result in local destruction of the ossicles and conductive hearing loss. Cholesteatomas can occur at any age but tend to be more aggressive in children. Acquired cholesteatomas are the most common type and result from retraction pockets that form in the TM in patients with long-term eustachian tube dysfunction. Otoscopic examination will reveal a white, round, pearly mass behind an intact TM, usually in the anterior superior quadrant of the middle ear. At initial diagnosis, hearing loss is generally not a problem. These patients should be referred to an otolaryngologist for further evaluation as the intervention of choice is surgical.²⁸⁻³⁰

Otitis Externa

Otitis externa (OE), also known as “swimmer’s ear” or “tropical ear,” is an infection or inflammation of the external ear canal. It is caused by a break in the skin in the external ear canal and changes in the canal environment leading to increased moisture and transition from an acidic to a basic pH.³¹ OE occurs commonly in situations of high humidity and warm temperature. Multiple bacterial and a few fungal organisms have been documented to cause OE.³²

Clinical Presentation

OE begins with itching, followed by pain and discharge. Cases may range from simply a painful, edematous canal without discharge to an erythematous and edematous canal associated with a clear odorless secretion, a seropurulent or debris-laden discharge.³¹ The infection also may rarely spread beyond the canal and into surrounding tissues. This is known as malignant OE. This is more common in the elderly and very rare in the healthy child. Pain from OE may also be accompanied by a feeling of fullness in the ear and reduced hearing secondary to canal swelling.

On clinical examination, generally no changes are visible external to the ear, except for discharge. Tender periauricular and preauricular lymph nodes may be palpable. If the child has malignant OE, erythema and edema of the skin adjacent to the affected ear may be visible.³¹ Rarely, facial paralysis, other cranial nerve abnormalities, vertigo, or sensorineural hearing loss may occur.

Pulling the pinna of the affected ear may produce increased pain because the canal skin is closely adherent to the under-

lying perichondrium and periosteum. Direct visualization of the canal will reveal an edematous, erythematous ear canal with thick, clumpy otorrhea. Cerumen will often appear white as opposed to its normal yellow color. The tympanic membrane is often not visible because of canal debris and swelling, but should appear normal.

Important Clinical Features and Considerations

It is important to differentiate OE from furunculosis, AOM with a ruptured TM, and mastoiditis. Furuncles of the ear canal present with a localized swelling originating from the hair-bearing portion of the canal. The swelling associated with a furuncle is localized to a single quadrant, whereas OE is concentric and involves the entire length of the canal.

It may be difficult to differentiate OE from AOM with a ruptured TM because the TM is often not visible due to pain, swelling, and debris associated with OE. Purulent secretions from AOM with a ruptured TM may also cause canal irritation and pain similar to OE. This should be kept in mind when choosing therapy (see “Management” section).

Children with mastoiditis may present with an obliterated postauricular fold, which may help in differentiation from OE. Tenderness over the mastoid bone as opposed to pain with pulling of the pinna may also be helpful in making the diagnosis of mastoiditis.

Complications of OE include ear canal stenosis, cellulitis, chondritis, parotiditis, persistent disease (chronic OE), and necrotizing or malignant OE. This is usually the result of systemic invasion by *P. aeruginosa*, and is very rare in healthy children.

Management

OE is caused by bacteria in a vast majority of cases. In one study of 2240 diseased ears, bacteria were cultured from 98.3% of adults and children with otitis externa.³² Of these, 53% were gram-negative, and 45.3% were gram-positive bacteria (38% *P. aeruginosa*, 9.1% *Staphylococcus epidermidis*, 7.8% *S. aureus*, 6.6% *Microbacterium otitidis*, 2.9% *Microbacterium alconae*). Fungi were isolated in only 1.7% of cases and included only *Aspergillus* and *Candida*.

Topical acetic acid has been used for several centuries to treat OE. Its efficacy is based upon its ability to reduce the pH of the canal environment, which restricts the growth of bacteria and fungi.³³ Acetic acid-containing solutions for treatment of OE are discouraged for many reasons: (1) they are painful to the patient because they irritate inflamed skin, (2) they have been shown to damage cochlear outer hair cells if they come into contact with the inner ear, and (3) treatment for up to 3 weeks may be required for them to be effective.³³

Topical antibiotics are the most common and preferred approach to the treatment of OE. Advantages include the high concentration of antibiotic delivered to the infection site and negligible systemic absorption of antibiotic when applied topically to the ear canal. Maintenance of antibiotic concentrations well over minimum inhibitory concentrations needed for pathogen eradication has been documented for up to 8 hours.³³

The oldest and most common topical antibiotic treatment for OE is a combination drug containing hydrocortisone, neomycin sulfate, and polymyxin B. Clinical studies have documented a clinical cure rate of 87% to 97%, which has

remained consistent over the last 20 years.^{34,35} Despite its proven efficacy, this treatment is associated with a high number of adverse effects, including hypersensitivity to neomycin, hydrocortisone, and thimerosal (a preservative found in one version of this drug) and irritation from propylene glycol (a solvent commonly used in this drug formulation). Eighteen percent to 35% of children who were patch tested have been shown to be hypersensitive to neomycin or thimerosal.³⁶ The redness, pain, and pruritis associated with hypersensitivity or irritation are easily mistaken for treatment failure.

The development of topical formulations of fluoroquinolones has allowed for effective single-drug treatment of OE. In the late 1990s, otic suspension and solution formulations of ofloxacin and ciprofloxacin/hydrocortisone became available. Direct comparisons with the older neomycin-polymyxin-hydrocortisone formulation have demonstrated equivalent efficacy. Clinical studies have shown cures of almost 100% in children treated with ofloxacin or ciprofloxacin twice a day or neomycin-polymyxin-hydrocortisone four times a day.^{34,35} Topical ofloxacin and ciprofloxacin also have the advantage of rarely causing hypersensitivity and being non-ototoxic.

The theoretical benefit of topical hydrocortisone in reducing symptoms associated with inflammation is not well established for OE. One study found that the addition of hydrocortisone to ciprofloxacin reduced the time to resolution of ear pain by only 0.8 day.³⁵ The only OE antibiotic formulation currently available without hydrocortisone is ofloxacin.

Gentle removal of canal debris and insertion of an ear wick prior to instillation of antibiotic drops may improve delivery of the medication. Necrotizing or malignant OE requires treatment with 2 to 3 weeks of intravenous antipseudomonal antibiotics.³¹

Pain management with ibuprofen, acetaminophen, or narcotics is an important part of OE management.

Summary

OE is generally a localized disease that responds well to appropriate outpatient, topical antibiotic therapy. A topical fluoroquinolone is the preferred method of treatment. Topical ofloxacin is preferred when there is the possibility of a TM rupture. OE can result in systemic infection in immunosuppressed children, requiring hospital admission and prolonged intravenous antibiotic therapy. Maintenance of a dry ear canal may prevent OE.

Vertigo

Vertigo is described as a hallucination of motion.³⁷ It is uncommon in children, and the differential diagnosis is broad (Table 51–2).³⁸ Vertigo can originate from central (neurologic) or peripheral (otologic, ophthalmologic) lesions.

Clinical Presentation

The most common causes of vertigo in children are migraine and benign paroxysmal vertigo (BPV).³⁹ It is important to obtain a detailed description of the patient's experience of dizziness in order to correctly classify it as vertigo. In younger children, it may be necessary to base the diagnosis of vertigo on parental description of the child's behavior during the

Table 51–2 Differential Diagnosis of Vertigo in Children

Central Lesions

- Seizures
- Trauma
- Neoplasm
- Infection
- Demyelination (multiple sclerosis)
- Familial ataxia
- Anemia
- Migraine
- Transient ischemic attack, cerebrovascular accident
- Hydrocephalus
- Dandy-Walker syndrome
- Arnold-Chiari malformation

Peripheral Lesions

Otologic

- Otitis media
- Cholesteatoma
- Tympanic membrane perforation
- Placement of pressure equalization tubes
- Perilymph fistula
- Endolymphatic hydrops
- Labyrinthitis
- Retrocochlear tumor or trauma
- Benign paroxysmal vertigo of children
- Vestibular neuronitis
- Benign paroxysmal positional vertigo

Ophthalmologic

- Refractive errors (ametropia)
- Amblyopia
- Latent strabismus
- Convergence insufficiency

Other

- Drugs
- Thyroid dysfunction
- Hypoglycemia
- Functional
- Addison's disease
- Heart disease/arrhythmia
- Hypoperfusion
- Vasculitis

episodes. For example, the child may suddenly stop and cling to a nearby object with a frightened look on his or her face and then cry to be picked up. Older children may simply state something like "I'm falling." Children may become pale or diaphoretic during these episodes. They do not experience a sleepy period after the episodes, nor do they become incontinent or unconscious. Vertigo may last anywhere from a few seconds to a few days.

CENTRAL ORIGIN

Vertigo of central origin is often associated with serious disease.³⁷ Basilar migraines may present with sudden onset of headache, vertigo, and cerebellar signs, including ataxia. A family history of migraines may be helpful in making this diagnosis. Cerebrospinal fluid obstruction by brainstem and posterior fossa lesions may result in hydrocephalus and symptoms associated with increased intracranial pressure in addition to cerebellar symptoms such as ataxia. Neurofibromatosis II is an autosomal dominant disorder characterized by various posterior fossa tumors. These children have sensorineural hearing loss or impaired speech discrimination.

PERIPHERAL ORIGIN

Vertigo of peripheral origin is commonly accompanied by horizontal nystagmus and may be associated with concomitant auditory symptoms. BPV “is a paroxysmal, non-epileptic, recurrent event characterized by subjective or objective vertigo that occurs in neurologically intact children” and accounted for 30.9% of cases of childhood vertigo in one series of 55 children.^{40,41} Age of onset is generally between 2 and 4 years, and BPV presents with a sudden episode of visible anxiety or fear followed by grasping of nearby people or objects for support. Children often ask to be picked up or refuse to stand. Older children may complain that they feel as if they will fall. These episodes may be associated with pallor, nausea, sweating, and sometimes unusual head postures. BPV is thought to fall on the continuum of migraine headache syndromes.⁴⁰ Benign paroxysmal positional vertigo (BPPV), however, is characterized by vertigo resulting from turning the head to a particular position. BPPV most commonly occurs after head injury in children and is believed to be due to displacement of free-floating otoconia into the posterior semicircular canal.⁴² Spontaneous resolution after a few months to years is likely.⁴⁰

Perilymphatic fistulas from disruption of the oval or round window, causing a connection between the middle and inner ear, may also form after head trauma or barotrauma. This generally presents with vertigo followed by progressive hearing loss and may be associated with a temporal bone fracture. Traumatic perilymphatic fistulas are difficult to demonstrate on imaging studies and are often identified on surgical exploration, and require surgical repair.⁴³

Ménière’s disease is an idiopathic condition of excessive endolymph. It presents with spontaneous attacks of prolonged vertigo, fluctuating hearing loss, and tinnitus. It is treated with a low-sodium diet, sometimes a diuretic, and occasionally surgery. Vestibular neuronitis is caused by a viral infection of a ganglion of the vestibular nerve. It presents with sudden onset of severe vertigo, made worse with head movement preceded or accompanied by an obvious viral infection. “Labyrinthitis” refers to an infection and/or inflammation of the labyrinth and cochlea. Children present with vertigo and sudden sensorineural hearing loss.

Management

Treatment of vertigo in children should be directed at its underlying cause.³⁸ The key is to not mistake central for peripheral vertigo. Referral to an otolaryngologist, neurologist, or ophthalmologist for cases in which there is no clear cause of a child’s vertigo is prudent.

Ramsay Hunt Syndrome

Ramsay Hunt syndrome (RHS) refers to an acute facial palsy associated with a herpetic eruption on the auricle. It is frequently complicated by vestibulocochlear dysfunction.⁴⁴ It is caused by reactivation of latent varicella-zoster infection in the geniculate ganglion. RHS is rare in children under 6 years, but older children have an incidence similar to adults. Chickenpox in children under 1 year is an important risk factor for development of RHS.⁴⁴ There is some evidence that the varicella vaccination may be protective against the development of RHS.^{44,45}

Presentation

Children with RHS generally present with milder symptoms than in adults.⁴⁴ Facial palsy may occur without associated herpetic lesions or with development of lesions several days later. In one study, approximately 88.3% of children developed herpetic lesions, half of which appeared simultaneously with the palsy.⁴⁴ RHS may cause hearing loss (24.4%), tinnitus (11.1%), vertigo (17.4%), and paralysis of cranial nerves (CNs) IX and X (extremely rare in children).⁴⁴

Important Clinical Features and Considerations

Differentiation of RHS without vesicular lesions from herpes simplex virus (HSV)–related Bell’s palsy may be difficult. Because HSV is believed to affect only the peripheral CN VII, whereas RHS arises from inflammation of the geniculate ganglion, there is some evidence to suggest that more severe cases of what appear to be Bell’s palsy may be RHS without the associated vesicular eruption.⁴⁵ The prognosis of RHS in children is better than for adults. Complete or near-complete resolution of the facial palsy and of hearing loss occurred in 78.6% and in 83.3% of cases, respectively, in one series of children.⁴⁴

Management

Acyclovir (80 mg/kg per day orally, or 45 mg/kg per day intravenously if the patient is unable to tolerate oral medications) has been shown to improve resolution of the facial palsy and hearing loss associated with RHS.^{44,45} In cases of apparent Bell’s palsy in which RHS is suspected, vigilance must be maintained in watching for the development of vesicles so that acyclovir may be initiated if necessary. The addition of prednisone to the treatment regimen may be beneficial only in severe cases of RHS.

Summary

Facial palsy associated with a vesicular eruption on the ear is diagnostic of RHS. RHS may be mistaken for Bell’s palsy because of delay in the appearance of vesicles or failure of the vesicles to appear. Treatment with acyclovir is recommended to improve prognosis.

Other Ear Disorders

Impacted Cerumen

Cerumen impaction occurs when the normal self-cleansing mechanism of epithelial migration is disrupted. When cotton-tipped devices are used to clean the ear canal, protective layers of keratin are rubbed away, exposing the underlying delicate skin cells. When these cells are exposed to minor trauma, an infection may result, which produces debris that can form the nidus of a wax plug.⁴⁶

Symptomatic impacted cerumen is an indication for removal. Instillation of ceruminolytics to soften the wax prior to removal is generally helpful. Cerumenex, Cerumol, benzocaine otic, aluminum acetate topical, alcohol, and oils may take more than 18 hours to disintegrate cerumen versus 90 minutes for the sodium bicarbonate solutions.⁴⁷ Hydrogen peroxide is another commonly used ceruminolytic, but its use has not been systematically studied. One study found that the liquid preparation of the stool softener docusate sodium (Colace) was much more effective as a ceruminolytic than Cerumenex.⁴⁸ Irrigation of the ear canal

after instillation of a ceruminolytic results in successful removal of cerumen in most cases. Some cases in which cerumen cannot be removed with the use of ceruminolytics or in which the child cannot cooperate adequately for safe removal may require referral to an otolaryngologist for treatment.

Cauliflower Ear

“Cauliflower ear” refers to a disfiguration of the cartilage of the ear generally following infection of a traumatic hematoma of the pinna.⁴⁹ Prompt evacuation of a hematoma of the pinna and prevention of infection is key to avoiding cauliflower ear.

Barotrauma

Barotrauma causes ear injury when the pressure in the middle ear is unable to adequately equalize with pressure external to the ear. This may happen when there is cerumen or a foreign body in the ear canal, although this is uncommon. More commonly, it occurs when there is a dysfunction of the eustachian tube.

Barotrauma to the ear can result in pain, reduced hearing, and vertigo. Rarely, it may result in facial nerve palsy, ossicle fracture or dislocation, or round window rupture.

Management of barotrauma of the ear may include use of vasoconstrictor nasal drops, prevention of pressure changes during an upper respiratory tract infection, use of Valsalva maneuvers to open eustachian tubes, and placement of myringotomy tubes. Traumatic TM rupture generally resolves after 10 to 14 days. If round or oval window rupture is suspected, referral to otolaryngology for surgical correction is recommended.

Complications of Ear Piercing

Infection is one of the most common complications of ear piercing. Although skin organisms are the most likely culprits, *P. aeruginosa* infection should be kept in mind for cases that do not respond promptly to antibiotics. Auricular chondritis can be slow to heal and may require aggressive therapy, including surgical débridement and drainage.⁵⁰ Empirical therapy should include coverage for *P. aeruginosa*.

Differentiation of infection from metal sensitivity may be challenging.⁵⁰ Itching is more likely to predominate over pain when a patient presents with a red ear following piercing. Removal of the stud is recommended.

Summary

Overuse of antibiotics in otherwise healthy children with ambiguous signs and symptoms of AOM/AOE should be avoided. Vertigo in children is uncommon. Peripheral vertigo is usually of a benign cause, whereas central vertigo is more often associated with a serious disease.⁵¹ An appropriate history and physical examination, a logical approach to antibiotic use, and follow-up medical care are three of the most important ingredients for the management of ear disease.

Chapter 52

Oral Lesions

Esther Maria Sampayo, MD

Key Points

Oral lesions may be divided into subgroups: congenital, infectious, tumor, or idiopathic.

Color, location, and history are essential components of determining the correct diagnosis.

Most oral conditions can be classified into the following categories: hyperemia of the oral mucosa, masses, vesicles, or ulcers.

Oral lesions may represent initial signs of systemic disease and life-threatening conditions.

Selected Diagnoses

- Congenital lesions
 - Alveolar and palatal cysts
 - Natal teeth
 - Epulis
 - Lymphangiomas, hemangiomas, and vascular malformations
 - Lingual thyroid
- Infectious lesions
 - Candidiasis
 - Herpes simplex infections
 - Coxsackievirus infections
 - Other infections
- Tumors
 - Pyogenic granuloma
 - Fibroma
 - Mucocele and ranula
 - Rhabdomyosarcoma
- Idiopathic lesions
 - Miscellaneous lesions
 - Recurrent oral ulcers
 - Lesions associated with systemic diseases

Discussion of Individual Diagnoses

Congenital Lesions

Alveolar and Palatal Cysts

Cysts are by far the most common of the congenital oral lesions (Table 52–1). They are caused by epithelial remnants on the palate or gums and are found in over 80% of newborns. Palatal cysts such as Epstein's or epithelial pearls appear as white or yellow keratin-containing cysts in the midline at the junction of the soft and hard palate. As many as three to six lesions measuring less than 3 mm in size can be seen. Alveolar cysts, also known as Bohn's nodules, dental lamina, or gingival cysts, appear on the mandibular or maxillary gingiva and alveolar dental ridges.¹ Palatal cysts are usually larger and less numerous than alveolar cysts; however, the two entities are otherwise clinically identical. The terms *Epstein's pearls* and *Bohn's nodules* are used interchangeably for both palatal and alveolar cysts of the newborns. These congenital lesions are asymptomatic and regress spontaneously within a few weeks or months.²

Natal Teeth

Teeth are classified as natal if they are present at birth or as neonatal if found within the first month of life. This premature eruption of primary teeth is most commonly found in the lower incisor alveolar ridge. Since only 1% to 10% are supernumerary, they only require extraction when there is poor crown formation or they are loose and tooth aspiration is a concern.³

Epulis

Epulis is a firm, fibrous, sarcomatous benign tumor that is usually pedunculated and arises from the alveolar ridge of the mandible or maxilla. Lesions may regress spontaneously; however, they require excision if they are associated with feeding or breathing difficulties or are cosmetically unappealing.⁴

Lymphangiomas, Hemangiomas, and Vascular Malformations

Lymphangiomas are congenital benign tumors of the lymphatic vessels. The most common intraoral site is the tongue. Lesions may also appear on the lips or buccal mucosa. They appear as soft, fluctuant, smooth masses with the color of surrounding tissues.

Table 52–1 Differential Diagnosis of Lesions of the Oral Mucosa

Congenital	Infectious	Tumor	Idiopathic
Alveolar cysts Bohn's nodules Dental lamina cysts Gingival cysts Epulis	Acute necrotizing ulcerative gingivitis (trench mouth, Vincent's angina)	Eruption cyst	Apthous stomatitis
Hemangioma	Candidiasis	Fibroma	Benign migratory glossitis (geographic tongue) Fordyce's granules
Lingual thyroid Lymphangioma	Coxsackievirus Hand, foot, and mouth disease Herpangina	Lipoma	
	Hairy tongue Herpes simplex Gingivostomatitis Labialis	Mucocele Pyogenic granuloma	Gingival hyperplasia Leukoplakia
Natal teeth Palatal cysts Bohn's nodules Epithelial pearls Epstein's pearls	HIV Measles	Ranula Rhabdomyosarcoma	Retrocuspid papillae
	Odontogenic cysts Papilloma Parulis (periapical abscess) Pericoronitis Scarlet fever Syphilis Varicella		

Abbreviation: HIV, human immunodeficiency virus.

Hemangiomas and vascular malformations may appear anywhere in the head and neck area, including the mouth. Clinically, hemangiomas are soft, purplish lesions that blanch with application of pressure and are usually associated with other vascular lesions throughout the body, especially on the skin. Vascular malformations have a bluish hue and should be auscultated for a thrill or a bruit. Hemangiomas are not present at birth. They manifest within the first month of life, exhibit a rapid proliferative phase, and slowly involute to near-complete resolution. Vascular malformations are more stable and fail to regress.

Treatment of lymphangiomas, hemangiomas, and vascular malformations is necessary if lesions cause cosmetic disfigurement, masticatory problems, or respiratory, speech, or swallowing difficulties. Treatment includes steroids, cryotherapy, embolization, sclerotherapy, surgery, and laser therapy.⁵ Furthermore, they may be associated with syndromes such as Rendu-Osler-Weber syndrome, Sturge-Weber syndrome, and Kasabach-Merritt syndrome.

Lingual Thyroid

Of all ectopic thyroids, 90% are found on the lingual dorsum, where they are referred to as lingual thyroid or ectopic lingual thyroid. A lingual thyroid is an asymptomatic nodular mass of the posterior lingual midline, usually less than 1 cm in size but sometimes reaching more than 4 cm. Surgical excision or radioiodine therapy are effective treatments for lingual thyroid, but no treatment should be attempted until an iodine radioisotope scan has determined that there is adequate thyroid tissue in the neck. In those patients lacking thyroid tissue in the neck, the lingual thyroid can be excised and autotransplanted to the muscles of the neck.⁶

Infectious Lesions

Inflammation of the soft tissues in the mouth resulting in mouth sores, otherwise known as stomatitis, is common

in childhood. Viral infections are by far the most common causes of stomatitis—in particular, infections with herpes simplex, Coxsackie, varicella-zoster, and Epstein-Barr viruses. Bacterial infections are rare and mostly secondary to the viral infections. In infants, oral candidiasis (thrush) is a common cause of stomatitis and is treated with nystatin. Most infections have a self-limiting course, and reassurance to the parents is essential. Treatment is supportive. Dehydration is a common complication that can be prevented by analgesics and hydration to avoid hospitalization.

Superficial ulcerations of the oral mucosa may present a diagnostic challenge to the emergency physician because of

FIGURE 52–1. Herpetic gingivostomatitis.

Table 52–2 Oral Ulcerations

Type	Location	Fever	Recurrence
Apthous ulcers	Buccal/labial	No	Yes
Coxsackie herpangina	Posterior pharynx, buccal, tongue, soft/hard palate	Yes	No
Herpes gingivostomatitis	Anterior pharynx, gingiva/hard palate, buccal/labial	Yes	No
Herpes labialis	Labial	Yes	Yes
Vincent's angina (ANUG)	Interdental papillae	Yes	No

Abbreviation: ANUG, acute necrotizing ulcerative gingivitis.

the similarity of one ulcer to another. Many features might help in the differential diagnosis. The age of the patient, time of onset, course of disease, and other associated symptoms are important components of the history (Table 52–2). Furthermore, the physical examination must take into consideration the lesion type (mass, ulcer, or vesicle), location, size grouping, and involvement of other organ systems of the body.⁷ Oral lesions associated with a toxic-appearing child could represent toxic shock syndrome or Stevens-Johnson syndrome.

Candidiasis

Candidiasis is the most common infection of the oral cavity. Candidiasis, also known as thrush, is caused by *Candida albicans* and appears as white plaque on the buccal mucosa, gingiva, palate, and tongue that typically does not scrap off with a tongue blade. When these patches are scraped or rubbed, pinpoint areas of bleeding can be seen underneath. Candidiasis occurs commonly in infants less than 1 year of age; if it occurs at a later age, the immunologic status of the child must be taken into account. Topical antifungal treatment with nystatin suspension or miconazole gel is the treatment of choice. Miconazole oral gel has been studied and found to be more effective than nystatin suspension. Miconazole also has a superior cure rate and a lower rate of recurrence.⁸

Herpes Simplex Infections

PRIMARY HERPETIC GINGIVOSTOMATITIS

Primary herpetic gingivostomatitis (Fig. 52–1) usually occurs in infants and young children. Intraoral infection with herpes simplex virus 1 initially presents with a prodrome of fever, pain, headache, malaise, and odynophagia as the predominant symptoms. Regional cervical adenopathy is also characteristic in the prodrome stage. Subsequently, diffuse pain in the oral cavity and lips may occur, followed by the development of yellowish fluid-filled vesicles located throughout the oral cavity on both mobile mucosa (buccal and labial) and mucosa attached to bone (gingiva and hard palate).⁹ These initial vesicles are rarely seen because they rupture spontaneously and progress to multiple groups of shallow, painful ulcers that are prone to superinfection. Treatment is supportive with analgesics and antipyretics. Topical application of “magic mouthwash,” which consists of diphenhydramine

and magnesium hydroxide, has also been advocated, although evidence does not indicate that it causes faster resolution.^{10,11} Mixtures with lidocaine added have demonstrated toxicity.¹² Acyclovir can shorten the duration of herpetic gingivostomatitis symptoms as compared to placebo. Treatment should be started within the first 3 days of disease onset. The dosage is 15 mg/kg 5 times daily for 5 to 7 days.^{13,14} Lesions usually heal in 1 to 2 weeks. The most common complication is dehydration.

SECONDARY HERPES LABIALIS

Recurrent infections may be expected in 30% to 40% of affected children secondary to latent herpes simplex virus in the trigeminal ganglion. This is manifested by stomatitis in the oral cavity or herpes labialis on the lips, which may recur in less severe form and resolve in 1 to 2 weeks as well. Fever, stress, sunlight, trauma, or fatigue may act as potential triggers. Treatment consists of acyclovir.

Coxsackievirus Infections

HAND, FOOT, AND MOUTH DISEASE

Hand, foot, and mouth disease is caused by enteroviruses and is most commonly associated with coxsackievirus A-16 or enterovirus 71.¹⁵ It primarily affects children under 10 years of age. It is usually seen during late summer and early autumn. This disease is highly communicable and is spread by oral-oral and fecal-oral routes. A brief prodrome of low-grade fever, malaise, cough, anorexia, and abdominal pain may occur.

Ulceration may occur anywhere in the oral cavity, but is most common on the hard palate, tongue, and buccal mucosa. The ulcer evolves from a small erythematous macule, through a papulovesicular stage to a yellow-gray ulcer with an erythematous border. These ulcers may coalesce, the tongue may become red and edematous, and the pain may interfere with oral intake; thus dehydration is the most common complication of this disease.

These lesions are self-limited and resolve without treatment in less than a week. Soon after the oral lesions, an exanthem may develop characterized by small erythematous macules or papules with a central gray vesicle on the hands more commonly than the feet, and on the sides of the fingers and dorsal surfaces of the foot more commonly than the palms and soles. The lesions may be asymptomatic or painful and resolve over 5 to 10 days without scarring.

Although most cases are benign and self-limiting, there are case reports of complications including myocarditis, meningoencephalitis, pulmonary edema, and even death. The Taiwan epidemic of 1998 secondary to enterovirus 71 caused significant morbidity and mortality secondary to neurogenic pulmonary edema.¹⁶

There is no specific treatment for hand, foot, and mouth disease. Current strategies are aimed at providing relief of painful oral lesions to ensure proper fluid intake. Topical anesthetics and analgesics composed of viscous lidocaine, diphenhydramine, and magnesium hydroxide, such as magic mouthwash, have traditionally been used for symptomatic relief, although studies have not demonstrated significant differences in time for the cessation of the signs and symptoms in cancer patients suffering from mucositis.^{10,11} Fur-

thermore some studies have demonstrated toxicity with topical lidocaine.¹² One study of children treated with acyclovir showed symptomatic relief and involution of lesions with 24 hours.¹⁷

HERPANGINA

Herpangina is typically caused by coxsackievirus group A1-6, -8, -10, and -22 serotypes during the late summer and early autumn months. Herpangina affects any age group but is most commonly seen in younger children less than 5 years of age. The prodrome is associated with fever and malaise. Presenting complaints often include anorexia, dysphagia, sore throat, headache, and neck and back pain. Characteristic lesions evolve from papulovesicular lesions to gray-based ulcers with an erythematous border. These are usually found on the soft palate, anterior tonsillar pillars, uvula, and tongue. There is no associated exanthem. These ulcers heal spontaneously in less than a week, and treatment is symptomatic.

Other Infections

Varicella-zoster virus, otherwise known as chickenpox, may have oral manifestations characterized by small bullae along the mucosal surface that rupture easily and become ulcerations that may become superinfected. These lesions also resolve spontaneously with the course of the disease.

Epstein-Barr virus, the etiologic agent of infectious mononucleosis, may also cause an ulcerative stomatitis or gingivitis and soft palatal petechial hemorrhages. These may be seen with the characteristic symptoms of sore throat, malaise, fever, fatigue, and lymphadenopathy.

Scarlet fever, caused by group B streptococcus, may have intraoral manifestations that precede the characteristic sandpaper-textured rash by 1 to 2 days. Exudative tonsillitis is often accompanied by erythematous oral mucous membranes, along with petechiae and punctate red macules on the hard and soft palate and uvula. The most classic presentation is that of a “strawberry tongue” caused by hyperemia and edema of the fungiform papillae, which project above the surface of the tongue. Circumoral pallor is also associated with this disease.

Hairy tongue results from overgrowth of the filiform papillae on the dorsum of the tongue. A yellow to black, discolored, thick layer of accumulated keratin on the tongue is characteristic. Multiple bacterial as well as fungal organisms may be cultured from the tongue. Treatment is empirical with oral rinses and débridement with a toothbrush.

Acute necrotizing ulcerative gingivitis, otherwise known as Vincent’s angina or trench mouth, is caused by an imbalance in the normal flora of the gingival sulcus with predominant presence of the spirochete *Borrelia vincentii* and the gram-negative bacillus *Fusiformis fusiformis*. Clinically, patients present with a sore mouth, and on physical examination, the interdental papillae are seen to be affected, which differentiates this condition from gingivostomatitis and aphthous ulcers. Treatment includes hydrogen peroxide mouthwash, débridement, and antibiotics such as penicillin or doxycycline (if >8 years old).

Koplik’s spots are pathognomonic for measles. These irregular bluish white lesions surrounded by an erythematous halo appear on the buccal mucosa opposite the second molars

2 to 3 days before the cutaneous rash of rubeola emerges. These lesions resolve spontaneously and are significant only in the early identification of the disease in a child who has been exposed.

Oral manifestations of primary, secondary, and tertiary syphilis may be characterized by *chancres*, *mucous patches*, or *gummas*, respectively. Hutchinson’s teeth, which are pointed, lateral incisors and notched central incisors, are also characteristic of syphilis.

Oral disease is frequently associated with human immunodeficiency virus (HIV). Many HIV-associated oral disorders occur early in HIV infection and therefore may be a presenting sign or symptom. The most common HIV-associated oral diseases are candidiasis, herpes simplex ulceration, oral hairy leukoplakia, and Kaposi’s sarcoma.¹⁸

A *parulis* or gum boil is a sessile nodule at the site where a draining sinus tract reaches the surface. An *odontogenic cyst*, such as a periapical cyst or abscess, is a soft, fluctuant gingival mass on the facial or lingual area of a carious or traumatized tooth that has undergone pulp necrosis and is thus nonvital. Antibiotics and management of the nonvital tooth via incision and drainage, root canal, or extraction is the treatment. *Pericoronitis* refers to the inflamed or infected tissue over erupting teeth.

A *papilloma* is a benign sessile or pedunculated exophytic papillary growth of stratified squamous epithelium anywhere in the mouth that may be white or pink in color. It is caused by human papillomavirus. Treatment is via excision.

Tumors

Pyogenic Granuloma

Pyogenic granulomas are a fast-growing reactive proliferation of endothelial cells, commonly on the gingiva and usually in response to chronic irritation. The lesions may be sessile or pedunculated with a smooth or verrucose surface that has a reddish hue due to vascularity of the tissue, with a gray pseudomembrane over the surface. They are painless and are prone to bleeding with trauma or manipulation. Treatment consists of complete local surgical excision. Recurrence is common.³

Fibroma

Fibroma is the most common benign soft tissue tumor. Frequently located on the gingiva, buccal mucosa, tongue, lips, or palates, it is soft or firm with a sessile or pedunculated base and usually less than 1 cm in size. It is usually secondary to chronic irritation.

Mucocele and Ranula

Mucocele and *ranula* are clinical terms for a pseudocyst that is associated with mucus extravasation into the surrounding soft tissues. These lesions occur as the result of trauma or obstruction to the salivary gland excretory duct. A mucocele originates from the minor salivary glands and presents as a painless, asymptomatic swelling that has a relatively rapid onset and fluctuates in size. It is commonly found in the labial mucosa of the lower lip. Treatment is surgical excision, yet occasionally the cyst may recur.

Ranula originates from the major salivary glands and presents as a painless, blue (if superficial) or translucent, unilat-

eral swelling of the floor of the mouth. However, the lesion may cross the midline if large. The ranula may interfere with speech, mastication, respiration, and swallowing because of the upward and medial displacement of the tongue. Treatment is surgical via excision or marsupialization, and the lesion also may recur.

Rhabdomyosarcoma

Rhabdomyosarcoma is a rare, rapidly growing malignant neoplasm of striated muscle. It is characterized by a painless, infiltrative, ulcerated, fixed, rapidly growing mass that occurs in the first decade of life. Treatment is via excision and chemotherapy. It has a very poor prognosis.

Idiopathic Lesions

Miscellaneous Lesions

Fordyce's granules are asymptomatic, multifocal, benign, small yellow papules that are present in 80% to 90% of adults and represent ectopic sebaceous glands that may coalesce to form plaques. They are bilaterally symmetric and are most commonly found on the buccal mucosa of the cheeks and mandibular molars as well as the vermilion of the upper lip. These developmental lesions appear around the age of 10 and increase in size and number around puberty. No treatment is required for Fordyce's granules, except for cosmetic removal of labial lesions.

"Geographic tongue" or *benign migratory glossitis* occurs secondary to desquamation of the filiform papillae in several patchy, irregular areas on the dorsum of the tongue. These areas heal over and new ones appear. Patients may complain of pain while eating spicy or salty foods. The etiology is not known, and reassurance that this is a benign condition is the recommended treatment.

Gingival hyperplasia is caused by gingival overgrowth, most commonly secondary to drugs such as dilantin, cyclosporine, and nifedipine. Studies have demonstrated that the interaction of these drugs with epithelial keratinocytes, fibroblasts, and collagen can lead to an overgrowth of gingival tissue in susceptible individuals. Gingival enlargement occurs primarily on the labial gingival mucosa and in between the teeth (interdental papillae area).

An *eruption cyst* is a soft, fluctuant, blue to dark red, well-demarcated odontogenic cyst that surrounds an erupting tooth (molar or canine) on the alveolar ridges. No treatment is necessary as the cyst often ruptures spontaneously.

Leukoplakia is a precancerous disease of the mouth that presents as painless, white plaques or patches on the tongue or buccal mucosa and is differentiated from candidiasis in that it does not scrape off. It is associated with smokeless tobacco use and may precede carcinoma.

Retrocuspid papillae are sessile nodules on the gingival margin of the lingual aspect of the mandibular cuspids and are a normal variant in children.

Recurrent Oral Ulcers

Recurrent oral ulcerations are usually categorized as either aphthous ulcers (canker sores) or recurrent herpes labialis (cold sores/fever blisters). The clinical appearance of these entities has frequently confused practitioners secondary to their similar characteristics. They both last 7 to 14 days; have a history of reoccurrence; and have similar

triggering factors, such as stress, mechanical irritation, and illness. However, they have different etiologies and therefore different treatments, thus correct identification is paramount.

Recurrent aphthous stomatitis (RAS) is a common condition that typically starts in childhood or adolescence as recurrent small, round, or ovoid ulcers with circumscribed margins, erythematous haloes, and a white to yellow or gray membrane floor. Most aphthous ulcers heal in 1 to 2 weeks and are associated with pain and interference with eating. RAS is classified as minor, major, and herpetiform on the basis of ulcer size and number. The principle differential diagnosis for RAS is recurrent herpes simplex infection.

The etiology of RAS is not entirely clear, and it is therefore termed idiopathic. RAS may be the manifestation of a group of disorders of quite different etiology, rather than a single entity. Immune mechanisms appear to play a role in persons with a genetic predisposition to oral ulceration. Deficiencies of iron, folate, and vitamin B₁₂ have also been implicated, as well as the association with immune deficiencies, stress, trauma, and food allergies.

The primary goals of therapy for RAS are relief of pain, reduction of ulcer duration, and restoration of normal oral function. Secondary goals include reduction in the frequency and severity of recurrences and maintenance of remission. Immunosuppressants currently appear to be the most effective in the management of RAS. Topical mixtures of corticosteroids and antibiotic and/or peroxide mouthwashes remain the mainstays of treatment. At best, they can reduce the number of painful ulcer days compared with controls, but they have no consistent effect on the incidence of ulceration. Systemic treatment with oral corticosteroids and immunomodulators may be utilized for more severe, intractable lesions, although the evidence so far has not demonstrated that their efficacy outweighs their toxic effects.¹⁹

Lesions Associated with Systemic Diseases

Systemic diseases associated with oral mucosa manifestations include gastrointestinal disorders such as Crohn's disease, ulcerative colitis, malabsorption disorders such as gluten-sensitive enteropathy, HIV infection, Behçet's syndrome, Kawasaki disease, toxic shock syndrome, malignancy (leukemia), immune-mediated disorders (agranulocytosis, cyclic neutropenia), trauma, Stevens-Johnson syndrome, epidermolysis bullosa, and lichen planus (Table 52-3).

Summary

The differential diagnosis of oral lesions is vast, and knowledge pertaining to the patient's age, general appearance, and associated symptoms, such as fever, pain, recurrence, or rash, is an important component of classification. During physical examination, attention to hyperemia of the oral mucosa and the type (mass, ulcer, or vesicle), color, size, and location of the lesion further guide the clinician to the correct diagnosis. The most common oral lesions in pediatrics are infectious in etiology and self-limiting. However, rapid recognition of oral mucosa manifestations in the toxic-appearing child is crucial in life-threatening conditions such as toxic shock syndrome and Stevens-Johnson syndrome.

Table 52–3 Oral Lesions Associated with Systemic Disease

Disease	Oral Mucosa	Systemic Findings
Behçet's syndrome	Ulcers	Uveitis, skin and genital ulcers
Crohn's disease	Ulcers, hyperplastic mucosa	Gastrointestinal symptoms, weight loss
Epidermolysis bullosa	Vesicles/bullae of teeth and mucous membranes	Vesiculobullous disorder of skin, Koebner's phenomenon
Kawasaki disease	Hyperemia, cracked lips, strawberry tongue	Fever > 5 days, exanthem, bilateral nonexudative limbic-sparing conjunctivitis, edema/erythema leading to desquamation of hands and feet, single anterior lymph node, arthritis, coronary aneurysm
Lichen planus	White papules or streaks	Violaceous pruritic rash, Wickham's striae (white cross-hatching), Koebner's phenomenon, pitted nails
Mucositis	Ulcers, exudates, pseudomembrane	Associated with neutropenia/chemotherapy
Scarlet fever	Hyperemia, strawberry tongue, circumoral pallor, pharyngitis	Diffuse cervical lymphadenopathy, sandpaper rash, Pastia's lines
Stevens-Johnson syndrome	Erythematous or hemorrhagic plaques, vesicles or bullae, pseudomembrane	Target lesions, exudative conjunctivitis, arthralgia, urethritis
Toxic shock syndrome	Hyperemia, strawberry tongue	Fever, vomiting, erythroderma, shock, coagulopathy

Chapter 53

Dental Disorders

Linda L. Brown, MD, MSCE

Key Points

There are over 400,000 pediatric emergency department visits a year secondary to dental-related complaints.

The management of dental injuries in children depends on whether the tooth is a primary or permanent tooth.

The urgency of treatment of a dental injury is dependent on the type of injury.

Selected Diagnoses

- Traumatic injuries
 - Crown fractures
 - Root fractures
 - Luxation injuries
 - Alveolar ridge fractures
- Nontraumatic disorders
 - Dental caries
 - Dentoalveolar abscess
 - Pericoronitis

Introduction and Background

Patients with dental-related complaints are seen commonly in emergency departments across the United States, with an estimated 2.95 million emergency department visits from 1997 to 2000 attributed to such complaints.¹ Children comprise about 15% of these visits, the majority (60% to 70%) of which are reported as nontraumatic in origin.^{2,3}

Prior to and during the evaluation of pediatric patients with dental-related complaints, it is important to remember the normal anatomy of the tooth. The tooth is divided into the crown, which is visible beyond the gingiva, and the root, which is buried beneath. The crown is composed of a hard covering of enamel over a layer of dentin, which acts to hydrate and cushion, and connects to the pulp, which acts as the neurovascular supply of the tooth. The periodontal ligament is a connective tissue hammock that anchors the tooth

in its socket, and also functions as a “double periosteum,” laying down cementum on one side and alveolar bone on the other.

A unique consideration in children is the need to understand normal dental development, as proper identification of primary versus permanent dentition may affect diagnosis and treatment. Tables 53–1 and 53–2 show the most commonly observed pattern and ranges of eruption and exfoliation, although normal variations may occur.^{4,5} Inspection of the affected tooth may also give clues to the practitioner. Primary teeth tend to be smaller, shorter, and milky white or opalescent in color, with a smooth occlusal surface, while permanent teeth are wider and white to gray in color, with a ridged occlusal surface.

Discussion of Individual Diagnoses

Traumatic Injuries

Pediatric dental trauma has a bimodal incidence, with a peak from ages 2 to 4 years and another from ages 8 to 10 years. Boys and girls are equally affected during this time period. However, in older school-age children and adolescents, boys are more frequently injured and sports-related trauma and altercations are often reported as the cause.^{6,7} Dental injuries may be classified as crown and root fractures, luxation injuries, and alveolar ridge fractures.

Each patient with dental trauma should foremost be considered a trauma patient. Evaluation should proceed with special attention given to the airway, as patients with dental trauma may also have other maxillofacial injuries that could result in blood and soft tissues occluding the airway. Subsequently, a careful history should be taken to include specifics about the mechanism of injury, symptoms (including pain, hot/cold sensitivity), and change in occlusion. With nonverbal children, asking the parent if the child’s teeth and occlusion appear “normal” may give added information. The oral cavity should then be examined to assess for damage to dentition, as well as for any soft tissue injury. Foreign debris and dental fragments may be embedded in the surrounding tissues. Finally, the teeth should be examined to assess for any change in their location, pain with percussion, presence of mobility, or swelling along the alveolar ridge.⁸ It is also important to examine the mandible by palpating along the temporomandibular joint and evaluating for normal, full, symmetric jaw opening.

Table 53–1 Typical Pattern of Eruption and Exfoliation of Primary Teeth

	Age at Eruption of Primary Teeth (mo)	Age at Exfoliation (yr)
Maxillary		
Central incisor	7–12	6–8
Lateral incisor	9–13	7–8
Canine	16–22	10–12
First molar	13–19	9–11
Second molar	25–33	10–12
Mandibular		
Central incisor	6–10	6–8
Lateral incisor	7–16	7–8
Canine	17–23	9–12
First molar	12–18	9–12
Second molar	20–31	10–12

Table 53–2 Typical Pattern of Eruption of Permanent Teeth

	Age at Eruption of Permanent Teeth (yr)	
	Maxillary	Mandibular
Central incisor	7–8	6–6.5
Lateral incisor	8–8.5	7–8
Canine	11–12	9–10.5
First premolar	10–11	10–11
Second premolar	10–11.5	10.5–11.5
First molar	6–6.5	6–6.5
Second molar	12–13	11–12
Third molar	17–21	17–21

Crown Fractures

Crown fractures are seen commonly in children, and it is important to correctly identify the exposed components, as treatment options and long-term outcome may depend upon this classification. These fractures are usually referred to as uncomplicated (involving enamel, dentin, cementum) versus complicated (with pulp involvement) fractures.

Patients with uncomplicated dental fractures (Fig. 53–1) rarely have pain without manipulation. Pain may be elicited with mastication as well as with exposure to hot or cold. The loss of the enamel and dentin layers may allow bacterial and chemical irritants access to the pulp.⁹ Treatment is therefore primarily aimed at protection of the pulp, with placement of a calcium hydroxide or glass ionomer coating, even without obvious exposure. Overall, the risk of long-term complications, including pulp necrosis, is low (<10%), and published guidelines from the American Association of Endodontists (AAE) state that referral for treatment within the next 24 hours is appropriate.¹⁰ A recent review looked at the effect that treatment delay of traumatic dental injuries had upon pulp and periodontal healing and, although evidence was limited, recommendations were made for treatment guidelines (Table 53–3).^{11,12}

Complicated fractures involve the pulp and can be identified by the presence of blood at the tooth core. Patients may present with pain, as the neurovascular supply of the tooth is exposed. It is also important to remember that dental fragments may become lodged in soft tissues or, less commonly, aspirated. Therefore, evaluation of soft tissue lacerations

**FIGURE 53–1.** Uncomplicated dental fracture.**Table 53–3** Treatment Guidelines

Type of Injury	Treatment Urgency*
Crown and crown + root fractures	Acute, subacute or delayed
Root fractures	Acute or subacute
Alveolar fractures	Acute [†]
Concussion and subluxation	Subacute
Extrusion and lateral luxation	Acute or subacute [†]
Intrusion	Subacute [†]
Avulsion	
Tooth not replanted at time of injury	Acute
Tooth replanted	Subacute
Primary tooth injury	
Primary with occlusal problems	Acute
Displaced into follicle of permanent tooth	Acute

*Acute, within a few hours; subacute, within the first 24 hours; delayed, after the first 24 hours.

[†]Evidence questionable.

must be complete, utilizing radiographs if needed. Chest radiographs may also be considered if large fragments are unaccounted for and a history of possible aspiration is obtained. These injuries are at a higher risk of pulp necrosis than uncomplicated fractures, although guidelines state that treatment, which may include pulp capping or pulpectomy, within 24 hours is still appropriate.^{10,11} Dental radiographs will also be needed on follow-up to evaluate for root fracture, which may not be clinically evident on presentation.

Root Fractures

Classified by their location along the root, these fractures are identified as coronal, midroot, or apical, and are seen most commonly in teeth with complete root formation, approximately 2 to 3 years after eruption.¹³ Coronal fractures may be associated with crown displacement and, therefore, are usually the easiest to diagnose. Fractures with displacement

FIGURE 53-2. Visible blood in the gingival sulcus.

often require immediate dental consultation for splinting. Midroot and apical fractures, however, may only be suspected by the presence of bleeding from the gingival sulcus after a traumatic event, and require follow-up intraoral dental radiographs for confirmation and evaluation for further treatment interventions.

Luxation Injuries

Luxation injuries may be classified as concussion, subluxation, intrusion, extrusion, lateral luxation, or avulsion injuries. Dental concussion injuries are seen commonly after trauma, when children may present with complaints of tenderness with biting pressure or with percussion of the tooth. The tooth remains immobile in the socket, however, which differentiates the injury from a subluxation injury, in which the tooth is loosened and mobile with palpation, although not displaced. Blood may also be visible in the gingival sulcus, as shown in Figure 53-2. With both concussion and subluxation injuries, the long-term risk to the primary and permanent tooth is low, although eventual pulp necrosis is possible, and the need for immediate intervention is usually limited. In the event of a subluxed tooth with significant mobility, a dental consultation should be obtained to assess the need for splinting or potential extraction, if primary dentition is involved. All other patients should have outpatient dental follow-up arranged to assess the need for radiographs and further intervention.^{11,12}

Intrusion injuries involve displacement of the tooth into the alveolar bone and crushing of the periodontal ligament (Fig. 53-3). They can result in significant long-term damage to the dentition. Although seen more frequently in primary teeth, intrusion of the permanent teeth can occur with significant trauma. On examination, the tooth will often be immobile and minimally tender to percussion. Occasionally it will not be visible beyond the gingiva, mimicking the look of an avulsed tooth. When the injury involves a primary tooth, the main concern is for the effect upon the underlying permanent dentition, with an estimated 50% to 75% damage rate.^{10,13} Since the damage occurs at the time of trauma, immediate intervention, including extraction, results in little improvement in outcome. Therefore, published treatment guidelines from the International Association of Dental Traumatology (IADT) state that, if the primary tooth is

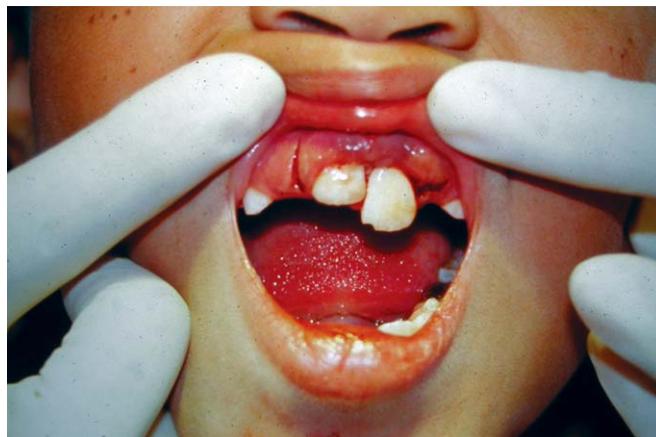

FIGURE 53-3. Intrusion injury.

intruded into the developing tooth germ, extraction is required. Otherwise, the tooth may be allowed to re-erupt spontaneously.^{14,15} It is important to note that allowing the tooth to re-erupt leads to unpredictable results, and practice variation is still possible between dental consultants.

When the intruded tooth is a permanent tooth, the most important factor in outcome has been found to be the amount of intrusion present. Several studies have reported that intrusions of less than 3 mm have an excellent prognosis, while those of greater than 6 mm have a universally poor outcome secondary to inflammatory root resorption and pulp necrosis.^{16,17} Guidelines published by the Royal College of Surgeons of England utilize the amount of intrusion to determine treatment regimens. The IADT and the AAE suggest that spontaneous re-eruption may be possible for teeth with incomplete root formation, whereas orthodontic or surgical repositioning is needed for teeth with complete root formation. Close dental follow-up within 24 hours, with the potential for future endodontic therapy, is also required.

Extrusion injuries are diagnosed when the tooth is partially displaced out of the socket and into the oral cavity. Similarly, in lateral luxation injuries, which constitute the largest proportion of all dental displacement injuries, the involved tooth or teeth are displaced relative to the other teeth. The direction of this movement can be buccal, labial, or lingual (Fig. 53-4), and the tooth when palpated will usually be mobile within the socket. Soft tissue injuries, including gingival lacerations, and root fractures will often be seen in association with these injuries. Emergent dental consultation is required for injuries with significant mobility or malocclusion, as immediate splinting may be required. When primary dentition is involved, extraction may be performed if exfoliation is predicted in the near future. As with most dental trauma, follow-up radiographs by a dentist are required to evaluate for further injury.

Avulsion injuries, also referred to as complete luxation injuries, are one of the most urgent dental injuries. The prognosis for the affected tooth is time dependent, and management is aimed at maintaining the viability of the periodontal ligament (PDL). Several published studies have reported that, after dry storage time of more than 15 to 30 minutes, almost all PDL cells have died, making successful reimplantation unlikely.¹⁴ Therefore, it is important to inform parents, teachers, and other caregivers of the appropriate steps to reimplant an

FIGURE 53-4. Lingual luxation injury.

avulsed tooth. After an injury, the tooth should immediately be identified as a primary versus permanent tooth. It is generally accepted that primary teeth should not be reimplanted to prevent further damage to the underlying permanent tooth secondary to inflammation or ankylosis. Once a permanent tooth is identified, it should be cleaned of debris by rinsing it briefly with saline (or water, if saline is unavailable). The tooth should not be scrubbed, as this will further damage PDL cells. The socket should then be examined for debris or significant damage and irrigated if necessary. The tooth can then be held by the crown and placed into the socket with slow, steady pressure. If immediate reimplantation is not possible, then the tooth should be placed in a liquid medium to help maintain viability of the PDL cells. Acceptable solutions include cell culture media such as Viaspan or Hank's Balanced Salt Solution. Milk, especially chilled milk, has also been found to be an excellent, and readily available, transport medium.¹⁸ Saline or the patient's own saliva are not ideal substitutes, but are more acceptable than dry storage. After the tooth has been reimplanted, emergent dental consultation is required for splinting, and close dental follow-up is required for an optimal outcome. Treatment guidelines from the IADT and AAE also state that these patients should receive a course of oral antibiotics (penicillin VK for 7 days or doxycycline if patients are penicillin allergic and > 8 years old), as several studies have suggested that antibiotics decrease the risk of inflammatory root resorption and may improve outcome.^{19,20} Tetanus status should also be assessed if significant debris was found contaminating the wound.

Alveolar Ridge Fractures

Alveolar ridge fractures occur in 5% to 9% of all dentoalveolar injuries.¹⁰ They are most commonly associated with anterior teeth and may be either single or segmental (Fig. 53-5). Identification of subtle fractures may be possible with palpation of the gingiva, looking for any evidence of crepitus or step-offs. The most important management strategy involves repositioning and splinting of the affected area, and therefore immediate dental consultation is often necessary. Oral antibiotics (penicillin VK or doxycycline) may also be utilized, although little evidence is available regarding the effectiveness of this strategy.

FIGURE 53-5. Alveolar ridge fracture.

Nontraumatic Disorders

Dental Caries

Between 50% and 75% of pediatric, nontraumatic, dental-related complaints seen in the emergency department are secondary to caries, with 18% due to “baby bottle” caries.^{2,3,21} Beginning with the fermentation of carbohydrates by oral bacteria and the production of acid, the enamel and dentin layers of the tooth are demineralized. Without intervention, decay erodes to the pulp, and inflammation, referred to as pulpitis, occurs.²² Patients may complain of pain as well as hot/cold insensitivity. On examination, dental caries appear as brownish cavitations in the tooth surface. With more advanced inflammation of the pulp, pain may be severe and may worsen with percussion of the tooth. Emergency department management should center on analgesia and appropriate referral to a dentist for removal of the affected area and placement of a filling.

Dentoalveolar Abscess

When inflammation of the pulp is left untreated, the localized collection of purulent fluid results in a dentoalveolar abscess. Patients complain of severe pain, and on examination have significant tenderness with percussion. The gingivae around the affected tooth often appear erythematous and swollen, and occasionally areas of fluctuance are palpated. Associated regional lymphadenopathy and facial swelling may also be present. When an apical or “periapical” abscess develops, fistula formation to the gingiva (Fig. 53-6) or, less commonly, to the face may occur. Often when this drainage occurs, the pain is less severe. Management in the emergency department focuses again on analgesia. Complications with dental abscess, including localized cellulitis and more severe extension into the soft tissues of the head and neck, require the addition of antibiotics. Oral penicillin, or erythromycin or clindamycin for patients with true penicillin allergy, are most commonly used for this purpose. Emergent otorhinolaryngology consultation should be obtained for patients requiring incision and drainage due to severe pain or with extension of infection into the deeper tissues of the head and neck. Close dental follow-up should be obtained for all patients who require more definitive treatment.

FIGURE 53-6. Fistula formation to the gingiva from a periapical abscess.

Pericoronitis

Pericoronitis refers to an inflammation of the soft tissues surrounding the crown of an erupting tooth. Food debris and bacteria become trapped under the gum overlying the tooth, and localized infection can result. This is most commonly associated with erupting wisdom teeth, and children often present with pain. In more severe cases, extension of this inflammation and secondary infection can result in cellulitis with regional lymphadenopathy and trismus. Primary treatment involves local irrigation with mouthwashes. If increased swelling and significant pain is present or if cellulitis is diagnosed, then treatment with oral antibiotic therapy may also be indicated. Appropriate follow-up with a dentist should be arranged to confirm improvement of patient symptoms or, if symptoms worsen, to evaluate the potential need for surgical removal of the flap.

Neck Infections

Amy L. Puchalski, MD

Key Points

Healthy children can have palpable cervical lymph nodes unassociated with infection or illness.

Anterior cervical nodes drain the mouth and pharynx, posterior cervical and occipital nodes drain the scalp, and retropharyngeal nodes drain the nasal cavity and paranasal sinuses.

Viral upper respiratory infections are the most common cause of lymphadenitis, but clinicians must consider other less common diseases in their differential (e.g., malignancy, granulomatous disease, cat scratch disease, tuberculosis, or atypical mycobacteria/scrofula).

Introduction and Background

Children commonly develop infections of the soft tissues of the neck due in part to their propensity for upper respiratory tract infections (URIs) and in part to their relatively large amount of lymphoid tissue compared to adults. Over half of all children have palpable cervical lymph nodes, and this number increases to 80% to 90% among 4- to 8-year-olds.¹ Viral lymphadenitis is the most common neck infection. It is important to follow these patients clinically for development of a secondary suppurative infection, which can lead to more serious morbidity. In addition, a directed history and physical examination is invaluable to help differentiate a suspected infectious process from either congenital neck masses or neoplasms.

Selected Diagnoses

- Lymphadenitis
- Retropharyngeal and parapharyngeal abscesses
- Lemierre syndrome
- Ludwig's angina
- Parotitis

Discussion of Individual Diagnoses

Lymphadenitis

Lymphadenitis from various causes is by far the most common neck infection in the pediatric population, and a thorough history and physical examination is imperative to help identify the likely etiology as well as the nidus for infection. Table 54–1 includes some key points on which to focus in obtaining the history of a patient presenting with enlarged neck lymph nodes. Lymph nodes are considered enlarged if they are cervical nodes greater than 10 mm or supraclavicular nodes of any size.² Other physical examination features may help differentiate the cause of lymphadenitis. Nodes in viral disease tend to be small, discrete, mobile, bilateral, and minimally tender. Bacterial infection is characterized by large, warm, tender, often unilateral, and sometimes fluctuant nodes. More chronic infectious lymph nodes are minimally tender, discrete, and adherent to underlying tissue, and lack signs of inflammation.² Often the emergency physician is faced with the decision of when to obtain surgical consultation for potential biopsy of an enlarged lymph node. A retrospective study in children sought to identify which patients undergoing lymph node biopsy were more likely to have significant disease. Table 54–2 summarizes some of those findings and gives suggestions for which children warrant biopsy. Of the patients in this study, over half had reactive hyperplasia, one third had granulomatous disease, 13% had a malignancy, and 3% had chronic lymphadenopathy.³

Viral Lymphadenitis

Viral infection is the most common cause of lymphadenitis in infants and children. Lymph node enlargement is most often a result of reactive hyperplasia of the lymphoid tissue in response to a URI, but the nodes can also be directly infected by the virus. The list of viral pathogens is lengthy and includes rhinovirus, adenovirus, enterovirus, measles, mumps, rubella, Epstein-Barr virus (EBV), cytomegalovirus (CMV), and human immunodeficiency virus (HIV). EBV infection classically presents with fever, exudative tonsillitis, fatigue, malaise, and often hepatosplenomegaly, along with enlarged bilateral cervical nodes. The lymphadenopathy may be more extensive and enlarged than with many other URIs and at times raises concerns for malignancy. Children with CMV infection clinically present similarly to those with EBV and can be differentiated with serologic testing. Up to 95% of children with EBV infection and 75% with CMV infection

Table 54–1 History in Children with Lymphadenitis

have cervical lymphadenopathy.² Adenovirus may cause conjunctivitis, pharyngitis, and a rash in addition to cervical lymphadenopathy and classic URI symptoms. Features of acute HIV infection are similar to other acute viral URIs with similar degrees of lymphadenopathy. Chronic HIV infection often causes large, soft nodes in the posterior triangle of the neck as well as generalized mild lymphadenopathy. It is important to question adolescent patients with cervical lymphadenitis about sexual activity to help in recommendations for possible outpatient HIV testing. Questioning about prolonged fever, weight loss, duration of lymphadenopathy, and malaise is important with suspected viral infection to help differentiate those patients who may have a more chronic or malignant process.

The need for testing with suspected viral lymphadenitis is usually minimal, and in the vast majority of cases no testing is needed. Serology for EBV and CMV may be considered in appropriate clinical scenarios. Recommendation for appropriate outpatient HIV testing should be considered for sexually active adolescents and children with failure to thrive or a history of recurrent infections. In rare instances, patients with significant or prolonged lymphadenopathy or with systemic symptoms out of proportion to those of a typical viral URI may require contrast computed tomography (CT) imaging of the neck to differentiate malignancy or suppurative lymphadenitis. In addition, fine-needle aspiration or open biopsy may be performed by consultants to rule out a malignant process, if one is suspected. Care of patients with viral lymphadenitis is largely supportive with the exception of those with HIV infection.⁴

Bacterial Lymphadenitis

Bacterial suppurative lymphadenitis is the most common cause of sudden onset of rapidly enlarging cervical lymph nodes.⁵ The bacterial pathogens responsible for the majority of these infections are streptococcus and staphylococcus species, but also include *Neisseria* species, *Bacteroides*, *Fusobacterium*, and other oral anaerobes. Infections are often polymicrobial, and up to 38% of bacterial lymphadenitis in children 2 to 16 years of age may include anaerobes.⁵ Children ages 1 to 4 years more commonly develop streptococcal and staphylococcal lymphadenitis, whereas older children and adolescents more often develop anaerobic and group A streptococcal infection.² Pathophysiologically, bacterial lymphadenitis is generally preceded by a pharyngeal infection, either viral or bacterial, which leads to superinfection of the cervical lymph nodes draining those regions. Impetigo on the face or scalp may also precede a bacterial cervical lymphadenitis.

Patients typically present with tender, warm, erythematous cervical and submandibular nodes following pharyngitis. Nodes may or may not feel fluctuant at the time of presentation. Overall, about 25% of bacterial lymphadenitis will progress to suppuration, more commonly occurring with staphylococcal infections. Generally, suppuration will occur within 2 weeks of initial cervical node enlargement.² Adjuvant testing is determined primarily by the initial history and physical examination. A complete blood count and blood culture in febrile patients should be considered. CT with contrast is the imaging study of choice if there is clinical concern for a focal abscess or need for surgical drainage, as it can differentiate cellulitis, phlegmon, and abscess. This study should be obtained on initial presentation in children with palpable areas of fluctuance, airway or vascular compromise, ill appearance, or any concern for a malignancy. Ultrasound may have a role in evaluating for the presence of fluid pockets, but will not provide sufficient information to determine need for surgical intervention.

Treatment of bacterial lymphadenitis includes antibiotics, either oral or intravenous, warm compresses, and analgesia if needed. The majority of children may be treated and followed in the outpatient setting as long as follow-up within 24 to 48 hours of initial presentation can be established to evaluate response to oral antibiotics. Potential choices for oral therapy include amoxicillin/clavulanate, clindamycin, and the cephalosporins. Inpatient treatment with intravenous antibiotics is reserved for children who have not responded adequately to oral antibiotics (persistent fever, increasing lymph node size or tenderness, developing fluctuance), and those who are ill appearing, have significant swelling or nodal involvement, or have a potential complication such as bacteremia, cellulitis, or development of a deep neck space abscess. Surgical consultation for incision and drainage should be obtained for children with abscess identified on CT.

MYCOBACTERIAL LYMPHADENITIS

Mycobacterial lymphadenitis falls into two groups: tuberculous and atypical mycobacterial infections. In infants and children, up to 90% of mycobacterial lymphadenitis is caused by atypical pathogens, with *Mycobacterium avium-intracellulare* and *Mycobacterium scrofulaceum* being the

most common.^{2,6,7} Atypical mycobacteria are the most common cause of granulomatous lymphadenitis and account for 7% to 8% of chronic lymphadenitis in children.^{1,6} In contrast, cases of tuberculous lymphadenitis outnumber atypical infection in the adult population.⁷ Lymphadenitis with atypical pathogens typically affects otherwise healthy children ages 1 to 5 years, more often from rural areas, who come in contact with and ingest contaminated soil, dust, eggs, and unpasteurized dairy products.^{2,6,7} Breaks in the gingiva from erupting teeth serve as a route by which atypical mycobacteria may then infect submandibular and cervical lymph nodes.¹ There is no documentation of human-to-human transmission of these pathogens.

Children with mycobacterial lymphadenitis will present with unilateral preauricular, submandibular, or upper cervical lymph nodes that enlarge over several weeks. These nodes are painless or only minimally tender and classically develop a violaceous color of the overlying skin. If untreated, the nodes may liquefy and eventually spontaneously drain through the skin, often resulting in significant cosmetic deformity. Patients are generally afebrile and lack significant systemic symptoms.^{2,6,8} Among 105 cases, the mean age of patients was 3 years, and most presented in the winter and spring with cervical or facial lymphadenitis (91%).⁹

Evaluation of children with suspected atypical mycobacterial lymphadenitis often includes purified protein derivative (PPD) testing, chest radiography, and possible contrast CT. Approximately half of the patients have a positive PPD skin test, with a typical area of induration between 5 and 15 mm.^{2,9} Chest radiography should be obtained to help differentiate from tuberculous infections, and should be negative in those with atypical disease.² An enhanced CT scan of the chest and neck is useful to establish the extent of involvement and development of suppuration. CT findings include a rim-enhancing mass with central lucency but minimal surrounding inflammation or fat stranding.^{6,8} The optimal treatment for atypical infection is resection to minimize the scarring and cosmetic deformity that occurs once nodes suppurate and drain, though there is still some controversy over surgical management. Initial therapy with oral macrolide antibiotics may be another option, particularly in children who are poor surgical candidates. In one review including 10 children who were initially treated with macrolide antibiotics, half were cured and half still required later surgical resection.⁸ Early surgical consultation for suspected atypical mycobacterial lymphadenitis should always be a part of the care of these children in the emergency department.

Tuberculous lymphadenitis is rare in infants and children and differs from atypical infection in presentation and treatment. Epidemiologically, it is seen more often in urban and immigrant populations or in immunocompromised children.^{2,6} Patients generally have systemic disease and constitutional symptoms at the time of presentation, and up to 20% will have generalized lymphadenopathy.² The route of infection is an extension from either the apical pleural or paratracheal nodes and typically affecting supraclavicular and lower cervical nodes.² Tuberculous disease will more often suppurate and drain through sinus tracts in the skin than will atypical mycobacterial lymphadenitis.² In addition to surgical consultation for biopsy or resection to aid in diagnosis and treatment, it is important to involve infectious disease specialists in initiating antituberculosis medication therapy

Table 54–3 Atypical Mycobacterial vs. Tuberculous Lymphadenitis

Atypical Mycobacterial	Mycobacterial
Healthy children	Immunocompromised
Rural populations	Urban and immigrant populations
Family PPD negative	PPD-positive contact, usually family
Age 1–5 yr	More common in adults
Minimal constitutional symptoms	Systemic symptoms, pulmonary disease
PPD negative or <15 mm	PPD positive, usually >15 mm
CXR negative	CXR usually positive
Resection to treat	Resection + TB medications to treat

Abbreviations: CXR, chest radiograph; PPD, purified protein derivative (of tuberculin); TB, tuberculosis.

as well as investigating the child's environment to establish the index case, who most often is a family member.¹⁰ A variety of social factors, clinical features, and diagnostic studies can be used to discriminate between atypical and tuberculous lymphadenitis (Table 54–3).

CAT-SCRATCH LYMPHADENITIS

This disease is most often seen in children and is caused by *Bartonella henslae*, a slow-growing gram-negative bacillus. It usually causes regional lymphadenopathy in immunocompetent patients. Transmission to humans is via a scratch from an infected young cat, though other animals such as dogs, rabbits, and monkeys have been implicated as well.⁶ Transmission between cats occurs through flea bites. Cervical nodes are the third most common lymph node region affected by this disease, with axillary and inguinal nodes being more commonly infected. Clinically, a granuloma may be seen half the time at the site of the initial inoculation, usually on the face or extremity, and it heals in about 1 week. Lymphadenitis develops 1 to 4 weeks after the initial inoculation, so this granuloma may not be evident at presentation. Enlarged lymph nodes may persist for 2 to 3 months before complete resolution. About half of the patients will have mild systemic symptoms such as low-grade fever or malaise. While this is generally a self-limited disease process, 10% to 35% of cases will progress to suppuration, possibly requiring incision and drainage or needle aspiration. A distinct clinical entity of cat-scratch disease is Parinaud's oculoglandular syndrome, consisting of a conjunctival granuloma and preauricular lymphadenopathy. Rarely children have other systemic complications, including encephalitis, rash, hepatosplenomegaly, thrombocytopenic purpura, erythema nodosum, and bacillary angiomatosis, though immunocompromised patients are usually those at risk for these complications.^{2,6,11}

Diagnosis generally relies on clinical suspicion with confirmatory serologic testing. The organism is very difficult to culture, but polymerase chain reaction tests from nodal tissue may be helpful. Uncomplicated lymphadenitis is usually self-limited, and treatment with oral antibiotics is not routinely recommended. One recent, small, placebo-controlled study in children and adults concluded, however, that azithromycin may provide a substantial decrease in lymph node volume.¹¹ Surgical consultation for incision and drainage or needle aspiration may be required for patients with very tender, fluctuant nodes.

TULAREMIA LYMPHADENITIS

One form of infection by the gram-negative rod *Francisella tularensis* is ulceroglandular, characterized by ulceration at the site of inoculation and painful regional lymphadenopathy.^{6,12} Exposure is through contact with infected animals, such as rabbits, or bites of infected ticks and mosquitoes.⁶ After a 2- to 6-day period of incubation, children with tularemia frequently develop constitutional symptoms such as fever, chills, malaise and arthralgias, pharyngitis, nausea and vomiting.¹² It typically affects children under the age of 10 years from May to September, when they are outdoors.⁶ While most children develop constitutional symptoms, adult patients do so less frequently. Another clinical form of tularemia is the oropharyngeal form, when exposure to contaminated water or milk results in oral ulcers, fever, pharyngitis, and cervical lymphadenopathy.¹² The most common complication of tularemia infection is pneumonia, which can affect up to 15% of children with lymphadenitis, although pericarditis and hepatitis have been seen as well.⁶

Diagnosis of tularemia depends primarily on serologic testing in the appropriate clinical setting. Either a fourfold increase in titers over a 2-week period or a single titer of 1 : 160 at the end of the second week of symptoms is diagnostic. The causative agent can be cultured from infected lymph nodes, though it may be difficult to isolate the organism. Treatment for tularemia lymphadenitis ideally consists of a 10-day course of streptomycin, gentamicin, or amikacin, though tetracycline, doxycycline, and ciprofloxacin are alternative choices.^{6,12}

OTHER CAUSES OF BACTERIAL LYMPHADENITIS

Actinomyces israelii is a gram-positive organism that is a rare cause of lymphadenitis in children in the United States. Half of all infections with this organism involve the neck and face and usually follow a dental procedure or oral trauma. Children present with a slowly growing, painless mass near the mandible; 10% of the time it will directly infect cervical nodes as well. Some patients will have chronic drainage through sinus tracts. Treatment consists of surgical resection plus a 6-month course of penicillin, clindamycin, erythromycin, or tetracycline.⁴

Brucellosis can cause mild cervical lymphadenitis along with nonspecific symptoms such as fever, malaise, fatigue, and anorexia. Disease is generally mild in children as opposed to adults, who can suffer more severe systemic complications. Patients are exposed through infected livestock and unpasteurized dairy products. Diagnosis can be made with serology, blood culture, or culture from lymph node tissue. A prolonged course of treatment with rifampin or streptomycin is required to prevent relapse.⁴ Finally, primary syphilis is a rare cause of cervical lymphadenopathy in patients with an oral chancre.

Histoplasmosis Lymphadenitis

Histoplasmosis is the most common fungal cause of lymphadenitis in the pediatric population. It is most commonly seen in the central United States and Ohio River valley, where infection occurs from inhalation of spores, often found in bat or bird droppings. Primary pulmonary infection is the most common manifestation, though young children and immunocompromised patients are at risk for disseminated

disease that includes generalized lymphadenopathy as one clinical finding. Fever, pneumonia, hepatosplenomegaly, disseminated intravascular coagulation, and failure to thrive are part of disseminated infection as well. Culture of infected lymph nodes or other tissue is the best way to diagnose this infection. Treatment of young children with disseminated disease or significant lymphadenitis consists of antifungal therapy such as amphotericin B along with excision of infected nodes. For the majority of patients, the disease is self-limited and requires only outpatient follow-up. Candida and Aspergillus can rarely cause lymphadenitis in immunocompromised patients as well.^{4,6,13}

Toxoplasmosis Lymphadenitis

Toxoplasmosis gondii is the most common cause of lymphadenitis due to a parasitic infection. Cervical lymphadenitis is the most frequent manifestation of infection acquired neonatally, though only 3% to 7% of cases in children involve cervical lymphadenitis. Most patients infected with toxoplasmosis remain asymptomatic. Of those with clinical manifestations, up to 90% will have cervical lymphadenitis. Immunocompromised children may suffer more serious consequences, such as blindness and central nervous system disease. Infection occurs through exposure to cats, cat litter, uncooked meat, or unpasteurized milk. Diagnosis is usually made with serum titers. Patients often undergo excisional biopsy of cervical nodes, as this infection is frequently confused with lymphoma or other malignancies. Otherwise healthy patients do not require additional systemic therapy for toxoplasmosis lymphadenitis.^{4,13}

Retropharyngeal and Parapharyngeal Abscesses

Deep neck space infections, including retropharyngeal and parapharyngeal abscesses, are polymicrobial infections that arise from lymphoid tissue in those spaces. Retropharyngeal abscesses (RPAs) most often affect children less than 6 years of age as they have lymph nodes in that space that can act as a nidus for infections that spread from the paranasal sinuses, middle ear, and nasopharynx. These lymph nodes involute by age 5 or 6 years. Older children and adolescents still suffer from deep neck space infections, though they are more often a result of direct trauma, spread from superficial cervical lymphadenitis, or spread from dental infection. These infections are typically polymicrobial, and commonly include streptococcal species, staphylococcal species, non-typable *Haemophilus influenzae*, Neisseria species, Veillonella, Peptostreptococcus, Bacteroides, and Fusobacterium.¹⁴ One retrospective review of both children and adults with deep neck space infections reported that 62% of the cultured abscess were polymicrobial infections, with *Streptococcus viridans* an etiologic agent in 39%, *Staphylococcus epidermidis* present in 21%, and anaerobes growing in 35%.⁵ In a study of 20 children who had cultures obtained intraoperatively, 13 were positive for group A streptococcus, 2 for *Staphylococcus aureus*, 1 for *H. influenzae*, and 1 for anaerobes.¹⁵

The clinical course of an RPA often begins with a preceding URI days to weeks prior to the abscess. Symptoms of the abscess may include fever, drooling, torticollis, pain with neck movement, poor oral intake, irritability, and trismus. Physical examination may reveal signs consistent with meningitis, such as nuchal rigidity, limited neck movement, ill appearance, drooling, and dehydration. Lateral neck swelling

and/or a bulge in the posterior oropharynx are physical signs of a possible RPA. Signs and symptoms are often nonspecific, and this disease entity largely affects preverbal children. Older children with parapharyngeal abscesses are likely to complain of a worsening sore throat, difficulty swallowing, pain with neck movement, palpable cervical lymphadenopathy, or neck swelling.

The mean age of children with RPA is 36 months, with 75% of patients less than 5 years of age. The primary chief complaint is neck pain, in 38% of cases, followed by fever (17%), sore throat (17%), neck mass (16%), and stridor (5%). The most common clinical finding documented is limited neck extension, seen in 45% of children. Torticollis is reported in 36.5% of children. Interestingly, few patients have respiratory compromise, with only 1.5% having stridor and 1.5% wheezing. Respiratory distress and compromise, while certainly a potential threat to these patients, may not be as common as once thought with RPA.¹⁵ Other concerning potential complications of deep neck space abscesses include sepsis, septic venous thrombosis, mediastinitis, and aspiration pneumonia if the abscess ruptures and purulent material is inadvertently inhaled.¹⁴ Children who have had recurrent deep neck space infections require evaluation for possible congenital neck lesions predisposing to infection in that space.¹⁶ The differential diagnosis in a child with a suspected RPA includes hematoma trauma, perforation from a foreign body or trauma, neoplasm involving retropharyngeal lymphoid tissue, hemangioma, a branchial cleft cyst, ectopic thyroid tissue, or myxedema.⁴

The diagnosis of a retropharyngeal or parapharyngeal abscess relies mainly on imaging studies as well as repeated clinical examination. A lateral neck radiograph is generally the best starting point, and it is important that those performing the radiography realize that optimal information is

gained when the film is a true lateral with the neck in slight extension and the patient in the inspiratory phase of respiration. Otherwise, the retropharyngeal space in a child may appear falsely enlarged. As a rule of thumb, the width of the retropharyngeal space is normally <50% of the width of C2 and a retropharyngeal space greater than 14 mm is abnormal¹⁷ (Fig. 54–1). In one study, 93% of patients with RPA had abnormal lateral neck radiographs while only 7% had normal radiographs.¹⁵ CT with contrast is best obtained in those patients with abnormal radiographs or symptoms that support the diagnosis of an RPA, and is generally useful in differentiating cellulitis, phlegmon, and focal abscess. Up to 97% of those with an RPA will have an abnormal CT, though some studies suggest a false-negative rate of up to 13% for identifying the presence of a focal collection of fluid.¹⁸ Airway fluoroscopy is another alternative in detecting retropharyngeal swelling, though it cannot differentiate cellulitis from abscess.

Treatment options include antibiotic therapy and, in some cases, surgical intervention. The decision to surgically drain an abscess depends on various factors, including CT findings of focal abscess, response to initial antibiotic therapy, and clinical toxicity. Some children with documented abscess may respond just as well to antibiotic therapy alone as to surgical drainage along with antibiotics.¹⁵ Early surgical consultation is helpful in following patients and determining the point at which operative intervention is necessary. All patients with retropharyngeal or parapharyngeal abscess require admission for intravenous antibiotics and monitoring for progression of symptoms and complications, such as upper airway obstruction. Progressive symptoms of airway obstruction may require endotracheal intubation or, as some data suggest, nasal continuous positive airway pressure for respiratory support.¹⁹ Intravenous antibiotic therapies to

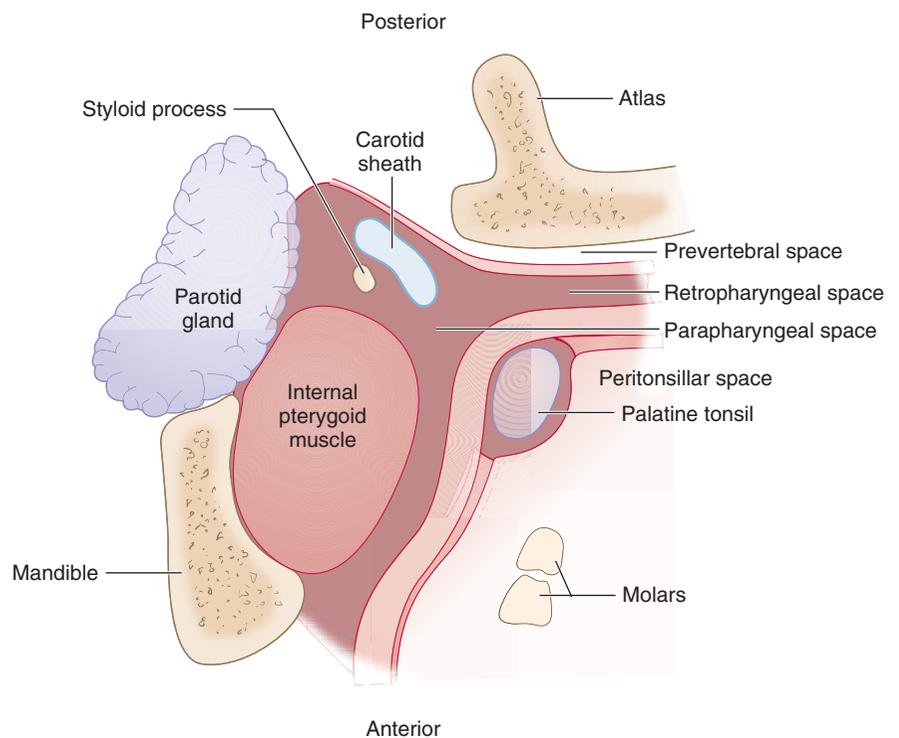

FIGURE 54–1. Anatomy of the retropharyngeal space.

consider include clindamycin, ampicillin/sulbactam, a third-generation cephalosporin, or a combination of penicillin and oxacillin or nafcillin.

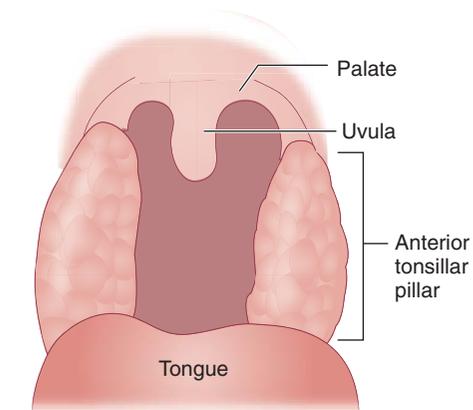

Other Airway Abscesses

Other airway abscess include peritonsillar, lateral or parapharyngeal, and pterygoid abscesses.^{20,21} The most common airway/neck abscesses requiring hospital admission include peritonsillar (45% to 49%), submandibular (10% to 22%), retropharyngeal (14% to 22%) buccal/masticator (0 to 11%), superficial (21%), and lateral or parapharyngeal (3% to 5%) abscesses.

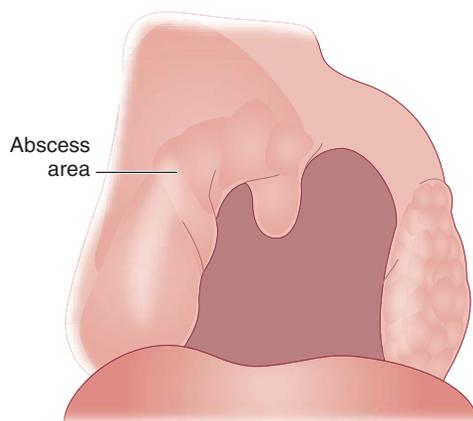

Knowledge of surrounding structures (Fig. 54–2) and the resulting clinical features can be used to discriminate between

abscesses (Table 54–4). Importantly, peritonsillar abscesses are an extension of tonsillar infection. The development of pus in this area leads to loss of landmark structures around the tonsils (tonsillar pillar effacement), bulging of the lateral pharyngeal wall and soft palate, and deviation of the uvula away from the infected side. While patients often have pain on chewing and mouth opening, true trismus is usually absent since masticator and pterygoid muscles are not affected. Parapharyngeal abscesses are deeper infections (see Fig. 54–2B) and do not disrupt the anatomy of the tonsillar pillars. Due to their location, they can involve muscles of mastication, causing trismus, swelling of the medial wall of the pharynx, and swelling along the angle of the mandible. Systemic toxicity is often prominent. Ptery-

Space/Abscess	Pain	Trismus	Swelling Sites	Dysphagia	Dyspnea
Peritonsillar	++	+	Lateral pharynx	++	–
Parapharyngeal anterior	++++	++++	Lateral pharynx and neck	++	+
posterior	+	+	Posterior pharynx	++	+++
Retropharyngeal	++	+	Posterior pharynx	++	++
Submandibular	++	–	Floor mouth	++	++
Masticator	++	++++	Hidden, face	–	–

A

B

FIGURE 54–2. A, Normal location of peritonsillar structures. B, Distortion of surrounding structures resulting from peritonsillar abscess.

goid abscesses, due to their location (see Fig. 54–1), also can cause true trismus. In addition to the clinical examination, differentiation between these infections often involves CT scanning. Peritonsillar abscesses are also easily identified by ultrasonography.

Guidelines for managing peritonsillar abscess support the use of bedside needle aspiration performed by non-otorhinolaryngology surgeons.²² A meta-analysis of 10 reports showed this technique to be 94% effective at relieving symptoms with few complications.²³ Most other abscesses (other than superficial abscess) require admission, intravenous antibiotics, and possible surgical drainage.

Lemierre Syndrome

Lemierre syndrome is a rare but serious constellation of symptoms caused by *Fusobacterium necrophorum*, a gram-negative obligate intracellular anaerobe that is part of normal oral flora. After initial tonsillitis or dental infection with the organism, patients develop bacteremia, venous thrombophlebitis, and septic emboli, most often to the pulmonary vasculature. High spiking fevers start about 1 week after onset of pharyngitis or dental infection, along with other nonspecific symptoms such as vomiting, fatigue, and weight loss. Often one side of the neck is swollen and tender to palpation, and patients who have already suffered from pulmonary emboli may complain of chest pain or dyspnea. Patients usually present to the emergency department in shock, and without appropriate therapy, mortality from sepsis is around 90%.⁴ Some cases of peritonsillar abscess caused by *Fusobacterium* do not necessarily progress to sepsis and thrombophlebitis. Laboratory findings are often consistent with sepsis, including leukocytosis with a left shift, thrombocytopenia, and prolonged coagulation times. Contrast CT of the neck and Doppler study of the jugular venous system are options for imaging modalities to diagnose venous thrombosis. A review at a single pediatric institution from 1996 to 2002 showed an increase in children admitted with clinical Lemierre syndrome as well as blood cultures positive for *Fusobacterium*.²⁴ Along with the respiratory and cardiovascular supportive measures required by these patients, options for intravenous antibiotic therapy include ticarcillin/clavulanate, ampicillin/sulbactam, clindamycin, and flagyl.²⁴ Certainly, very broad coverage should be initiated in any febrile child with signs of sepsis, but consideration should be given to including anaerobic coverage initially when a child has complaints of a severe sore throat or prominent neck swelling and tenderness. Anticoagulation is a controversial treatment considered in patients with documented jugular venous thrombophlebitis.²⁴

Ludwig's Angina

Though more often seen in the adult population, older children and adolescents may present to the emergency department with this infection of the sublingual space in the floor of the mouth. This is a polymicrobial oral flora infection that is often associated with poor oral hygiene or a recent dental procedure. Patients often present with fever, trismus, and difficulty swallowing due to elevation of the base of the tongue, and are at risk for airway obstruction. Progression of infection to cause mediastinitis is another life-threatening complication in addition to airway obstruction. Many patients require a tracheostomy to protect their airway until

the infection resolves. A subset of one study that examined 36 cases of Ludwig's angina showed that 75% required a tracheostomy as part of their therapy. One half of the patients underwent awake, elective tracheostomy while half attempted endotracheal intubation. Of the latter group, over half of these attempts were unsuccessful and required emergent tracheostomy.⁵ Therefore, elective awake tracheostomy is the best option for airway protection when time allows. Treatment consists of surgical drainage as well as antimicrobial therapy aimed at covering oral flora.

Parotitis

While the bulk of the parotid gland is preauricular in location, the tail of the parotid extends below the mandible. Thus, infection or swelling of this gland can present as neck swelling. Parotitis in children is most often viral in etiology, although bacterial infection or obstruction of Stensen's duct by stones can also result in parotid swelling. Typical viral etiologies of parotitis include enterovirus, CMV, influenza, parainfluenza, and HIV. Mumps should also be considered, particularly in unimmunized children or those with signs and symptoms of orchitis. *Staphylococcus aureus* is the most common bacterial cause of parotitis, and atypical mycobacterial infections of the gland can occur as well. Viral parotitis usually presents with bilateral parotid swelling following low-grade fever and malaise. Treatment is supportive, consisting of pain control and a bland diet. Consideration should be given to sending acute mumps titers with the intention of outpatient convalescent titers to be sent by the primary care provider. Children with bacterial parotitis may be more ill appearing, and have more significant pain and fever than those with viral infection. It is vital to look for expressed purulent material from Stensen's duct in children with parotitis to help differentiate viral from bacterial etiologies. Choices for outpatient antibiotic therapy include clindamycin and amoxicillin/clavulanate to provide coverage for *Staphylococcus*, *Streptococcus*, and oral flora. Warm compresses, massaging the gland, and use of sialagogues, such as lemon drops, provide symptomatic relief as well. Children with HIV or a past history of mumps parotitis maybe more susceptible to recurrent parotitis.⁴

Summary

Emergency physicians frequently encounter children with infectious lesions of the neck in their clinical practice. While many of these are viral, bacterial infections must be excluded as their progression can lead to deep neck space abscesses, mediastinitis, or airway compromise.²⁵ Contrast CT of the neck is indicated if the patient fails to respond to initial antibiotic therapy. Surgical consultation for possible biopsy or incision and drainage should be obtained for children with deep space infections, airway compromise, or those who are not responding to initial therapy or conservative management.

Neck Masses

Amy L. Puchalski, MD

Key Points

Most pediatric neck masses are benign.

Palpable lymph nodes in a neonate are not normal.

Malignancy of a mass or node should be considered if it is supraclavicular, enlarges over 6 weeks, is greater than 4 cm, is associated with constitutional symptoms, or causes central nervous system, airway, or vascular symptoms.

Congenital neck lesions should be considered in patients with a history of recurrent neck infections.

Benign neoplasms
Thyroid nodules
Salivary tumors
Neurofibromas
Malignant neoplasms
Lymphoma
Neuroblastoma
Thyroid carcinoma
Rhabdomyosarcoma
Ewing's sarcoma
Langerhans' cell histiocytosis

Congenital Masses Presenting in the Neonatal Period (Table 55–1)

Cystic Hygroma

This multiloculated cystic proliferation of lymphatic tissue is present at birth in 50% to 65% of cases, with nearly all others presenting by the end of the second year of life.¹ About 70% of these lesions are in the neck, usually on the left side.¹ On physical examination, cystic hygromas are large, compressible, soft mobile masses that are nontender and located in the posterior triangle of the neck.^{1,2} They can be transilluminated and in some instances are confused with hemangiomas if hemorrhage occurs with minor trauma. They grow in proportion to the infant and can become acutely larger with an upper respiratory tract infection, superinfection, or trauma. Larger lesions may cause stridor, dysphagia, failure to thrive, or airway compromise. Diagnosis is based on computed tomography (CT) scan with contrast or ultrasound, though the latter imaging modality may not give information required to plan surgical resection. Sometimes needle decompression may be used to temporarily relieve acute airway obstruction. Lesions rarely regress spontaneously, thus treatment requires total surgical resection, and recurrence of cystic hygromas is possible if resection is incomplete.^{1,2}

Hemangiomas

Hemangiomas are the most common head and neck lesion of infancy, affecting 2.5% of newborns. About one third of lesions are present at birth, with the remainder generally presenting by age 1 month. They grow in size over the first year of life, and then begin to involute. Approximately 80%

Introduction and Background

When faced with a child with a neck mass, the emergency physician should consider an infectious etiology, a congenital lesion, or a neoplasm. This chapter focuses on congenital lesions, benign neoplasms, and malignant neoplasms (see Chapter 54, Neck Infections, for information on lesions caused by neck infections). Fortunately, the majority of neck masses in children are benign. A thorough history and physical examination along with close follow-up will aid in differentiating those pediatric patients who require evaluation for possible malignancy.

Selected Diagnoses

- Congenital masses presenting in the neonatal period
 - Cystic hygroma
 - Hemangioma
 - Cervical teratoma
 - Congenital muscular torticollis
- Congenital masses presenting in infancy and childhood
 - Branchial cleft anomalies
 - Thyroglossal duct cyst
 - Dermoid cyst
- Acquired benign masses
 - Laryngocele
 - Ranula

Table 55–1 Congenital Neck Masses

Lesion	Location	Age at Presentation	Physical Examination
Cystic hygroma	Posterior triangle	~½ at birth, remainder by 2 yr	Soft, compressible, cystic, transilluminates
Thyroglossal duct cyst	Midline anterior neck	2–10 yr	Soft, nontender, moves with tongue movement
Branchial cleft anomalies	Preauricular to supraclavicular area, anterior to SCM	Various	Tags, fistulas, sinus tracts, cystic lesions
Dermoid cyst	Usually midline	Birth–2 yr	Nontender, mobile, does not move with tongue
Hemangioma	Various	By age 1 mo	Soft, mobile, nontender, vascular appearance; deep lesions may be flesh colored

Abbreviation: SCM, sternocleidomastoid muscle.

Table 55–2 Branchial Cleft Anomalies

Branchial Arch	Resultant Structures	Location of Anomalies	End Point
First	Eustachian tube, tympanic cavity, mastoid air cells	Preauricular anomalies, parotid cyst	External auditory canal
Second (most common)	Palatine tonsil, tonsillar fossa, hyoid bone	Mid to lower neck, anterior to SCM	Tonsillar fossa
Third (rare)	Thymus, inferior parathyroids	Lower 1/3 of neck, anterior to SCM	Piriform sinus
Fourth (extremely rare)	Superior parathyroids	Lower neck	

Abbreviation: SCM, sternocleidomastoid muscle.

to 90% will resolve completely by age 5 years without any intervention. Those that involve deeper structures and organs are less likely to regress without any intervention. On physical examination, hemangiomas are soft, mobile, nontender, and bluish or red in color, though very deep lesions may not cause any cutaneous discoloration and have a rubbery consistency. Complications of hemangiomas include hemorrhage, ulceration, necrosis, and superinfection. Hemangiomas in the head and neck region may cause airway obstruction, and very large lesions can lead to high-output cardiac failure and consumptive coagulopathy or thrombocytopenia (Kasabach-Merritt syndrome). Treatment of extensive lesions, those involving vital structures, or those with residual cosmetic defect includes therapy with steroids, sclerotic agents, laser treatments, or, rarely, radiation therapy.^{1,2}

Cervical Teratomas

Teratomas are masses consisting of differentiated ectoderm, mesoderm, and endoderm that can present in various locations. Between 2% and 9% involve the head and neck region, with the majority of those being cervical. Most cervical teratomas are present at birth, and they very rarely present after age 2 years. Neonatal teratomas are benign lesions, unlike those presenting in adulthood, which generally are malignant. These lesions most commonly present with some degree of airway or esophageal obstruction in the neonatal period. They often have palpable cystic areas, are about 5 to 10 cm in size at presentation, do not transilluminate, and are usually fixed to deep cervical fascia or the hyoid.³ The differential diagnosis of cervical teratomas includes thyroglossal duct cyst, cystic hygroma, goiter, branchial cleft cyst, lymphangioma, hemangioma, laryngocele, and lipoma. Teratomas are treated by surgical resection.⁴

Congenital Muscular Torticollis

Congenital muscular torticollis, or sternocleidomastoid tumor of infancy, is a focal area of fibrosis and shortening

within the sternocleidomastoid muscle identifiable within a few weeks of birth, most often a result of birth trauma. Clinically, shortening of the sternocleidomastoid muscle causes the head to tilt toward that side while the chin points away from the affected side. A firm mass can be palpated and sometimes seen within the muscle. Treatment rests on physical therapy with range of motion and stretching exercises. In rare cases in which the lesion does not resolve by age 6 months, facial and cranial anomalies, such as hemihyperplasia, may result. In such extreme cases, surgical correction may be required.¹

Congenital Masses Presenting in Infancy and Childhood

Branchial Cleft Anomalies

Remnants of branchial arches, pouches, and grooves can present clinically as sinus tracts, fistulas, cystic lesions, or skin tags.⁵ Remnants of the second branchial groove, which result in lesions anterior to the midportion of the sternocleidomastoid, are the most common. Table 55–2 shows the embryology and locations of anomalies associated with each of the four branchial arches. Cystic lesions resulting from these anomalies often present with recurrent infections⁶ or increase in size during upper respiratory tract infections. While lesions often present in infancy, some are diagnosed later in childhood or even adulthood. Contrast CT and magnetic resonance imaging (MRI) are the imaging modalities used to diagnose these lesions when clinical suspicion arises. Lesions are treated with resection once any concomitant infection has been treated.^{1,2}

Thyroglossal Duct Cyst

These lesions arise when the tract by which the thyroid descends from the foramen cecum in the tongue to the neck does not close. They are the most common congenital neck mass in children and usually present between ages 2 and

10 years.¹ On physical examination, thyroglossal duct cysts are midline, soft, smooth, nontender lesions that move with swallowing or tongue protrusion.⁷ These lesions often come to attention when they become secondarily infected. They can be confused with dermoid cysts, sebaceous cysts, submental lymphadenopathy, ectopic thyroid or neoplasm, lipomas, and cervical lymphadenopathy. Twenty-five percent to 35% of these lesions contain ectopic thyroid tissue, so thyroid scan or ultrasound prior to surgical resection is necessary to document the location of active thyroid tissue. Complications are generally limited to secondary infection of the cyst, hypothyroidism following surgical treatment, and development of thyroid adenocarcinoma in adulthood, which occurs in about 10% of patients with thyroglossal duct cysts.¹ Children with a history of resection, especially of previously infected lesions, have a 10% rate of recurrence.¹

Dermoid Cysts

Dermoid cysts are lesions consisting of ectodermal tissue that is buried beneath the skin surface. They can potentially contain sebaceous glands, hair follicles, and connective tissue. Their location is generally midline, and they are nontender and mobile, unless they become infected. They are often confused with thyroglossal duct cysts given their location, and can be differentiated by the fact that they do not move with tongue movement. Dermoid cysts rarely undergo malignant transformation, and treatment of these benign lesions consists of surgical excision.²

Acquired Benign Masses

Laryngocele

These rare lesions consist of a dilated laryngeal saccule that becomes filled with air and mucus, causing it to extend laterally from the airway. They cause a soft tissue mass lateral to the thyroid cartilage with associated hoarseness due to airway compression. Laryngoceles can be diagnosed with CT, MRI, or laryngoscopy and require surgical intervention for treatment.²

Ranula

A ranula is a mucocele of a salivary gland, usually the submandibular gland, caused by partial obstruction of the salivary duct. It initially presents as a mass on the floor of the mouth, but can progress to rupture into the anterior neck muscles, forming a pseudocyst. This latter entity is referred to as a *plunging ranula* and is treated with surgical excision. Patients usually undergo imaging with CT or MRI to establish the diagnosis prior to definitive treatment.²

Benign Neoplasms

Thyroid Nodules

Thyroid nodules are less common in children than adults, with a prevalence of 0.2% in 9- to 16-year-olds and 1.8% in 11- to 18-year-olds.⁸ However, palpable thyroid nodules are more likely malignant in children than adults, with 25% to 55% of pediatric thyroid nodules representing malignant disease. Benign lesions are generally asymptomatic, presenting as nontender lesions in the thyroid. Less commonly, benign nodules may be slightly tender or inflamed if they are cystic in nature and become hemorrhagic or infected. Some

patients may suffer from hoarseness or dysphagia, though this may indicate a malignancy. The differential diagnosis for a palpable thyroid nodule or adenoma includes cervical lymphadenopathy, an asymmetric thyroid lobe, Hashimoto's thyroiditis, thyroglossal duct cyst, and dermoid cyst.⁹ Evaluation should include measurement of thyroid function and a thyroid nuclear scan, ultrasound of the thyroid, and surgical consultation for possible biopsy or excision. Fine-needle aspiration is well documented to be a reliable method of evaluation of thyroid nodules in adults, but given the high rate of malignancy in the pediatric population, some advocate excisional biopsy as an alternative.⁹

Salivary Tumors

Salivary tumors are rare and usually involve either the parotid or submandibular gland. Hemangiomas are the most common benign lesion of salivary glands and present as previously discussed. Pleiomorphic adenomas are the next most common, usually occurring in children after the age of 1 year. Lymphangiomas are the third most common benign salivary tumor. CT and MRI are used to assist in diagnosis and plan for surgical resection in lesions other than hemangiomas. A thorough physical examination in a child with a parotid mass should include assessment for facial nerve involvement.²

Neurofibromas

These benign lesions of neural tissue components are seen in children with neurofibromatosis, usually type I, for which neurofibromas are one of the diagnostic criteria. Occasionally solitary lesions develop in otherwise normal patients. Neurofibromas are usually either cutaneous or plexiform, and have the potential of becoming very extensive and involving deep structures of the neck. The cutaneous lesions are usually small, soft, and flesh colored, sometimes being confused with lipomas or hemangiomas. A small percentage of lesions can undergo malignant transformation to neurofibrosarcomas. Treatment may consist of observation of lesions with resection when symptoms of neurologic impairment or significant cosmetic deformity become issues.²

Malignant Neoplasms

Approximately 5% of pediatric malignancies involve the head and neck, with lymphomas and rhabdomyosarcoma comprising 50% of the diagnoses.¹ Among children under age 6 years, the most common head and neck malignancy is neuroblastoma, followed by non-Hodgkin's lymphoma, rhabdomyosarcoma and Hodgkin's lymphoma. In the 7- to 13-year-old group, lymphomas predominate, followed by thyroid malignancy and rhabdomyosarcoma. In the adolescent population, Hodgkin's lymphoma is by far the most common malignancy of the neck.¹ Malignant lesions are generally painless, firm, and adherent to underlying tissue, often with a matted feeling.¹ It is important to maintain a high degree of suspicion for malignancy in children presenting with neck masses in order to appropriately evaluate and refer those who require biopsy for evaluation.¹⁰

Lymphoma

Overall, about 11% of childhood malignancies are lymphomas. In the pediatric population, lymphomas usually cause a mediastinal or abdominal mass, but, in general,

lymphomas of the neck occur as enlarged lymph nodes.¹¹ Both Hodgkin's and non-Hodgkin's lymphoma occur in children, with non-Hodgkin's being slightly more common and having a peak incidence between ages 7 and 11 years.¹² In contrast, Hodgkin's lymphoma is seen later in adolescence.^{2,12} Certain pediatric populations are more at risk for lymphoma, including those with congenital immunodeficiencies or human immunodeficiency virus infection, or recipients of organ and bone marrow transplants.¹² Clinically, children present with painless cervical lymphadenopathy¹³ that feels rubbery, matted, and fixed to underlying tissue. Constitutional symptoms such as fever, weight loss, and night sweats may be present. Physical examination may reveal more diffuse lymphadenopathy, hepatosplenomegaly, or signs of a mediastinal mass, including respiratory compromise and superior vena cava syndrome.¹² Initial evaluation in a patient with suspected lymphoma includes a contrast CT to evaluate the extent of disease, a chest radiograph to evaluate for mediastinal involvement, and laboratory work to evaluate for bone marrow involvement and tumor burden, including electrolytes, complete blood count, calcium, phosphorus, magnesium, lactate dehydrogenase, and urinalysis.¹² Ultimately, diagnosis rests on biopsy of involved lymph nodes. In the emergency department, patients with concern for tumor lysis syndrome may require hydration and alkalization, while those with airway compromise may require intubation or arrangement for emergent radiation therapy or chemotherapy to reduce airway compression.

Neuroblastoma

Neuroblastoma is the second most common solid tumor in pediatrics, usually occurring in children under age 5 years. Cervical disease is the third most common location for neuroblastoma, following disease within the abdomen and chest. Neuroblastoma of the head and neck region may present with a cervical mass or enlarged cervical nodes, Horner's syndrome, proptosis, periorbital ecchymosis, nasal obstruction, and epistaxis. Prognosis is generally better in children less than 1 year of age. Treatment is dependent on the stage of the disease and involves many modalities, including resection, radiation, chemotherapy, and peripheral stem cell transplantation.²

Thyroid Carcinoma

About 2% of pediatric malignancies are thyroid carcinoma, and almost all cases are papillary thyroid carcinomas.^{8,14} Most pediatric patients are in mid to late adolescence, and the disease is two to three times more common in girls.⁹ Important historical factors in patients presenting with a thyroid nodule include a history of radiation therapy to the neck, family history of multiple endocrine neoplasia type II (MEN II), history of autoimmune thyroiditis, and complaints of hoarseness or dysphagia, as these all put patients at increased likelihood of a malignant process.⁹ Thyroid nodules in children are more likely to be malignant than nodules in adults. On physical examination, 70% of children with thyroid carcinoma have cervical lymphadenopathy at presentation.⁹ Most patients are euthyroid, though thyroid function tests, calcitonin, and antithyroid antibodies should remain part of the initial laboratory evaluation.² Treatment of papillary thyroid carcinoma with thyroidectomy, lymph node dissection, and radioactive iodine generally yields excel-

lent survival rates. Lung metastasis are not uncommon, so obtaining a chest radiograph is an important part of the evaluation of a child presenting with a thyroid mass. Medullary thyroid carcinoma is rare in pediatrics and generally limited to cases of MEN IIa (medullary thyroid carcinoma, hyperparathyroidism, pheochromocytoma) or MEN IIb (medullary thyroid carcinoma, pheochromocytoma, mucosal neuromas, marfanoid habitus). It usually occurs in adolescence and is a more aggressive tumor than papillary carcinoma.⁵ An elevated serum calcitonin raises concern for this disease.

Rhabdomyosarcoma

This is the most common soft tissue malignancy of the head and neck in the pediatric population, though it usually presents with disease in the nasopharynx or oropharynx. Some children will develop tumors of the neck musculature primarily and may have symptoms such as dysphagia or hoarseness. Only about 10% of cases develop cervical lymph node metastatic disease; however, because of the potential for malignant cervical lymphadenopathy, a prompt and thorough examination of the oral cavity and nose must be completed. Multimodal therapy yields the best outcomes, and children with this disease generally have better survival than adults.²

Ewing's Sarcoma

This disease is one of the primitive neuroectodermal tumors seen in children, and while it most commonly presents as long bone disease, patients can have a primary neck lesion or metastatic disease in cervical lymph nodes. Primary head and neck tumors have a better prognosis than primaries of the pelvis and proximal extremities. Almost all patients have some metastatic disease at presentation, usually to lung or bone. Prognosis is best in those who undergo multimodal therapy and do not have gross metastatic disease at presentation.²

Langerhans' Cell Histiocytosis

This disease entity has an unclear etiology, representing perhaps either a malignant process or an immune response, and has a wide array of clinical presentations. Up to 20% of the patients will have cervical or generalized lymphadenopathy, and other manifestations include chronic seborrheic rashes, chronic otitis media, lytic skull and other bony lesions, failure to thrive, diarrhea, hepatosplenomegaly, pancytopenia, and interstitial pneumonitis. It is important for emergency physicians to be aware of this clinical entity when evaluating infants and children with cervical lymphadenopathy in order to ask about these other associated symptoms and refer for biopsy.²

Posttransplantation Lymphoproliferative Disorder

Approximately 2% of transplant patients develop this proliferation of B cells, which is thought to be associated with Epstein-Barr virus (EBV) infection. Cervical lymphadenopathy and tonsillar hypertrophy are manifestations of the disease seen in the neck, though generalized lymphadenopathy and hepatosplenomegaly should be assessed in the physical examination. Treatment consists of decreasing immunosuppression as well as starting ganciclovir to potentially treat EBV.²

Summary

Neck masses in children are due to a wide array of etiologies.¹⁵ Diagnosing a congenital lesion is important so that consideration can be given to possible surgical intervention. Differentiating a benign lesion from a malignant lesion is clearly vital in determining the course of treatment. Historically, suspicion for malignancy should be raised when a mass is painless, rapidly enlarging, associated with constitutional symptoms, supraclavicular in location, or causing central nervous system, airway, or vascular compromise. Any suspicion of malignancy warrants imaging studies¹⁶ and surgical referral for possible biopsy to establish a definitive diagnosis.

Chapter 56

Management of Acute Asthma

Sharon R. Smith, MD

Key Points

Any asthma patient can present with a sudden, severe exacerbation regardless of baseline asthma severity.

The vast majority of asthma patients will require bronchodilators *and* anti-inflammatory agents to control exacerbation symptoms.

Recurrent wheezing in very young infants may not be asthma; a cardiac etiology should at least be considered during the evaluation.

wheezing, hyperinflation, and increased respiratory effort (see Chapter 57, Bronchiolitis). Bronchiolitis is typically seen in children younger than 12 months and rarely in those older than 2 years. Young children who develop infection with respiratory syncytial virus (RSV) are more likely to have wheezing illnesses during the toddler and early school years.³ Treatment of RSV does not affect subsequent development of wheezing or asthma. Children sometimes wheeze in association with other viral upper respiratory infections (URIs).⁴ Those who wheeze with almost every URI have “recurrent wheezing.” Some of these patients continue to have wheezing and other asthma symptoms as they get older, while others do not. Although it may not be possible to diagnose asthma in young children, those with recurrent wheezing who respond to asthma therapy should be managed similarly to any child with a formal diagnosis of asthma.^{4,5}

Confounding Diagnoses

Vocal cord dysfunction (VCD) is a clinical condition characterized by abnormal adduction of the vocal cords or spasm in a partially closed position. Children with VCD may present with wheezing and dyspnea.^{6–8} These children typically have normal or near-normal respiratory rate and oxygen saturation, unlike children with asthma. The spasm typically resolves in minutes to hours without treatment. On rare occasion the spasm is so severe that it requires airway management, such as intubation. Causes of VCD include gastroesophageal reflux, sinusitis, allergens, and psychogenic factors. Some children have both asthma and VCD, and the VCD may cause an asthma exacerbation to appear more severe. A definitive diagnosis of VCD is made by evaluating the symptomatic patient with direct laryngoscopy to visualize the vocal cords. Therapies that may be helpful include relaxation techniques, helium-oxygen (heliox) therapy, or panting, which increases the glottic aperture and may decrease symptoms. Children with only VCD usually do not respond to β -agonists or steroids.

Infants with cardiac disease may present with intermittent wheezing or unexplained tachypnea. Cardiac conditions that may cause wheezing include vascular rings (often with right aortic arch); abnormalities with large left-to-right shunts, such as ventricular septal defects or patent ductus arteriosus; or any abnormality that can cause pulmonary edema. Otherwise healthy infants (no history of prematurity, bronchopulmonary dysplasia, or infection) are unlikely to have asthma or a primary pulmonary etiology for wheezing in the

Introduction and Background

Asthma is the most common chronic disease of childhood, and accounts for approximately 1.8 million pediatric emergency visits annually.¹ The National Health Interview Survey completed in 2001 estimates that over 6 million children in the United States have asthma. The highest prevalence rates are noted in children 5 to 14 years of age, boys, and African Americans. Making the diagnosis of asthma in the emergency department (ED) may be difficult. For the purposes of this chapter, an asthma patient is defined as any child who presents with a history of asthma by report of parents, or has had two or more wheezing episodes without another reason (or chronic illness). The *National Asthma Education Program Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma* from the National Institutes of Health defines asthma as “a chronic inflammatory disorder of the airways. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly at night and in the early morning. These episodes are usually associated with widespread but variable airflow obstruction that is often reversible either spontaneously or with treatment.”²

There are many reasons a child can develop wheezing. The first episode of wheezing may be a symptom of a chronic illness, such as asthma or cystic fibrosis, or caused by a number of other etiologies. The differential diagnoses for asthma are listed in Table 56–1. Bronchiolitis is an acute infectious disease of the lower respiratory tract, preceded by fever, rhinitis, or both, and characterized by tachypnea,

first few weeks of life. A cardiac evaluation should at least be considered for any infant younger than 12 weeks of age who presents with recurrent wheezing not suggestive of any other etiology.⁹

History

Key information must be obtained when a child presents with an acute asthma exacerbation. With respect to the current exacerbation, the clinician should ask about triggers (typical and potential), infectious symptoms, duration of asthma symptoms, frequency of rescue medications, chronic medications, time of last medication doses, and peak flow rates. Questions regarding past exacerbations should cover the last ED visit, number of ED visits within the past year, last hospital admission, number of hospital admissions, intensive care unit admissions, and prior intubations.

Potential triggers, such as animal dander and cigarette smoke, should be identified, and the caregivers educated about the importance of avoiding triggers whenever possible. Continued exposure to triggers may decrease response to therapy. Other possible triggers include infection, allergies, dust mites, exercise, and a change in weather. The patient should be evaluated for URIs, such as otitis media and sinusitis, and appropriately treated. Children with allergic rhinitis may benefit from chronic therapy, which may prevent future acute exacerbations.¹⁰

Frequent ED visits or hospital admissions suggest poor control of asthma or underlying severe disease. These chil-

dren should be closely monitored in the ED. It is also important to ask about intensive care admissions and intubations for asthma. These children are more likely to have a severe course and are prone to fatal asthma. Risk factors for fatal asthma include intensive care unit admission, prior intubation, two or more admissions or more than three ED visits within a year, and either an ED visit or admission within the previous month.¹¹⁻¹⁴ Children with fatality-prone asthma may be discharged from the ED if they respond well to therapy, but extreme caution should be used if there is any concern about access to medications, ability to return to the ED, follow-up, or if the child or parent reports uncertainty about being discharged.

Clinical Presentation

Infants and toddlers with asthma or recurrent wheezing present with cough and wheezing that has a high-pitched, squeaky, expiratory sound and is more musical sounding than wheezing in older children and adults. Parents may report that the infant is breathing faster than normal, is having “trouble” breathing, or is not drinking as well as usual. Toddlers may be irritable, and are not able to communicate that they are short of breath. School-age children and adolescents present similarly to adults, with cough, wheezing, shortness of breath, and chest tightness. Children with asthma typically cough before they wheeze. Fever may accompany wheezing due to atelectasis, URIs (otitis media, sinusitis, pharyngitis), and, infrequently, bacterial pneumonia. Children with asthma who present with minimal aeration or difficult-to-hear breath sounds are likely to have significant airway obstruction and warrant immediate therapy.

Severity of Asthma

Assessment of the severity of an asthma exacerbation helps to determine management, evaluate the response to treatment, and communicate with other medical providers.¹⁵ A global sense of severity can be obtained using the information in Table 56–2.² The best objective measure of severity is spirometry or pulmonary function testing, such as forced expiratory volume in 1 second (FEV₁) or forced vital capacity (FVC). However, most EDs do not have the equipment or trained staff to perform pulmonary function testing. Therefore, peak expiratory flow rate (PEFR) is commonly used as an alternative objective measure of airway obstruction and asthma severity. PEFR reflects the caliber of the airways and

Table 56–2 Severity of Asthma Exacerbations

	Mild	Moderate	Severe
PEFR	>80%	50–80%	<50%
Oxygen saturation	>95%	91–95%	<91%
Respiratory rate			
<6 yr old	<30/min	31–60/min	>60/min
≥6 yr old	<20/min	21–50/min	>50/min
Wheezing	End expiratory	Entire expiratory	Inspiratory and expiratory or None due to minimal air exchange
Accessory muscle use	None/mild	Increased	Significantly increased
Speech/infant cry	Normal/normal	Phrases/softer cry	Single words/grunting or no crying

Abbreviation: PEFR, peak expiratory flow rate.

the degree of obstruction. It can be easily obtained in most EDs and correctly performed by the majority of children 5 years of age or older. In order for the test to be valid, the child must stand, take a deep breath, and blow quickly and forcefully through the PEFR tube.¹⁶ Traditionally, the best of three attempts is used as the PEFR. A height-based chart can be used to determine the predicted PEFR for an individual child (Table 56–3). PEFR classification of severity is as follows: mild, greater than 80% of predicted; moderate, 50 to 80% of predicted; and severe, less than 50% of predicted.²

A validated scoring system should be used to assess obstruction for younger children, sicker children, or those who are unable to correctly perform spirometry or PEFR. There are numerous examples of scoring systems for asthma.^{17,18} A classic scoring system is the Pulmonary Index Score (PIS).¹⁷ The PIS is the aggregate of four measures: respiratory rate, wheezing, inspiratory/expiratory ratio, and accessory muscle use; each is rated on a 3-point scale. The PIS correlates well with pulmonary function tests, but the inspiratory/expiratory ratio makes this score difficult to use. Another example of an asthma scoring system is the Pulmonary Score (PS), which is derived from the PIS and has been shown to correlate with PEFR, FEV₁, and FVC. The PS does not include the inspiratory/expiratory ratio and uses an age-dependent respiratory rate (Table 56–4). The PS correlates well with PEFR in children with mild to severe asthma exacerbations.¹⁹ PS ≤ 3 suggests mild, PS 4–6 moderate, and PS > 6, severe exacerbation.

Chronic severity of the underlying disease state is difficult to determine in the ED, and does not always correlate with the severity of the current exacerbation. For instance, a child with mild asthma that is poorly controlled may present with a severe exacerbation. However, the chronic management of asthma is determined by severity of the underlying disease, and knowing the severity may help determine discharge medications. Chronic asthma is defined as mild intermittent, mild persistent, moderate persistent, and severe persistent disease.² Persistent asthma is thought to occur in children because of chronic underlying inflammation. Symptoms of persistent asthma (when the child is not acutely ill) include coughing, wheeze, or shortness of breath 2 or more days a week during the daytime, 2 or more days a week at night, and/or 2 or more times a week during moderate exercise or play. Treating children with persistent asthma early in life (younger than 3 or 4 years of age) with anti-inflammatory agents may improve the inflammation and prevent long-term changes in lung function.^{21,22} Children with persistent asthma should be treated with inhaled steroids.²³ Starting a child on inhaled steroids in the ED should be done in consultation with the primary care physician whenever possible.

Assessment of Oxygenation/Ventilation

Oxygenation and ventilation should be evaluated for all children presenting with an asthma exacerbation.¹⁵ Few pediatric studies specifically address the need for arterial blood gas determinations in children with asthma, but in general they

Table 56–4 Pulmonary Score (PS)

Score	Respiratory Rate		Wheezing*	Accessory Muscle Use
	<6 yr	≥6 yr		
0	<30	<20	None	No apparent activity
1	31–45	21–35	Terminal expiration	Mild increase
2	46–60	36–50	Entire expiration	Increase apparent
3	>60	>50	Inspiration and expiration	Maximal activity

*If no wheezing due to minimal air exchange, score as 3.

are considered painful, invasive, and unnecessary. Noninvasive measures of oxygenation and ventilation are readily available. The arterial partial pressure of oxygen (P_{aO_2}) is commonly estimated using pulse oximetry. For most children, an O_2 saturation of 90% correlates with a P_{aO_2} of 60 mm Hg. The pulse oximeter probe can be placed on a finger or toe; placing a sock over a toe probe may help warm the foot and prevent removal by the child. True ventilation can only be assessed by measurement of the arterial partial pressure of carbon dioxide (P_{aCO_2}), but noninvasive measurements may still provide important information despite their inherent limitations. The partial pressure of CO_2 from a capillary blood gas sample is often higher than the P_{aCO_2} , especially in a sick child with poor perfusion. End-tidal CO_2 is not accurate because significant airway obstruction with a rapid respiratory rate prevents movement of CO_2 into peripheral air spaces (nose and mouth), and underrepresents the P_{aCO_2} . Measuring of P_{aCO_2} in a well-appearing child with oxygen saturation above 90% is not necessary. Studies suggest that children with oxygen saturations above 90% to 92% and PEFRs greater than 25% to 30% are unlikely to have an elevated P_{aCO_2} .^{15,24,25}

Management

Initial assessment for children with asthma includes respiratory rate, room air oxygen saturation, heart rate, blood pres-

sure, auscultation for breath sounds, assessment of respiratory effort and accessory muscle use, level of consciousness, and a measure of severity (PEFR or severity score). Children with a severe exacerbation should be placed on continuous pulse oximetry and cardiac monitoring. Treatment pathways have the potential to improve efficiency of care, improve quality of care, and lower costs. Developing evidence-based pathways that reflect local and institutional practices may be helpful (Table 56–5).¹⁵ The three basic components of asthma therapy are oxygen, bronchodilators, and corticosteroids, with specific medications, dosing, and options for each (Table 56–6).

Oxygen

Oxygen should be provided to any child who presents with respiratory difficulty and oxygen saturation below 95%.² Humidified oxygen is more comfortable and less drying to the nasal and airway mucosa than oxygen alone, and should be used whenever possible.

Bronchodilators

Bronchodilators are used to relax bronchial smooth muscle, and inhibit the release of inflammatory mediators. β_2 -Agonists are the drugs of choice for treating acute bronchoconstriction. β_2 -Agonists work by attaching to the β receptors on bronchial smooth muscle, resulting in activation of cyclic

Table 56–5 Asthma Treatment Algorithm

	β -Agonists	Corticosteroids	Monitors
Mild Exacerbation PEFR > 80% or PS \leq 3 RAO ₂ sat \geq 95%	MDI with spacer q15min \times 3 \leq 30 kg: 4 puffs $>$ 30 kg: 8 puffs <i>or</i> Albuterol nebulized q15min \times 3 Assess after each treatment. If worsening or no improvement, move to moderate exacerbation pathway. Discharge: PEFR > 80% or PS \leq 3	2 mg/kg prednisone or equivalent (max. 60 mg) Give ASAP	Pulse oximeter
Moderate Exacerbation PEFR 50–80% or PS 4–6	Intermittent albuterol treatment with ipratropium (500–750 μ g), then continuous albuterol treatment(s) <i>or</i> For children < 24 mo of age: albuterol with ipratropium (250 μ g) q15min \times 3 If worsening or no improvement, move to severe exacerbation pathway. If improving but not ready for discharge, consider admission. May attempt another continuous treatment or series of 3 nebulized treatments. Discharge: PEFR > 80% or PS \leq 3	2 mg/kg prednisone or equivalent (max. 60 mg) Give ASAP	Pulse oximeter
Severe Exacerbation PEFR < 50% or PS > 6	Intermittent albuterol treatment with ipratropium (500–750 μ g), then continuous albuterol treatment(s) <i>or</i> For children < 24 mo of age: albuterol with ipratropium (250 μ g) q15min \times 3 Consider ancillary medications If worsening clinical condition or no improvement, admit to intensive care unit. Give continuous nebulized albuterol until admission or transfer. Consider starting an intravenous line.	2 mg/kg prednisone or equivalent (max. 60 mg) Give ASAP	Pulse oximeter Cardiac monitor

Abbreviations: ASAP, as soon as possible; MDI, metered-dose inhaler; RAO₂ sat, room air oxygen saturation; PEFR, peak expiratory flow rate; PS, Pulmonary Score.

AMP. This leads to bronchodilation, enhanced mucociliary clearance and vascular integrity, and inhibition of inflammatory mediator release. Albuterol is the most commonly used bronchodilator. Other bronchodilators include levalbuterol, terbutaline, and salmeterol (a long-acting agent not used in emergency management).

Albuterol is delivered by nebulization or metered-dose inhaler (MDI) (see Table 56–6).^{26–28} Oral albuterol is not appropriate because it has variable absorption from the gas-

traintestinal tract, and has significantly less efficacy compared to the inhaled route. Nebulized albuterol delivered via face mask can be given as a series of small doses with patient assessment between doses, or continuously with frequent assessments.^{29–32} Typically, a series of one to three smaller doses are used for younger children (under 24 months) who have difficulty tolerating longer treatments or for children with mild exacerbations. Continuous albuterol is a combination of three or four smaller doses given over 45 to 60 minutes.

Table 56–6 Emergency Department Medications

Medication	Dose	Route	Details
Corticosteroids (Choose one)			
Prednisolone (Orapred)	2 mg/kg (max. 60 mg)	PO	Preferred for children unable to swallow pills (palatable). Give once as soon as possible.
Prednisone	2 mg/kg (max. 60 mg)	PO	Appropriate for children able to swallow pills. Give once as soon as possible.
Methylprednisolone (Solu-Medrol)	2 mg/kg (max. 80 mg)	IV/IM	For critically ill children who cannot safely take oral medications. Consider giving if significant vomiting. Give once as soon as possible.
Dexamethasone (Decadron)	0.6 mg/kg (max. 10 mg)	PO/IM	Consider using highly concentrated parenteral formulation (10 mg/ml).
β-Agonists (Choose one)			
Albuterol (may switch route if desired)	2.5 mg (children < 30 kg) 5.0 mg (children ≥ 30 kg)	Nebulized	Repeat q15–20min as needed. Add normal saline (dilute to minimal volume [4 ml], flow [6–8 L/min]). Consider this option for mild exacerbations, children < 24 mo of age.
	<i>or</i> 10 mg (children < 30 kg) 20 mg (children ≥ 30 kg)	Nebulized	Continuous treatment (lasts 45–60 min). Add normal saline (dilute to minimal volume [4 ml], flow [6–8 L/min]). Repeat as needed for moderate to severe exacerbations. Consider admission if > one continuous treatment required.
	<i>or</i> 4 puffs (children <30 kg) 8 puffs (children ≥ 30 kg)	MDI/spacer	Repeat q15–20min as needed. Child should breathe 6–8 times between each puff.
L-Albuterol (levalbuterol) (Xopenex)	1.25–2.5 mg	Nebulized	Repeat q15–20min as needed. Continuous dosing not well studied.
Anticholinergic			
Ipratropium bromide (Atrovent)	250 mcg (max. 750 μg)	Nebulized	Give ONLY with albuterol, q15–20min. Recommended for moderate to severe exacerbations. Safety/efficacy not studied when used with continuous albuterol.
Ancillary Medications			
Consider using ONLY if severe exacerbation, or moderate exacerbation with no response to above medications. These have no proven advantage over combined β-agonist and corticosteroid therapy. Add cardiac monitoring.			
Epinephrine (1 : 1000)	0.01 mg/kg (max. 0.3 mg)	SubQ	Consider for life-threatening exacerbations. May repeat q15–20min × 3 if needed.
Terbutaline	0.01 mg/Kg (max. 0.25 mg)	SubQ	Consider if very poor aeration. May repeat q15–20min × 3 if needed.
	<i>or</i> 10 μg (over 20 min)	IV bolus	Bolus is followed by a continuous drip.
	<i>and</i> 0.1–0.2 μg/kg/min	IV drip	Increase drip as needed in 0.1-μg/kg/min increments. STOP immediately if ventricular dysrhythmias or hypotension develops.
Magnesium sulfate	25–50 mg/kg (over 30 min) (max. 3 g)	IV bolus	Consider if intensive care unit admission anticipated.
Heliox	70 : 30 (helium : oxygen) 80 : 20 (helium : oxygen)	Face mask or Ventilator	Consider if significant hypoxia (if oxygen saturations 80–85% with maximal O ₂ therapy). May give albuterol at same time.
Ketamine	0.5–1.0 mg/kg	IV	Use as sedative for intubation. Use atropine or glycopyrrolate as premedication. Consider adding benzodiazepine prior to intubation.

Abbreviations: IM, intramuscular; IV, intravenous; MDI, metered-dose inhaler; PO, oral; SubQ, subcutaneous.

Continuous albuterol is used for children with moderate to severe exacerbations. Blow-by nebulization (not using a face mask) is not an effective method to deliver albuterol. An MDI can be used to deliver albuterol to children of any age. A mask with a spacer device is appropriate for children younger than 5 years of age, and a mouthpiece with a spacer device is appropriate for older children. The child should breathe six to eight times between each puff. The exact number of puffs required has not been well studied. Some children and parents will know the correct number of puffs needed from prior experience. MDIs can even be used for children with severe exacerbations.³³ Levalbuterol is the *R*-isomer of albuterol. Some studies suggest that levalbuterol may be more efficacious for some children with asthma; however, it is also more expensive than albuterol.^{34,35} Levalbuterol should be considered for children who use it at home or have a history of improved benefit over albuterol (see Table 56–6). More studies are needed to support universal use of levalbuterol for all children with an acute asthma exacerbation.

Anticholinergics

The anticholinergic agent ipratropium bromide (Atrovent) is useful in the management of children with moderate to severe asthma exacerbations.^{36–39} Ipratropium is similar to atropine, but contains an ammonium group, which prevents systemic absorption. It blocks acetylcholine receptors at the neuromuscular junction of bronchial smooth muscle, resulting in bronchodilation. Studies in children with moderate to severe asthma have shown improved bronchodilation when ipratropium and albuterol are used in combination compared to albuterol alone. This benefit is not seen in children with mild exacerbations. A series of two to three albuterol treatments with 250 mcg of ipratropium with each (total 500 to 750 mcg of ipratropium) is more beneficial than one treatment. Doses larger than 750 mcg have not been studied. Ipratropium causes bronchodilation, but is not as effective as albuterol and is not used as monotherapy. Combination MDIs with both albuterol and ipratropium have not been well studied in children with asthma.

Corticosteroids

Corticosteroids are the only therapy directly aimed at reducing inflammation, and play a vital role in the treatment of children with acute asthma exacerbations (see Table 56–6).^{40,41} Corticosteroids decrease production of inflammatory mediators, and increase production of β receptors. Inflammatory mediators cause increased secretions, mucosal edema, and spasm of smooth muscle in the bronchial tree. Corticosteroids should be given as early as possible in the course of an exacerbation. Improvement in lung function begins within an hour, although clinical benefit may not be apparent for 2 to 4 hours after administration. When possible, the oral route is preferred because it obviates the need for intravenous catheter placement, is well tolerated, and is as efficacious as the intravenous route. Palatable formulations of methylprednisolone are available that enhance compliance among children. All children who present with an acute exacerbation should be treated with corticosteroids except those with a mild exacerbation who have not received any β -agonist therapy prior to arrival. If these children do not improve after one β -agonist treatment, the clinician should consider starting corticosteroids. Dexamethasone, not typically used for asthma,

has been shown to be effective and is also a reasonable choice (see Table 56–6). Although inhaled corticosteroids (ICS) may provide some benefit to children with an acute exacerbation, parenteral corticosteroids remain the mainstay of acute asthma management.^{42–44}

Ancillary Therapies

Administration of albuterol and corticosteroids is adequate treatment for the majority of children with asthma. Children with moderate to severe exacerbations may benefit from the addition of ipratropium. Additional medications may provide benefit to some children who do not initially respond to basic therapy, but there is limited evidence to support any significant improvement in outcome.^{15,45,46} Commonly used adjuncts for children with moderate or severe exacerbations include subcutaneous epinephrine, intravenous or subcutaneous terbutaline, intravenous magnesium sulfate, heliox, ketamine, and aminophylline (see Table 56–6).^{47,48} These are all second- or third-line therapies, and necessitate the addition of cardiac monitoring because of potential side effects. Addition of ancillary therapies can be considered for children with severe exacerbations or those with moderate exacerbations not responding to conventional therapies.

Epinephrine stimulates α receptors and nonspecific β receptors and causes bronchodilation.^{47,48} It can be given subcutaneously or nebulized via face mask. Racemic epinephrine offers no advantages over nebulized albuterol, and there are increased side effects related to a receptor activity (vasoconstriction, pallor). Subcutaneous epinephrine was the drug of choice for acute asthma before the development of inhaled β -agonists, but now is rarely used. Subcutaneous epinephrine, along with continuous nebulized albuterol, may be considered for children with a life-threatening exacerbation or those deteriorating rapidly (see Table 56–6).

Terbutaline is a β_2 -agonist, and can be given intravenously or via MDI (see Table 56–6).^{15,47,48} Although terbutaline is an effective bronchodilator, albuterol is the β -agonist of choice for acute exacerbations. Intravenous terbutaline may be considered for a severe exacerbation that is not responding to continuous nebulized albuterol and corticosteroids. Typically, terbutaline is administered intravenously as a bolus and followed by a continuous drip. There is some evidence to suggest that intravenous terbutaline may decrease the length of stay for children admitted to an intensive care unit. There is a small risk of ventricular dysrhythmias, so all children on intravenous terbutaline must have continuous cardiac monitoring. Terbutaline should be stopped immediately if dysrhythmias or hypotension develops.

Magnesium sulfate causes bronchodilation and stimulates calcium channels on mast cells, which results in decreased release of histamine. It is given as an intravenous bolus (see Table 56–6); it is not effective as an inhaled agent. The use of magnesium is controversial.^{15,47,48} Some studies suggest improved bronchodilation when added to inhaled albuterol, whereas other studies do not support these findings. Magnesium may be considered for children with a severe exacerbation not responding to other therapies. Side effects include flushing, tachycardia, bradycardia, hypotension, and muscle weakness.

Heliox is an inhaled combination of helium and oxygen, often in 70 : 30 or 80 : 20 mixtures.^{49–51} The lower density of helium allows the mixture to pass through narrow airways

with less turbulence than oxygen alone, and can improve distal oxygen delivery. This may improve hypoxia and gain time for other therapies to work. Helium is an inert gas with no direct therapeutic benefit.

Ketamine is used primarily as an induction agent for children with asthma who require intubation. There are limited pediatric studies evaluating its use for asthma therapy, and it is not routinely used (see Table 56–6).⁵² Theophylline or intravenous aminophylline are rarely used in asthma management. If a child takes theophylline for chronic asthma, a serum theophylline level should be measured in the ED, and the result used to guide therapy. Theophylline is unlikely to improve bronchodilation when continuous albuterol is used, and there are numerous side effects, including nausea, vomiting, and cardiac dysrhythmias.

Potential Complications

Pneumothorax and pneumomediastinum are rare complications of asthma.^{24,25} Pneumothorax often presents with sudden onset of chest pain with shortness of breath. A pneumomediastinum should be suspected in children who develop pain in the neck or shoulder or crepitus. Specific treatment is usually not required. Maintaining oxygen saturation above 95% with high-flow oxygen may be helpful for both conditions because it facilitates the reabsorption of nitrogen from the surrounding tissues. A thoracostomy tube should be considered if the pneumothorax is greater than 25% or is enlarging, the patient requires positive pressure ventilation (PPV), or oxygen saturation remains below 90% despite maximal oxygen therapy. A tension pneumothorax or pneumomediastinum from asthma is extremely rare, but requires immediate decompression with needle thoracostomy or needle pericardiocentesis (see Chapter 168, Thoracostomy; and Chapter 180, Pericardiocentesis).

Respiratory Failure

Children with asthma may develop respiratory compromise or failure. The most common cause of respiratory failure is ineffective ventilation from a combination of severe obstruction and muscle fatigue. Infants and young children initially will be tachypneic, fussy, and irritable. As respiratory failure ensues, infants and younger children become sleepier, do not interact with parents, may be cyanotic, and can develop paradoxical breathing. Older children may have decreased level of consciousness and tachypnea. Elevated Paco_2 (>60 mm Hg), rapidly increasing Paco_2 , and tachypnea are signs of muscle fatigue and impending respiratory failure.^{15,24} A sudden decrease in level of consciousness or drop in respiratory rate is an ominous sign. Supplying high-flow oxygen can maintain oxygen saturation above 90% but may be falsely reassuring, leading to underrecognition of hypoventilation and early respiratory failure. An arterial blood gas measurement should be considered in a child with continued oxygen saturation less than 90% on maximal oxygen therapy, no improvement despite aggressive treatment, and mental status changes.

Intubation

Most children with asthma do not require intubation, and are able to oxygenate and ventilate even with significant bronchoconstriction. Any child with apnea, respiratory failure, or progressively deteriorating mental status should be intu-

bated.^{15,24,25} The emergency physician should consider planning for intubation in children with increasing hypercarbia, inability to maintain oxygen saturation above 80% to 85% on maximal supplemental oxygen, or significant fatigue (decreasing respiratory rate without accompanying improvement in oxygenation or ventilation) (see Chapter 3, Rapid Sequence Intubation). Ketamine is a good induction agent under these circumstances and can be used along with an anticholinergic agent (atropine or glycopyrrolate) to decrease oral secretions, and a benzodiazepine to decrease dysphoria or emergence reactions.

Positive pressure ventilation (PPV) may be useful instead of intubation for some children.^{53–55} PPV is a noninvasive way to decrease the work of breathing, improve oxygenation and ventilation, and re-expand atelectasis. PPV allows the child to control respiratory rate, tidal volume, and inspiratory and expiratory time. A tight-fitting face or nasal mask is used to deliver continuous positive airway pressures between 2 and 6 mm H₂O. Younger children may not tolerate the tight-fitting mask because of fear or anxiety. Some sedation may be required to utilize this technology, but is often less than what is required for intubation. This modality has not been well studied in children and should be viewed as a short-term measure for respiratory support.

Outpatient Treatment Versus Admission

Primary care physicians will successfully manage most asthma patients as outpatients. Any child seen in the ED for an acute asthma exacerbation should have follow-up with their primary provider within 7 days of the ED visit to evaluate recovery from the acute event, discuss reasons for the ED visit, and update the action plan to prevent future ED visits.^{2,15} Consultation with a pulmonologist or allergist should be considered for children with life-threatening exacerbations, frequent ED visits, frequent hospitalizations, poor control, or lack of ongoing primary care.⁵⁶

Almost 30% of children treated for asthma in the ED are admitted.^{57,58} It is difficult to predict who will require admission early in the course of therapy. After initial therapy, children should be considered for discharge to home if the following are true:

- PEFr is greater than 70% to 80% of predicted
- There is minimal to no wheezing
- There is little or no work of breathing
- Medications can be filled
- Follow-up can be obtained
- Return to ED is feasible if needed

Admission should be considered if any of these conditions cannot be met or there are social issues that raise concern about the ability of the caregiver to adequately care for the child at home. Other reasons that may influence the decision to admit include hospital or ED standards, cost of care, or the availability of a short-stay or observation unit. Consideration should be given to transferring a child to a facility with pediatric critical care capability if he or she requires intubation, requires continuous albuterol therapy for 2 or more hours, is worsening, is not improving with conventional therapy, or cannot be closely monitored in the current facility.

All children discharged to home must be given prescriptions for their acute medications and have the ability to fill them. Albuterol should be prescribed, either as a nebulized solution premixed with normal saline or with a prescription

Table 56–7 Discharge-to-Home Medications

Medication	Dose	Route	Details
Corticosteroids (Choose one)			
Prednisolone (Orapred)	2 mg/kg/day (max. 60 mg)	PO	Preferred for children unable to swallow pills (palatable). Once-a-day dosing preferred, but may divide and give bid. Give for a total of 3–5 days.
Prednisone	2 mg/kg/day (max. 60 mg)	PO	Appropriate for children able to swallow pills. Once-a-day dosing preferred, but may divide and give bid. Give for a total of 3–5 days.
Dexamethasone (Decadron)	0.6 mg/kg (max. 10 mg)	PO	One dose given in ED. Second dose given at home the following day.
β-Agonists (Choose one)			
Albuterol (may use either/ both routes if desired)	2.5–5.0 mg	Nebulized	Add normal saline (dilute to minimum 4 ml) with each treatment. Give q3–4h at home, AND space to q5–6h as tolerated.
	<i>or</i> 4 puffs (children < 30 kg) 8 puffs (children ≥ 30 kg)	MDI/spacer	Give q3–4h at home, AND space to q5–6h as tolerated. Child should breath 6–8 times between each puff.
L-Albuterol (levalbuterol) (Xopenex)	1.25–2.5 mg	Nebulized	Give q3–4h at home, AND space to q5–6h as tolerated.
Inhaled Corticosteroids (Choose one)			
Consider doubling the dose for children currently taking an inhaled corticosteroid (use corticosteroid child is currently taking). Consider starting an inhaled corticosteroid for children with persistent asthma: any child with 2 or more days per week of coughing, wheezing, and shortness of breath at night, during the day, or with exercise. Consult with PCP when possible before starting. Use fluticasone for children discharged to home with an MDI and spacer, and budesonide for children discharged to home with nebulizer.			
Fluticasone (Flovent)	44 µg/actuation (children < 12 yr)	MDI with face mask <i>or</i> MDI/mouthpiece	2 puffs bid if never taken before. Double dose if currently taking. PCP will determine length of therapy.
	<i>or</i> 110 µg/actuation (children ≥ 12 yr)	MDI/mouthpiece	2 puffs bid if never taken before. Double the dose if currently taking. PCP will determine length of therapy.
Budesonide (Pulmicort Respules)	0.5 mg/day (max. 1.0 mg/day)	Nebulized	May divide and give bid. Double the dose if currently taking. PCP will determine length of therapy.

Abbreviations: bid, twice daily; ED, emergency department; MDI, metered-dose inhaler; PCP, primary care provider.

for normal saline, or in the form of an MDI with a spacer device. Training on proper use of the nebulizer or the technique for an MDI should be provided to the family in the ED if they are previously uneducated in asthma medication administration. Albuterol is typically given every 4 to 6 hours depending on need, and the family should be educated about how to decrease the frequency as the exacerbation resolves. Oral prednisone solution or tablets should be continued for 3 to 5 days, given once daily or divided and given twice daily (Table 56–7).⁴⁰

Children who are categorized with any level of persistent asthma should be discharged to home with ICS. Although several studies suggest that ICS given during an acute exacerbation are beneficial, most show that ICS alone are less efficacious than parenteral corticosteroids. However, chronic ICS has clear benefit and no significant side effects. If ICS are already being used, doubling the dose during the acute exacerbation should be considered.⁴² The primary provider should be consulted before initiating ICS whenever possible. If the primary provider cannot be reached, ICS should be started, and adjustments in dosing can be done during follow-up (see Table 56–7).

It is important to discuss reasons for the ED visit with the family. These may include lack of understanding about how and when to use medications, lack of appropriate medica-

tions, uncertainty about when or how to contact the primary provider, or lack of an asthma action plan. There may be other reasons for the ED visit, such as parental anxiety or inability to fill medication prescriptions. It is also important to emphasize the need for follow-up with the primary provider within a week of the ED visit.

The role of newer medications, such as leukotriene inhibitors, in the acute management of asthma has yet to be determined. One study of adult ED patients showed modest benefit from adding intravenous montelukast, a leukotriene inhibitor, to standard acute management.⁵⁹ No studies have been published showing similar results in children.

Another challenge for asthma care is linking children seen in the ED with their primary providers, and finding ways to establish regular asthma care. Regular care may improve adherence to medical and preventive management plans and should improve the relationship between the family and primary provider. Teaching families early recognition of an acute exacerbation, and how and when to start or escalate therapy, may prevent future ED visits.

Chapter 57

Bronchiolitis

Deborah A. Levine, MD

Key Points

Bronchiolitis is the most common lower respiratory infection in children less than 2 years of age.

There is a risk of apnea and dehydration, especially in the youngest infants.

Infants with prematurity, chronic lung disease, and congenital heart disease are at risk for severe disease.

Diagnostic tests are not useful in management of bronchiolitis.

bronchiolitis are parainfluenza virus, human metapneumovirus, influenza virus, adenovirus, rhinovirus, enterovirus, and herpes simplex virus.

The viral etiologic agent invades the respiratory tract, causing necrosis and sloughing of the respiratory epithelium of the smaller airways, and initiates an immune response with inflammatory infiltration and edema. The bronchioles become narrowed from this cellular infiltrate, edema, and mucus, leading to air trapping and atelectasis. The infant's airway is smaller than its adult counterpart, which drastically further limits airflow. This leads to an increased work of breathing with respiratory distress. If severe airway obstruction ensues, ventilation-perfusion mismatch, hypoxemia, and respiratory muscle fatigue and failure may subsequently develop.

Introduction and Background

Bronchiolitis is an acute viral-induced inflammation of the airways of the lower respiratory tract resulting in airway obstruction. It is the most common lower respiratory tract infection in children under 2 years of age, with a peak age between 2 and 6 months.¹ Reinfection can occur at any age. Each year approximately 12% of infants develop bronchiolitis.² Between 1997 and 2000, there were over 700,000 emergency department (ED) visits (22.8 per 1000) by infants less than 1 year of age for a lower respiratory infection. Approximately half of these visits occurred during January and February.³ Thirty percent of these ED patients were hospitalized, and 68% of these hospitalized patients were under 1 year of age. Respiratory syncytial virus (RSV) bronchiolitis was the leading cause of infant hospitalization each year during 1997 through 2000.³ Hospitalizations continue to rise compared to prior years' data.⁴ The total medical expenses for ED patients with lower respiratory infection were approximately \$200 million during that time period.³ Bronchiolitis-associated deaths occur in approximately 95 children a year.⁵ Three fourths of the deaths are in infants less than 1 year of age.⁵

Recognition and Approach

Bronchiolitis is a common cause for hospitalization and can result in severe morbidity and mortality. RSV causes the majority of cases of bronchiolitis, especially during the winter and early spring months.⁶ Other etiologic pathogens causing

Clinical Presentation

Bronchiolitis usually presents with symptoms of an upper respiratory infection, such as coryza for 1 to 2 days. These symptoms progress to wheezing, cough, and tachypnea. Patients can be febrile as well. Respiratory symptoms in infants often cause post-tussive emesis, irritability, and difficulty with feeding (Table 57-1). Infants with a mild form of bronchiolitis can appear playful and have adequate hydration with mild wheezing. More significant presentations of bronchiolitis include lethargy, signs of dehydration, and significant respiratory accessory muscle use (intercostal and supraclavicular retractions), head bobbing, and/or nasal flaring. Apnea can occur in up to 20% of hospitalized infants and may be the initial manifestation of bronchiolitis, before respiratory symptoms begin.⁷ The risk of apnea is usually abated by the third day of infection. Younger age (<2 months), prematurity, or radiographic findings such as infiltrates or atelectasis have been described as risk factors for apnea in patients with bronchiolitis.^{8,9}

Premature infants, those with congenital heart disease, those with chronic lung disease (e.g., cystic fibrosis, bronchopulmonary dysplasia, congenital pulmonary anomaly), those who are immunocompromised, and infants younger than 3 months of age are at risk for a severe course of bronchiolitis.¹⁰ Complications from bronchiolitis, such as intensive care unit admission, mechanical ventilation, and death, were highest in children with cardiac disease, chronic lung disease, immunocompromised status, gestation less than 37 weeks or age less than 6 weeks.¹⁰ Patients age 13 months and younger who

Table 57-1 Clinical Manifestations of Bronchiolitis by Age

Neonate	Infant/Young Child
Lethargy	Coryza
Irritability	Wheezing
Poor feeding	Retractions
Apnea	Flaring
Fever	Tachypnea

present to an ED are more likely to have severe illness if they have a toxic appearance, oxygen saturation less than 95%, gestational age less than 34 weeks, respiratory rate greater than 70 breaths/min, atelectasis on chest radiograph and are younger than 3 months.¹¹ Death rates from bronchiolitis are highest in infants ages 1 to 3 months and infants weighing less than 1500 grams at birth.¹²

Bronchiolitis is a clinical diagnosis based on signs and symptoms from the history and physical examination. Since there is no confirmatory test or “gold standard” for diagnosing bronchiolitis, laboratory testing is not helpful. Pulse oximetry is helpful in the identification of infants with moderate to severe hypoxemia associated with bronchiolitis. No study has demonstrated the utility of a complete blood count in diagnosing bronchiolitis or directing therapy.¹³ Elevated white blood cell counts have limited usefulness in diagnosing bacterial disease as well.¹³

Because RSV is the most common etiology in bronchiolitis, virology testing is frequently performed. Rapid viral antigen detection tests on nasopharyngeal specimens are 80% to 90% sensitive compared to viral cultures.¹⁴ These have limited usefulness except for epidemiologic surveillance, cohorting inpatients to reduce nosocomial spread, and perhaps designating a patient at lower risk for concurrent serious bacterial infection.^{15,16}

Chest radiographs are not indicated for making the diagnosis of bronchiolitis, but can exclude other disease processes that may present with wheezing, such as foreign body or congestive heart failure. Some studies have reported a more severe clinical course in patients with atelectasis on chest radiographs.^{10,11} Other studies have found an increased rate of treatment with antibiotics in bronchiolitis patients with lobar infiltrates, but equal recovery times, compared to those with normal radiographs.¹⁷ Radiologic findings suggestive of bronchiolitis are hyperinflation, flattened diaphragm, atelectasis, and peribronchial cuffing. Infiltrates may be present as well.¹⁸ There is limited evidence to support the routine use of diagnostic testing in most children with bronchiolitis since no studies have addressed the impact of testing on patient outcomes. Patients who are severely ill or toxic in appearance or those with an unusual clinical course may be good candidates for laboratory and radiographic testing. Differential diagnosis of bronchiolitis includes other infectious, inflammatory, anatomic, and systemic conditions (Table 57-2).

Important Clinical Features and Considerations

Infants with bronchopulmonary dysplasia can have episodes of wheezing that may mimic respiratory infections such as

Table 57-2 Differential Diagnosis of Bronchiolitis

Asthma
Pneumonia
Cystic fibrosis
Foreign body
Congestive heart failure and congenital heart disease
Acquired heart disease, such as myocarditis
Tracheoesophageal fistula
Gastroesophageal reflux
<i>Mycoplasma pneumoniae</i> infection
<i>Chlamydia trachomatis</i> infection
Congenital rings, webs
Pulmonary sequestration
Toxins, poisonings (organophosphates)

bronchiolitis, but these infants are also at risk for respiratory infections.¹ Patients with pneumonia can present with wheezing, especially with an interstitial processes due to viral etiologies. The clinician should look for systemic signs of congestive heart failure in patients with undiagnosed congenital or acquired heart disease. These infants can present acutely with respiratory distress and wheezing but may have accompanying organomegaly, cardiac murmur, peripheral edema, and abnormal chest radiograph and/or electrocardiogram.

Fever can be a presenting sign of bronchiolitis. The decision to adequately exclude other sources of infection such as meningitis, bacteremia, urinary tract infection, or bacterial enteritis in the febrile infant with bronchiolitis is a difficult one for the emergency physician, who must ask the question, does every febrile infant with bronchiolitis warrant a complete fever evaluation, including lumbar puncture? A recent large, prospective, multicenter study of febrile infants less than 60 days of age with fever greater than 100.3° C studied the risk of serious bacterial infection in infants with RSV and bronchiolitis. Although the infants with bronchiolitis had a lower rate of serious bacterial infections compared to infants without bronchiolitis (7.1% vs. 12.5%, $P = 0.069$), this was not statistically significant. Both groups of infants had substantial rates of urinary tract infection. There were too few patients in the study with either meningitis or bacteremia to draw meaningful conclusions about these two types of infection.¹⁹ Other studies have reported low rates of serious bacterial infections in infants with bronchiolitis but also lack sufficient sample sizes to adequately compare rates of the most severe infections.^{15,16,20-23} Studies examining the rates of concomitant bacterial infection in older infants and children with bronchiolitis show low rates of such infection, though the prevalence of urinary tract infection may still merit screening in these patients.^{20,24} The incidence of serious bacterial infections in febrile infants with bronchiolitis remains low but not negligible. Until larger studies are completed, febrile infants with bronchiolitis may still be at risk for concomitant bacterial infections. Emergency physicians must plan the evaluation of the febrile infant based on this information.

Acutely, approximately 10% to 20% of infants with bronchiolitis require hospitalization. Potential morbidity and mortality may occur due to respiratory failure, dehydration, and apnea. Aspiration and bacterial superinfection are

uncommon.^{25,26} Otitis media is a common secondary infection, occurring in up to two thirds of infants with bronchiolitis.²⁷ Approximately 15% to 25% of patients with bronchiolitis will develop asthma.²⁸ In children followed for 18 to 20 years, bronchiolitis in infancy was a significant predictor of asthma in early adulthood (odds ratio, 3.37; 95% confidence interval, 1.12–10.10).²⁹ Another large prospective study of children found that a history of RSV bronchiolitis within the first year of life was a significant risk factor for wheezing at age 6, but this risk decreased with age.³⁰

Management

There remains considerable controversy over the management of bronchiolitis. Historically, bronchiolitis is a self-limited illness, requiring only supportive care such as adequate oxygenation and hydration until the disease abates.¹⁴ Nasal suctioning is commonly employed to reduce secretions. Occasionally, mechanical ventilation is necessary to maintain gas exchange.

Pharmacologic therapy has been commonly employed in the treatment of infants and children with bronchiolitis.³¹ β -Agonists, bronchodilators, corticosteroids, antivirals, and immunoglobulins have been studied in infants with bronchiolitis. Many of these are small studies in varied populations (different clinical severity) and settings (hospitalized vs. outpatients) using nonstandardized definitions of bronchiolitis (such as the inclusion of infants with recurrent wheezing) and heterogeneity of outcome measures (various respiratory scores, admission criteria). Therefore, the evidence base for the treatment of bronchiolitis is not particularly strong.

Epinephrine

Epinephrine contains α - and β -adrenergic properties resulting in vasoconstriction, which has been postulated to reduce the airway edema associated with bronchiolitis, decreasing airway obstruction.³² Acutely wheezing patients who received 0.01 mg/kg of subcutaneous epinephrine versus placebo had a significantly better clinical appearance.³³ A meta-analysis of 14 studies of children treated with nebulized epinephrine versus placebo or salbutamol showed no overall difference in admission rates among outpatients or length of stay among inpatients.^{34,35} There was evidence supporting the use of epinephrine among outpatients based on short-term benefits such as clinical score, oxygen saturation, heart rate, and respiratory rate during the first 90 minutes of drug administration. A recent multicenter, randomized, double-blind controlled trial comparing nebulized epinephrine to placebo in 194 hospitalized infants with bronchiolitis showed no difference in length of hospital stay or time until discharge between the groups.³⁶ The more severely affected patients in this study who received epinephrine had a longer length of stay than those who received placebo. Adverse effects reported included pallor and tachycardia, but these were well tolerated without sequelae.³⁷ Overall, there may be some benefit from nebulized epinephrine, but larger, well-designed studies are warranted to evaluate its use in bronchiolitis.

Bronchodilators (Including Anticholinergics)

Bronchodilators are the mainstay of therapy for bronchiolitis. This is due to the belief that the pathophysiology of

bronchiolitis may be similar to that of asthma (reversible bronchospasm). A meta-analysis of prospective, randomized, controlled trials involving over 900 patients ages 24 months or younger who received bronchodilators (albuterol, salbutamol, or ipratropium bromide) revealed a statistically significant improvement in clinical score compared to placebo-treated infants, though the magnitude of the difference was of questionable clinical significance.³⁸ No improvement in oxygenation, rate of hospitalization, or length of hospital stay was found in the bronchodilator-treated infants.³⁸ Although there was a modest improvement in clinical respiratory score in bronchodilator-treated infants, patients with a history of wheezing who may respond better to bronchodilators were included. A meta-analysis of five outpatient randomized controlled trials of inhaled β -agonists in over 250 patients revealed no difference in hospital admissions or respiratory rate. There was a statistically significant increase in oxygen saturation and heart rate in the infants treated with β -agonists, but this was clinically insignificant.² Nebulized ipratropium bromide was evaluated in four studies included in a systematic review. No differences in hospitalization rates or clinical scores were noted in patients who received this drug as either a single agent or when used in combination with other bronchodilators.³⁹ Based on the literature, the use of nebulized bronchodilators does not alter clinical course or hospitalization rates in patients with bronchiolitis.

Corticosteroids

The similarity between the clinical presentation of bronchiolitis and asthma has encouraged clinicians to utilize common therapies such as bronchodilators and corticosteroids. Corticosteroids have been thought to help in the early phase of bronchiolitis, moderating bronchiolar inflammation and the production of inflammatory mediators such as leukotrienes and cytokines.^{40–43} However, most studies contain few patients, differing clinical scoring systems, various dosages and routes of medication delivery, and nonstandardized outcome measures.^{44,45}

A meta-analysis of six clinical trials of corticosteroid therapy in the treatment of over 300 hospitalized infants with bronchiolitis showed that infants treated with corticosteroids (either parenteral or oral) had a lower mean length of stay than those patients in the placebo group. The mean clinical score (including wheezing, oxygen saturation, accessory muscle use, and respiratory rate) at 24 hours after initial therapy was lower in those infants who received steroids compared to the placebo group.⁴⁶ Based on these results, steroids may improve the course of bronchiolitis but probably only when applied to a more severely affected, hospitalized population. Also, the clinical importance of these results are questionable since the benefit of reducing hospitalization by less than half a day may be clinically insignificant. A systematic review of 14 studies of over 900 patients with bronchiolitis treated with oral, parenteral, or inhaled steroid showed conflicting results among studies with regard to hospitalization rate or duration of inpatient stay. Collectively, these studies failed to show significant improvements in clinical scores or hospitalization rates in infants treated with corticosteroids.³⁷

Few studies have examined the role of steroids in the management of patients with bronchiolitis in the ED until recently.

Two studies found beneficial effects of corticosteroids given to bronchiolitic patients in the ED, rather than later in their hospital courses.^{44,45} One study that enrolled only patients with the first episode of wheezing and utilized a higher dose of oral dexamethasone in the ED found a significantly decreased rate of hospitalization (19% vs. 44%) and a greater improvement in clinical score at 4 hours in the steroid-treated group.⁴⁵

Preliminary results of a recently completed multicenter, randomized, controlled trial of the effectiveness and safety of the administration of oral dexamethasone for acute moderate to severe outpatient bronchiolitis indicated no difference between groups with regard to the need for hospitalization.⁴⁷ In conclusion, there are no data to support the use of steroids in ED patients with bronchiolitis at the current time.

Ribavirin

Ribavirin is the only Food and Drug Administration–approved antiviral medication for RSV disease. It is administered as a continuous aerosol. Initially, a series of randomized controlled trials found ribavirin to decrease the severity of RSV bronchiolitis, and thus it was recommended as a standard therapy.^{48,49} Subsequently, a systematic review of 10 randomized, controlled trials of ribavirin found that it reduced the duration of mechanical ventilation and may reduce the length of hospital stay, but has not been shown to reduce mortality or respiratory deterioration. No adverse effects have been reported.⁵⁰ Due to conflicting reports in the literature, high costs, and potential teratogenicity to health care personnel, ribavirin is currently not recommended.¹⁴

Immunoglobulin Therapy

RSV intravenous immune globulin and monoclonal antibody (palivizumab) administered intramuscularly given in monthly doses prophylactically during RSV season have been shown to reduce RSV-related hospitalizations in high-risk infants.^{39,51} RSV immune globulin was studied as a treatment for acute bronchiolitis and found not to alter the days of hospitalization or mechanical ventilation, but did show a trend toward shorter stays in the intensive care ward.^{52,53} Currently there is evidence only to support the use of palivizumab in the prevention of RSV bronchiolitis in high-risk populations; it is not indicated in the treatment of active disease.¹⁴

Additional Therapies

Other novel treatment modalities have been studied in patients with bronchiolitis. Heliox is a helium-oxygen mixture that has a lower density than regular air. This lower density lowers air resistance, especially in obstructed bronchioles, improves airflow and ventilation, and decreases the work of breathing. Two small studies of nonintubated infants with bronchiolitis treated with Heliox showed improvements in clinical scores.^{54,55} Intramuscular interferon alfa-2, herbal treatments, antibiotics, surfactant, aerosolized furosemide, nebulized recombinant human deoxyribonuclease, and hypertonic saline have also been studied in small numbers of infants with bronchiolitis, but none has conclusively been shown to be effective, and these therapies are therefore not routinely recommended.⁵⁶⁻⁶¹

Summary

The following are indications for admission in a patient with bronchiolitis: hypoxia (defined as oxygen saturation less than 90% to 95% depending on elevation), dehydration, poor feeding, lethargy, severe respiratory distress (respiratory rate > 60 breaths/min, retractions, flaring, head bobbing, poor air entry), or an unreliable caregiver. Very high-risk infants include those with a history of prematurity, heart disease, lung disease, or young age (<3 months), and all should be strongly considered for admission.

Infants with severe nasal congestion or tachypnea may not be able to feed sufficiently and may be at risk for dehydration and/or aspiration. Patients with hypoxia need supplemental oxygen. Cautious practice patterns should be exercised with the youngest infants (<3 months) with bronchiolitis and those with comorbidities who may develop a more severe course and have the highest risk for apnea. Infants with severe hypoxia or CO₂ retention require intensive care management for possible mechanical ventilation. Infants with a history of apnea require intensive care monitoring since recurrence of apnea is common. Intravenous access is indicated for infants who have apnea and those with dehydration. Empirical therapy with antibiotics is not warranted unless bacterial infection is suspected. Infants and children who are discharged need close follow-up (within 1 to 2 days). Parents must be made aware of possible complications of the disease and should be assessed for telephone access and available transportation if the clinical condition worsens.

Prevention

Vigilant hand washing and contact isolation of affected patients can prevent spread of the viral pathogens causing bronchiolitis. The monoclonal antibody palivizumab, given intramuscularly on a monthly basis during RSV season, is the currently indicated prophylactic therapy for infants at high risk for RSV disease. Purified fusion protein vaccines against the most common etiologic viral causes of bronchiolitis are currently under development and appear promising.

Chapter 58

Pneumonia

Shari L. Platt, MD

Key Points

Causative pathogens of pneumonia in children can be difficult to identify.

Streptococcus pneumoniae is the most common bacterial cause of pneumonia in children.

Viral causes of pneumonia in children vary based on age and season.

Tachypnea is the most reliable clinical predictor of pneumonia in children.

Laboratory and radiologic testing offers limited diagnostic benefit.

Introduction and Background

Community-acquired pneumonia (CAP) is one of the most common infections in children and is the leading cause of mortality in children worldwide. Acute respiratory illnesses are responsible for more than 5 million fatalities each year in children less than 5 years of age in developing countries. The annual incidence in children less than age 5 is approximately 35 to 40 cases per 1000 in Europe and North America.¹ The mortality rate from pneumonia in children in the United States has declined by 97% from 1939 to 1996.² This decline is primarily attributable to the introduction of penicillin in the 1940s. Availability of the measles vaccine and improved access to medical care for poor children, primarily as a result of the Medicaid program, have contributed to further reduction in mortality rates recorded from 1963 to 1985. The rate of pneumonia remains high in developing countries. The World Health Organization (WHO) reported a global annual incidence of clinical pneumonia in children less than 5 years of age estimated to be 146.5 million new cases in developing countries and 2.1 million new cases in developed countries.³ The definition of clinical pneumonia for the purpose of the WHO estimates encompasses pneumonia, bronchiolitis, and reactive airways disease associated with respiratory infections.

Recognition and Approach

Probably the greatest challenge in the approach to children with pneumonia is that the microbiologic etiology is difficult to identify. This is primarily due to limitations of diagnostic testing modalities: blood cultures, antigen testing and antibody titers, and the need for invasive means to retrieve specimens.^{1,4} Two studies illustrate our limited ability to diagnose the etiology of pneumonia in children. In a prospective study of 168 ambulatory children with CAP, an etiologic agent was identified in only 43% of cases.⁵ These included *Streptococcus pneumoniae* (27%), *Mycoplasma pneumoniae* (7%) and *Chlamydia pneumoniae* (6%). Patients with *S. pneumoniae* frequently had a mixed infection (40%). Of 157 patients tested for viral infection, 20% were positive by culture and/or direct fluorescent antibody test. Viral etiologies identified included respiratory syncytial virus (RSV), influenza viruses A and B, parainfluenza viruses 1 and 3, adenovirus, enterovirus, cytomegalovirus, and herpes simplex virus. All viral isolates were identified in children less than 8 years of age.⁵ A similar study, in 254 hospitalized children with CAP, identified a potential causative agent in 85% of cases.⁶ Extensive diagnostic testing accounted for the relatively high yield in this study. Similar etiologies identified, in decreasing frequency of occurrence, included *S. pneumoniae*, *Haemophilus influenzae*, *M. pneumoniae*, *Moraxella catarrhalis*, *C. pneumoniae*, *Streptococcus pyogenes*, and *Chlamydia trachomatis*. Viral etiologies included (most common to least common) RSV, rhinovirus, parainfluenza viruses 1 through 3, adenovirus, influenza virus A and B, coronavirus, human herpesvirus 6, Epstein-Barr virus, and varicella-zoster virus. Mixed viral-bacterial infections were detected in 30% of patients, and 41% of patients had more than one microbiologic agent identified. Of interest, of 93 patients with *S. pneumoniae*, only one had a positive blood culture. The remaining 92 patients were diagnosed based solely on serologic evidence.⁶

A prospective analysis seeking to identify etiologic agents via a pneumolysin-based polymerase chain reaction assay identified a respiratory pathogen in 79% of 154 pediatric patients with lower respiratory tract infection. The most common etiologic agent was *S. pneumoniae* (44%). Of 68 patients with *S. pneumoniae* infection, 18% had a co-infection with another bacteria and 31% had a co-infection with a virus. Atypical agents (*M. pneumoniae* and *C. pneumoniae*) accounted for 22% of all infections (14% and 9%, respectively). The most common viral etiologies included

influenza viruses A and B, RSV, parainfluenza viruses 1 through 3, and adenovirus.⁷ While *S. pneumoniae* remains the most common bacterial cause for pneumonia in children, atypical infections are emerging as a common respiratory pathogen, particularly in adolescents.⁸ In developing countries, aspiration from the upper respiratory tract accounts for nonserotypable *H. influenzae* as a cause of pneumonia in children.⁹

Published data reveal the limitations of diagnostic testing in pneumonia, with nearly 30% to 40% of cases unidentified. To aid management decisions, common patterns of infectious agents exist that help to guide diagnosis and therapy. Age is the most helpful marker for the cause of pediatric pneumonia. When considering age as a factor, *S. pneumoniae* remains the most common agent for all ages, and is reported as a causative agent in 15% to 35% of all childhood pneumonias. The atypical agents *M. pneumoniae* and *C. pneumoniae* are less common in children less than 5 years of age (<10%) and occur in increasing proportions in adolescents, reported as high as 50% in some studies. Viral etiologies, most commonly RSV, adenovirus, and influenza viruses A and B, are most common in infants and children less than 2 years of age (30%). The incidence of viral infection reduces dramatically with age.^{1,4,10}

Other factors that aid in identifying the etiology of pneumonia include season and vaccine status. Viral infections, specifically RSV and influenza virus, peak in late fall and winter, though there is little seasonal influence on bacterial causes. Immunization status is also a helpful indicator of disease potential. Influenza infection is less likely if a child has received the influenza vaccine during the same season. *Haemophilus influenzae* type B vaccination eliminates the potential for this infection in children. The conjugated pneumococcal vaccine imparts partial protection from this pathogen as the causative agent.^{4,10}

Clinical Presentation

Children with pneumonia present with a variety of clinical findings. Early findings are varied, and most cases present initially with symptoms of an upper respiratory infection. These may include low-grade fevers and rhinorrhea. Intermediate and late findings include fever, tachypnea, and cough. Several studies have sought to identify pneumonia based solely on clinical findings. These studies define the “gold standard” for pneumonia diagnosis as the chest radiograph.^{11,12} Tachypnea was defined based on the WHO definition, as follows: in children less than 2 months old, respiratory rate (RR) greater than 60 breaths/min; in children 2 to 12 months old, RR greater than 50 breaths/min; and children older than 12 months, RR greater than 40 breaths/min.^{13,14} In 1997, a Canadian task force developed an evidence-based guideline to diagnose pneumonia in children. This guideline states that, although no single clinical finding may accurately diagnose pneumonia, the absence of a cluster of signs, specifically respiratory distress, tachypnea, crackles, and decreased breath sounds, excludes the presence of pneumonia with a sensitivity of 100%.¹ These findings were applied to a cohort of 319 children who had a chest radiograph for possible pneumonia, 20% of whom had radiologic findings consistent with pneumonia. The Canadian guideline had a 45% sensitivity and 66% specificity for the diagnosis of pneumonia when

applied to this patient cohort. Additionally, tachypnea was only 10% sensitive and 5% specific in this study.¹⁵

Despite these findings, several other studies have identified tachypnea as the best clinical indicator. A report on 572 children less than 2 years old, 7% with radiologic signs of pneumonia, defined tachypnea as having a 74% sensitivity and 76% specificity to identify pneumonia.¹⁶ In a trial comparing clinical data to chest radiographs in 110 children, of 59 patients diagnosed with pneumonia, 35 had positive findings on chest radiograph. Of all clinical findings, the sensitivity to diagnose pneumonia was best for tachypnea (74%; specificity 67%), followed by retractions (71%) and rales (46%). Combinations of these improved specificity slightly, but did not improve sensitivity to recognize pneumonia. When the cohort was stratified by age, tachypnea was most sensitive: 83% in the youngest infants (<6 months old).¹⁷ In a prospective study examining RR cutoffs for pediatric patients hospitalized with pneumonia, a RR greater than 57 in infants 2 to 11 months old, a RR greater than 48 in children 1 to 5 years old, and a RR greater than 36 in children more than 5 years old identified severe pneumonia requiring hospitalization.¹⁸ These findings closely parallel the WHO definitions for tachypnea.

A prospective study of 570 children ages 1 to 16 years identified the following risk factors to be statistically significant in predicting pneumonia: history of fever, decreased breath sounds, crackles, retractions, grunting, fever, and tachypnea. A multivariate prediction model including fever, decreased breath sounds, crackles, and tachypnea had a sensitivity of 98%, but only an 8% specificity. Of note, fever and tachypnea alone were 93% sensitive for identifying pneumonia in this study.¹⁹ This highlights the difficulty in predicting pneumonia based solely on clinical evaluation, though fever and tachypnea seem to strongly suggest the potential for lower respiratory infection and warrant further evaluation.

Pulse oximetry has also been examined as a predictor of pneumonia in children. Of 803 children less than 2 years of age who had a chest radiograph performed for respiratory symptoms, 80 (11%) had an opacity suggesting pneumonia. Mean pulse oximetry was not predictive of pneumonia in this cohort.²⁰ The addition of laboratory studies to aid diagnosis has been evaluated in several ways. A study of 154 hospitalized children with CAP, of whom 79% had an identifiable etiology, compared etiologies of pneumonia with respect to clinical and laboratory findings. This analysis revealed that wheezing was most commonly seen in patients with either a viral or an atypical bacterial etiology (41%) compared to patients who had a bacterial etiology (14%). Laboratory studies showed that bacterial etiologies were more likely to be associated with bacteremia and elevated serum procalcitonin compared to viral or atypical causes. A multivariate logistic analysis of all variables identified two predictors of bacterial pneumonia: elevated temperature (>38.4°C) less than 72 hours after admission and presence of a pleural effusion, with a sensitivity of 79% and specificity of 59%.⁷ Of 1248 febrile infants less than 60 days of age, three simple variables—rales, RR greater than 60 breaths/min, and absolute band count less than 1500/mm³—identified 85% of infants with lobar pneumonia (85% sensitivity and 59% specificity).²¹ It has been reported that, in a cohort of febrile children, leukocytosis as a sole diagnostic finding may indicate pneumonia, despite a lack of supportive clinical

findings. A prospective cohort study of 278 febrile (temperature > 39.0°C) children less than 5 years of age with a white blood count (WBC) greater than 20,000/mm³ identified a lobar infiltrate in 26% of patients (36 of 146) who had a radiograph performed and no signs of pneumonia.²²

Important Clinical Features and Considerations

Differentiating bacterial and viral causes of pediatric pneumonia remains a challenge to the emergency physician. Since treatment guidelines may be directly influenced by microbiologic causes, identifying bacterial pneumonia is an important goal. As already mentioned, the most helpful differentiating epidemiologic factor is age, since viral causes are more likely in children less than age 2 years; however, there is much overlap. The only clinical finding that correlates with viral infection is wheezing, yet specificity is low.⁷ Laboratory evaluation has been used as an adjunct to help differentiate the cause of pneumonia. Serum procalcitonin, C-reactive protein (CRP), and interleukin-6 (IL-6) were measured in 126 children hospitalized for pneumonia. Children with bacterial pneumonia had higher serum procalcitonin and CRP concentrations than children with viral infections, though the specificity was low. If all three markers were elevated, the specificity for bacterial pneumonia was greater than 80%.²³ In a similar study, procalcitonin was found to be more sensitive and specific than CRP, IL-6, or WBC count for differentiating bacterial and viral causes of pneumonia in hospitalized children.²⁴ Despite these studies, procalcitonin has not become a widely used test in the evaluation of a child with pneumonia.

Radiographs have not been traditionally thought to be helpful in distinguishing viral from bacterial pneumonia, though alveolar infiltrates are suggestive of a bacterial etiology.²⁵⁻²⁷ A systematic literature review of five studies examined this relationship and reported a low sensitivity and specificity of chest radiography in the identification of a bacterial etiology.²⁸ These studies are limited since there is no reliable reference standard. As mentioned previously, identifying the microbiologic etiology of childhood pneumonia is difficult, and therefore it is problematic to assess the diagnostic capability of a radiograph related to the microbiologic etiology; as a result, the test accuracy estimate of the radiograph may be falsely low.²⁸ A prospective report examined the influence of laboratory tests, specifically the WBC count, erythrocyte sedimentation rate, and serum CRP, in combination with the radiograph to aid in diagnostic capability.²⁹ In 254 children admitted to the hospital with pneumonia, a bacterial etiology was identified in 53%. Of these, 72% had an alveolar infiltrate (most commonly lobar) compared to 49% of patients with a viral infection. There was no difference between etiologies in patients with an interstitial infiltrate; 50% identified a bacterial etiology. Though there remains a fair amount of overlap, this study supports the finding that a lobar alveolar pattern is more likely to represent a bacterial etiology while an interstitial pattern does not differentiate between viral and bacterial infections. An elevated CRP (>80 mg/dl) suggested a bacterial cause (72% sensitivity and 52% specificity); however, laboratory findings did not significantly enhance the sensitivity of the radiograph in identifying a cause for pneumonia.²⁹

Radiographic findings of focal consolidation suggest a bacterial etiology for pneumonia, although an atypical pneumonia (*Mycoplasma*) may also be represented, illustrating the lack of specificity to differentiate cause by radiograph findings alone. This overlap is exemplified when looking at a diffuse interstitial pattern. Given the proper clinical setting, atelectasis due to reactive airways disease may be indistinguishable from a viral or atypical process manifesting as a diffuse interstitial pattern. A unique finding that strongly supports a bacterial etiology is a “round pneumonia,” which appears as a circular lesion in the retrocardiac area. A round pneumonia is most commonly caused by *S. pneumoniae* in children. Other possible infections include *H. influenzae*, *M. tuberculosis*, and *Klebsiella*. In the case of occult pneumonia in febrile children with leukocytosis,²² round pneumonia is often discovered, despite few clinical respiratory findings.

In an effort to reduce radiation exposure and cost, the utility of the lateral chest radiograph was recently examined. In a review of 1268 children who had a chest radiograph, 19% with pneumonia, radiologists found the frontal view alone to have a sensitivity of 85% and specificity of 98% to diagnose pneumonia.³⁰ Pediatric emergency physicians found no difference in the sensitivity or specificity for identifying pneumonia on radiograph with or without the lateral view (91% vs. 87% sensitivity and 58% vs. 57% specificity, respectively).³¹ The lateral view adds little diagnostic information for patients with lobar infiltrates; however, it may aid in diagnosing pneumonia in a small number of patients with a nonlobar infiltrate seen on the frontal view.

A systematic review identified a single trial examining the utility of the chest radiograph in diagnosing pneumonia in children. In 522 ambulatory children less than 5 years of age with a clinical diagnosis of pneumonia, there was no difference in outcome (time to recovery) when comparing children who had and did not have a chest radiograph performed.^{32,33} Children who had a chest radiograph performed were more likely to receive antibiotic therapy and to be admitted to the hospital. When considering cost, inconvenience, and potential adverse effects associated with the chest radiograph, routine use of the chest radiograph in a child with suspected pneumonia is discouraged if the clinical presentation and management issues are straightforward.

While there are no reported studies examining clinical signs and symptoms of pneumonia and a negative chest radiograph in children, there is one report in the adult literature. A cohort of 2706 patients with clinically suspected CAP found only 1795 (66%) with radiographic confirmation of disease. Of the 34% of patients with a normal radiograph, only 7% developed a consolidation within 72 hours of presentation. There were no differences in pulmonary symptoms, laboratory testing, or mortality risk. The patients with a confirmed consolidation were more likely to have *S. pneumoniae* bacteremia (64%) compared to 14% of patients with no consolidation. Of patients with a consolidation, 92% of these were in the lower lobe and 25% also had a pleural effusion.³⁴ In children, the presence of tachypnea, rales, and fever suggests pneumonia, regardless of radiographic findings, but there are no well-established studies to support a diagnosis of clinical pneumonia in children. Management options may be based on clinical severity and reliability of the patient for follow-up. If a patient is only mildly ill and will reliably follow up, no antibiotic therapy is recommended. At follow-

up, a repeat radiograph may be performed or antibiotic treatment initiated if clinically indicated. If at the initial visit the patient is moderate to severely ill and/or follow-up is not guaranteed, then appropriate antibiotic therapy may be initiated based on the age of the patient and pattern of infection.

The most common impersonator of pneumonia in children is atelectasis associated with reactive airways disease, asthma, and/or bronchiolitis. Fever or markers of inflammation do not help to differentiate pneumonia, since patients with reactive airways disease may have fever and/or inflammation due to atelectasis or upper respiratory tract infection. As reported previously, wheezing is unlikely in patients with typical bacterial infections; however, atypical causes such as *M. pneumoniae* or *C. pneumoniae* should be considered. Foreign bodies may also mimic pneumonia; however, a high suspicion for aspiration or history of choking, unilateral hyperaeration, or asymmetric breath sounds may suggest the need for further investigation.³⁵

The risk of bacteremia remains a consideration in children with pneumonia. In 86 patients with findings suggestive of a bacterial process (temperature > 40° C, lobar infiltrate on chest radiograph, WBC count > 20,000/mm³ or absolute band count > 2000/mm³, ill appearance, tachypnea, tachycardia, or otitis media), only 1 had a bacterial pathogen (*H. influenzae*) isolated by blood culture.³⁶ These findings are supported in additional studies with similarly low rates of bacteremia in pediatric patients with pneumonia. These studies support the lack of utility of blood cultures in patients with pneumonia, and suggest that they be reserved for the child who is toxic and/or ill appearing, is immunocompromised, has an underlying illness, or has not responded to conventional therapy.

The most common complications of pneumonia in children include necrosis, empyema, parapneumonic effusion, and lung abscess. A multicenter, retrospective study involving eight children's hospitals in the United States examined 368 hospitalized children with pneumococcal pneumonia. Of these, 133 were complicated cases and required thoracostomy drainage. The frequency of complicated cases increased during the study period from 23% in 1994 to 53% in 1999. Patients with complicated pneumonia were older (mean age 45 vs. 27 months) and more likely to be of white race and to present with chest pain. Ninety-eight percent of all patients recovered completely from the pneumonia. Antibiotic resistance was not more prevalent in the complicated patients; however, pneumococcal serotype 1 was responsible for 24% of the complicated cases and only 4% of the noncomplicated cases.³⁷ Pneumococcal serotype 1 is not included in the heptavalent pneumococcal conjugate vaccine, and therefore the vaccine may have a smaller impact upon the incidence of complicated pneumonia than anticipated. The issue of serotype surveillance, particularly in complicated pneumonia, remains an important component of future preventive measures.

Management

The British Thoracic Society has published an evidence-based guideline for treatment of childhood pneumonia.^{38,39} Their consensus confirms a lack of good supporting evidence for management decisions. Treatment studies have small patient numbers, high recovery rates for both therapy modal-

ities, and do not examine harm. Furthermore, the strategy to study nontreatment of a child with pneumonia is challenging.

Currently, the treatment of a child with CAP is based upon the clinical presentation and the presumed etiologic agent. Since identification of the etiologic agent remains difficult, antibiotic therapy is empirical in most cases and certainly most often in the emergency department. The reported use of antibiotics ranges from 10% to 45% to treat undifferentiated lower respiratory tract infections despite a likely viral etiology.⁴⁰⁻⁴⁴ The issue of overuse of antibiotics is concerning, and antibiotic resistance continues to rise. Observation and close follow-up without antibiotic treatment is strongly recommended in children with a presumed viral etiology or who are relatively well appearing with only mild respiratory symptoms, as long as there is reliable follow-up.

In children who are moderately ill and/or have a presumed bacterial source of infection, antibiotics may be initiated. Since the causative pathogen is rarely known, and radiologic features do not distinguish etiology, the choice of antibiotics is based on established patterns of infection related to age and clinical findings. Several studies have found little difference in outcome when comparing different treatment modalities. One study of 88 children less than 5 years of age with pneumonia compared treatment with azithromycin and amoxicillin-clavulanate and found no difference in effectiveness. The same study compared treatment with azithromycin to erythromycin estolate in 59 children older than 5 years with pneumonia and also found no difference in outcome. Four children failed treatment, but there was no difference in failure rates among the different antibiotic regimens. Adverse events were recorded in 67% of patients who received amoxicillin-clavulanate, 25% who received erythromycin, and in 14% who received azithromycin. The most common adverse events were diarrhea and rash.⁵ Another study supports the use of azithromycin for pediatric bacterial pneumonia, both classic and atypical patterns.⁴⁵ Oral azithromycin is found to be well tolerated with very few treatment-related adverse events.^{46,47}

The choice of an antibiotic regimen is guided by age, severity of illness, and likelihood of a bacterial pathogen (Table 58-1).^{1,5,37,39,48,49} Parenteral therapy is indicated for children who require hospitalization and who are unable to tolerate oral medication. In these cases, ampicillin or a second-generation cephalosporin (e.g., cefuroxime) is recommended. In hospitalized children 5 years and older, the addition of an oral macrolide is recommended. Replacement by an appropriate oral agent may be initiated after 2 to 4 days of clinical improvement, with resolution of fever and the ability to tolerate oral medication.¹

Since empirical antibiotic therapy is so commonly initiated, the role for extensive microbiologic testing is of questionable value. In a prospective study of 153 hospitalized children with acquired pneumonia, only 9% had fever lasting more than 48 hours after onset of antibiotic treatment. Of these, most had RSV and *H. influenzae* infection, with more than half identified as mixed viral-bacterial etiologies. At follow-up, 94% of all patients showed no pneumonia-related symptoms. There is no role for expensive microbiologic testing in otherwise healthy children with CAP since most make a rapid, uneventful recovery after a brief hospital stay and short course of antibiotics, regardless of etiology.⁵⁰

Table 58–1 Guidelines for Antibiotic Regimen for Community-Acquired Pneumonia in Children

Age	Most Common Bacterial Pathogen	First-Line Therapy	Second-Line Therapy
<5 yr	<i>Streptococcus pneumoniae</i>	Amoxicillin (high dose: 80–90 mg/kg/day)	Second- or third-generation cephalosporin Amoxicillin-clavulanate Macrolide*
5 yr and older	<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i>	Macrolide	Second- or third-generation cephalosporin
All ages	<i>Staphylococcus aureus</i>	Macrolide Nafcillin Amoxicillin Amoxicillin-clavulanate	Vancomycin Nafcillin
Hospitalized children	Penicillin-resistant <i>S. pneumoniae</i>	Ampicillin IV Ampicillin IV Add oral or IV macrolide	Second- or third-generation cephalosporin IV Second- or third-generation cephalosporin IV Add oral or IV macrolide

*Azithromycin, clarithromycin, or erythromycin.

The heptavalent pneumococcal vaccine was introduced in 2000, and showed 97% effectiveness in reducing invasive pneumococcal disease in children less than 5 years of age based on results from the Kaiser Permanente effectiveness trial of over 36,000 children.⁵¹ Utilizing the same patient database, the overall incidence of positive radiographic pneumococcal pneumonia in children was reported to be reduced by 18% in immunized children, with a 32% reduction in children less than 1 year of age and a 23% reduction in children less than 2 years of age. There was no difference in children older than 2 years of age.⁵²

Children with the following clinical signs and symptoms should be considered for hospital admission regardless of the decision to initiate antibiotic therapy as they may require more intensive monitoring¹: age less than 6 months, toxic appearance, severe respiratory distress, need for supplemental oxygen, dehydration, vomiting, no response to appropriate oral antimicrobial therapy, immunocompromised status, noncompliant caregiver, and presence of bilobar pneumonia.

Summary

Despite how commonly it occurs, childhood pneumonia continues to challenge the practitioner. Diagnostic testing and identification of the causative agent are limited. Routine blood tests and/or cultures are not recommended since they provide little information. Radiologic testing does not differentiate between viral and bacterial causes of pneumonia. A clinical diagnostic approach is applied for most patients, with tachypnea as the most reliable predictor of pneumonia. Wheezing suggests an atypical or viral etiology. Empirical therapy is discouraged for mildly ill children with pneumonia due to the concern for antibiotic resistance. Antimicrobial therapy is recommended for children in whom a bacterial etiology is strongly suspected or who are moderately to severely ill.

Chapter 59

Cystic Fibrosis

Eron Y. Friedlaender, MD, MPH

Key Points

Emergency physicians must be prepared both to manage acute complications of disease and to recognize signs and symptoms of undiagnosed disease in cystic fibrosis patients.

Given that cystic fibrosis is a progressive disease, signs and symptoms change with age.

Complications of cystic fibrosis are potentially life threatening; early identification and aggressive interventions in the acute care setting are essential for improving outcome.

Introduction and Background

Prompt recognition of complications and timely institution of aggressive treatment is essential for decreasing morbidity and mortality in cystic fibrosis (CF) patients. While investigation into correction of the underlying genetic defects responsible for the expression of disease holds promise,¹ current management of patients with CF in acute care settings must focus on relief of symptoms and correction of organ dysfunction. The emergency physician must appreciate the spectrum of multiorgan dysfunction and be familiar with available interventions.

Recognition and Approach

CF is the most common inherited lethal condition among whites in most Western countries. In the United States, the estimated frequency is 1 in 3200 white live births.² Most cases represent transmission of an autosomal recessive disorder in which a single gene mutation on the long arm of chromosome 7, where the cystic fibrosis transmembrane conductance regulator (CFTR) is encoded, is responsible for expression of the disease.³⁻⁵

Patients with CF experience generalized dysfunction of all exocrine gland secretions. This results in viscous mucoid secretions that obstruct normal functioning of the respira-

tory and gastrointestinal tracts. In addition, identification of the characteristic electrolyte losses (predominantly sodium and chloride) from altered absorption within sweat glands, especially in the context of well-described clinical features, allows for diagnosis of CF in affected individuals. The manifestations and severity of disease vary significantly from individual to individual,⁶ posing challenges to practitioners in recognition of the disease and predicting complications.

Clinical Presentation

The diagnosis of CF is largely based on clinical criteria rather than genetic testing (Table 59-1). The Cystic Fibrosis Foundation Consensus Panel issued guidelines, later supported by recommendations from the World Health Organization, on which to base the clinical diagnosis of CF. They also provide guidance on the appropriate use and interpretation of laboratory tests to confirm CFTR dysfunction.⁷⁻¹⁰ Despite the availability of prenatal and neonatal screening,^{11,12} only a minority of affected individuals are identified through these programs; most are recognized upon presentation with defining clinical features.^{8,13-15}

Although many clinical presentations are consistent with the diagnosis of CF, the classic triad is defined as chronic pulmonary disease, malabsorption due to pancreatic insufficiency, and elevated concentrations of sweat electrolytes.^{6,14} However, few undiagnosed patients present acutely with this constellation of findings. Furthermore, emergency medicine physicians are not positioned to make a definitive diagnosis of cystic fibrosis given the nature of confirmatory testing, but should be familiar with the clinical features that would prompt referral for ultimate definitive diagnosis. In the pediatric population, commonly associated, although nonspecific, signs and symptoms of undiagnosed CF include failure to thrive despite adequate caloric intake, persistent cough, chronic pneumonia, jaundice or conjugated hyperbilirubinemia, hypochloremic alkalosis, rectal prolapse (Fig. 59-1), nasal polyposis (Fig. 59-2), unexplained cirrhosis, and malabsorption manifested by either chronic diarrhea, milk allergy, or vitamin K deficiency.^{8,13,14} In patients with known disease, familiarity with complications of CF and initiation of management is expected knowledge for emergency physicians as many of these processes are potentially life-threatening or disabling without intervention.

Table 59–1 Clinical Features of Cystic Fibrosis (CF)

Chronic Sinopulmonary Disease

Persistent cough
Airway colonization or infection with *Staphylococcus aureus* or *Pseudomonas aeruginosa*
Endobronchial disease
Pansinusitis
Nasal polyposis

Gastrointestinal/Nutritional Disease

Meconium ileus
Distal intestinal obstruction syndrome
Pancreatic insufficiency
Malabsorption (exocrine dysfunction)
CF-related diabetes (endocrine dysfunction)
Recurrent pancreatitis
Rectal prolapse
Biliary cirrhosis
Failure to thrive (protein-calorie malnutrition)
Deficiency of vitamins A, D, E, and K

Metabolic Disease

Hypochloremia
Hyponatremia
Metabolic alkalosis

Musculoskeletal Disease

Pathologic bone fractures
Kyphosis

Infertility/Obstructive Azoospermia

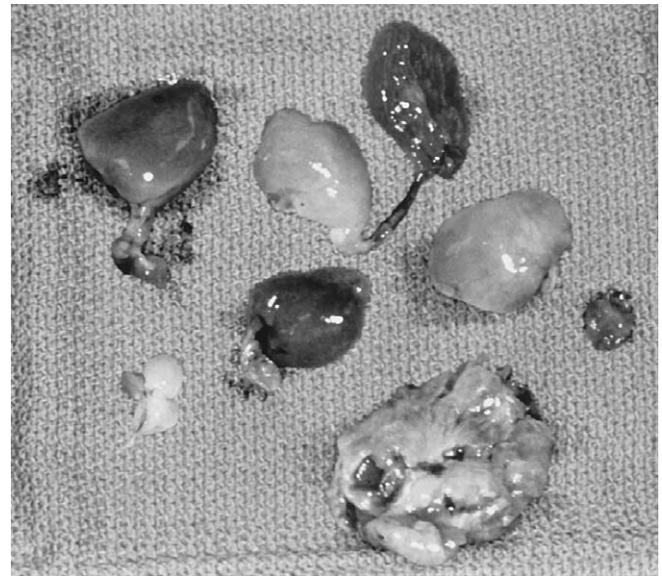

FIGURE 59–2. Nasal polyp.

FIGURE 59–1. Rectal prolapse.

Important Clinical Features and Considerations

Emergency management of patients with CF largely revolves around disease complications rather than diagnosis. Many of these complications are age specific and share management techniques applicable to a number of different disease states. Most conditions requiring emergency intervention relate to either pulmonary or sinus disease, gastrointestinal disorders, metabolic derangements, or musculoskeletal complaints.

Pulmonary or Sinus Disease

The predominant pulmonary conditions acutely compromising the health of CF patients include pneumothorax, pulmonary hemorrhage, pulmonary exacerbations, cor pulmonale, and respiratory failure. Pneumothorax, resulting from either a pleural tear or rupture of a subpleural bleb during an acute increase in intra-airway or intrapleural pressure, typically presents with the sudden onset of chest pain that may be referred to the shoulder, dyspnea, and cyanosis. It typically occurs in CF patients with advanced pulmonary disease.¹⁶ Hemoptysis results from erosion of an inflamed or infected area of bronchiectatic lung into a bronchial vessel.^{14,17} Life-threatening pulmonary hemorrhage occurs with expectoration of more than 300 to 500 ml of fresh blood in 24 hours.^{14,18}

Pulmonary exacerbations are characterized by an acute or subacute worsening of obstructive airway disease from bacterial infection and subsequent local inflammatory reactions. Patients may present with increased cough productive of sputum, dyspnea, tachypnea, fever, fatigue, anorexia, weight loss, or hemoptysis.¹⁴ Examination may demonstrate reduced pulmonary function and possibly rales, rhonchi, decreased aeration, and accessory muscle use.¹⁴ Chest radiographs have limited utility in defining pathophysiology of acute disease in CF patients; the airways and submucosal glands rather than the interstitium and alveolar spaces of the lung are predominantly affected.⁸ During pulmonary exacerbations, however, peribronchial thickening, patchy infiltrates, or hyperinflation above baseline may be appreciated on plain films.

Patients with advanced lung disease from CF may present with complications related to cor pulmonale^{19–21} or respiratory failure.²² The majority of mortality related to CF is due to respiratory decompensation,^{6,23} precipitated by overwhelming bacterial infection, right-sided heart failure, or irreversible obstructive disease compromising oxygenation and ventilation. Pulmonary hypertension develops from long-standing respiratory insufficiency and associated hypoxemia,

with subsequent right ventricular hypertrophy. Acute stressors such as pulmonary exacerbations may precipitate congestive heart failure, seen clinically as cyanosis, increased respiratory effort, tachycardia, a gallop rhythm, hepatic congestion, peripheral edema, and ascites. Chest radiography demonstrates cardiomegaly with prominent pulmonary vasculature. Respiratory insufficiency from CF may also require emergent intervention. Patients present with distress related to inability to sufficiently ventilate, defined by hypercarbia and hypoxemia. This may represent the natural progression of disease in end-stage patients or may result from an aggressive infectious process in an individual with otherwise stable disease. Recent evidence has also documented metabolic alkalosis as a precipitant of respiratory failure in adults with CF, and should be considered in the fluid and ventilatory requirements of these patients.²⁴

Sinusitis is a common infection of the upper airways of patients with CF. Symptomatic disease presents with facial pain or swelling and air-fluid levels on radiographs.

Gastrointestinal Disorders

Gastrointestinal complications of CF that may require emergent care include meconium ileus, distal intestinal obstruction syndrome (DIOS), rectal prolapse, pancreatic insufficiency, and hepatobiliary disease. Meconium ileus is exclusively a disease of the neonate, typically resulting in intestinal obstruction in the first 48 hours of life. Exceptionally dense intestinal contents resulting from both a failure to secrete water into the intestinal lumen and abnormally viscous mucus cause the impaction, typically at the terminal ileum. Patients present with vomiting, abdominal distention after feeding, visible peristaltic waves across the abdomen, and failure to pass meconium after birth.²⁵ Abdominal radiographs may show dilated loops of bowel, granular material or calcifications within the intestinal lumen, and an absence of air-fluid levels.²⁵ A contrast enema may further demonstrate the site of impaction and the resulting microcolon of disuse associated with this condition.²⁵ Early recognition of meconium ileus is imperative to preventing potential life-threatening complications, including intestinal perforation and volvulus.²⁵

DIOS, formerly referred to as meconium ileus equivalent, occurs in older patients (beyond childhood) with CF. This complication is similarly characterized by impaction of abnormally desiccated stool at or near the ileocecal junction.^{5,14} Crampy abdominal pain and a mass in the right lower quadrant are suggestive of this process.⁵ An obstruction series will demonstrate air-fluid levels and dilated loops of bowel.⁵ Complications of DIOS have included intussusception and volvulus.

Rectal prolapse (see Fig. 59–1) may present in young patients with CF suffering from malnutrition and overall poor tissue integrity.¹⁴ In undiagnosed patients, the finding of rectal prolapse, especially when recurrent, warrants outpatient screening for CF given the strong association between the two conditions. Rectal prolapse most often affects children 3 years of age and younger.⁵

Metabolic Derangements

Pancreatic insufficiency manifests as both exocrine and endocrine dysfunction. Given the progressive nature of pancreatic disease in CF, older patients tend to have more severe

complications related to abnormal pancreatic function. The majority of patients have some degree of malabsorption due to compromised pancreatic enzyme activity. The loss of exocrine function has been associated with recurrent pancreatitis. Of note, young children who present with failure to thrive and malabsorptive symptoms ought to be evaluated for CF. Endocrine dysfunction, resulting in CF-related diabetes (CFRD), tends to affect an older population: 9% of children with CF, 26% of adolescents, and 35% of individuals 20 to 29 years of age.^{26,27} Typical age of onset is 18 to 21 years. CFRD is distinct from both types 1 and 2 diabetes mellitus as both insulin and glucagon secretion are impaired.^{26,28} Therefore, ketoacidosis rarely accompanies hyperglycemia.^{14,28}

Hepatobiliary disease in CF results in a high frequency of gallstones. In addition, 1% to 3% of patients develop hepatic cirrhosis with associated biliary obstruction and portal hypertension. Uncommonly, esophageal varices and hepatic failure ensue.

Acute metabolic derangements in patients with CF may develop under conditions in which an individual experiences increased sweating, poor oral intake, or during physical stress, including intercurrent illnesses. Most commonly, hyponatremia, hyponatremia, and a metabolic alkalosis develop.^{14,29–32}

Musculoskeletal Problems

Finally, older patients with CF universally suffer from osteopenia and osteoporosis, predisposing them to pathologic bone fractures.^{26,28,33} Chronic malnutrition, gonadal dysfunction, physical inactivity, frequent glucocorticoid use during episodes of pulmonary insufficiency, and long-standing respiratory acidosis contribute to the reduced bone density. Specifically, patients with CF have been shown to have significantly higher rates of rib and vertebral fractures.^{28,33,34} Kyphosis is a second musculoskeletal complication of CF that results in back pain and disability in a majority of older patients.^{26,33}

Management

Pulmonary and Sinus Complications

Immediate management of pulmonary-related complications of CF begins with stabilization of the airway and breathing. In patients with pneumothoraces, this may require tube thoracostomy if the air leak involves greater than 10% of the volume of the hemithorax, or needle decompression if hemodynamics are compromised. Pleural sclerosis (surgical or chemical) or parietal pleurectomy may ultimately be indicated in the inpatient setting as definitive therapy.^{17,35,36} Patients with pulmonary hemorrhage require constant monitoring of hemodynamic parameters with aggressive intervention to correct tachycardia or hypotension. Parenteral antibiotics with coverage against staphylococcal and pseudomonas disease must be initiated early as pulmonary hemorrhage may be an indication of bacterial infection.^{17,18} In addition, vitamin K at a dose of 5 mg should be administered if the prothrombin time is prolonged, and blood products should be replaced if blood losses are ongoing. Surgical ligation of the bleeding vessel or bronchial artery embolization may be required to manage massive pulmonary hemorrhage.^{18,37}

Treatment of pulmonary exacerbations entails antibiotic therapy and aggressive chest physiotherapy.³⁸ CF patients have characteristic bacterial pathogens acquired in a predictable, age-dependent sequence.⁸ Young children with CF typically are infected with *Haemophilus influenzae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*.^{14,39} *Haemophilus influenzae* is most prevalent at ages 2 to 5 years, while *S. aureus* reaches maximum prevalence at ages 6 to 17 years.^{8,14} Symptomatic infection with these organisms is best treated on an outpatient basis with trimethoprim-sulfamethoxazole or amoxicillin-clavulanate, or with either a parenteral penicillin (nafcillin or oxacillin) or a first-generation cephalosporin (cefazolin) in patients with severe infection or worsening of symptoms on an outpatient regimen.^{8,39} Vancomycin is indicated for patients with suspected or confirmed methicillin-resistant species of *S. aureus*. *Pseudomonas aeruginosa* reaches 80% prevalence by age 18 years and responds to treatment with an oral quinolone (ciprofloxacin) or, if inpatient care is indicated due to degree of illness, a parenteral β -lactam (ticarcillin) combined with an aminoglycoside (tobramycin or gentamicin).^{8,39-41} Of note, many patients with CF have increased renal clearance of antibiotics and thus require more frequent dosing intervals.^{14,39} Late-emerging pathogens include *Pseudomonas cepacia*, *Pseudomonas maltophilia*, *Alcaligenes xylosoxidans*, *Aspergillus*, and nontuberculous mycobacteria.⁸ Similar pathogens cause sinus infections in patients with CF; therapy should be broad spectrum and include coverage of *Pseudomonas*.¹⁴

Cor pulmonale and respiratory failure typically present in patients with end-stage disease. Management of the former includes provision of oxygen, diuretics (furosemide),⁴² and possibly digitalis. Respiratory failure may respond to initiation of supplemental oxygen and chest physiotherapy with a combination of parenteral antibiotics, bronchodilators, subcutaneous epinephrine, and/or aerosolized recombinant human deoxyribonuclease (rhDNase).⁴³ Aerosolized hypertonic saline has been promoted as an alternative to the rhDNase, but must be used with caution as it may cause paradoxical bronchospasm.⁴⁴ In the event these measures fail to reverse hypoxia and work of breathing, mechanical ventilation must be considered with the knowledge that patients with a history of significant pulmonary insufficiency prior to an acute decompensation have poor outcomes from such interventions.⁴⁵

Gastrointestinal Complications

Gastrointestinal complications of CF may also require emergent management. Meconium ileus rarely presents outside of the newborn nursery; however, with early discharge following delivery, exceptions may occur. These patients should be treated with a diatrizoate methylglucamine enema to break up the impacted fecal material and release the obstruction. If these measures fail, emergent laparotomy is indicated.⁴⁶ Similarly, patients with DIOS should be initially managed with a barium, diatrizoate methylglucamine, or saline enema.^{14,47} Oral or rectal mineral oil and *N*-acetylcysteine, or the addition of a balanced electrolyte lavage solution containing polyethylene glycol, may also help to relieve the impaction.^{5,25} For patients unable to tolerate the large volume required (5 to 6 L for adults), administration through a nasogastric tube at a rate of 20 to 40 ml/kg (maximum 1 L/hr)

may be necessary.⁵ Aggressive intravenous hydration must be maintained, with close monitoring of electrolytes, during therapy with serial enemas given the potential for dramatic fluid shifts from the high osmotic load. The enema should be repeated several times prior to resorting to laparotomy given the added morbidity of a surgical procedure. If the patient exhibits signs of peritoneal irritation, however, enemas are contraindicated and surgical consultation should not be delayed.

Rectal prolapse usually responds to simple manual reduction. The clinician should assess the need for sedation in the young child who resists the maneuver, then place the patient in the knee-chest position, lubricate the prolapsed tissue, and apply firm pressure to the edges of the prolapse, with one finger in the central orifice guiding the reduction until it resolves. Petrolatum gauze should be taped over the anus as a pressure dressing to help prevent recurrence, which is common. Pulmonary consultation as an outpatient is required to adjust pancreatic enzyme replacement and assess nutritional status, with the goal of improving stool bulk and maximizing tissue integrity. Surgical intervention is rarely indicated, unless manual reduction fails or prolapse recurs with such frequency that it is disabling.

Hepatobiliary disease, manifesting usually as gallstones and infrequently as hepatic failure,¹⁴ requires accurate confirmation of the acute process with ultrasound and evidence of biliary obstruction on liver function studies in the former condition and signs of coagulopathy or abnormal synthetic function of albumin in the latter process. Both require supportive care. Patients with gallstones typically require pain control and a low-fat diet, with ultimate surgical consultation as an outpatient for definitive management. In the event the patient has cholecystitis, parenteral antibiotic therapy is necessary. Liver failure represents end-stage disease, and emergency department management is largely supportive in terms of treating coagulopathy and encephalopathy until inpatient care can be arranged.

Metabolic Complications

Exocrine dysfunction from pancreatic insufficiency rarely causes acute issues and may be treated on an outpatient basis with adjustment of pancreatic enzyme replacements and fat-soluble vitamins. Pancreatitis, which may complicate exocrine dysfunction, requires bowel rest and pain control with close monitoring as an inpatient. CFRD requires insulin therapy, either chronically or intermittently if symptoms occur exclusively during periods of physical stress. Often, insulin requirements are significant as many patients with CF exhibit some degree of insulin resistance.²⁶

Hypoelectrolytemia requires targeted correction of the specific metabolic derangement with frequent monitoring of serum electrolytes.

Musculoskeletal Complications

Musculoskeletal disease, including discomfort from kyphosis or pathologic bone fractures, requires pain control, splinting if practical, and follow-up with both orthopedic surgery and pulmonary consultants to optimize nutrition, investigate the severity of hypogonadism, initiate an exercise regimen, and consider use of antiresorptive medications such as calcitonin and etidronate.

Summary

Improved outcomes and life expectancies for patients with CF have largely been attributed to early recognition of affected individuals, allowing for timely maintenance care as well as aggressive management of disease complications to be initiated. Familiarity with the signs and symptoms of CF and the most common urgent and emergent complications is essential to reducing the burden of disease imposed by this debilitating condition.

Upper Airway Disorders

Robert Bruce Wright, MD and Terry P. Klassen, MD

Key Points

Since the specific diagnosis of an upper airway disorder is almost always made on clinical grounds, laboratory and radiographic testing is unnecessary and not recommended in most instances.

Evidence supports the administration of steroids to all children who present to the emergency department with croup of any severity.

The findings of neck stiffness and torticollis help distinguish retropharyngeal abscess from other upper respiratory infections.

The changing epidemiology of patients with epiglottitis has shifted toward older patients and those who have not been immunized against *Haemophilus influenzae*.

Suspecting an airway foreign body is the most important step in making the diagnosis, since many patients are initially asymptomatic.

Introduction and Background

Differences in the anatomy of the pediatric airway render children more susceptible to acute airway compromise than adults (see Chapter 2, Respiratory Distress and Respiratory Failure). The narrowed subglottic area of a child's upper airway is completely encircled by cricoid cartilage and restricted in its ability to expand. The subglottic connective tissue can become rapidly edematous, causing further reduction in the airway caliber. Upper airway disorders include infectious, inflammatory, and mechanical conditions that can exacerbate these differences. Many upper airway disorders have similar presenting signs and symptoms and can be diagnosed clinically. The need to differentiate rapidly between various upper airway disorders is paramount to begin definitive therapy, and in some cases may be life saving. For this reason, knowledge of advanced pediatric airway management is a significant part of management (see Chapter 3,

Rapid Sequence Intubation; and Chapter 4, Intubation, Rescue Devices, and Airway Adjuncts).

Selected Diagnoses

- Croup
- Bacterial tracheitis
- Retropharyngeal abscess
- Epiglottitis
- Foreign bodies

Discussion of Individual Diagnoses

Croup

Croup, otherwise known as laryngotracheobronchitis, is one of the most common causes of infectious upper airway obstruction in children. It primarily affects children between the ages of 6 months and 6 years and is rare after that.¹ Peak occurrence is around age 2, but recurrences are possible. Males are slightly more affected than females (1.4 : 1).¹ The most common etiologic agents are viral, with parainfluenza (types 1 and 3) and respiratory syncytial virus being the most frequent.¹ The estimated health care costs of emergency department (ED) visits and hospitalizations for croup caused by parainfluenza virus are between \$20 and \$56 million.²

Clinical Presentation

Croup can begin as an upper respiratory tract infection (URI) with symptoms of coryza and cough. Fever may or may not be present during the illness, and if present usually ranges from 38° C to 39° C. Approximately 1 to 2 days after URI symptoms have begun, edema in the subglottic area increases and the symptoms of a hoarse voice and barking, "seal-like" cough become predominant. Symptoms usually peak on day 3 or 4 of the illness. Symptoms of croup have traditionally been classified as mild, moderate, or severe according to the Westley Croup Score, devised in 1978.³ The Westley Croup Score is an aggregate number based on the presence or degree of severity of the following: stridor, retractions, air entry, cyanosis, and level of consciousness; it is used primarily as a research tool. Symptoms of croup are traditionally worse at night and when the child is agitated. Severe cases will have suprasternal and intercostal retractions plus biphasic stridor upon auscultation. Cyanosis is rare in

children even with severe croup. In contrast to children with epiglottitis, the child with croup is not toxic appearing and is usually not drooling. The differential diagnosis of croup and other disorders affecting the upper airway is presented in Table 60–1.

The diagnosis of croup is primarily a clinical one. Additional tests for diagnosis are generally not necessary or recommended. The most common ancillary tool is a radiograph of the soft tissues of the neck when the clinician suspects other diagnostic possibilities, such as foreign body or epiglottitis. The classic presentation of croup on radiograph is the “steep sign” that results from subglottic edema in moderate to severe disease (Fig. 60–1).

Management

Many children with croup present to the ED, but many are also managed at home without seeking medical attention or are seen in the outpatient setting. Of those who present to the ED, most can be treated briefly and then managed as outpatients. Patients are admitted if they have ongoing symptoms of stridor at rest after appropriate ED management, or the social situation is not safe to allow the child to return home with the current caregivers. This can include poor access to transportation or lack of communication to call for assistance if needed.

The child who presents to the ED has often had cold air exposure, which often improves symptoms. Parents will also mention that they have tried some form of mist therapy prior to arriving in the ED. It is thought that the mist may soothe the inflamed airway, and the comfort of being held by a caregiver while the mist is being given may decrease anxiety and prevent hyperventilation.⁴ Three randomized controlled trials have looked at the benefit of mist therapy in the ED.^{5–7} The most recent study, by Neto et al.,⁷ showed that there was no statistical difference in clinical symptoms when children who were given dexamethasone received mist or no mist therapy in the ED. The authors concluded that mist therapy is of no benefit in the ED.⁷

A systemic review from the Cochrane Library has clearly demonstrated the effectiveness of corticosteroids for the treatment of croup.⁸ The most common steroid studied is dexamethasone, but budesonide, methylprednisolone, and fluticasone have also been used in trials. Dexamethasone given at a dose of 0.6 mg/kg results in improvement of croup symptoms within 6 hours and decreases return ED visits and admissions to hospital. Studies have shown no differences between the route of delivery (inhaled, oral, and intramuscular) or type of steroid (dexamethasone, budesonide, or fluticasone) used.

FIGURE 60–1. Soft tissue radiograph of the neck in a patient with croup showing typical subglottic narrowing (“steep sign”).

For mild croup, a recent study⁹ demonstrated that those children who received a single dose of dexamethasone (0.6 mg/kg) had a significantly lower chance of returning to medical care. In addition, there was a faster resolution of symptoms and decreased parental anxiety. Based on all of these findings, children who present to the ED with croup symptoms of any severity (mild, moderate, or severe) should receive dexamethasone unless otherwise contraindicated. The dose of dexamethasone has been debated. The majority of studies used a dose of 0.6 mg/kg with a maximum of 10 mg, but some authors have demonstrated effectiveness using doses of 0.15 and 0.3 mg/kg as well.¹⁰

For children who present with symptoms of moderate to severe croup, racemic epinephrine (2.25%) has been used since 1971.¹¹ It is postulated that the local vasoconstriction caused by the epinephrine relieves symptoms. A nebulized dose of 0.5 ml of racemic epinephrine mixed with 2.5 ml of normal saline is given over 5 to 10 minutes. Alternatively if racemic epinephrine is not available, 5 ml of L-epinephrine (1 : 1000) may also be nebulized.^{12,13} As the effect of either form of epinephrine has been estimated to last approximately 2 hours, the child must be observed in the ED for this time period before discharge. If there is no worsening of symptoms within 2 to 3 hours, and the patient has received steroids, he or she may be safely discharged.¹⁴ For those patients who continue to have stridor or who need repeat treatment

Table 60–2 Suggested Management Plan for Croup		
Mild (Croup Score ≤ 2)	Moderate (Croup Score 3–8) Severe (Croup Score > 8)	
Oral dexamethasone in a dose of 0.15–0.6 mg/kg (max 12 mg)	Racemic epinephrine (2.25%) Dexamethasone	
Responds to Treatment		
YES		
>2 hr	<2 hr	NO
Discharge home with reliable caregivers	Repeat racemic epinephrine Consider admission	Repeat racemic epinephrine Consider other diagnosis Admit for airway management and monitoring

with racemic epinephrine, continued observation or admission is necessary (Table 60–2).

Bacterial Tracheitis

First described prior to the 1940s, and again in the postantibiotic era by Jones et al. in 1979,¹⁵ bacterial tracheitis is an infectious illness of the upper airway with subglottic edema and purulent tracheal secretions. Cases have been reported in children ages 3 weeks to 13 years, with presentation in the winter months being the most common.^{16,17} The overall mortality has been estimated at approximately 4%.¹⁶ The most common bacterial agents responsible for bacterial tracheitis are *Staphylococcus aureus*, *Streptococcus pneumoniae*, α -hemolytic streptococcus, and *Moraxella catarrhalis*. Rarely in this day, due to current immunization practices, *Haemophilus influenzae* has also been found in respiratory cultures of patients with bacterial tracheitis.^{15,16,18} It is not clear whether bacterial tracheitis is an entity in itself or represents overcolonization of bacteria in children with croup.

Clinical Presentation

Bacterial tracheitis shares common presentations with both croup and epiglottitis. In comparison to croup, bacterial tracheitis usually presents with a high fever and a systemically toxic-appearing child. The patient has a poor response to treatment with racemic epinephrine and steroids. The illness usually presents with a longer duration of symptoms than croup. In contrast to epiglottitis, the patient with bacterial tracheitis usually has an insidious onset of symptoms, and patients can exhibit both inspiratory and expiratory stridor. The patient with bacterial tracheitis is comfortable lying flat and will not drool.¹⁶ Patients with bacterial tracheitis usually have an elevated white blood cell count. Recent studies have suggested that bacterial tracheitis is becoming less severe, with lower morbidity and a decrease in the need for intubation.¹⁷

The use of lateral neck radiographs as a tool for diagnosis is controversial. Although not reliable for diagnosis, some authors suggest that irregularities of the tracheal mucosa and a partially detached membrane may serve as additional clues¹⁸

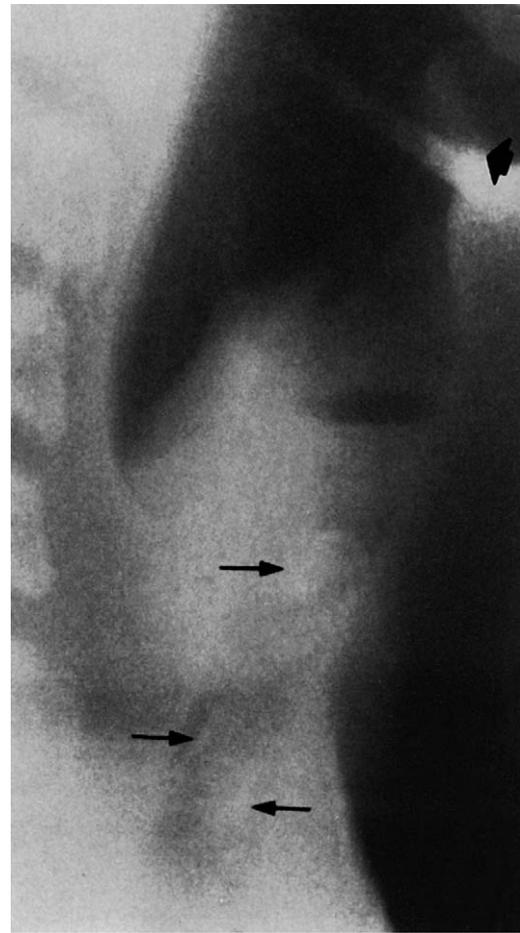

FIGURE 60–2. Bacterial tracheitis in a lateral soft tissue radiograph with obscured tracheal airway caused by sloughed mucosa (arrows). The epiglottis (arrowhead) is normal. (From Cummings CW (ed): Otolaryngology—Head & Neck Surgery, 4th ed. Philadelphia: Elsevier Mosby, 2005, p. 4364.)

(Fig. 60–2). In order to make a confirmatory diagnosis, direct visualization of the upper airway is necessary. One will see purulent material and secretions, which may form a pseudomembrane that is easily removed with minimal bleeding.¹⁶

Management

The first priority in managing the patient with bacterial tracheitis is securing the airway. In addition to intubation, secretions and debris can be removed from the airway with the use of suction and lavage. Treatment should include broad-spectrum antibiotics to cover the most common pathogens. Patients usually remain intubated until respiratory secretions and debris are minimal and fever has subsided. Pediatric intensive care specialists and otolaryngologists should be consulted early and for ongoing management beyond the ED.

Retropharyngeal Abscess

Retropharyngeal abscess (RPA) is a potentially serious deep space infection in the otherwise sterile retropharyngeal space. RPA usually results from lymphatic spread of infection, although hematologic spread is also possible. Trauma from direct invasion of the retropharyngeal space or by

foreign bodies can also be potential etiologies for RPA. The majority of cases of RPA occur in children less than 6 years of age, with cases reported in children as young as 2.5 months.^{20,21} This may be due to the high concentration of lymph nodes in younger patients.^{20,22,23} Several bacterial agents are responsible for RPA. Those that have been found on aspiration are *Staphylococcus aureus*, *Klebsiella* species, and group A β -hemolytic streptococci as well as several anaerobes.^{24,25}

Clinical Presentation

The presentation of RPA is often subtle and nonspecific. The same symptoms as croup, epiglottitis, and bacterial tracheitis are seen, which can make the diagnosis difficult. In a recent review, the most common presenting symptoms were neck pain, fever, sore throat, and neck mass.²⁶ Respiratory distress and stridor were seen in only 5% of patients presenting with RPA and are more common in the younger child.²⁷ The complaints of neck stiffness and torticollis help distinguish RPA from other upper respiratory infections, including croup, epiglottitis, and bacterial tracheitis.²⁸ The majority of children will be febrile with an elevated white blood cell count.^{29,30} Common physical findings include a child who has limited neck movement, including neck extension and rotation.²⁶

Diagnosis can be confirmed by a combination of plain radiographs and computed tomography (CT). The inspiratory lateral soft tissue radiograph in full extension that shows increased thickness of the prevertebral soft tissue space can have a sensitivity as high as 90%.²⁸ The presence of air-fluid levels or gas within the retropharyngeal space strongly suggests the diagnosis of RPA. Once RPA is suspected on plain radiographs, CT with enhancement may be used for confirmation and to help in determining whether the observed swelling is cellulitis or phlegmon or has evolved to an abscess in need of immediate surgical drainage. CT also aids in identifying the anatomic location for surgical incision and drainage.

Management

In the unstable child with significant respiratory distress, achieving a secure airway is the first priority. In the stable patient without airway compromise, elective intubation is not recommended. Procedural sedation for imaging studies needs to be used with caution in children with upper airway lesions, as sedation may convert a child with a stable airway to one with an unstable airway. Once the airway is secure, antibiotic treatment is commenced and directed toward eliminating the common bacteria responsible for RPA. Success rates for antibiotic treatment alone have ranged from 25% to 50%.^{30,31} If antibiotic therapy has failed, surgical

drainage or CT-guided aspiration are other possibilities. Overall mortality from RPA is relatively low.³¹

Epiglottitis

Epiglottitis is a serious and possibly life-threatening infection of the epiglottis and surrounding tissue. If left untreated, it can progress rapidly to complete airway obstruction and death. The most common organism responsible for epiglottitis is *H. influenzae* type b, but due to current immunization practices, the incidence has dropped significantly.³² In children less than 5 years of age, the incidence of *H. influenzae* epiglottitis decreased from 41 cases per 100,000 in 1987 to 1.3 per 100,000 in 1997.³² Other organisms, including *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Pseudomonas* species, *Klebsiella pneumoniae*, *Pasturella multocida*, and *Neisseria* species, are replacing *H. influenzae* as the primary causative agents.³³

Clinical Presentation

A recent study demonstrated that the epidemiology of patients with epiglottitis has shifted toward older patients and those who have not been immunized against *H. influenzae*.³³ Symptoms regardless of age remain the same. These can include high fever, “hot potato” voice, drooling, and positioning of the head and neck to maintain airway patency. The patient is usually described as appearing toxic or anxious and can be found sitting in a tripod position. In patients who present with classic symptoms, including older children, the physician must take steps to exclude this diagnosis in order to not miss a potentially fatal disease. Laboratory findings typically include a high white blood cell count but are not necessary to make the diagnosis.

Diagnosis of epiglottitis is based primarily upon the constellation of symptoms noted previously. When the diagnosis is suspected, a physician competent in managing the difficult pediatric airway should accompany the patient at all times (Table 60–3). This should include all stages of investigation that occur in and outside of the ED. Direct visualization of the posterior pharynx and epiglottis is strongly discouraged as there is a high chance that complete airway obstruction may occur due to further local trauma or increasing anxiety and distress in the patient.²⁰ If the patient is stable and radiographs can be performed without causing further distress, they may aid in confirming epiglottitis or diagnosing other entities such as croup or RPA. The lateral neck radiograph (Fig. 60–3) will demonstrate a round, thickened epiglottis (“thumbprint” sign) along with a loss of the vallecular air space and thickening of the aryepiglottic folds. Direct visualization of the supraglottic area should be performed under controlled and optimal conditions in the pediatric operating

Table 60–3 Suggested Management Plan for Epiglottitis

<i>Definite</i>		<i>Suspected</i>	
<i>Unstable</i>	<i>Stable</i>	<i>Stable</i>	<i>Unstable</i>
Notify ear, nose, and throat (ENT) and anesthesia consultants immediately Attempt bag-valve-mask ventilation Intubate if in respiratory failure	Place in position of comfort (POC) Minimal handling and investigations Notify ENT and anesthesia consultants for direct visualization of airway in operating room		Place in POC Minimal handling Notify ENT and anesthesia consultants Intubate if in respiratory failure

FIGURE 60–3. Epiglottitis. Marked thickening of the epiglottis (arrow) and aryepiglottic folds (arrowheads) is seen. Mild hypopharyngeal overdistention is also present. (From Cummings CW (ed): *Otolaryngology—Head & Neck Surgery*, 4th ed. Philadelphia: Elsevier Mosby, 2005, p. 4362.)

room with proper airway equipment. An otolaryngologist should be present should the need for a surgical airway arise.

Management

Once the airway is secure, the goal of therapy is to eradicate the offending bacterial organisms. Single therapy with ampicillin-sulbactam or ceftriaxone was found to be used most commonly in a recent review and was effective.³³ Patients usually remain intubated in the pediatric intensive care unit until there is evidence of an air leak around the endotracheal tube. Direct visualization of the supraglottic area may also be performed to assess clinical progress.

Foreign Bodies

Foreign body aspiration is a common pediatric problem that has the potential to lead to a partial or complete airway obstruction. Suspecting the diagnosis is the most important step in making the diagnosis, as patients can be asymptomatic prior to and after the aspiration. The majority of events will occur in the toddler age group but can happen at any age. Common foods that are aspirated are peanuts, hot dogs, candy, popcorn, and grapes.^{34,35} Other items can include pieces of rubber balloons, coins, toys, or other nonorganic objects that are found commonly in the child's environment.

Clinical Presentation

Usually a coughing episode precedes symptoms of ensuing respiratory distress, but this may not always happen. Drooling, respiratory distress with accessory muscle use, stridor, and wheezing may be present as the degree of obstruction worsens. Depending on the location of the foreign body,

symptoms will vary. For example, an extrathoracic foreign body may cause inspiratory and expiratory stridor, whereas an intrathoracic foreign body may be associated with expiratory wheezing.

Investigations with radiographs are helpful if the aspirated object is radiopaque. Radiographs may also be useful if the aspirated agent is in a bronchus and “air trapping” has occurred. This is indicated by hyperinflation of the affected lung on the side in which the foreign body is present. If the history is suggestive, a normal chest radiograph does not rule out the possibility of foreign body aspiration, and bronchoscopy must be performed to confirm or refute the diagnosis.

Management

There are several techniques for removal of foreign bodies. These can include the use of rigid esophagoscopy, flexible endoscopy, or balloon-tipped (Foley) catheters with fluoroscopic guidance³⁶ (see Chapter 162, Foreign Body Removal). These methods all have high success rates. For aspirated foreign bodies, bronchoscopy is the method of choice with a very high success rate.³⁷

Syncope

Theodore E. Glynn, MD and Earl J. Reisdorff, MD

Key Points

Most children with syncope can be effectively assessed by history, physical examination, and 12-lead electrocardiogram.

Most syncopal events result from benign causes.

Despite the low incidence, physicians must reasonably exclude serious cardiac disorders as a cause of syncope.

Pregnancy-related causes of syncope should be considered in adolescent women.

Introduction and Background

Syncope is defined as a transient loss of consciousness and postural tone with spontaneous recovery.¹ Between 15% and 50% of children will have at least one episode of syncope before reaching adulthood.^{2,3} Children with syncope typically have a rapid return to normal mental status without any residual deficit.⁴ The terms *presyncope* and *near syncope* are used to describe the feeling that a patient is about to pass out and can precede a true syncopal attack.^{1,5} Etiology and outcome are similar to that in children with syncope. Most children and adolescents with syncope have an excellent prognosis, with long-term survival that parallels the general population.⁶ Nonetheless, some children will have an underlying life-threatening disorder.

Recognition and Approach

Causes of syncope can be divided into cardiac and noncardiac disorders (Table 61–1). Some experts further delineate a third cause of syncope termed *neurocardiogenic syncope*.⁷ The causes of syncope are numerous, and serious life-threatening disorders fall into each category. Individual children with syncope can have cardiac and noncardiac derangements that contribute to causing syncope. Neurocardiogenic (vasovagal) syncope is the most common cause in adolescents and adults.^{3,5,8–10} Under the age of 6 years, breath-holding, sei-

zures, and arrhythmias are more likely to be the cause of syncope than are the case in older children.

Since a child with syncope has a normal physical examination up to 96% of the time, a detailed history of events surrounding the syncopal episode is essential in guiding the diagnostic evaluation.¹⁰ Performing extensive diagnostic testing for all patients has a poor diagnostic yield and is not cost effective.² Determining the cause of syncope requires attention to certain historical factors, a focused physical examination, minimal laboratory evaluation, and electrocardiographic (ECG) analysis. With these basic diagnostic elements, the clinician can identify those children who require a more detailed assessment, looking for more concerning causes.

Clinical Presentation

Distinguishing “benign” syncope from a rare yet life-threatening entity does not require an extensive diagnostic evaluation in most cases.^{2,10} In fact, defining the absolute cause of syncope in every case in the emergency department (ED) is impractical and simply impossible. The patient and parents should be cautioned that finding a definitive cause is often not possible. Nonetheless, it is the obligation of the emergency physician to reasonably exclude serious conditions within the diagnostic limitations of the ED.

A screening process involving a focused history, a symptom-specific physical examination, and a 12-lead ECG identifies patients requiring a more intensive diagnostic evaluation and subspecialty referral, usually as an outpatient.^{2,10} The presence of certain features that are typical for serious causes of syncope indicate that a more detailed workup may be indicated, to include laboratory tests, echocardiogram, stress test, tilt-table testing, electrophysiologic testing, cardiac catheterization, electroencephalography, and advanced imaging of the head or chest (e.g., magnetic resonance imaging, computed tomography [CT]).

History

The history and physical examination are sufficient to determine the cause of syncope in 25% to 77% of cases.^{11,12} The circumstances preceding a syncopal episode provide clues to the underlying cause. For example, if a diaphoretic, weak, and tachycardic child has missed meals, hypoglycemia is a consideration. Dieting, diuretic use, and exertional activity can lead to orthostatic hypotension. The activity and

Table 61–1 Causes of Syncope***Cardiac****Structural Defect**

Aortic stenosis
 Hypertrophic cardiomyopathy
 Primary pulmonary hypertension
 Congenital heart defects
 Eisenmenger's syndrome
 Hypoplastic left heart syndrome
 Interrupted aortic arch

 Atrioventricular block

Noncardiac**Neurally Mediated**

Vasovagal (also known as vasodepressor and neurocardiogenic)
 Cough syncope
 Micturition syncope
 Gastrointestinal origin (defecation, swallow syncope)
 Breath-holding spells (suspected etiology is autonomic dysregulation)

Orthostatic or Altered Blood Pressure Control

Idiopathic
 Dehydration or blood loss
 Drug-induced vasodilation

Cerebrovascular, Neurologic, Pulmonary, and Psychiatric

Intracranial hemorrhage
 Seizure
 Hypoglycemia
 Migraine—vertebrobasilar vascular spasm
 Toxin/drug exposure
 Pulmonary embolism
 Psychogenic
 Hyperventilation

*Individual patients may have coexisting cardiac and noncardiac underlying etiologies for their syncope.

Table 61–2 Clinical Features Suggestive of Serious Cardiovascular Causes of Syncope*

History of rapid onset without prodrome (e.g., “face plant,” or no warning symptoms and inability to protect face from fall)
 Syncope onset while recumbent
 Syncope preceded by chest pain or palpitations
 Syncope during exercise
 Recurrent syncope, especially over hours or days
 Congenital deafness
 History of congenital heart disease or any structural heart defect
 History of use of medications or illicit drugs with cardiac side effects (see Chapter 137, Cardiovascular Agents)
 Marfanoid appearance or family history of collagen vascular disease
 Family history of cardiomyopathy or sudden death (especially at young age)
 Abnormal cardiovascular examination (e.g., murmur)

*List is not all inclusive.

position of the child at the time of the event also provide hints. If, at the onset of the event, the child was crying, urinating, defecating, or coughing, a vagally-mediated syncope event is probable. Changing positions from lying to standing just prior to syncope indicates orthostatic hypotension. Syncope that occurs when a child is sitting is more likely to be a cardiac arrhythmia. Typical vagally-mediated (neurocardiogenic) episodes are preceded by nausea, lightheadedness, and a slow visual loss.

Witnesses can provide information as to the duration of the event as well as any concomitant seizure activity (e.g., abnormal eye movement or urinary incontinence). A slow recovery or mental confusion following the event suggests a seizure.¹³ Severe pallor or cyanosis suggests a cardiac origin. A menstrual history should be taken, since both the physiologic intravascular volume changes of pregnancy as well as bleeding from an ectopic pregnancy can lead to syncope. The use of any over-the-counter or prescription drugs (especially those that prolong the QT interval) should be determined. Illicit drugs (including volatile substances) or ethanol misuse can cause syncope. Historical factors that can indicate more serious causes of syncope include the lack of any prodromal symptoms, syncope during exertion, a supine position at onset of symptoms, and recurrent episodes over a short time period (Table 61–2).

Key elements in a family history include sudden death, heart disease, hypercholesterolemia, diabetes, epilepsy, or recurrent syncope. The family history is most relevant in cases in which the cause of syncope is uncertain. Family members with a history of sudden cardiac death, arrhythmias, seizures, congenital deafness, or early-onset myocardial infarction further raise the consideration of a potential cardiac condition.

Physical Examination

A rapid assessment of the airway, breathing, and circulation is axiomatic for the emergency physician. Review of the temperature, pulse, respiratory rate, orthostatic blood pressure, and pulse oximetry is additionally helpful in this regard. In adolescents, a standing blood pressure of less than 80 mm Hg is abnormal, and a decrease in the systolic blood pressure of

≥ 30 mm Hg or an increase in heart rate ≥ 25 to 30 beats per minute on standing is diagnostic of orthostatic hypotension, especially when accompanied by a feeling of lightheadedness.^{14,15} Orthostatic testing may further identify children who have abnormal autonomic reflex mechanisms. Beyond a general assessment and attention to all vital signs, the physical examination must focus on the cardiovascular and neurologic systems.

The cardiovascular system is closely examined, including auscultation for murmurs, gallop rhythms, irregularity, and extracardiac sounds suggesting valvular disease or left ventricular dysfunction. It is important to listen for murmur characteristics suggestive of ventricular outflow obstruction (i.e., hypertrophic cardiomyopathy [HCM]). Auscultatory findings of HCM include a fourth heart sound (S_4) as well as a murmur of turbulence or obstruction emanating from the left ventricular outflow track. This murmur classically increases in intensity during performance of the Valsalva maneuver or other activities that decrease venous return (standing). The murmur of HCM decreases with maneuvers that increase venous return (squatting).

A midsystolic click is heard with mitral valve prolapse. The presence of any heaves or thrills on chest palpation may indicate valvular disease or a cardiomyopathy. Auscultation over the carotid arteries (primarily for translated cardiac murmurs) must be performed.

A focused neurologic examination is performed, beginning with the child's mental status. Persistent or focal neurologic findings suggest brain injury (e.g., leakage from an arteriovenous malformation, shaken infant syndrome) or a seizure. The value of carotid sinus massage as a diagnostic maneuver in children is limited.¹⁶ Other physical features associated with cardiovascular disease are an abnormal facies, marfanoid habitus, deafness, and ataxia. Neurogenic

etiologies are suspected in the presence of ash-leaf spots, café-au-lait spots, or cleft palate.

Diagnostic Evaluation

Most children with syncope require limited laboratory evaluation. If bleeding or anemia is suspected, a complete blood count is indicated. Patients with seizures, an altered mental status, or a history of diabetes require testing of blood glucose. In menstruating adolescents, a pregnancy test should be obtained. Serum electrolytes (including magnesium, calcium, and phosphorus) are measured if the history suggests an electrolyte disturbance, dehydration, endocrine abnormality, or malnutrition. Electrolytes are also measured if there are abnormalities on the ECG. A urinalysis can reveal dehydration and malnutrition if there is an elevated specific gravity or ketonuria. Ketonuria with an elevated urine glucose may indicate hypovolemia from diabetic ketoacidosis. Toxicologic screens and arterial blood gas analyses are performed only as indicated by the history and physical examination.

Electrocardiography and cardiac rhythm monitoring are the most important diagnostic studies for excluding life-threatening cardiac conditions. Attention is paid to the heart rate, rhythm, conduction intervals (PR interval, QRS complex duration, and QT interval) and chamber hypertrophy (Table 61–3). Moreover, the ECG can provide information on heart chamber size, thereby revealing the presence of structural heart disease.

Advanced outpatient studies (e.g., echocardiography, tilt-table testing) should be coordinated with specialists. Subsequent outpatient advanced studies can include Holter monitoring, angiography, electroencephalography, and cardiac electrophysiology studies. Heart rate and blood pressure responses to formal tilt-table testing can often define the physiologic causes of syncope.^{17,18} In summary, children with

Table 61–3 Electrocardiography (ECG) Features Associated with Disorders Causing Syncope*

Disorder	ECG Abnormality
Arrhythmogenic right ventricular cardiomyopathy (dysplasia)	Right bundle branch block or prolonged QRS > 111 msec in leads V_1 to V_3 in absence of right bundle branch block with T-wave inversion in V_2 and V_3 (if older than 12 yr)
Brugada syndrome	Left bundle branch configuration to ectopic beats Right bundle branch block with ST segment elevation in V_1 to V_3
Conduction defects from multiple diseases (e.g., Lyme disease, myocarditis, rheumatic fever)	Incomplete right bundle branch block with ST segment elevation in V_1 and V_2 Type II second- or third-degree atrioventricular block
Hyperkalemia	Early narrow and peaked T waves with short QT interval, later widening of QRS complex with P-wave amplitude diminishing
Hypocalcemia	Eventual loss of P waves, high-degree atrioventricular block, sine wave pattern, and asystole
Hypokalemia	Prolonged QT interval
Idiopathic subaortic stenosis (hypertrophic cardiomyopathy)	ST segment depression with flat T waves and prominent U wave Nonspecific ST segment and T-wave abnormalities
Ischemia (e.g., arteritis or anomalous coronary artery)	Left ventricular hypertrophy with QRS complexes that are tallest in the mid-precordial leads Prominent Q waves in the inferior (II, III, aV_F) or precordial (V_2 to V_6) leads, or both With anomalous coronary arteries, resting ECG is often normal
Long QT syndrome	Focal ST segment elevation or depression, Q waves, T-wave inversion
Pericarditis	Reciprocal changes may be present
Wolff-Parkinson-White syndrome	QT interval > 0.46–0.50 msec, although may need stress test to uncover prolongation of QT Diffuse ST segment elevation, PR interval depression Delta wave, short PR interval with wide QRS complex

*The list is not all inclusive and only describes common ECG findings for listed diseases. Other ECG findings can occur with listed diseases. Adapted from Rothrock SG (ed): Pediatric Emergency Medicine Pocketbook, 5th ed. Lompoc, CA: Tarascon Publishing, 2006.

syncope who are seen in the emergency department are most often adequately evaluated by review of the vital signs, including orthostatic changes, a complete blood count, a glucose level, a 12-lead ECG, and continuous cardiac rhythm monitoring. A urine pregnancy test is performed on postmenarcheal females.

Differential Diagnosis

Most children seen in the ED with transient loss of consciousness have neurocardiogenic (vasovagal) syncope. This can involve as many as 80% of cases, followed by neurologic disorders such as seizures (9%).¹⁰ About 5% of children seen in the ED for syncope have a cardiac cause for the event.^{4,10,19}

Neurally Mediated Syncope

Neurocardiogenic syncope is caused by the vasovagal reflex. It is the most common cause of syncope in healthy children and adolescents.⁹ This phenomenon accounts for 50% to 80% of infants and children presenting to pediatric EDs with syncope.^{10,20,21} Neurocardiogenic syncope and other neurally mediated disorders causing syncope (e.g., cough syncope, micturition syncope, swallow syncope) are thought to share a similar underlying mechanism.⁷ There is a triggering event that stimulates sympathetic activity, followed by a clinical prodrome of parasympathetic or vagal hyperactivation (e.g., nausea, vomiting). Then, there is an abrupt withdrawal of sympathetic activity with persistence of parasympathetic activity. Resulting hypotension or bradycardia result in syncope unless the patient lies down and the causative stimulus is removed.^{7,22} Fluid shifts with decreased thoracic blood volume and increased splanchnic, pelvic, and leg blood volumes contribute to hypotension.²³ In some patients, autonomic nervous system-mediated alterations in cerebral blood flow may be the cause of syncope.²⁴

The three main clinical variants of neurocardiogenic syncope are vasodepressor (marked hypotension), cardioinhibitory (profound bradycardia), and mixed (combined hypotension-bradycardia).^{8,9} Children often report prodromal feelings of nausea, diaphoresis, and light-headedness prior to passing out. These symptoms often give them the time to sit or lie down, accounting for the fact that patients with neurocardiogenic syncope rarely hurt themselves during their episodes. Emotional or physical stressors frequently incite episodes. The associated loss of consciousness is brief, especially if the patient is allowed to assume a recumbent position. There is a rapid return to baseline mental status. Short-term recurrence is rare unless the patient is allowed to stand soon thereafter. Multiple episodes within a short period of time are more likely associated with structural cardiac disease or a neurologic disorder.

While a typical history with a normal examination is all that is required to diagnose neurocardiogenic syncope, the role of adjunct testing is controversial. Tilt-table testing is used to diagnose this disorder in adults; however, use of this test in children is controversial.⁷ In children and adolescents, this test has 43% to 57% sensitivity and 83% to 100% specificity for diagnosing neurocardiogenic syncope.⁷ Interestingly, tilt-table testing leads to a marked decrease in the frequency and magnitude of symptoms in patients with neurocardiogenic syncope. Use of this test allows patients to identify prodromal symptoms that they may not have previ-

ously recognized, institute preventative measures (i.e., sitting down), and prevent syncope.⁷ The prognosis for all forms of neurally-mediated syncope is excellent. The risk of recurrent events diminishes over time.

Cardiac Syncope

Cardiac causes of syncope are important to identify. The 1-year mortality of all patients (adults and children) with a cardiac cause of syncope is 18% to 33%.^{25,26} Cardiac disease must be considered in children with a variety of clinical features, including exertional syncope, absence of a prodrome, recurrent episodes, onset while recumbent, and associated chest pain or palpitations (see Table 61–2). Cardiac disease causes syncope due to low cardiac outflow (due to either obstruction or low-output conditions) or arrhythmias (see Chapter 63, Dysrhythmias). Structural heart disease resulting in outflow obstruction–related syncope includes valvular heart disease (e.g., congenital or acquired aortic stenosis) and HCM. Conditions that depress myocardial function include both inflammatory processes (e.g., myocarditis) and ischemia (e.g., anomalous origin of a coronary artery). Arrhythmogenic syncope can occur in patients with congenital heart disease as well as those with “structurally normal” hearts (see Chapter 30, Congenital Heart Disease; and Chapter 66, Postsurgical Cardiac Conditions and Transplantation). Reentrant tachyarrhythmic syndromes (e.g., Wolff-Parkinson-White [WPW]), as well as prolonged QT and Brugada syndromes can cause malignant dysrhythmias leading to sudden cardiac death. Intermittent atrioventricular (AV) block (sometimes referred to as a “Stokes-Adam attack”) can cause syncope that is accompanied by tonic-clonic seizure activity occurring 10 to 20 seconds after the onset of asystole. These events are usually short-lived, with a rapid return to normal mentation. Patients suffering from this life-threatening disorder may be misdiagnosed as having a seizure disorder.^{8,27}

STRUCTURAL HEART DISEASE

HCM is the most common cause of sudden cardiac death in young athletes.^{28,29} HCM may initially present as syncope or seizure during or immediately after exertion due to decreased cerebral perfusion. HCM causes syncope due to a low cardiac output. This usually occurs when the patient develops tachycardia in the presence of a structurally reducing filling volume. Atrial fibrillation associated with HCM results from secondary atrial enlargement. Atrial fibrillation further decreases ventricular filling, increasing the risk of syncope. The physical findings of HCM can be subtle. A fourth heart sound (S₄) is usually audible. The murmur usually increases with increased Valsalva maneuvers. The ECG may reveal left ventricular hypertrophy with a strain pattern or may be normal in up to 25% of cases.^{30–32}

In familial right ventricular dysplasia, the myocardium is composed of abnormal fatty cells and degenerated myocardial cells. This erratic architecture can lead to ventricular dysrhythmias that cause syncope.^{33,34} Mitral valve prolapse rarely causes syncope.³⁵ However, some patients with mitral valve prolapse have an elevated adrenergic tone that predisposes them to arrhythmia.³⁶

Severe aortic stenosis causes syncope from a cardiac outflow obstruction. The murmur of aortic stenosis is a systolic murmur at the middle and upper parasternal areas asso-

ciated with a palpable thrill at the base of the heart. Peripheral pulses can be diminished. With coarctation of the aorta, infants can develop syncope, elevated systolic and diastolic blood pressures, and decreased or absent femoral pulses. Anomalous coronary arteries cause syncope, dysrhythmias, and sudden cardiac death during exercise. Ischemia-induced arrhythmia presumably results from compression or kinking of the aberrantly coursing vessel. Subclavian steal syndrome causes syncope by diverting blood from the cerebral basilar circulation. Congenital heart disease raises concerns about life-threatening ventricular arrhythmias. There is an increased incidence of ventricular tachycardia following repair of tetralogy of Fallot, presumably because of elevated right ventricular pressures from persistent obstruction in the right ventricular outflow track. Atrial and ventricular arrhythmias and AV block resulting in syncope and sudden death are associated with specific procedures for repairing many congenital cardiac defects (see Table 61–3; also see Chapter 66, Postsurgical Cardiac Conditions and Transplantation). Adolescents with primary pulmonary hypertension usually experience dyspnea on exertion. Syncope from pulmonary hypertension results from an inadequate cardiac output through a progressively narrowing and constricting pulmonary vascular bed. There is no murmur until pulmonary hypertension becomes extremely advanced.^{26,37,38}

RHYTHM ABNORMALITIES

Cardiac rhythm and conduction disturbances can cause syncope by decreasing cardiac output and reducing cerebral perfusion (see Chapter 63, Dysrhythmias). Bradycardias can result from excess vagal tone or sick sinus syndrome. Bradycardia or asystole can be seen with neurocardiogenic (vasovagal) syncope. Congenital heart block presents as marked bradycardia and complete AV dissociation in the fetus or neonate. Unfortunately, congenital heart block can go undetected for years. Lyme disease can cause complete heart block that is transient and usually does not require a cardiac pacemaker.^{9,39,40} In addition, other forms of infectious as well as noninfectious myocarditis can cause arrhythmogenic syncope.

Supraventricular and ventricular tachycardia can cause syncope.^{41,42} In sick sinus syndrome, an episode of atrial tachycardia or atrial flutter may spontaneously terminate without the prompt return of normal sinus rhythm or a junctional escape rhythm. Thus a period of asystole follows immediately after spontaneous termination of the aforementioned tachycardia, resulting in syncope. Syncope after pacemaker insertion in a patient with sick sinus syndrome (“tachy-brady” syndrome) suggests that a tachyarrhythmia is the underlying cause. Though sick sinus syndrome is more common following corrective surgery for congenital heart disease, it can also occur in an otherwise “normal” heart.⁴³

WPW syndrome is associated with a shortened PR interval, an abnormal QRS complex that is often slurred in its initial portion (delta wave), and tachycardia owing to a reentrant accessory pathway (bundle of Kent) between the atria and the ventricles. The most common arrhythmia associated with WPW syndrome is a reciprocating or reentrant loop supraventricular tachycardia. Tachycardia rarely causes syncope by itself.^{44,45} Atrial fibrillation with transmission of the impulses across both the AV node and accessory pathway results in ventricular rates as high as 300 to 400 beats per

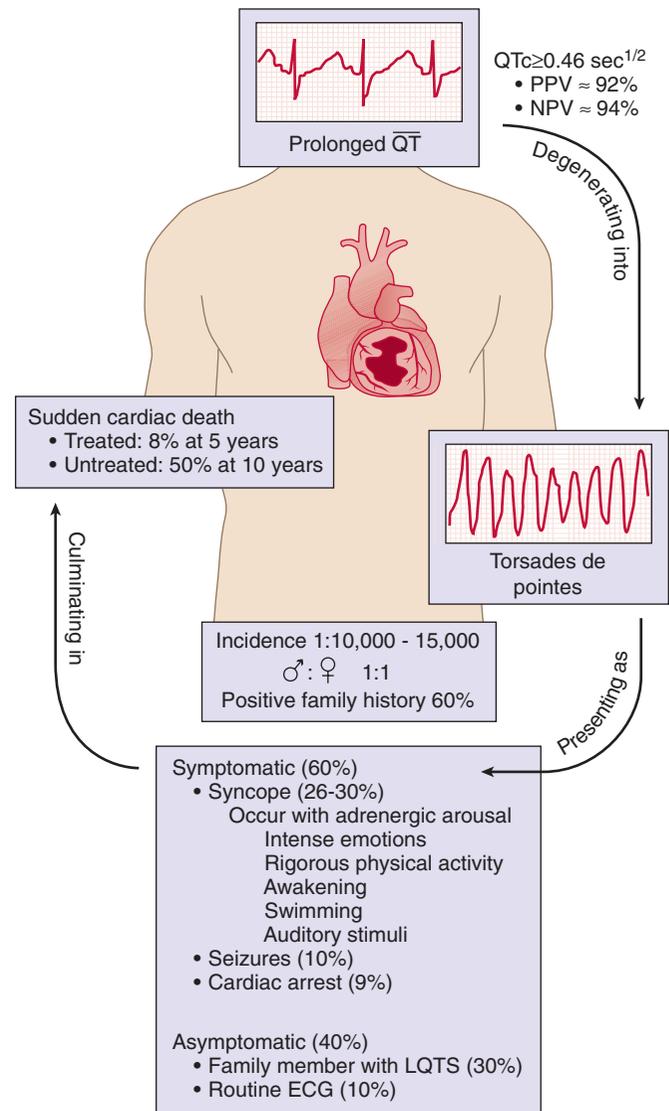

FIGURE 61–1. Key clinical characteristics of inherited long QT syndrome (LQTS), including prolongation of QT interval on electrocardiogram (ECG), commonly associated arrhythmia (torsades de pointes), clinical manifestation, and long-term outcomes. Abbreviations: NPV, negative predictive value; PPV, positive predictive value; QTc, corrected QT interval.

minute. This can rapidly lead to hemodynamic instability and syncope.

Congenital long QT syndrome is a rare inherited condition resulting from delayed ventricular repolarization (Fig. 61–1). There is an increased risk of fatal ventricular arrhythmias, most commonly polymorphic ventricular tachycardia (torsades de pointes). Patients have a 50% ten-year mortality if untreated, and 9% of children with long QT syndrome suffer sudden cardiac death as their initial presentation.^{46,47} This syndrome can be associated with congenital deafness. Patients with long QT syndrome typically manifest a corrected QT interval (QT_c) greater than 0.46 seconds on ECG, although this may be difficult to assess when the patient is in normal sinus rhythm. Because the QT interval varies with the heart rate, the QT_c (QT interval ÷ square root of R-R interval) must be used to determine prolongation. Using a QT_c of 0.46

seconds as a cutoff provides positive and negative predictive values that approach 95% in the identification of patients with long QT syndrome.⁴⁶ Certain genotypes of congenital long QT syndromes may have QT intervals that overlap with normal values, ranging from 0.42 to 0.47 in up to 40% of cases.⁴⁸ In addition to QT interval abnormalities, ECG manifestations that may be present include abnormally shaped or giant T waves as well as U waves.⁴⁶ Approximately two thirds of children with long QT syndrome will manifest symptoms (most commonly syncope) prior to definitive diagnosis. Syncope is often precipitated by events causing sinus tachycardia (e.g., exertion, a sudden startle, emotional upset). Patients with long QT syndrome require cardiology referral if asymptomatic, and admission and monitoring if symptomatic.

In some children, exercise-induced tachycardia increases prolongation of the QT_c interval and can assist with making the diagnosis.⁴⁹ Acquired QT prolongation is usually secondary to electrolyte imbalances, malnourishment, and drugs, such as antiarrhythmics, antidepressants, and phenothiazines⁴⁰ (see <http://www.qtdrugs.org/>). Catecholamine-induced polymorphic ventricular tachycardia can occur in the child with stress-induced or emotionally induced syncope.^{50,51} The syndrome of idiopathic exercise-induced ventricular tachycardia in children and adolescents is another cause of syncope.^{52,53} Diagnosis requires continuous cardiac monitoring during the event.

Noncardiac Syncope

Noncardiac causes of syncope include hypoglycemia, breath-holding spells, neurally-mediated disorders, basilar migraine, toxins (carbon monoxide and inhalant abuse), and psychogenic illness. Hypoglycemic patients have a history of diminished oral intake or use of medications (e.g., insulin) that cause their glucose to drop. Importantly, patients usually remain confused until glucose levels return to normal (see Chapter 106, Hypoglycemia).

Breath-holding spells are a common cause of syncope in infants, although an exact physiologic cause and description can only be inferred from limited case series.^{54,55} Severe breath-holding spells are associated with a loss of consciousness, whereas simple spells are not. Severe breath-holding spells have been reported in 1.7% to 4.6% of healthy children.^{55,56} The typical age of onset is 6 to 24 months, with up to 15% of affected children having an onset within the first 6 months of life.^{54,56} Most infants and children have frequent spells (more than once per week), and most have resolution of symptoms by the age of 4 years.⁵⁶ While the etiology is unknown, many experts believe this disorder is due to autonomic dysregulation, which leads to cerebral anoxia through a variety of mechanisms.^{55,57} Many patients have iron deficiency anemia, and up to 88% of patients having improved symptoms following iron therapy regardless of whether or not they are anemic.⁵⁸ Inheritance of breath-holding spells is autosomal dominant, with up to 27% of parents and 21% of siblings having a history of breath-holding spells.⁵⁹

There is a distinctive sequence of events in breath-holding spells. Initially, there is provocation resulting in crying or emotional upset that leads to a noiseless state of expiration accompanied by color change and ultimately loss of consciousness and postural tone.⁵⁶ Occasionally, brief jerking or urinary incontinence occurs. The event usually terminates

with an inspiratory gasp or spontaneous resumption of quiet breathing.⁵⁴ Recovery of normal tone and mental status may take a few minutes, making the differentiation of this disorder from seizures difficult.⁵⁴ The color change is used to differentiate between the more common cyanotic spells (52% to 62% of cases), less common pallid spells (19% to 28%), and spells with mixed or unclassifiable features (19% to 20%).^{54,56} Cyanotic spells are believed to be due to hypersympathetic effects, with more prolonged crying, intrapulmonary shunting, hypoxia, and cerebral anoxia leading to loss of consciousness.⁵⁵ Pallid breath-holders have hyperparasympathetic effects with associated asystole or bradycardia causing cerebral hypoperfusion and anoxia.⁵⁵ Iron is the only therapy that has been shown to decrease the frequency of breath-holding spells.⁵⁸ Rarely, anoxic episodes and seizures are so frequent that pacemaker implantation is required in children with breath-holding spells.⁶⁰

Tussive syncope or post-tussive syncope is provoked by severe coughing paroxysms. These episodes can be associated with respiratory illnesses, including bronchospasm from an acute infection, asthma, pertussis, or cystic fibrosis. Presumably, severe paroxysms of coughing result in reduced cardiac output owing to the high intrathoracic pressures.

An atypical migraine headache can cause syncope. These patients usually have other symptoms atypical for syncope, including visual changes, ataxia, and vertigo. Other neurologic causes of syncope include central nervous system trauma, tumors, and cerebrovascular accidents involving arteriovenous malformations (see Chapter 41, Headaches).

Many drugs can cause syncope, including both prescription and nonprescription medications, even when used as recommended. Certain drugs can cause QT prolongation (e.g., droperidol) with resultant torsades de pointes (see <http://www.qtdrugs.org/>). Prolongation of the QT_c is exacerbated with the concurrent use of macrolides (e.g., erythromycin) and ketoconazole. Substances of abuse such as cocaine, alcohol, marijuana, inhalants, and opiates can all cause an acute loss of consciousness (usually as a consequence of intoxication or inebriation). Inhalant abuse (especially freons) can result in ventricular tachycardia and death. There is an increased frequency of sudden death in preadolescent boys taking tricyclic antidepressants for attention-deficit/hyperactivity disorder.⁶¹

Important Clinical Features and Considerations

Differentiating Syncope from Other Events

Seizures and breath-holding spells share characteristics with true syncope that makes differentiating these entities difficult. Obviously, an appropriate disposition and treatment decision are based on an accurate diagnosis. Misdiagnosing a patient as having a tonic-clonic seizure can have unfavorable consequences if the underlying cause of the event is actually a malignant dysrhythmia. Patients with congenital heart block or long QT syndrome frequently develop tonic-clonic activity or posturing that is easily misinterpreted as seizure activity. The lack of postictal confusion is one important factor that can differentiate most cases of syncope from seizure episodes. Breath-holding spells, although generally benign and self-limited, can often be incorrectly suspected

of being a seizure due to the common occurrence of cyanosis and myoclonic jerking. Hypoglycemia is typified by a gradual onset of depressed mental status. Moreover, hypoglycemia is associated with hyperadrenergic symptoms without hemodynamic compromise. In summary, a detailed history surrounding an episode supplemented by an ECG may allow the clinician to successfully determine the exact etiology.

Syncope can be readily confused with a seizure. Seizures are the most common mimic for a syncopal event. Given the variety of presentations of syncope as well as seizures, it can be extremely difficult to ultimately define the episode. Complicating this yet further, a brief seizure can follow a vasovagal episode. Yet one more confounding factor is that cardiac dysrhythmias can accompany status epilepticus. For this reason, patients who have a first-time, nonfebrile seizure require an ECG to assess for QT prolongation or other important abnormalities⁶² (see Table 61–3).

Patients with seizures commonly have a prodromal aura; this is uncommon with syncope. Facial cyanosis, frothing at the mouth, tongue biting, postictal drowsiness, and prolonged mental status changes after the event suggest a seizure. When the cause of the patient's symptoms is unclear, evaluation for both syncope and seizure is required. Electroencephalography may differentiate between syncope and seizure. Seizures may present with atypical findings; for example, temporal lobe epilepsy may demonstrate only simple motor activity, which often appears semipurposeful.

Syncope and the Athlete

Exertional or exercise-induced syncope is associated with a significant risk of sudden cardiac death, and thus referral for a complete noninvasive cardiac evaluation is indicated. HCM is the most common cause of sudden death in young competitors, followed by anomalous origin of a coronary artery. Other causes of sudden death in the athlete are arrhythmogenic right ventricular cardiomyopathy, myocarditis, and dilated cardiomyopathy.²⁹ Unfortunately, sudden cardiac death is often the first manifestation of disease in such patients. However, up to one third of patients will suffer exertional syncope or chest pain prior to sudden cardiac death.^{29,63} The physical examination of patients with HCM may reveal an S₄ due to impaired ventricular relaxation as well as a systolic ejection murmur that is elicited or accentuated by Valsalva maneuver. Typical ECG changes may be present (see Table 61–3). Athletes with sickle cell trait have up to a 21-fold higher risk of sudden death during exertion compared to nonsicklers. The reasons for this remain unclear. Since malignant arrhythmias may play a role in athletes with sudden death, liberal distribution of automated external defibrillators to sporting events and training sites may improve outcome from syncope in this population.⁶⁴

Management

When treating the child with syncope, assessing the airway, breathing, and circulation is important. Orthostatic vital signs are taken. However, most children presenting with syncope will be asymptomatic in the ED. Treatment must be specific to any identifiable cause. A complaint-focused history and physical examination, as well as an ECG, should guide management. A rapid bedside glucose measurement is obtained and pulse oximetry is performed. Further labora-

tory assessment is of limited use unless there evidence of a specific metabolic derangement (e.g., dehydration with orthostasis).² Children with persistent alterations in mental status or focal neurologic deficits require a CT scan, electrolyte measurements, and toxicologic screens (including carbon monoxide). Unstable tachyarrhythmias are treated by pediatric advanced life support guidelines. If a tachycardia is toxin-induced, therapy focuses on the underlying cause. For example, sodium bicarbonate is used for cocaine- and tricyclic-induced wide-complex tachycardia. Likewise, diazepam or lorazepam may slow a cocaine-induced narrow-complex tachycardia. Initially, hypotension is treated with a bolus of isotonic fluid (20 ml/kg). If this is ineffective, inotropic agents may be required. If all diagnostic studies are normal, the child does not require immediate therapeutic intervention in the ED, and a serious cause for syncope is not suspected, the child should be sent home under the care of a responsible adult who can observe the child and ensure follow-up with the primary care provider. A key task remains the identification of that minority of patients who require a further, more sophisticated cardiac evaluation or specialty referral.

Summary

Most infants, children, and adolescents with syncope have a benign cause for their complaints. A directed history, physical examination, and ECG can identify children requiring more intensive testing. Clinicians must be able to identify clinical and ECG features signifying that a serious disorder may be causing syncope. Knowledge of the presentation of common and serious disorders causing syncope can improve the efficiency of the ED diagnostic evaluation and help identify serious and life-threatening disorders.

Chest Pain

Stephen R. Knazik, DO, MBA and Earl J. Reisdorff, MD

Key Points

Chest pain in children rarely indicates a serious cardiac problem.

A musculoskeletal origin accounts for most cases of chest pain in children.

The history, the physical examination, and limited diagnostic testing will reveal most serious causes of chest pain.

Multidetector computed tomography scanning with thin collimation (0.6 to 1.25 mm) is as accurate as angiography at detecting pulmonary emboli and aortic dissections and is more accurate than plain radiography for detecting pneumonia, pulmonary and aortic injury, effusions, atelectasis, pneumothorax, and pneumomediastinum.

Introduction and Background

Chest pain is a fairly infrequent complaint among pediatric emergency department (ED) patients. At Children's Hospital of Michigan, of 68,260 children seen in 2002, 219 patients (0.32% of patients without sickle cell disease) had a chief complaint of chest pain (S. Knazik, unpublished data, January 2005). This is similar to the experience in a pediatric hospital in Spain, where 0.34% of patients younger than 14 years complained of chest pain as part of their ED presentation.¹ Chest pain causes considerable anxiety among patients and parents often due to concern about cardiac disease. Unlike adults, cardiac disease (especially atherosclerotic disease) rarely causes chest pain in children. Most often, chest discomfort is caused by relatively benign processes (e.g., musculoskeletal disease), even in children with serious underlying conditions. Notable exceptions include children with sickle cell disease who develop acute chest syndrome, children with cancer or central venous catheters who develop pulmonary emboli (PEs), and children with collagen vascular disorders who develop aortic dissection. Fortunately, the medical history, physical examination, and, when needed, simple

diagnostic testing usually can exclude serious causes of chest pain.

Recognition and Approach

Musculoskeletal pain (including costochondral pain) is the most common cause of pain among children referred to pediatric cardiology clinics (76% to 89%).^{2,3} Other causes include exercise-induced asthma (4% to 12%), gastrointestinal causes (8%), and psychogenic causes (4%). In one study of 50 children referred to a cardiology clinic, no patient had a cardiac cause of discomfort.² Another study reported that 7% of children had a supraventricular tachyarrhythmia as the cause of the chest pain.³

Among ED patients, common causes of chest pain include musculoskeletal (64%) and idiopathic (21%).⁴ Cardiac problems are found in only 4% to 5%. Other causes include pulmonary (13%), psychological (9%), and trauma (5%).³ Younger children are more likely to have cardiac or respiratory problems, while children older than 12 years have a higher incidence of psychogenic pain. Although electrocardiograms (ECGs) are frequently obtained (nearly one half of all patients), only 16% of ECGs are "abnormal." However, only 2% of all ECGs demonstrate abnormalities that are related to the final diagnosis.

Clinical Presentation

Chest pain is a symptom, not a diagnosis. Since chest pain is a symptom, discussion about chest pain in the preverbal child is problematic. Preverbal children are usually brought to the ED for respiratory symptoms or changes in general appearance and not chest pain. Treatment and symptomatic relief are based on the presumed cause of the chest pain (Table 62-1). The exact etiology is often not identified during a single ED visit.

Despite the generally benign nature of most cases of chest pain, certain conditions require prompt medical attention. Many of these causes are readily apparent, such as penetrating trauma or acute chest syndrome, while others (e.g., myocarditis) can present in a subtle fashion. Inflammatory cardiac disease and congenital disorders are particularly concerning due to the potential for fatal arrhythmias, heart failure, and cardiogenic shock⁵ (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis; and Chapter 30, Congenital Heart Disease).

Table 62–1 Differential Diagnosis of Chest Pain**Musculoskeletal**

Chest wall contusion
 Costochondritis
 Malignancy
 Muscle strain
 Rib fracture
 Slipping rib

Pulmonary

Acute chest syndrome (sickle cell disease)
 Acute sickle cell vaso-occlusive crisis
 Asthma
 Bronchitis
 Malignancy
 Pleurisy
 Pneumomediastinum
 Pneumonia
 Pneumothorax
 Pulmonary embolism

Gastrointestinal

Achalasia
 Cholecystitis
 Colonic flexure syndrome
 Esophageal foreign body
 Esophageal spasm
 Esophagitis
 Fitz-Hugh–Curtis syndrome
 Gastritis
 Gastroesophageal reflux
 Hepatitis
 Pancreatitis
 Peptic ulcer disease
 Splenomegaly

Cardiovascular

Aortic dissection
 Arrhythmia (especially tachycardias)
 Congenital vascular anomalies
 Coronary angiitis (Kawasaki disease)
 Mitral valve prolapse
 Myopericarditis
 Pericarditis
 Pneumopericardium

Other

Child abuse
 Hyperventilation
 Idiopathic
 Psychogenic
 Pyelonephritis
 Toxins (cocaine, amphetamines, volatile substance abuse)

Pneumomediastinum or pneumothorax can occur in patients who have status asthmaticus or pertussis. Any condition requiring a pronounced increase in the work of breathing (e.g., diabetic ketoacidosis) can result in musculoskeletal discomfort from chest wall inflammation. Inflammatory cardiac disease (pericarditis, myocarditis) must be considered in any ill-appearing child with chest pain or congestive heart failure. Lyme disease is an important cause of myocarditis in the Northeast during seasons when children are outdoors (April to September). The late summer months are also associated with an increase in the incidence of Coxsackie virus infection with a resultant increase in viral pericarditis.

Chest trauma can result in rib fractures, pulmonary trauma, and abdominal trauma that can cause pain that

refers to the chest and shoulder girdle (Kehr's sign). Importantly, intrathoracic injuries may occur following trauma with minimal to no external evidence (see Chapter 24, Thoracic Trauma; and Chapter 25, Abdominal Trauma).

Esophageal injury (e.g., Boerhaave's syndrome) can occur in children and can be notoriously difficult to diagnose. Congenital or acquired abnormalities of the coronary arteries (e.g., coronary angiitis from Kawasaki disease) may also produce chest discomfort. Aortic dissection must be excluded in children with Down or Marfan syndrome who present with chest or back pain.⁶ Aortic dissection is also associated with invasive medical procedures performed on children with congenital heart disease.⁶

Differences between Pediatric and Adult Chest Pain Complaint

Unlike adults, myocardial ischemia from atherosclerotic coronary artery disease is extremely rare in children. Nonetheless, in rare cases of extreme familial hyperlipidemias, atherosclerotic disease can appear in childhood. Children can develop coronary artery occlusion from trauma or congenital coronary artery anomalies such as coronary artery fistulas, severe myocardial bridging (coronary artery compression during systole by overlying myocardial muscle), or anomalous origin of the coronary arteries. Chest pain often occurs during or immediately after exercise. A coronary artery embolus with subsequent myocardial infarction can occur as a consequence of hypercoagulability due to malignancy or due to emboli from endocarditis, a prosthetic valve, or a patent foramen ovale.⁷ In addition, nephrotic syndrome can cause hypercoagulopathy resulting in coronary artery occlusion.⁸ Finally, sickle cell disease can cause microvascular cardiac ischemia. In older children with severe sickle cell disease and chest pain, nuclear medicine cardiac stress testing is abnormal in 64% of cases.⁹ Adolescents who use cocaine and amphetamines may develop arrhythmias, aortic dissection, and ischemia that all can be felt as chest pain or discomfort.

When compared to adolescents, younger children tend to have more cardiorespiratory disease and less psychogenic disease.⁴ Adolescents can have chest pain from trauma or as a consequence of exertion, coronary artery vasospasm from cocaine abuse, or pulmonary barotrauma. Inhalant abuse through the act of “huffing” can cause chest pain as a result of barotrauma or pulmonary atelectasis. Pulmonary barotrauma (bilateral pneumothoraces and pneumomediastinum) has also been reported in association with “ecstasy” abuse.¹⁰

The child with sickle cell disease may have chest pain on the basis of vaso-occlusive ischemia, osseous infarction, pulmonary infarction, or acute chest syndrome. Acute chest syndrome is characterized by a pulmonary infiltrate in a child with difficulty breathing, pain, cough, and frequently fever.¹¹ The pathophysiology of acute chest syndrome is incompletely understood. However, it almost certainly involves microvascular occlusion within the lungs, ribs, and bony thorax from sickling erythrocytes with a resulting parenchymal lung infiltration. Frequently, the radiographic findings associated with acute chest syndrome mimic pneumonia. Additionally, concurrent pneumonia occurs in up to one third of children¹¹ (see Chapter 127, Sickle Cell Disease).

Children with a PE differ in several important respects from adults. While 70% of adults have an underlying risk factor, nearly 95% of children have a major risk factor for PE.¹² The most common risk factors include the presence of a central venous catheter, underlying cancer, congenital heart disease, sepsis, trauma, and acquired or genetic prothrombotic defects (e.g., factor V Leiden, antithrombin deficiency, antiphospholipid antibodies, nephrotic syndrome, proteins S and C deficiency, hyperhomocystinemia).¹² Unlike in adults, upper extremity deep venous thrombi are a common source for emboli since central venous catheters often involve veins in the proximal upper extremity, or the central chest or neck¹³ (see Chapter 130, Disorders of Coagulation).

History

The medical history should focus on the usual elements used to assess any person with pain, including the pain character, onset, duration, progression, intensity, radiation, and ameliorating factors. Other potentially important symptoms include fever, fatigue, dyspnea, diaphoresis, orthopnea, and syncope (or near syncope). A brief appetite and dietary history and assessment of elimination patterns may help to determine if a gastrointestinal disorder is causing pain. Current prescription medication use should be noted. Certain medications (e.g., tetracycline, metronidazole, nonsteroidal anti-inflammatory agents) can produce chest pain as a consequence of gastrointestinal irritation, esophagitis, or reflux.¹⁴

If a psychogenic basis for chest pain is suspected, the clinician should inquire about potential stressors. These include schoolwork, family problems, peer pressure, chronic disease or disability in parents, family moves, psychiatric disorder in parents, and poor coping abilities.¹⁵

A past medical and family history to exclude hemoglobinopathies is important regardless of ethnicity. Pulmonary embolism should be considered in children with central venous catheters, underlying cancer, sepsis, recent trauma, or other disorders that promote development of thrombi. Sudden death in young relatives increases the suspicion that a congenital cardiac defect is present. An inquiry regarding recent illness, trauma, and any hospitalizations or surgeries should also be included. A comment on the approximate developmental stage is helpful to provide a context for the quality of the information self-reported by the child.

Physical Examination

The physical examination should focus on a global constitutional assessment, a pulmonary examination, and a cardiovascular examination. The child's general constitution can be gauged by noting his or her general appearance, including weight, hydration status, temperature, pulse, respiratory rate, and blood pressure. When coarctation or dissection of the aorta is a diagnostic consideration, four-extremity blood pressures are performed. Orthostatic vital signs may reveal a rise in pulse of greater than 20 to 25 beats per minute with standing if there is volume depletion.¹⁶

The head and neck examination focuses on detecting additional infectious disease processes as well as detecting lymphadenopathy. The chest wall is first observed for signs of increased work of breathing (e.g., retractions). The chest wall is palpated to identify areas of point tenderness or reproducible pain along the ribs, costochondral junction, and spine. Pulmonary auscultation focuses on the detection of

wheezing, rhonchi, diminished breath sounds, or a pleural friction rub. Hyperresonance to percussion may indicate a pneumothorax, while dullness to percussion is found with effusions and infiltrates. Wheezing can be extremely faint or nonexistent in the child with severe bronchospasm.

The cardiac examination should include an evaluation for the point of maximal impulse, as well as auscultation for murmurs and quality of the heart sounds. Hemic or flow murmurs may be present simply as a function of physiologically appropriate tachycardia. A cardiac rub or Ewart's sign suggests pericarditis. Ewart's sign is an area of dullness with bronchial breathing and bronchophony below the angle of the left scapula due to compression of the left lung by pericardial effusion. If pneumomediastinum is suspected, auscultation over the sternum may detect Hamman's crunch, which is heard in a minority of patients with pneumomediastinum.¹⁷

Although the abdominal examination involves the entire abdomen, it should carefully focus on the upper half of the abdomen. The abdominal examination specifically seeks any masses, tenderness, guarding, or potential foci for referred pain. Importantly, chest pain and epigastric pain can be concurrent. Right-sided abdominal tenderness can be the result of gallbladder disease in the obese adolescent or the patient with sickle cell disease, liver disease, or peptic ulcer disease. Epigastric tenderness may indicate esophageal, pancreatic, stomach, or intestinal pathology as the cause of chest pain. Left-sided abdominal tenderness may indicate pancreatic, splenic, or gastric disorders as the underlying cause of chest pain.

Diagnostic Testing

If the history and physical examination are sufficient to exclude serious causes, no further diagnostic tests are indicated. Ancillary diagnostic testing has an extremely low diagnostic yield in children with chest pain.³ Although it is frequently impossible to establish an absolute cause of the chest discomfort, the physician must reasonably exclude life-threatening pathology. A sensitive and thoughtful discussion with the child and parents explaining the unlikelihood of a cardiac cause is sufficient for establishing reassurance. This instructive discussion should mention the pathophysiologic differences between chest pain in children and in adults as well as the diagnostic limitations of an ED evaluation.

The chest radiograph provides additional information about the cardiovascular and pulmonary systems. The chest film can detect barotrauma, pneumonia, pleural-based processes, and osseous abnormalities, including malignancies. The cardiac and vascular silhouettes are clearly seen, and the area behind the heart can be inspected for retrocardiac infiltrates. Special attention is paid to the apices for small pneumothoraces. In pneumomediastinum, radiographically apparent subcutaneous emphysema (especially about the neck) is a common finding, as is pneumomediastinal air that commonly appears parallel to the left heart border.¹⁷ Plain radiographs in pulmonary embolism may be normal or reveal atelectasis, small infiltrates, a wedge-shaped defect, absence of pulmonary vasculature, or a pleural effusion.¹⁸

The ECG and echocardiogram are usually of limited assistance in defining the cause of chest pain in children.⁴ A rational approach is to reserve these tests for children who have other concomitant conditions or symptoms that increase

the likelihood of a life-threatening or cardiac causes of pain. Certain ECG patterns suggest serious underlying cardiac disease that can cause chest discomfort due to ischemia, inflammation, or palpitations due to arrhythmias. A baseline ECG in Wolff-Parkinson-White syndrome usually manifests with a short PR interval and a delta wave that widens the appearance of the QRS complex. Long QT syndrome is associated with polymorphic ventricular tachycardia. ST segment elevation or depression occurs during acute ischemia, with eventual development of Q waves and T-wave inversion during a myocardial infarction. Pericarditis often causes diffuse ST segment elevation and PR interval depression. Arrhythmogenic right ventricular cardiomyopathy (or dysplasia) is associated with T-wave inversion in V_2 and V_3 with a right bundle branch block, or a prolonged QRS (>110 msec) in leads V_1 to V_3 in the absence of right bundle branch block. A left bundle branch configuration to ectopic beats is present. Patients with this disorder are at risk for developing ventricular tachycardia. The ECG in idiopathic hypertrophic subaortic stenosis often shows nonspecific ST-segment and T-wave abnormalities, left ventricular hypertrophy with QRS complexes that are tallest in the midprecordial leads, and prominent Q waves in the inferior (II, III, aV_F) or precordial (V_2 to V_6) leads (see Chapter 61, Syncope). Children with this disorder are at risk for chest pain or sudden death during or immediate after exertion.

Computed tomography (CT) of the chest may be required to exclude certain life-threatening disorders. A chest CT can accurately detect an otherwise occult pulmonary contusion, pneumothorax, subtle pneumonia, pleural effusions, pneumomediastinum, esophageal rupture, aortic aneurysm, and aortic dissection. Newer multidetector CT scans with thin collimation (0.6 to 1.25 mm), rapid data acquisition, improved resolution and quality of images, diminished motion artifact, and accurate depiction of subsegmental pulmonary arteries are as accurate as pulmonary angiography for detecting pulmonary emboli.^{19,20} However, accuracy of ventilation-perfusion scanning, angiography, and CT scanning for diagnosis of PE in children has been extrapolated from adult studies; there have been no individual large series or direct comparisons of these tests in children.

Nuclear medicine imaging for cardiac ischemia is performed at the discretion of a pediatric cardiologist. Recently, positron emission tomography has also been shown to be effective in assessing myocardial perfusion.²¹

Finally, other laboratory testing is used selectively, based on the presumed differential diagnoses. A complete blood count is useful to assess for hemoglobinopathies, anemia, or malignancies. Other serum assays are rarely helpful in determining the cause of chest pain. Serum troponin is elevated in 55% to 71% of children with myocarditis who have had symptoms for less than 1 month, and in nearly half of all children with pericarditis.²²⁻²⁶ Lyme titers can be obtained in children with presumed pericarditis. Brain natriuretic peptide (BNP) may be a useful marker for Kawasaki myocarditis, with most cases manifesting a level greater than 50 pg/ml.²⁷ Use of BNP in other disorders associated with myocarditis is undefined. Nonspecific indices for inflammatory processes (e.g., erythrocyte sedimentation rate and C-reactive protein) rarely assist in determining an exact cause of chest pain, although elevations in these parameters increase the probability that an organic disease is present. Fecal occult

blood testing, as well as measurement of liver and pancreatic enzymes, may help to identify abdominal causes of chest pain. Blood cultures are often recommended in patients with pneumonia, although the yield is low in children who are healthy with no underlying disease. Blood cultures may be of use in children at risk for serious disease or abnormal pathogens (e.g., sickle cell disease, neutropenia, cancer).

Oxygen saturation is an important measurement in patients with chest pain or shortness of breath. During vaso-occlusive episodes, this number may be falsely depressed by up to 10% if pulse oximetry is used instead of the traditional co-oximetry used during arterial blood gas analysis.²⁸

Important Clinical Features and Considerations

Children with chest pain can be sorted into categories with a high and low risk of serious disease based on their history, physical examination, and oxygen saturation augmented by an ECG and chest radiograph if indicated (Table 62–2). Abnormal vital signs, hypoxia, dyspnea, diaphoresis, and syncope are indicators of the need for further diagnostic testing. Any abnormal vital signs should be repeat-tested and warrant an explanation prior to discharging the child with chest pain. The general impression of an experienced physician is helpful in garnering a “global sense” for whether or not the patient has a life-threatening condition. Finally, the failure to have symptomatic improvement during the ED course should also lead the physician to consider potentially serious conditions (see Table 62–2).

Clinical Pearls and Pitfalls

Children with sickle cell disease and a new infiltrate with cough, fever, or respiratory complaints are defined as having

Table 62–2 Select Features Associated with Serious Cause of Chest Pain

Historical Features	Examination and Diagnostic Features
Pain associated with:	Marfanoid appearance
Exertion	Respiratory distress
Dyspnea	Abnormal vital signs:
Syncope	Tachycardia
Illicit drug use	Bradycardia
Trauma	Hypotension
Family history of:	Tachypnea
Sudden death in young family members	Friction rub or pathologic murmur
Marfan's syndrome	Abnormal lower extremity pulses
Sickle cell disease	Abnormal lung examination
Past medical history of:	Presence of a central venous access catheter
Sickle cell disease	Hypoxemia
Congenital heart disease	Abnormal electrocardiogram (see Chapter 61, Syncope)
Cancer	Evidence of specific medical diseases associated with serious cardiac effects (e.g., Kawasaki, Lyme diseases)
Congenital deafness	Appearance or odor of toxic inhalation agents
Medications/drugs with cardiac side effects:	
Antihypertensives	
Antiarrhythmics	
Phenothiazines	
Anticholinergics	
Sympathomimetics (legal and illegal)	

acute chest syndrome. All patients with this diagnosis require hospital admission. Admission should be strongly considered for sickle cell patients with acute chest pain or difficulty breathing even if no infiltrate is seen on chest radiograph. One prospective study of children with acute chest syndrome found that nearly half of all patients were admitted with an alternate diagnosis. While fever (80%) and cough (62%) were the most common symptoms in children less than 10 years old, 44% had chest pain, 41% complained of shortness of breath, a third complained of pain in the abdomen or extremities, and 45% were tachypneic on admission.¹¹ Importantly, radiographic and clinical findings appeared a mean 2.5 days after hospital admission.¹¹ For this reason, clinicians should consider the diagnosis of acute chest syndrome in children with severe vaso-occlusive crises, any respiratory symptoms including cough or shortness of breath, or tachypnea on admission even if the initial radiograph is normal. Even if acute chest syndrome is not initially present, these symptoms may identify a group of patients at risk for developing this disorder.

PE is often missed in children. One study found that only 50% of children who died from a PE had suggestive symptoms, and the diagnosis was only suspected in 15% prior to death.²⁹ Most children have serious underlying disorders with signs and symptoms that overlap with PE (e.g., cancer, sepsis). Unlike adults, there are no studies that have detailed the typical presentation or developed scoring systems for stratifying children into categories of high or low risk for thromboemboli. For this reason, clinicians must consider the diagnosis of PE in any child with risk factors (e.g., central venous catheter, cancer, sepsis, recent trauma) who has any acute cardiac or respiratory complaint or change in vital signs, oxygen saturation, or chest radiography (see Chapter 130, Disorders of Coagulation).

Pulmonary barotrauma is a consideration in every patient with bronchospasm and chest pain. The chest film must be closely inspected along the left cardiac border and in the cervical soft tissue for extrapulmonary air. The lateral radiograph may be more sensitive than a frontal view for detecting pneumomediastinum.³⁰

Potential Complications

Undiagnosed congenital lesions may progress to heart failure. Myocarditis can produce malignant arrhythmias or cardiogenic shock. Children suspected of having myocarditis should be monitored for hemodynamically unstable cardiac arrhythmias.

Pneumothorax can progress to hemodynamically compromising tension pneumothorax. Rarely, pneumomediastinum can progress to pneumomediastinum with hypotension due to compression of the heart and inadequate cardiac contraction. For this reason, any child with pulmonary barotrauma who is discharged requires a mandatory recheck in the ED or physician's office, including a repeat chest radiograph, to determine any progression of disease. Any worsening of symptoms requires hospitalization.

Management

Immediate Therapeutic Interventions

The management of the child with chest pain is determined both by symptoms and by presumptive diagnosis. If a serious

cardiopulmonary disorder is suspected, oxygen is supplied and intravenous access is obtained. Cardiac rhythm monitoring and continuous oxygen saturation monitoring are appropriate in the patient with abnormal vital signs, especially hypoxia. Patients who must leave the department for additional testing (e.g., CT, echocardiography) require continuous cardiac and oxygen saturation monitoring. Personnel who can intervene acutely must accompany the child.

Secondary Therapeutic Interventions

During the ED evaluation, analgesics should be administered to children with significant pain. Children with musculoskeletal disease are often best treated with acetaminophen or a nonsteroidal anti-inflammatory agent. Parenteral narcotics are administered if pain is severe or immediate analgesia is desired. If there is bronchospasm, aerosolized β -agonists and systemic steroids are given. For gastrointestinal disease (e.g., epigastric discomfort) antacids, proton pump inhibitors, or histamine₂-receptor blockers are appropriate. In children with acute chest syndrome, exchange transfusion is recommended for severe symptoms, severe anemia, or hypoxia, or for patients who do not improve with administration of intravenous fluids, antibiotics, and pain medications.^{11,31} Patients with pulmonary emboli require anticoagulation, with consideration of thrombolytic therapy if severe hypoxia or persistent hypotension is present.

Summary

Most cases of chest pain in children are caused by benign conditions. Prognoses are further stratified based on the underlying cause of the pain and coexisting medical conditions. The clinical course of each disorder causing chest pain is varied. Chest wall pain may disappear in days, while pain from rib fractures may take 4 to 6 weeks to completely resolve. The reassessment of pulmonary barotrauma, including a repeat chest radiograph, is indicated in all cases. Patients with chest disorders (and their parents) should be encouraged to return to the ED or see their physician immediately if pain or breathing worsens, if symptoms of infection develop, or if any new concerning symptoms (e.g., syncope) occur.

The decision to admit each patient is based on the requirement for inpatient care or intervention, continuous cardiac and respiratory monitoring for deterioration, or inpatient diagnostic evaluation. Most suspected serious cardiovascular conditions require admission to the hospital or ED cardiology consultation with an expedited outpatient evaluation. Serious noncardiac disorders requiring admission include severe pneumonia, pulmonary embolism, pulmonary barotrauma (unless minor), pulmonary contusion, acute chest syndrome in sickle cell disease, and serious intra-abdominal disorders causing chest pain.

Dysrhythmias

Stephanie J. Doniger, MD and Ghazala Q. Sharieff, MD

Key Points

Paroxysmal supraventricular tachycardia is the most common symptomatic dysrhythmia.

Arrhythmia treatment depends on whether the patient has a pulse, hemodynamic stability, and the presenting rhythm.

Atrial flutter and atrial fibrillation in children are largely attributed to structural heart disease (i.e., repaired and unrepaired congenital heart disease).

Bradycardias are defined as a heart rate less than the lower limit of normal for a child's age. The most common cause is sinus bradycardia, which is for the most part benign. Other causes include first-, second-, and third-degree (complete) heart blocks.

Long QT syndrome may be either hereditary or acquired, and may manifest as syncope or sudden death. On electrocardiogram, the most accurate determination of the QT interval is calculated using the Bazett formula ($QT_c = QT/\sqrt{RR}$), with a QT_c greater than 460 ms as prolonged.

Introduction and Background

Pediatric dysrhythmias are much less common than dysrhythmias that occur in adults. However, with the advent of life-saving procedures to repair congenital heart diseases, there has been a notable increase in postoperative dysrhythmias, thereby increasing the overall incidence of dysrhythmias in the pediatric population. The overall incidence of arrhythmias is 13.9 per 100,000 emergency department (ED) visits and 55.1 per 100,000 pediatric ED visits (children under 18 years of age).¹ Among children with arrhythmias, the most common are sinus tachycardia (50%), supraventricular

tachycardia (13%), bradycardia (6%), and atrial fibrillation (4.6%).¹

The presentation of dysrhythmias can serve as a diagnostic challenge to clinicians, in that most children present with vague and nonspecific symptoms such as “fussiness” or “difficulty feeding.” Despite the infrequency and vague presenting symptoms, it is critical to identify and appropriately manage these disorders. When left unrecognized and untreated, dysrhythmias can lead to further decompensation.

The Electrocardiogram in Pediatrics

A review of pediatric emergency department utilization of electrocardiograms (ECGs) revealed that the most common reasons for obtaining ECGs in children are chest pain, suspected dysrhythmias, seizures, syncope, drug exposure, electrical burns, electrolyte abnormalities, and abnormal physical examination findings. The most life-threatening are dysrhythmias, either primary or caused by electrolyte disturbances, drug exposure, and burns.² Patients presenting with dysrhythmias should have an immediate ECG in order to expeditiously identify the underlying disorder and facilitate appropriate therapy.

When evaluating ECGs, it is advisable to use a systematic approach with special attention to rate, rhythm, axis, ventricular and atrial hypertrophy, and the presence of any ischemia or repolarization abnormalities. It is essential to interpret pediatric ECGs based on age-specific rates and intervals³⁻⁵ (Table 63-1). In children, the cardiac output is mostly determined by heart rate and not stroke volume. For this reason, age- and activity-appropriate heart rates must be recognized. Average resting heart rate varies with age: newborns can have a heart rate ranging from 90 to 160 beats per minute (bpm) and adolescents from 50 to 120 bpm.³ Heart rates grossly outside the normal range for age should be closely scrutinized for dysrhythmias. Using the heart rate, dysrhythmias can be further classified into two categories: tachydysrhythmias (rate greater than the upper limit of normal for age), and bradydysrhythmias (rate less than the lower limit of normal for age). Once the rate has been established, the rhythm must be determined. Normal sinus rhythm is characterized by P waves preceding each QRS complex, a regular PR interval, and a normal P wave axis (0 to +90 degrees).

Next, it is useful to measure intervals—the PR interval, the QRS duration, and the QT interval. The PR interval, which is measured as the time from the onset of the P wave to the onset of the QRS complex, also varies with age as the

The authors would like to acknowledge CDR Jonathan T. Fleenor, MD in the division of Pediatric Cardiology at the Naval Medical Center San Diego for his electrocardiogram contributions.

Table 63–1 Pediatric Electrocardiogram Normal Heart Rate (HR) and Intervals by Age

Age	HR	PR Interval (sec)	QRS Interval (sec)
1st wk	90–160	0.08–0.15	0.03–0.08
1–3 wk	100–180	0.08–0.15	0.03–0.08
1–2 mo	120–180	0.08–0.15	0.03–0.08
3–5 mo	105–185	0.08–0.15	0.03–0.08
6–11 mo	110–170	0.07–0.16	0.03–0.08
1–2 yr	90–165	0.08–0.16	0.03–0.08
3–4 yr	70–140	0.09–0.17	0.04–0.08
5–7 yr	65–140	0.09–0.17	0.04–0.08
8–11 yr	60–130	0.09–0.17	0.04–0.09
12–15 yr	65–130	0.09–0.18	0.04–0.09
≥16 yr	50–120	0.12–0.20	0.05–0.10

heart matures. In neonates, it ranges from 80 to 150 msec and in adolescents from 120 to 200 msec (see Table 63–1).^{3–5} A prolonged PR interval suggests a type I atrioventricular (AV) heart block. The QT interval represents the time from onset of depolarization to completion of repolarization. It is measured from the onset of the QRS complex to the end of the T wave, where it returns to the baseline. For greatest accuracy, the QT and preceding R-R intervals should be measured for three consecutive beats and averaged. Due to wide variability in heart rates, the QT interval must be corrected for the heart rate by utilizing the Bazett formula ($QT_c = QT \div \text{square root of the RR interval}$).⁶ A prolonged QT interval is defined as a QT_c greater than or equal to 460 msec. A QT_c within the range of 420 to 460 msec is considered borderline, and warrants further assessment.^{7–9}

Once normal intervals are evaluated, the ECG can then be scrutinized for chamber size and T-wave morphology. The P-wave height and width can be used to determine if there is right atrial enlargement and left atrial enlargement, respectively. Ventricular hypertrophy can be identified by determining whether the voltages in the precordial leads are greater than the upper limit of normal for the age group. Unlike the adult population, children tend to have nonspecific T-wave changes. This is often a source of great controversy. What is agreed upon is that flat, inverted T waves are normal in the newly born, while upright T waves in V_1 after 3 days of age are a sign of right ventricular hypertrophy.¹⁰

Selected Diagnoses

- Tachydysrhythmias
 - Sinus tachycardia
 - Supraventricular tachycardia
 - Atrial flutter
 - Atrial fibrillation
 - Premature atrial contractions
 - Premature ventricular contractions
 - Ventricular tachycardia
 - Ventricular fibrillation
- Bradycardias
 - Sinus bradycardia
 - Conduction abnormalities
- Sinus arrhythmia
- Long QT syndrome

Discussion of Individual Diagnoses

Tachydysrhythmias

Tachycardia is defined as a heart rate beyond the upper limit of normal for the patient's age. Tachycardias can be classified broadly into those that originate above the AV node (i.e., supraventricular), those that originate from the AV node (AV node reentrant tachycardias), and those that originate from the ventricle. The vast majority of tachycardias are supraventricular in origin. Those that are ventricular in origin are typically associated with hemodynamic compromise.⁴ Upon recognition of a tachycardia, stepwise questioning can help evaluate the ECG tracing. Is the rhythm regular or irregular? Is the QRS complex narrow or wide? Does every P wave result in a single QRS complex? Once this is established, treatment options are considered according to whether or not the patient has a pulse, and the presenting rhythm on ECG¹¹ (Fig. 63–1).

Sinus Tachycardia

Sinus tachycardia can be differentiated from other tachycardias by a narrow QRS complex and a P wave that precedes every QRS complex. The rate is usually greater than 140 bpm in children, and greater than 160 bpm in infants. Sinus tachycardia is benign. It can be seen in normal healthy individuals during anxiety, pain, or exercise or with fevers. Pulse rate has been shown to increase linearly with temperature in children greater than 2 months of age. For every 1° C (1.8° F) increase in body temperature, pulse rate increases an average of 9.6 bpm.¹² Sinus tachycardia can also be associated with such underlying conditions as hypoxia, anemia, hypovolemia, shock, myocardial ischemia, pulmonary edema, hyperthyroidism, medications (catecholamines), hypocalcemia, and illicit drug use. Most commonly, it is a result of dehydration and hypovolemia.¹⁴ Since children augment cardiac output by increasing heart rate rather than stroke volume, heart rate increases appear early, while hypotension is a late sign of dehydration. Treatment aimed at correcting the heart rate alone may be harmful to the patient, since the tachycardia is a compensatory response to sustain adequate cardiac output. For this reason, treatment of sinus tachycardia is largely targeted at treating the underlying disorder, rather than treating the tachycardia itself.

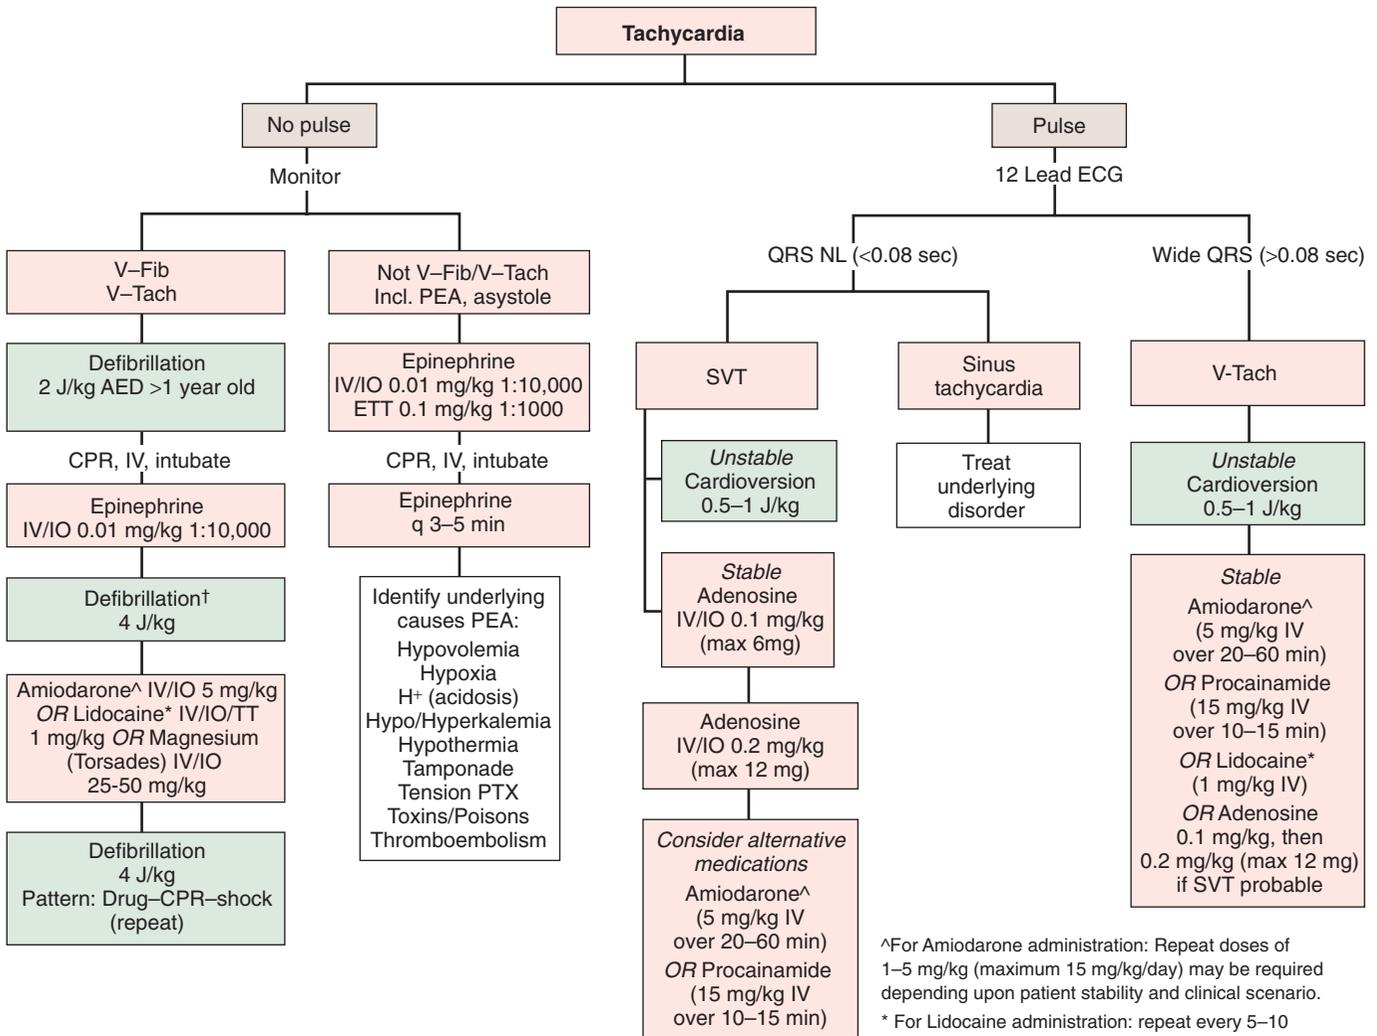

Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (SVT) is the most common symptomatic dysrhythmia in infants and children. In neonates and infants with SVT, the heart rate is greater than 220 bpm. In older children, SVT is defined as having a heart rate of more than 180 bpm.¹³ The ECG shows a narrow QRS complex tachycardia, either without discernible P waves or with retrograde P waves with an abnormal axis (Fig. 63–2). The QRS duration is usually normal but is occasionally increased with aberrancy.

RECOGNITION AND APPROACH

There are three types of SVT. The most common is AV reentrant tachycardia. In addition to the normal conduction from the sinoatrial (SA) node to the AV node, to the bundle of His, and then to the Purkinje fibers, there is an accessory “bypass” pathway in conjunction with the AV node. This pathway is

Algorithm for Tachycardias

^For Amiodarone administration: Repeat doses of 1–5 mg/kg (maximum 15 mg/kg/day) may be required depending upon patient stability and clinical scenario.
 * For Lidocaine administration: repeat every 5–10 minutes after initial bolus, to total dose 3 mg/kg. After return of perfusion, follow with continuous infusion @20–50 mcg/kg/min.
 † Perform 5 cycles of CPR between each defibrillation attempt.

FIGURE 63-1. Approach to managing infants and children with tachycardia. Abbreviations: CPR, cardiopulmonary resuscitation; ETT, endotracheal tube; IO, intraosseously; IV, intravenously; NL, normal; PEA, pulseless electrical activity; PTX, pneumothorax; SVT, supraventricular tachycardia; TT, transtracheal; V-Fib, ventricular fibrillation; V-Tach, ventricular tachycardia.

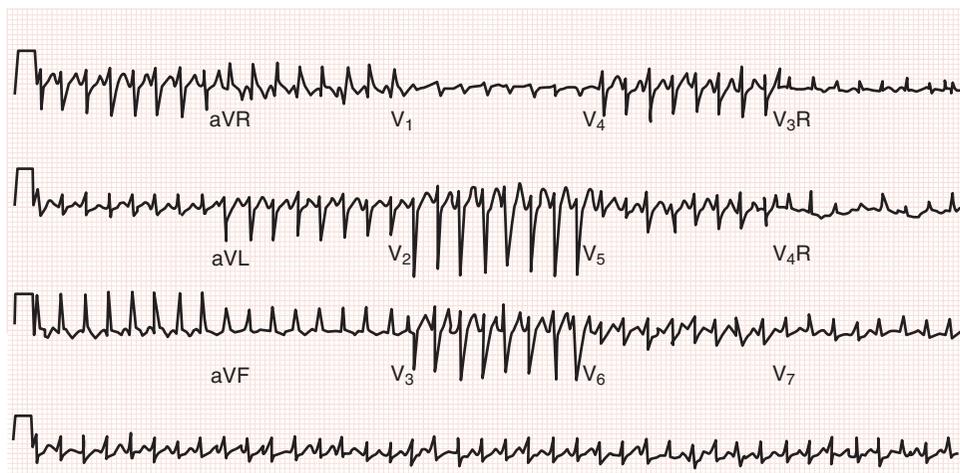

FIGURE 63-2. Supraventricular tachycardia. This 13-year-old male had no previous cardiac history. After playing football, he began having palpitations and difficulty breathing. After a delay in treatment of approximately 48 hours, he presented with this rhythm and congestive heart failure. The patient had subsequent episodes, prompting radioablation treatment. (Photo courtesy of Stephanie Doniger, MD, Children’s Hospital, San Diego.)

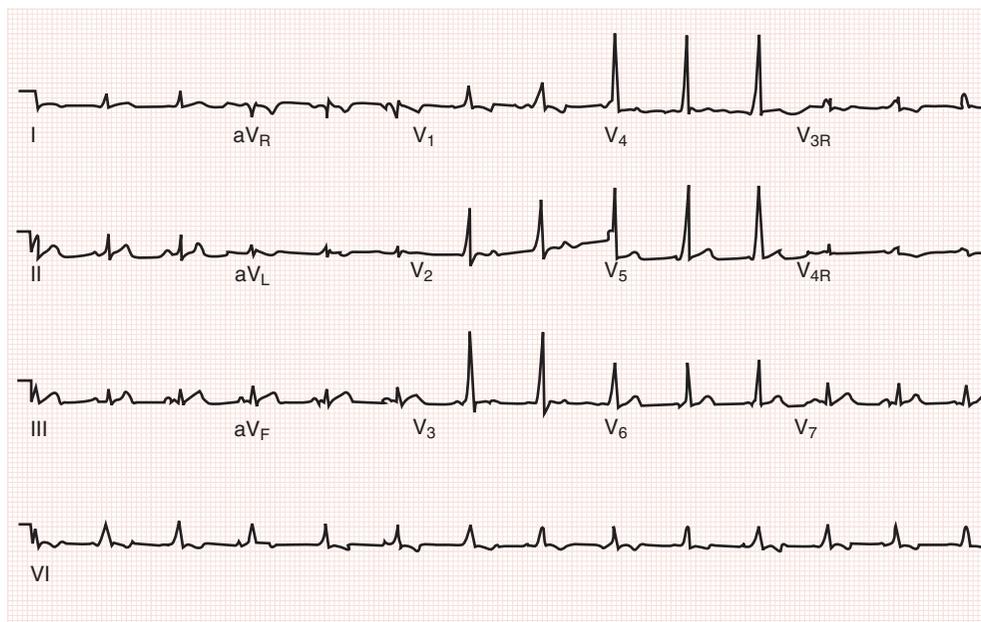

FIGURE 63-3. Wolff-Parkinson-White (WPW) syndrome. This child presented in supraventricular tachycardia. After being converted to sinus rhythm, the delta waves were apparent. The delta wave is a positive inflection in the upstroke of the QRS complex. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

an anatomically separate bypass tract, such as the bundle of Kent, which is seen in Wolff-Parkinson-White (WPW) syndrome. Conduction through this accessory pathway occurs more rapidly than through the normal conduction pathway, creating a cyclic pattern of reentry independent of the SA node. Typical ECG findings of WPW syndrome are a short PR interval, a wide QRS complex, and a positive inflection in the upstroke of the QRS complex, known as the delta wave (Fig. 63-3).

The second type of SVT is AV nodal/junctional tachycardia, which is a cyclical reentrant pattern from dual AV node pathways that are simultaneously depolarized. The third type of SVT, ectopic atrial tachycardia, is rare and is manifested by the rapid firing of a single ectopic focus in the atrium. The hallmark of ectopic atrial tachycardia is the presence of different P wave morphologies. Each P wave is conducted to the ventricle and, since the ectopic atrial focus is faster than the SA node, it takes over rate determination.

CLINICAL PRESENTATION

The majority of infants with SVT present at less than 4 months of age, with a 3 : 2 male : female ratio.¹⁴ Among this group, almost one half of cases are idiopathic, while 24% are associated with conditions such as fever and drug exposure, 23% are due to congenital heart disease (most commonly Ebstein's anomaly, single ventricle, L-transposition), and 10% to 22% are due to WPW syndrome.^{13,15} Among older children, causes are more likely to be WPW syndrome, concealed bypass tracts, or congenital heart disease. AV reentrant tachycardia is more common in children presenting at less than 12 years of age, while AV nodal/junctional tachycardia becomes more evident in adolescents.⁵ Other causes include hyperdynamic cardiac activity as is seen in response to catecholamine release or drug use, and postoperatively following cardiac repair. Toxic causes of SVT include stimu-

lants (amphetamines, caffeine, ephedrine, tobacco), β -agonists (albuterol), anticholinergics (atropine), salicylates, theophylline, tricyclic antidepressants, and phenothiazines. SVT may also result from nontoxic disorders such as anxiety, anemia, sedative and ethanol withdrawal, dehydration, acidosis, exercise, fever, hypoglycemia, hypoxemia, and pain.

The diagnosis often begins in triage, with the nurse reporting a heart rate that is "too fast to count." In neonates and infants with SVT, the heart rate is often between 220 and 280 bpm.^{11,13} Most patients do not have an underlying cause to account for the tachycardia, such as fever, dehydration, fluid or blood loss, anxiety, or pain. Important historical factors include a relationship to exercise, meals, or stress; color changes; neurologic changes; and syncope. A past medical history significant for cardiac problems, current medications, allergies, or a family history of sudden death or cardiac disease should be investigated.

The clinical presentation of SVT is dependent on the patient's age, duration of the dysrhythmia, and rate of the dysrhythmia. Though infants are unable to verbally describe symptoms, the history may elicit nonspecific complaints, such as "fussiness," lethargy, poor feeding, pallor, sweating with feeds, or simply "not acting right." Complaints of older children with SVT may be initially described as "pounding in the chest," chest pain, dizziness, or shortness of breath.

If congestive heart failure is present, caregivers may describe pallor, cough, and respiratory distress. Although many infants can tolerate SVT well for 24 hours, within 48 hours 50% develop heart failure and may deteriorate rapidly.¹³ Congestive heart failure rarely develops secondary to SVT in older children.

In particular, episodes of SVT in children with WPW syndrome usually occur early in the first year of life. Episodes of SVT often resolve during infancy but may recur later in life, usually between 6 and 8 years of age.¹⁶ The characteristic

finding of delta waves is not present during an episode of tachydysrhythmia. It is not until the patient returns to sinus rhythm that these waves become evident. In addition, children with WPW syndrome, especially those older than 12 years of age, are predisposed to developing atrial fibrillation.

MANAGEMENT

Management of SVT always begins with ensuring that the patient is maintaining good airway, breathing, and cardiovascular status. It is important to promptly administer oxygen, and to obtain a 12-lead ECG with rhythm strip. Clinicians must expeditiously differentiate between infants and children who are stable and those who are unstable. In children with asymptomatic SVT or with mild heart failure, vagal maneuvers such as applying ice to the face of an infant or having an older child blowing through a straw may be attempted. If these are unsuccessful, adenosine is administered through an intravenous (IV) line that is preferably close to the heart. Due to its extremely short half-life, adenosine must be pushed at the most proximal port and flushed (with 5 ml normal saline) quickly in order to be effective. The initial dose of adenosine is 0.1 mg/kg (up to 6 mg), and it can be increased to 0.2 mg/kg per dose (up to 12 mg) if the first dose is ineffective. An effective response is a brief period of asystole on ECG, with the return of a normal sinus rhythm. Failure to terminate the dysrhythmia after the second dose of adenosine in a stable patient should prompt consultation with a pediatric cardiologist. Alternatives include procainamide (10 to 15 mg/kg IV over 30 to 45 minutes, followed by a continuous infusion at 20 to 80 mcg/kg per minute if needed, up to 2 g/day) and amiodarone (5 mg/kg over 20 to 60 minutes, with a maximum single dose of 150 mg followed by bolus dosing of 1 to 5 mg/kg if needed, and a maximum daily dose of 15 mg/kg).¹⁷ Continuous infusions of amiodarone should be avoided as this route causes leaching of toxic metabolites from IV tubing. Amiodarone must not be used in neonates (birth to 30 days old) as it may cause a gasping syndrome (respiratory distress, metabolic acidosis, followed by cardiac arrest). Importantly, amiodarone is not approved by the Food and Drug Administration for use in children, although the American Heart Association recognizes that this is an important agent whose therapeutic benefit outweighs theoretical risks in certain pediatric dysrhythmias (see <http://www.americanheart.org/>). β -Blockers such as propranolol or esmolol may be used for SVT, but with caution, as propranolol may cause hypotension. Digoxin is effective in converting SVT; however, the onset of action is slow. β -Blockers, calcium channel blockers, and digoxin should be avoided in SVT or atrial fibrillation/flutter with a wide QRS complex (i.e., WPW syndrome) as these agents can increase the transmission through the bypass tract and induce ventricular tachycardia or ventricular fibrillation. If the SVT has a narrow QRS complex, a bypass tract is not conducting beats via an accessory pathway and these agents should not increase the ventricular rate. In addition, calcium channel blockers (e.g., verapamil, diltiazem) should be avoided in children less than 1 year of age and used cautiously in older infants and children (1 to 8 years old), as cardiovascular collapse and death can occur due to electromechanical dissociation.^{13,18}

Alternatively, immediate synchronized cardioversion is warranted in a child with unstable SVT with severe heart

failure and poor perfusion. Cardioversion is initiated at 0.5 joules/kg, and can be increased up to 1 joule/kg. Adenosine may be given prior to cardioversion if intravenous access has already been established. In unstable patients, cardioversion should not be delayed for attempts at IV access or sedation.

Adenosine has negative chronotropic, dromotropic, and inotropic actions of short duration. Its action is in blocking AV conduction and sinus pacemaker activity, terminating almost all SVTs in which the AV node forms a reentry circuit. Adenosine can be both diagnostic and therapeutic. If the diagnosis of SVT is in question, adenosine can be administered to stable patients who have a regular tachycardia, to monitor for a response. Adenosine is not effective with nonreciprocating atrial tachycardia, atrial flutter, atrial fibrillation, or ventricular tachycardia. There are minimal hemodynamic consequences associated with adenosine administration.¹⁹ Contraindications include a denervated heart (transplant) and second- or third-degree heart block unless a pacemaker is present. Additionally, adenosine can worsen bronchospasm in asthmatics and increase heart block or precipitate ventricular arrhythmias in patients taking carbamazepine, verapamil, or digoxin.

The evaluation of SVT includes attempts at determining the etiology of SVT in order to prevent future episodes. Laboratory studies may include electrolytes (especially potassium, calcium, magnesium, and glucose), complete blood count, toxicology screen, blood gases, and thyroid function tests. Additionally, creatine kinase and troponins may be added if myocarditis is suspected. Imaging studies can include a chest radiograph (including anteroposterior and lateral views) and echocardiogram. Once stabilized, the majority of patients with new-onset SVT require hospital admission to investigate the underlying cause of SVT, and the potential for long-term medical management or radiofrequency ablation.²⁰ Clinicians can safely discharge patients with a history of SVT, minor symptoms such as palpitations, and a clear precipitant.

SUMMARY

Supraventricular tachycardia is the most common type of tachyarrhythmia in childhood. The most common type of SVT is reentrant tachycardia, one cause of which is WPW syndrome. In patients presenting with SVT, symptoms can vary from nonspecific to florid heart failure. Upon their presentation to the ED, it is crucial to quickly distinguish stable from unstable patients. Unstable patients require more aggressive, immediate cardioversion, while vagal maneuvers and adenosine are first-line treatments for stable patients. Collaboration with cardiology can help discover the underlying cause of the SVT, and determine the most appropriate prophylactic regimen for the child in preventing future episodes.

Atrial Flutter

Atrial flutter is an uncommon rhythm in the pediatric population. Atrial rates may range from 240 to 450 bpm,⁴ with the ventricular response depending on the AV nodal conduction. The pacemaker lies in an ectopic focus.

Causes of atrial flutter in children are largely attributed to structural heart disease, including dilated atria, myocarditis, or acute infection. It is most notably associated with postoperative complications of congenital heart disease repairs,

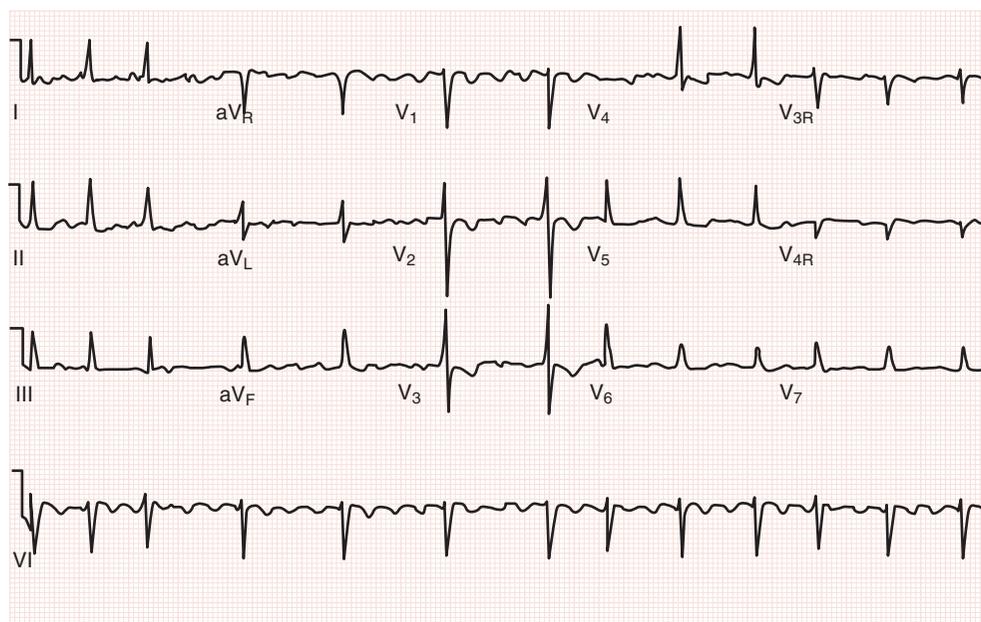

FIGURE 63–4. Atrial flutter. This electrocardiogram is from a child who had a Fontan repair for hypoplastic left heart. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

such as atrial septal defect (ASD) repairs, the Mustard operation for D-transposition of the great arteries, or the Fontan procedure for single ventricle. These procedures cause atrial flutter via disruption in the conduction system, such as when there is suturing through the atrial septum. Occasionally, patients who have had ventricular surgeries, such as tetralogy of Fallot repair, may present with atrial arrhythmias. Atrial flutter is also seen in such conditions as Duchenne’s muscular dystrophy and central nervous system injury.

CLINICAL PRESENTATION

On ECG, the hallmark pattern is “saw-toothed” flutter waves, which are best viewed in leads II, III, and V₁. The atrial rate is on average approximately 300 atrial bpm.³ Since the AV node cannot respond this quickly, there is an AV block that can present as a 2 : 1, 3 : 1, or 4 : 1 block. The QRS complex is generally normal in configuration (Fig. 63–4).

Significant cardiac pathology usually accompanies atrial flutter. Since cardiac output is determined by the ventricular rate, with atrial flutter, the ventricular rate is too fast to maintain an efficient cardiac output. Atrial arrhythmias are an important cause of morbidity and mortality in patients with congenital heart disease.

MANAGEMENT

Initially, the clinician must recognize whether the patient is hemodynamically stable. An unstable patient may require electrical cardioversion, with consideration given to adding heparin to prevent embolization.^{4,21} In patients receiving digoxin, it is advisable to avoid electrical cardioversion, unless the condition is life-threatening, since the combination is associated with malignant ventricular arrhythmias.^{22,23} Alternatives in those receiving digoxin are rapid atrial pacing with catheterization or cardioversion with lower current settings.²¹ For patients who are hemodynamically stable, digoxin is administered to increase AV blockade, thereby slowing the ventricular rate. Propranolol (1.0 to 4.0 mg/kg

per day PO, divided three to four times per day) may also be added. Recurrences are then prevented by administering quinidine.

SUMMARY

Although atrial flutter is an uncommon dysrhythmia in children, its presence can suggest an underlying cardiac problem. In those who have underlying congenital heart disease, atrial flutter is an especially important cause of morbidity and mortality. The mainstay of treatment lies in cardioversion for hemodynamically unstable patients, while stable patients receive digoxin with or without propranolol.

Atrial Fibrillation

Atrial fibrillation is another rare rhythm in children. It is defined as disorganized, rapid atrial activity with atrial rates ranging from 350 to 600 bpm.¹⁵ The ventricular rate is variable, and is dependent upon a varying AV block. Children at increased risk of developing atrial fibrillation include patients with an underlying structural heart defect (e.g., congenital mitral valve disease), those with hyperthyroidism, and those who have had an intra-atrial operative procedure.

CLINICAL PRESENTATION

The rhythm of atrial fibrillation is described as being irregularly irregular, alternating between fast and slow rates. On ECG, hallmark features are irregular atrial waves, with beat-to-beat variability of the waves’ size and shape. This is best recognized in lead V₁. The atrial rate may range from 350 to 600 atrial bpm, with a variable ventricular response. The QRS complexes appear normal.

As with atrial flutter, atrial fibrillation is associated with decreased cardiac output. With a significantly increased ventricular rate, incoordination between the atria and ventricles occurs, thereby decreasing cardiac output. A patient presenting with atrial fibrillation generally has significant underlying cardiac pathology.

MANAGEMENT

Upon presentation to the emergency department, hemodynamically unstable patients warrant immediate cardioversion. However, in patients who are hemodynamically stable, digoxin can be administered for ventricular rate control, allowing for a 24-hour time period in order to assess its efficacy. After that time period elapses, should digoxin prove to be ineffective, a second medication may be added, such as propranolol, esmolol, or procainamide. Alternatively, calcium channel blockers such as verapamil may be considered for rate control in children. It is important to note that IV verapamil (0.1 to 0.3 mg/kg per dose, with a maximum of 10 mg/dose) should not be used in children younger than 1 year of age, and should be used with caution in those between 1 and 8 years of age, due to the risks of apnea, bradycardia, hypotension, and cardiac arrest.²⁴ In patients who have undergone cardioversion, recurrence is common. During admission, cardioverted patients are often started on an agent to keep them in normal sinus rhythm (e.g., amiodarone, procainamide, quinidine, or a β -blocker).²⁵

SUMMARY

Atrial fibrillation is an irregularly irregular rhythm, with rapid atrial rates and beat-to-beat variability. Its presence usually suggests an underlying cardiac pathology in the pediatric population. Those patients who are stable may receive digoxin, while those who are hemodynamically unstable require cardioversion. Admission is warranted for patients who are newly diagnosed with atrial fibrillation or are diagnosed with chronic atrial fibrillation with rapid ventricular rate, or with cardiovascular compromise.

Premature Atrial Contractions

Premature atrial contractions (PACs) are common in children, and are defined as premature P waves with premature QRS complexes. There is an incomplete compensatory pause, making the premature beat less than two normal cycles. While most P waves have a subsequent QRS wave, rarely are PACs nonconducted.

The majority of children presenting with PACs are healthy children and neonates. Others include postoperative cardiac surgery patients and those with hypoxia, use of sympathomimetic drugs, hyperthyroidism, and digoxin toxicity. With the exception of treating the underlying disease or drug toxicity, no treatment is necessary for PACs.

Premature Ventricular Contractions

A premature ventricular contraction (PVC) is a premature wide QRS complex that has a distinct configuration and is not preceded by a P wave. They may appear in patterns of two consecutive PVCs (couplet), alternating PVC with normal QRS complex (bigeminy), or a PVC every third beat (trigeminy). The SA node maintains a normal conduction pace, and the PVC replaces a normal QRS complex while maintaining a rhythm. Three or more consecutive PVCs is considered ventricular tachycardia. The morphology of PVCs may be further classified into unifocal PVCs and multifocal PVCs. Unifocal PVCs have the same configuration in a single lead, and originate from a single focus. Alternatively, multifocal PVCs have an abnormal, inconsistent configuration in a single lead, and originate from different foci.

Although most children who have PVCs are healthy, PVCs can be associated with congenital heart disease, mitral valve prolapse, long QT syndrome (LQTS), and cardiomyopathies (dilated and hypertrophic). Malignant etiologies further include electrolyte imbalances, drug toxicities (general anesthesia, digoxin, catecholamines, amphetamines, sympathomimetics, phenothiazines), cardiac injury, cardiac tumors, myocarditis (Lyme and viral), hypoxia, and an intraventricular catheter.

CLINICAL PRESENTATION

For the most part, patients with PVCs are asymptomatic. When examined, 50% to 75% of otherwise normal children may have PVCs on Holter monitoring.⁴ It is crucial to determine whether or not the heart has underlying pathology. This can be accomplished by history and physical examination, 12-lead ECG, and chest radiograph. If all of these are normal, no further investigation is necessary. For couplets and multiform PVCs, referral to a pediatric cardiologist and further investigation is indicated.

Though PVCs are for the most part benign, when left unrecognized and untreated, there is a risk of developing ventricular tachycardia in those patients with a serious underlying cause. PVCs are considered malignant if they are associated with underlying heart disease, if there is a history of syncope or family history of sudden death, if they are precipitated or increased with activity, if they have multiform morphology, or if there are symptomatic runs of PVCs or frequent episodes of paroxysmal ventricular tachycardia.

MANAGEMENT

Children presenting with PVCs require evaluation and possibly treatment of conditions that are likely to cause cardiopulmonary compromise. Evaluation is required when there are two or more PVCs in a row, they are multifocal in origin, there is an “R-on-T phenomenon,” or there is underlying heart disease. The R-on-T phenomenon is when a PVC occurs on the T wave, which is considered a “vulnerable period” for stimulating abnormal rhythms. This can be seen with hypoxia or hypokalemia, and may result in life-threatening arrhythmias.²⁶ For patients with an underlying cause (e.g., electrolyte abnormality, hypoxia, severe acidosis), treatment consists of managing the underlying cause. Treatment is with IV lidocaine (1 mg/kg per dose), followed by a lidocaine drip (20 to 50 mcg/kg per minute). Amiodarone, procainamide, and β -blockers are reserved for those patients who are refractory to lidocaine.¹⁵

Asymptomatic patients presenting with isolated PVCs and normal cardiac structure and function require no treatment. Those who have frequent PVCs should have an evaluation to rule out myocarditis. Use of 24-hour Holter monitoring may be necessary to distinguish isolated PVCs from SVT. Patients with PVCs should avoid stimulants such as caffeine, theophylline, and pseudoephedrine since they may precipitate more frequent PVCs. While most patients with coupled PVCs or bigeminy may not require therapy, a pediatric cardiologist should be consulted.

Ventricular Tachycardia

Although rare in children, ventricular tachycardia is an important rhythm to recognize and promptly treat. Nonperfusing ventricular rhythms are seen in up to 19% of pediatric

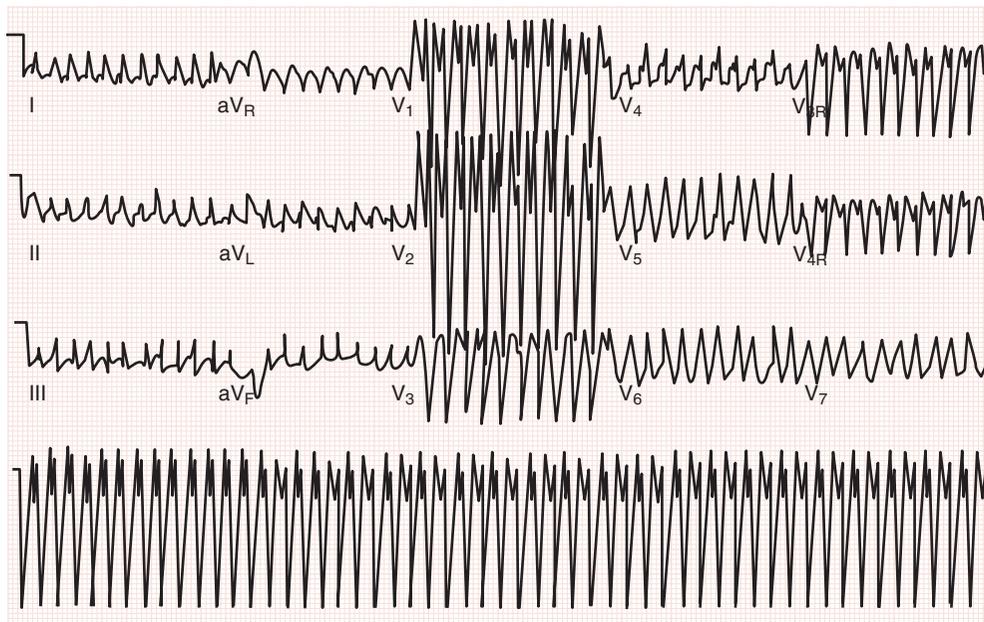

FIGURE 63–5. Ventricular tachycardia. This is an example of an extraordinarily fast ventricular tachycardia with a heart rate of almost 300 bpm. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

cardiac arrests, when sudden infant death syndrome (SIDS) cases are excluded.²⁷ By definition, ventricular tachycardia is three or more consecutive PVCs, with heart rates ranging from 120 to 200 bpm. The rate may be as rapid as 400 or 500 bpm.²⁸

Ventricular tachycardia may result from electrolyte disturbances (hyperkalemia, hypokalemia, hypocalcemia), metabolic abnormalities, congenital heart disorders, myocarditis, or drug toxicity. Other causes include cardiomyopathies, cardiac tumors, acquired heart disease, LQTS, and idiopathic causes.

CLINICAL PRESENTATION

On ECG, the QRS complexes have a wide configuration. The QRS duration is prolonged, ranging from 0.06 to 0.14 seconds. Complexes may appear monomorphic, with a uniform contour and absent or retrograde P waves. Alternatively, the QRS complexes may appear polymorphic, or vary randomly as is seen in torsades de pointes. Electrocardiogram findings that further support the presence of ventricular tachycardia include the presence of AV dissociation with the ventricular rate exceeding the atrial rate (Fig. 63–5).

Children can generally tolerate rapid ventricular rhythms for a few hours. However, decreased cardiac output and hypotension can quickly follow. Though the heart may be contracting and pulses palpable in some patients with ventricular tachycardia, those contractions are hemodynamically inefficient and can ultimately lead to syncope and death if left untreated. Ventricular tachycardia can also decompensate into ventricular fibrillation, which is a nonperfusing, terminal arrhythmia.

MANAGEMENT

In a patient with ventricular tachycardia, the urgency of treatment depends on the patient's clinical status. Initially, it must be determined whether or not the patient has a pulse and is hemodynamically stable. The American Heart Association

has set forth treatment algorithms¹¹ in order to facilitate prompt treatment for this potentially fatal rhythm (see Fig. 63–1).

Ventricular tachycardia with a pulse in an unstable patient warrants immediate synchronized cardioversion at 0.5 to 1 joule/kg. It is important to pretreat conscious patients with light sedation (i.e., IV midazolam 0.1 mg/kg). Pharmacologic interventions include amiodarone (see dosing recommendations/cautions in the section on SVT), procainamide (10 to 15 mg/kg IV over 30 to 45 minutes), and lidocaine (1 mg/kg IV bolus, repeated every 5 to 10 minutes, with a maximum total dose of 3 mg/kg). When using procainamide, the infusion is stopped once the arrhythmia resolved, if the QRS widens more than 50% over the baseline, or if hypotension develops.

Pulseless ventricular tachycardia should be treated as ventricular fibrillation. Amiodarone has been studied extensively in adults as a treatment modality for hemodynamically unstable ventricular tachycardia and recurrent ventricular fibrillation.²⁹ It is a class III antidysrhythmic agent that results in potassium channel blockade. It also has some properties of class I (sodium channel blockade), class II (β -blockade), and class IV (calcium channel blockade) agents. Therefore, it is useful in treating both supraventricular and ventricular tachyarrhythmias.³⁰ Amiodarone is considered a class Ib recommendation for ventricular tachycardia with a pulse, secondary to the paucity of directly relevant published information on the safety profile in children.³¹

After cardioversion, the return to normal sinus rhythm is usually transient. If lidocaine or procainamide is used to achieve sinus rhythm, it should be continued: lidocaine at 20 to 50 mcg/kg per minute, procainamide at 20 to 80 mcg/kg per minute (maximum dose of 2 g/day). However, a continuous infusion of amiodarone leads to leaching of toxic metabolites, requiring bolus dosing of 1 to 5 mg/kg as needed (maximum of 15 mg/kg per day). In polymorphic ventricular tachycardia, temporary atrial or ventricular pacing may be required.

Overall, the treatment goal is to keep the heart rate less than 150 bpm in infants and less than 130 bpm in older children.

Ventricular Fibrillation

Ventricular fibrillation is an uncommon rhythm in the pediatric population, but is certainly life-threatening. The hallmark is chaotic, irregular ventricular contractions without circulation to the body. Causes of ventricular fibrillation include postoperative complications from congenital heart disease repair, severe hypoxemia, hyperkalemia, medications (digitalis, quinidine, catecholamines, anesthesia), myocarditis, and myocardial infarction.

CLINICAL PRESENTATION

On ECG, the rhythm is one of bizarre QRS complexes with varying sizes and configurations. It is characterized by a rapid, irregular rate.

MANAGEMENT

Ventricular fibrillation is an uncommon cause of cardiac arrest in infants less than 1 year of age, but the incidence increases with increasing age.²⁷ With the increased use and efficacy of automatic external defibrillators (AEDs) in the adult setting, controversy has arisen regarding the use of AEDs in prehospital treatment of children in cardiac arrest. Many adult AEDs deliver high energy settings for defibrillation. In addition, some rhythms presenting in children, such as sinus tachycardia and SVT, may be misinterpreted by the AED as “shockable rhythms.” Currently AEDs are approved for children older than 8 years of age.²⁷ However, according to the American Heart Association International Liaison Committee on Resuscitation, AEDs may be used in children 1 to 8 years of age without signs of circulation, ideally with the pediatric energy setting. For a lone rescuer responding to a child without signs of circulation, cardiopulmonary resuscitation (CPR) for 1 minute is recommended prior to attaching an AED or activating the Emergency Management System. For documented ventricular fibrillation or pulseless ventricular tachycardia, defibrillation is recommended.¹¹

Ventricular fibrillation is a nonperfusing rhythm. Therefore, CPR must be initiated immediately. Ventricular fibrillation is treated the same as ventricular tachycardia without a pulse. Defibrillation is initiated at 2 joules/kg, and then increased to 2 to 4 joules/kg, then to 4 joules/kg. Perform 5 cycles of CPR between each individual defibrillation attempt. If defibrillation is unsuccessful, epinephrine (0.01 mg/kg 1 : 10,000 solution) should be given, and repeated every 3 to 5 minutes as necessary.

If pulseless ventricular tachycardia is refractory to defibrillation, antiarrhythmics are indicated: amiodarone (5 mg/kg IV bolus) or lidocaine (1 mg/kg IV bolus, repeated to a maximum of 3 mg/kg) may be used. Although the pediatric dosing of amiodarone has not been clearly established, the recommended loading dose is 5 mg/kg IV and may be given over minutes to 1 hour. If rate control is not achieved, the dose may be repeated in 5-mg/kg IV increments, to a maximum of 15 mg/kg per day IV.¹⁷ Clinicians should be aware that higher doses are associated with immediate side effects (e.g., prolonged QT, bradydysrhythmias, AV blocks). For polymorphic ventricular tachycardia (torsades de pointes), the mainstay of treatment is magnesium (20 to 50 mg/kg IV to a maximum of 2 g) administered slowly.

SUMMARY

Though uncommon in the pediatric population, ventricular fibrillation is a nonperfusing, potentially lethal dysrhythmia. Defibrillation is the mainstay of therapy, with epinephrine as an adjunct when defibrillation is unsuccessful.

Bradydysrhythmias

Bradycardia is defined as a heart rate slower than the lower limit of normal for the patient’s age (see Table 63–1), while in adults it is defined as a heart rate less than 60 bpm. Mechanisms of bradycardia include depression of the pacemaker in the sinus node and conduction system blocks. Complete heart block is a common cause of significant bradycardia in pediatric patients and may be acquired or congenital.

Bradycardia in children may be attributable to vagal stimulation, hypoxemia, acidosis, or an acute elevation of intracranial pressure. The most common cause of bradycardia in the pediatric population is hypoxemia. It is important to correct hypoxemia prior to increasing the heart rate with medicines in children.

Sinus Bradycardia

Sinus bradycardia includes a heart rate less than the lower limit of normal for the patient’s age (see Table 63–1), while maintaining P waves preceding each QRS complex. Usually, the heart rate is less than 80 bpm in infants and less than 60 bpm in older children.³² Sinus bradycardia is predominantly a benign entity, most often seen in athletes and during sleep.

However, sinus bradycardia can also be associated with underlying causes. One such ominous cause is an acute onset of increased intracranial pressure as part of Cushing’s triad of bradycardia, hypertension, and irregular respirations. It can also be associated with hyperkalemia, hypercalcemia, hypoxia, hypothermia, hypothyroidism, and medications (digitalis, β -blockers). Just as with sinus tachycardia, the treatment of sinus bradycardia is targeted at the treatment of the underlying cause.

An important distinction must be made between sinus bradycardia and junctional (nodal) bradycardia. On ECG, junctional bradycardia has either no P waves or inverted P waves after QRS complexes. QRS complexes have normal configuration, and generally have rates between 40 and 60 bpm. Junctional bradycardia may occur in an otherwise normal heart, postoperatively, with digitalis toxicity, or with increased vagal tone. If the patient is asymptomatic, no acute treatment is indicated. However, if the patient has signs of decreased cardiac output, atropine or pacing may be indicated.⁴

Conduction Abnormalities

RECOGNITION AND APPROACH

First-degree AV block is an abnormal delay in conduction through the AV node. This type of AV block is a disturbance in the conduction between the normal sinus impulse and its eventual ventricular response. This manifests as a prolonged PR interval on ECG. Meanwhile, the heart is maintained in sinus rhythm, with a normal QRS configuration. There are no dropped beats. First-degree heart block can be an incidental finding on an otherwise normal ECG. Common causes include an infectious disease in an otherwise healthy child.

It may also be associated with myocarditis (e.g., rheumatic fever, Lyme disease), cardiomyopathies, and congenital heart disease (ASD, Ebstein's anomaly).

There are two types of second-degree AV block: Mobitz type I (Wenckebach) and Mobitz type II. In *Mobitz type I or Wenckebach phenomenon*, the PR interval progressively lengthens until a QRS complex is dropped. This usually occurs over three to six cardiac cycles, followed by a long diastolic pause, and then resumption of the cycle. There are occasional and frequent P waves that conduct, and the QRS configuration is normal. The block is due to an increased refractory period at the level of the AV node. Though this can be seen in otherwise healthy individuals, it can also be seen in patients with myocarditis, myocardial infarction, cardiomyopathies, congenital heart disease, and digoxin toxicity, and postoperatively following cardiac repairs.

Mobitz type II second-degree heart block is known as the “all or none” phenomenon. There is either normal AV conduction with a normal PR interval, or completely blocked conduction. The failure of conduction is at the level of the bundle of His, with a prolongation of the refractory period in the His-Purkinje system. Since some of the atrial impulses are not conducted to the ventricle, the ventricular rate depends on the number of conducted atrial impulses.

Third-degree heart block, otherwise known as complete heart block, occurs when none of the atrial impulses is conducted to the ventricles. There is a complete loss of rhythm conduction from a working atrial pacemaker, thereby allowing the ventricular pacemaker to take over. On ECG, the P waves are completely dissociated from the QRS complexes. Even though they are dissociated, both the atrial and ventricular rhythms are regular, maintaining regular P-P intervals and R-R intervals, respectively. The QRS duration is usually normal if the block is proximal to the bundle of His, while a wide QRS complex indicates that the block is most likely in the bundle branches (e.g., surgically induced complete heart block). Oftentimes, the ventricular rhythm is slower than normal (Fig. 63–6).

Complete heart block may be an isolated anomaly. It may also be congenital, and is associated with structural lesions such as L-transposition of the great arteries and maternal connective tissue disorders. Acquired heart block may result from cardiac surgery, especially when there is suturing in the atrium. This effect can either be transient, resolving within 8 days postoperatively, or permanent. Other etiologies include infectious causes such as myocarditis, Lyme disease, rheumatic fever, and diphtheria, and inflammatory disorders such as Kawasaki disease and lupus. Complete heart block is also associated with myocardial infarction, cardiac tumors, muscular dystrophies, hypocalcemia, and drug overdoses.

CLINICAL PRESENTATION

Children presenting with first-degree heart block are largely asymptomatic, but have the potential to progress to further heart block, including second- and third-degree heart blocks. Those with second-degree, type I (Wenckebach) block rarely progress to complete heart block, while those with type II second-degree block frequently progress to complete heart block.⁴ Children with complete heart block, most notably in infancy, may present with signs of congestive heart failure. Older children may present with syncope attacks, otherwise known as Stokes-Adams attacks, with heart rates less than 40 to 45 bpm, or even sudden death.

Patients presenting with complete heart block may have symptoms related to hypoperfusion, including fatigue, dizziness, impaired exercise tolerance, syncope, confusion, and sudden death.³³ Acquired or surgically induced heart block generally has a slower ventricular rate, between 40 and 50 bpm, than is common with congenital complete heart block, which generally manifests with a rate of 50 to 80 bpm.⁴

Management

Management of bradycardia includes identification of the etiology and appropriate cardiopulmonary resuscitation, with assisted ventilation, oxygenation, and chest compressions as indicated. If symptomatic bradycardia persists despite

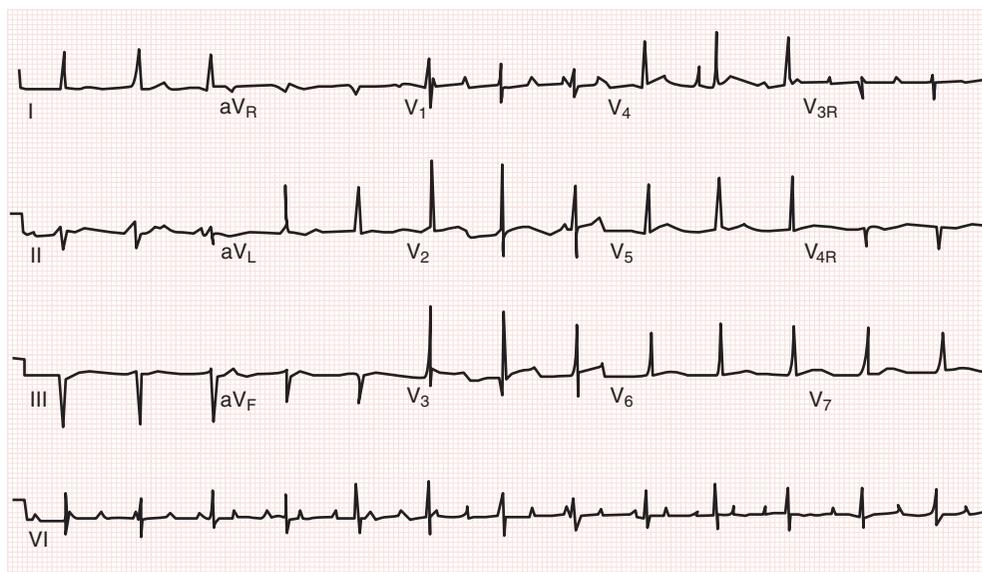

FIGURE 63–6. Complete heart block. This electrocardiogram is of an infant presenting at birth; notice the complete dissociation of P waves from QRS complexes. The child's mother had systemic lupus erythematosus, which is commonly associated with complete heart block. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

initial resuscitative measures, pharmacologic intervention is initiated with epinephrine at 0.01 mg/kg IV or atropine at 0.02 mg/kg IV (minimum 0.1 mg, maximum single dose is 0.5 mg in children and 1 mg in adolescents). Chest compressions are indicated for neonates or infants with heart rates less than 60 bpm with hemodynamic compromise.¹¹

No treatment is indicated for a first-degree heart block. However, if suspicious features are present, patients may require evaluation for underlying disease (i.e., Lyme disease, rheumatic fever). For second-degree heart block, treatment is directed at the underlying cause. In patients with Mobitz type II second-degree heart block, a prophylactic pacemaker may be warranted, since there is a risk of progressing to complete heart block. For complete heart block, the mainstay of therapy is a pacemaker. While the patient is awaiting pacemaker insertion, it may be necessary to administer atropine or isoproterenol, which temporarily increases the heart rate, or to apply an external pacemaker.

Sinus Arrhythmia

A frequent finding on ECG assessment is sinus arrhythmia, which is the normal phasic variation in the heart rate. By definition, a P wave is present prior to each QRS complex. This can be best demonstrated on a long rhythm strip, when the heart rate varies with the cycle of respiration. As the heart rate increases with inspiration, the R-R interval consequently decreases. Conversely, the heart rate decreases with expiration while the R-R interval increases. Since this is a benign entity, no treatment is necessary.

Long QT Syndrome

LQTS, otherwise referred to as prolonged QT syndrome, is a disorder of delayed ventricular repolarization, characterized by prolongation of the QT interval on ECG. Prolongation of the QT interval may be either hereditary or acquired. Jervell and Lange-Nielsen syndrome is an autosomal recessive form of LQTS associated with congenital deafness, whereas Romano-Ward syndrome is an autosomal dominant form that is not associated with deafness. Congenital LQTS has an estimated incidence of 1 in 10,000 to 15,000 and is responsible for 3000 to 4000 cases of sudden death each year in the United States.⁷ While congenital forms of LQTS present in childhood, patients with the acquired type of LQTS usually present in their fifth or sixth decades of life.⁷ There are many causes of acquired LQTS, with medications among the most common (Table 63–2). It is also seen with electrolyte abnormalities, such as hypokalemia, hypocalcemia, and hypomagnesemia.

Table 63–2 Drugs That Prolong the QT Interval

Antiarrhythmics (classes IA and III)
Antiemetics: droperidol
Antifungals: ketoconazole
Antihistamines: astemizole, terfenadine
Antimicrobials: erythromycin, trimethoprim-sulfamethoxazole
Antipsychotics: haloperidol, risperidone
Organophosphate insecticides
Phenothiazines: thioridazine
Promotility agents: cisapride
Tricyclic antidepressants: amitriptyline

Clinical Presentation

Patients with LQTS commonly present between the ages of 9 and 15 years with recurrent episodes of syncope.³⁴ Of the patients with acquired LQTS, 60% of affected individuals are symptomatic at diagnosis.^{7,35} Syncopal episodes are often precipitated by intense emotion, vigorous physical activity, or loud noises. Syncopal episodes may be mistaken for seizures as they can result in loss of consciousness, tonic-clonic movements, and temporary residual disorientation following the event.

Spontaneous return of consciousness usually follows a syncopal episode, but the dysrhythmia has the potential to degenerate into ventricular fibrillation and sudden death. Approximately 10% of children with LQTS present with sudden death. Age at presentation is related to death, with younger children more likely to die suddenly.³⁶ LQTS may present in infancy as SIDS, or later in life as near drowning. Children may also present with milder symptoms such as diaphoresis, palpitations, or light-headedness.

When a patient presents with syncope, there are a number of historical factors that should be viewed as warning signs of potential cardiac disease and sudden death. Syncope that occurs with exertion is almost always an ominous sign. The strongest risk factors for developing malignant dysrhythmias or sudden death include a prior history of syncope, documented ventricular tachydysrhythmias, and a history of resuscitated cardiac arrest. Furthermore, a history of congenital deafness and the female gender are both independently associated with an increased likelihood of recurrent cardiac events.

The hallmark dysrhythmia of LQTS is a polymorphic ventricular tachycardia known as *torsades de pointes* (“twisting of the points”), a French term first used in 1966 by Desserenne to describe a QRS axis shifting back and forth around the baseline³⁷ (Fig. 63–7). During this dysrhythmic episode, cardiac output is markedly impaired, often resulting in syncope or seizures. Although many of these events are self-limiting, with the spontaneous return of consciousness, the dysrhythmia has the potential to degenerate into ventricular fibrillation and sudden death. With the potential for fatal consequences in undiagnosed affected individuals, the recognition of LQTS is of paramount importance.

LQTS should be considered, and an ECG obtained, in any patient presenting with a suggestive history, including first-degree relatives of a known LQTS carrier; family history of syncope, seizures, or sudden death; a sibling with SIDS; seizure of unknown etiology; and unexplained near drowning. Other risk factors include congenital deafness, and bradycardia in infants. Suggestive features of syncopal episodes include those that are triggered by emotion, exertion, or stress and those that are associated with chest pain or palpitations.

On ECG, the QT interval is manually measured, with lead II generally accepted as being most accurate. To account for the normal physiologic shortening of the QT interval that occurs with increasing heart rate, the QT_c is calculated using the Bazett formula⁶: $QT_c = (QT/\sqrt{RR})$.

Current practice identifies a QT_c of 460 msec as prolonged in infants and children and a QT_c of 500 msec as prolonged in neonates. A QT_c value between 420 and 460 msec is borderline and warrants additional assessment.^{8,9} Though ECG

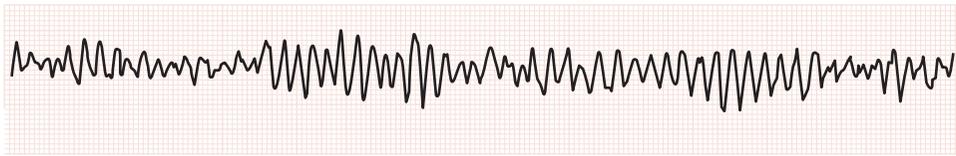

FIGURE 63–7. Rhythm strip showing torsades de pointes. This child had a history of dilated cardiomyopathy, and returned to sinus rhythm after defibrillation. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

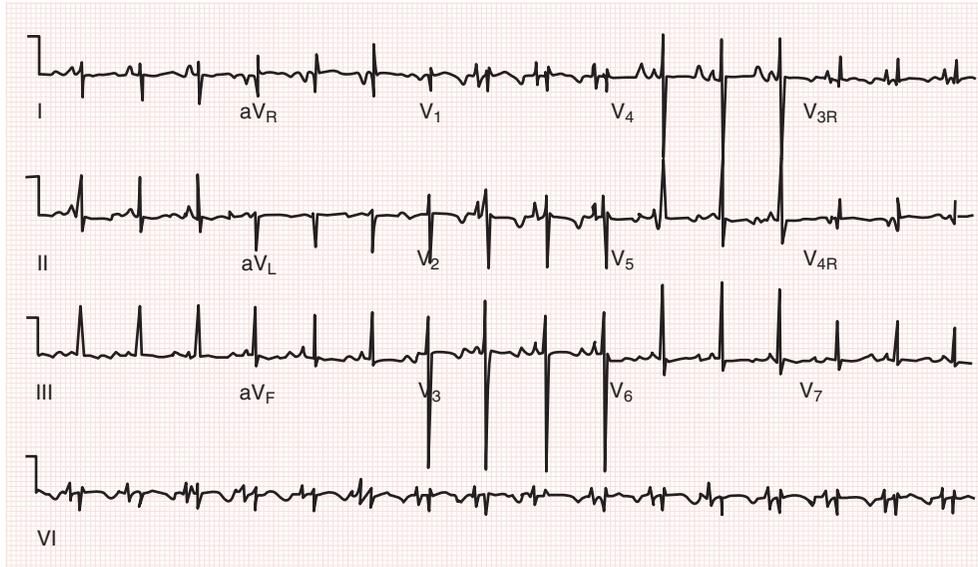

FIGURE 63–8. Long QT syndrome without associated heart block. A markedly prolonged QT interval is calculated with the Bazett formula⁶: $QT_c = QT \div \text{square root of the preceding R-R interval}$. Thus

$$QT_c = 0.452 / \sqrt{0.612} \\ = 578 \text{ msec}$$

Of note, for improved accuracy three consecutive R-R intervals and QT intervals are averaged, where each small box = 0.04 msec. (Photo courtesy of CDR Jonathan T. Fleenor, MD, Naval Medical Center, San Diego.)

equipment automatically calculates the QT and QT_c , in those patients with suggestive history an ECG with manual calculation of the QT_c should be performed, as the computer calculation often is inaccurate. If the diagnosis of LQTS is suspected but the screening ECG is not diagnostic, increasing sympathetic activity such as with vagal maneuvers may trigger abnormalities on ECG. These abnormalities include QT interval prolongation, prominent U waves, T-wave alternans, and ventricular dysrhythmias (Fig. 63–8).

Management

Patients presenting with LQTS may require emergency intervention. Patients presenting with an episode of polymorphic ventricular tachycardia or torsades de pointes of unknown etiology should receive IV magnesium (25 to 50 mg/kg to a maximum of 2 g). Serum electrolytes and a toxicology screen should be obtained. β -Blockers may be useful in suppressing catecholamine surges and further dysrhythmic activity. In patients with torsades due to prolonged QT interval, β -blockers may worsen the blood pressure, whereas they improve the hemodynamic status of patients with a normal QT interval associated with polymorphic ventricular tachycardia. Patients with recurrent ventricular tachycardia may require temporary transcutaneous ventricular pacing.

Any patient with a compatible history, borderline prolongation of the QT interval with symptoms, or identified LQTS should be referred to a cardiologist for further management. Admission is limited to those who are symptomatic or have cardiovascular compromise. Holter monitoring may be helpful in capturing a prolonged QT interval not apparent on a resting ECG. Therapy is aimed at reducing sympathetic activity of the heart, either pharmacologically or surgically. Long-term β -blocker use is generally recommended as the initial therapy of choice as these drugs effectively eradicate dysrhythmias in 60% of patients, and decrease mortality from 71% in untreated patients to 6% in those who are treated.^{38,39} Alternative therapies include left-sided cervicothoracic sympathetic ganglionectomy and implantation of automatic implantable cardiac defibrillators.

Once a patient is diagnosed with LQTS, an ECG should be performed on all other family members. All affected individuals, regardless of age, should be restricted from competitive sports but not necessarily recreational sports. Patients should be educated to avoid triggering factors, such as certain medications, loud noises, emotionally stressful situations, and dehydration. Because of the high risk of unexpected cardiac events, family members and close friends should be instructed in CPR and consider purchasing a home AED.

Summary

Due to the potentially severe consequences of untreated disease, the recognition of LQTS is of utmost importance. Physicians must always consider this diagnosis in patients presenting with syncope. A personal and family history of syncope, seizures, congenital deafness, or sudden death should be noted. Syncope that is recurrent or associated with exercise, emotion, chest pain, or difficulty breathing is worrisome. Identification of a patient with LQTS necessitates further assessment of all first-degree relatives. With appropriate treatment of affected individuals, the significant morbidity and mortality associated with LQTS is greatly reduced.

Chapter 64

Pericarditis, Myocarditis, and Endocarditis

Ghazala Q. Sharieff, MD and Todd Wylie, MD, MPH

Key Points

Pericarditis and myocarditis may occur simultaneously.

Pleuritic chest pain that is relieved by sitting upright and increased with the supine position suggests pericarditis.

Pericardiocentesis can be life-saving in patients with cardiac tamponade.

Clinicians must not rely on a normal echocardiogram to exclude endocarditis.

Endocarditis prophylaxis is mandatory in patients with prosthetic valves, a history of previous bacterial endocarditis, complex cyanotic heart disease, or surgical systemic pulmonary shunts or conduits.

Selected Diagnoses

Pericarditis
Myocarditis
Infective endocarditis

Discussion of Individual Diagnoses

Pericarditis

Pericarditis is an inflammatory condition of the pericardial lining of the heart. Pericarditis alone may not cause significant hemodynamic compromise; however, the complications of pericardial effusion and cardiac tamponade can result in shock, cardiac arrest, and death. Both infectious and noninfectious etiologies of pericarditis exist¹ (Table 64–1). Among infectious causes, viral etiologies (coxsackievirus A and B, echoviruses, influenza viruses) are most common. Bacterial organisms most commonly associated with pericarditis include *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Borrelia burgdorferi* (Lyme disease), and *Mycobacterium tuberculosis*.¹

The pericardium consists of two layers, the visceral layer and the parietal layer. In a healthy person, a small amount (10 to 15 ml in a child) of serous fluid normally exists between the visceral and parietal pericardial layers. When inflammation of the pericardium occurs, fluid accumulates between the two layers of the pericardium and forms a pericardial effusion. Normally, the pericardium does not affect filling of the heart. However, a significant pericardial effusion may limit the filling capacity of the heart chambers, resulting in increased end-diastolic filling pressures and decreased cardiac output. Large effusions may lead to cardiac tamponade. Acute development of an effusion is more likely to result in tamponade because the pericardium does not have the capacity to accommodate an abruptly increased volume.

Clinical Presentation

Symptoms vary depending on the etiology and how rapidly a pericardial effusion develops. Common presenting symptoms include respiratory difficulty, fever, and substernal chest pain that may radiate to the left shoulder, scapula, or trapezius. Chest pain is often accentuated by lying flat or respiratory motion, and improved with sitting forward. Patients with a viral etiology may have a recent history of a viral illness, including upper respiratory tract symptoms and fever. Physical findings vary depending on the severity of disease. With a small effusion, the only sign on physical examination may be a friction rub. With more serious disease, tachypnea and tachycardia develop. The lungs are generally clear to auscultation. Signs of cardiac tamponade include distended neck veins, clear lungs, weak peripheral pulses, tachycardia, distant heart tones with auscultation, and a pulsus paradoxus. Beck's triad (hypotension, distended neck veins, and muffled heart tones) is present in less than half of all patients with cardiac tamponade.

Laboratory evaluation of a patient with suspected pericarditis includes a complete blood count (CBC), electrolytes, glucose, blood urea nitrogen, and creatinine. The CBC may reveal an elevated white blood cell count in the presence of bacterial pericarditis or normocytic, normochromic anemia associated with chronic disease. The CBC may be normal with other etiologies. Appropriate cultures including blood, urine, and viral serology should also be obtained depending upon the suspected etiology. An erythrocyte sedimentation

Table 64–1 Causes of Pericarditis

Idiopathic*
Infectious
Viral* (echovirus, coxsackievirus, adenovirus, cytomegalovirus, hepatitis B, infectious mononucleosis, HIV/AIDS)
Bacterial* (<i>Pneumococcus</i> , <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Mycoplasma</i> , Lyme disease, <i>Haemophilus influenzae</i> , <i>Neisseria meningitidis</i>)
Mycobacteria* (<i>Mycobacterium tuberculosis</i> , <i>Mycobacterium avium-intracellulare</i>)
Fungal (histoplasmosis, coccidioidomycosis)
Protozoal
Immune-inflammatory
Connective tissue disease* (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, mixed)
Arteritis (polyarteritis nodosa, temporal arteritis)
Early post–myocardial infarction
Late post–myocardial infarction (Dressler syndrome),* late post-cardiotomy/thoracotomy,* late posttrauma*
Drug induced* (e.g., procainamide, hydralazine, isoniazid, cyclosporine)
Neoplastic disease
Primary: mesothelioma, fibrosarcoma, lipoma, and the like
Secondary*: breast and lung carcinoma, lymphomas, leukemias
Radiation induced*
Early post–cardiac surgery
Device and procedure related: Coronary angioplasty, implantable defibrillators, pacemakers
Trauma: Blunt and penetrating,* post–cardiopulmonary resuscitation*
Congenital
Cysts, congenital absence
Miscellaneous
Chronic renal failure, dialysis related
Hypothyroidism
Amyloidosis
Aortic dissection

*Etiologies that manifest as acute pericarditis.
 Abbreviations: AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.
 From LeWinter MM, Kabbani S: Pericardial diseases. In Zipes DP (ed): Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia: WB Saunders, 2005, pp 1757–1781.

rate may be elevated, with high values (>50 to 60 mm/hr) seen in tuberculosis, Kawasaki disease, and autoimmune diseases.² Cardiac troponins are elevated in nearly half of all cases of pericarditis, with nearly one quarter meeting the threshold for myocardial infarction.^{3,4} These cardiac tests may be a marker for subclinical involvement of the myocardium.

The electrocardiogram (ECG) typically shows diffuse ST-segment elevation in both the limb and precordial leads with associated upright T waves (leads I, V₅, and V₆). ST-segment depression in aV_R and PR-segment depression in leads II, aV_F, and V₄ to V₆ may also be present (Fig. 64–1). With chronic pericarditis, the ST-segment elevation resolves and widespread T-wave inversion develops. A large effusion can cause generalized ECG low voltage and electrical alternans (alternate-beat variation in the direction, amplitude, and duration of any component of the ECG waveform), although this is an uncommon finding.

The initial chest radiograph usually demonstrates clear lung fields. An effusion may be mistaken as cardiomegaly. A large effusion may give the appearance of a “water-bottle”-shaped heart. An echocardiogram is the diagnostic study of choice. It can reveal an effusion, quantify the effusion, and demonstrate the thickness of the pericardium. An echocar-

diogram also allows evaluation of cardiac hemodynamic function.

Advanced techniques of nonsurgical percutaneous pericardial biopsy, pericardioscopy, cytologic analysis of pericardial fluid, and molecular techniques such as polymerase chain reaction and fluorescent in situ hybridization are currently available for diagnostic purposes.^{5–7} Such techniques significantly improve diagnosis of specific etiologies, but are not immediately available in the emergency department (ED).

Management

In an unstable patient with cardiac tamponade, a pericardiocentesis should be performed expeditiously (see Chapter 180, Pericardiocentesis). An initial normal saline fluid bolus (20 ml/kg) is administered if hypotension is present. Antibiotics should be initiated until a bacterial source can be excluded. Recommended antibiotics include nafcillin (150 mg/kg per 24 hours intravenously [IV], divided every 4 to 6 hours) and cefotaxime (100 to 150 mg/kg per 24 hours IV, divided every 6 hours).⁸ A pediatric cardiology consult is obtained, and the patient is admitted to a pediatric intensive care unit for further management.

Pericardiocentesis may be safely deferred in stable patients with no evidence of decompensation, particularly if removal of fluid is for diagnostic purposes only. Stable patients should be admitted to the hospital for further evaluation, bed rest, and initiation of antibiotics and anti-inflammatory agents. The clinician should consider administration of salicylates (50 to 75 mg/kg per 24 hours PO, divided every 6 hours) or ibuprofen (10 mg/kg PO, divided every 6 hours).⁸ Corticosteroids have only been found effective with certain etiologies of pericarditis (i.e., autoreactive).⁹ However, they should not be used until a bacterial etiology can be excluded. Corticosteroids are also not recommended in acute viral pericarditis.

Myocarditis

Myocarditis is an inflammation of the heart muscle resulting from infectious and noninfectious causes. It may occur in conjunction with pericarditis or in isolation. The most common etiology in North America is viral (coxsackievirus A and B, echoviruses, and influenza viruses),^{10,11} while parasites (e.g., Chagas' disease) are most common in underdeveloped countries. There are numerous other causes, including nonviral infections, drugs, endocrine disorders, radiation, and collagen vascular diseases.

Clinical Presentation

Multiple factors, including the etiology and patient age, influence the clinical presentation. Neonates and infants may present with lethargy, poor feeding, irritability, pallor, fever, or failure to thrive.¹² Wheezing is an important physical examination finding that is often mistakenly attributed to a viral syndrome.¹³ Symptoms suggestive of heart failure, such as diaphoresis with feeding, rapid breathing, or respiratory distress, may be present.¹² Older children and adolescents can present with similar features. In addition, they may complain of weakness, fatigue, chest pain, and shortness of breath.¹² With viral myocarditis, there may be a recent history of a nonspecific viral syndrome. Potential findings on physical examination include tachypnea, tachycardia, hyperthermia or hypothermia, hypotension, and wheezing or rales due to congestive heart failure. Signs of poor

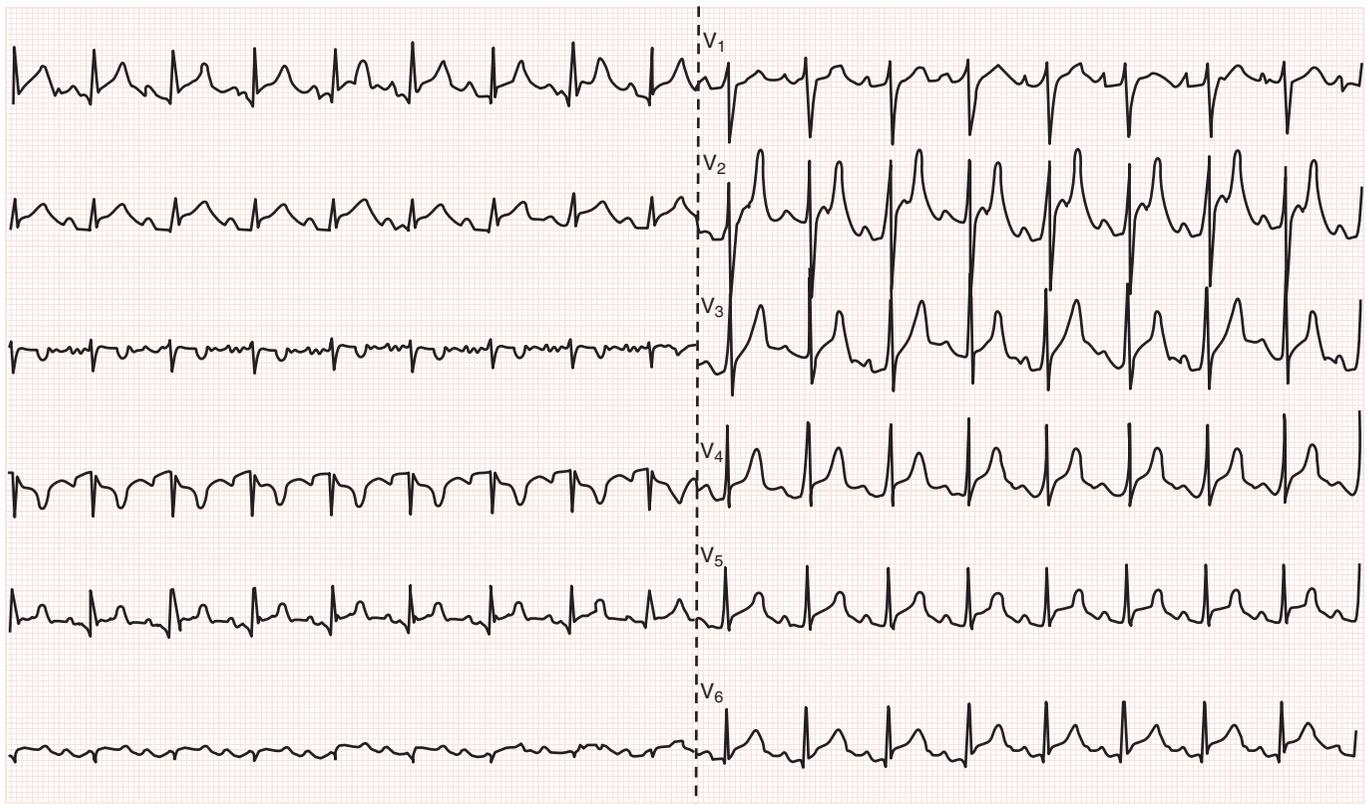

FIGURE 64-1. Typical electrocardiogram in pericarditis with PR segment depression and diffuse ST segment elevation. (Photo courtesy of Amal Mattu, MD, Program Director, Emergency Medicine Residency, University of Maryland School of Medicine, Baltimore, Maryland.)

perfusion and heart failure, including tachycardia, weak pulses, decreased capillary refill time, cool mottled extremities, jugular venous distention, hepatomegaly, and lower extremity edema, may be present. Heart tones may include an S_3 , and may be muffled if pericarditis is present. Although several types of dysrhythmias occur, the most common dysrhythmia is sinus tachycardia. Sinus tachycardia that is faster than expected for the degree of fever (an average of 9.6 beats/min for every 1°C increase in body temperature) may indicate myocarditis.¹⁴

A CBC, electrolytes, glucose, blood urea nitrogen, creatinine, sedimentation rate, C-reactive protein, and cardiac enzymes may occasionally provide information in patients with myocarditis. While an elevated white blood cell count may be present in many cases, a lymphocytic predominance on the differential suggests a viral etiology. The sedimentation rate and C-reactive protein are usually elevated, but normal values do not rule out myocarditis. Elevation of creatine kinase MB and lactate dehydrogenase can occur. Cardiac troponins are elevated in 35% to 71% of cases.^{15,16} Brain natriuretic peptide may be a useful marker, with most cases of Kawasaki myocarditis manifesting a level greater than 50 pg/ml.¹⁷ Accuracy of this test for diagnosing other types of myocarditis has not been studied well. Blood samples as well as throat, nasopharyngeal, stool, and urine specimens should be sent for culture to identify bacterial or viral pathogens. Endomyocardial biopsy is the gold standard for diagnosis of myocarditis.

Of the multiple ECG abnormalities that may occur, sinus tachycardia is the most common dysrhythmia. Other abnor-

malities such as premature ventricular beats, junctional tachycardias, ventricular tachycardias, and even second- and third-degree atrioventricular blocks may also be present. A low-voltage QRS complex, less than 5 mm in all limb leads, suggests myocarditis or tamponade. As pericarditis may occur simultaneously, the ECG may show ST-segment elevation and PR-interval depression.¹²

Radiologic evaluation should include a chest radiograph and an echocardiogram. The chest radiograph may show cardiomegaly and pulmonary edema. An echocardiogram can demonstrate changes in myocardial function. If heart failure is present, an echocardiogram will show increased left ventricular end-diastolic and systolic dimensions. Other potential echocardiogram findings include left ventricular wall dysfunction, decreased ejection fraction, segmental wall motion abnormalities, or global hypokinesia.

Management

Initial management should focus on respiratory and circulatory status. All patients in respiratory distress are placed on supplemental oxygen and cardiac monitoring and pulse oximetry are initiated. If the patient continues to deteriorate, or is in cardiogenic shock, endotracheal intubation and ventilatory support may be necessary. Vascular access should be obtained immediately.

Goals for managing patients with myocarditis-induced heart failure include reduction of high ventricular filling pressures, a decrease in systemic vascular resistance, and improvement in oxygen delivery and oxygen consumption. Toward this goal, diuretics, inotropes, and afterload reducing

agents are administered. Intravenous furosemide is used to decrease fluid overload and preload. Digoxin is not recommended in myocarditis since it is ineffective acutely, and there is evidence that this agent increases production of cytokines and increases mortality in myocarditis.¹² Inotropic agents such as dopamine or dobutamine may be necessary if cardiogenic shock is present. Afterload reducing agents help reduce the workload of a poorly functioning myocardium, and if hypotension is not present, an easily titrated IV agent such as nitroprusside may be used to decrease systemic vascular resistance (see Chapter 8, Circulatory Emergencies: Shock).

High-dose intravenous gamma globulin (2 g/kg given over the first 24 hours) in the setting of acute myocarditis may improve ventricular function and survival.¹⁸ The use of immunosuppressive agents such as steroids or cyclosporine in acute myocarditis is controversial, and therefore should not be initiated in the ED. All patients with myocarditis should be admitted to an intensive care unit for further management and observation. The diagnosis of myocarditis often cannot be confirmed in the ED as many patients present with a seemingly benign viral illness with weakness, fever, and emesis; however, it is more important to recognize that the child is critically ill, initiate treatment, and admit the patient.

Infective Endocarditis

The incidence of infective endocarditis in children is approximately 1 case per 1000 hospital admissions.^{19,20} The majority of infective endocarditis cases in the Western world are now associated with congenital heart disease. Up to 69% to 87% of all childhood endocarditis cases occur in children with congenital heart defects.¹⁹⁻²¹ Central venous catheters are also a risk factor for infective endocarditis.²² Other risk factors include immunodeficiency states and intravenous drug abuse.

Clinical Presentation

Clinical signs and symptoms of infective endocarditis can vary. Subacute endocarditis has an insidious onset over several weeks with nonspecific signs and symptoms. Flulike symptoms with low-grade fever, cough, decreased appetite, nausea, weight loss, generalized myalgias, and joint pains may all be present. Physical examination often reveals a fever and a heart murmur. Acute endocarditis develops rapidly over several days to weeks with high fevers, malaise, a toxic appearance, and congestive heart failure. A new or changing murmur is more common with acute endocarditis due to the larger size of vegetations associated with it. However, as few as one quarter of children with endocarditis have a new murmur noted on examination.^{23,24} Physical findings of embolic phenomena (arterial clot, stroke) are also more common in acute endocarditis.

Embolization of infected vegetations can involve any organ system of the body, but most commonly involves the brain, spleen, and kidneys. Emboli may cause infarction or abscess development in these organs. Diffuse or focal glomerulonephritis, nephrotic syndrome, and renal failure may result from emboli to the kidneys. Infective endocarditis involving the right side of the heart may result in emboli to the lungs, causing pneumonia, abscesses, and pulmonary emboli. Cardiac complications may include perforation of valve leaflets, leading to valve insufficiency and congestive heart failure. Conduction disorders may develop secondary to

myocardial abscesses. Splenomegaly is present in nearly a third of all cases, while petechiae are present in one quarter of cases.^{23,24} Other uncommon peripheral signs of infectious endocarditis include Osler's nodes (pea-sized subcutaneous nodules on the palms, soles, and digits), Janeway lesions (painless palmar macules), and splinter hemorrhages.

Streptococci and staphylococci, particularly *S. aureus*, are the most commonly identified infectious organisms. *Staphylococcus aureus* was identified in 39% of cases in one study.¹⁹ More recent studies have identified *Streptococcus viridans* in 26% to 32% of cases and *S. aureus* in 27% to 29% of cases.^{23,24} Staphylococci are also common causative organisms in neonates, as are fungal organisms such as *Candida* species.²² Gram-negative organisms have been identified but are much less common. Fungal organisms are more likely to occur in neonates and IV drug abusers.²²

Unfortunately, no single test is definitive for endocarditis. The CBC generally shows a normocytic and normochromic anemia, and the white blood cell count may be elevated. Both the erythrocyte sedimentation rate and serum C-reactive protein are usually elevated. In prolonged cases, the rheumatoid factor is positive approximately half the time. The urinalysis may show proteinuria, microscopic hematuria, and white or red blood cell casts. Blood cultures are the most important laboratory test for identifying infective endocarditis. Three sets should be drawn within the first 24 hours.²⁵ The echocardiogram is the radiologic study of choice, as it is helpful for identifying presence, size, and location of vegetations. However, it is important to note that the echocardiogram may appear normal in as many as 21% to 54% of cases.^{23,24} The Duke criteria are a combination of diagnostic parameters and echocardiographic findings used to identify infective endocarditis²⁶ (Table 64–2).

Management

Initial management depends on the patient's presenting condition. Unstable patients require aggressive initial interventions. Maintaining a patent airway, adequate oxygenation and ventilation, and circulatory support are the primary objectives. If patients present with signs of embolic phenomena (e.g., stroke, arterial clot) or other complications, therapy should be directed toward those problems until the patient is stabilized. All patients diagnosed with infective endocarditis, or suspected of having infective endocarditis, require hospitalization. This should include all patients with fever and high-risk congenital heart disease (see Table 64–2), those with indwelling central venous access catheters, IV drug users, and patients with physical examination findings suspicious for endocarditis regardless of underlying disease.

Medical treatment consists of parenteral antibiotics, generally at least two agents, for 6 weeks. Since multiple organisms cause infective endocarditis, antibiotic therapy needs to be directed by culture results and sensitivities. Initial empirical antibiotic combinations should cover common infecting organisms (*S. viridans*, *Streptococcus bovis*, and enterococci) and should include the following IV drugs: (1a) penicillin G 150,000 units/kg per day, divided every 4 to 6 hours (maximum 24 million units/day), or (1b) ampicillin 200 mg/kg per day, divided every 4 hours (maximum 12 g/day), PLUS either (2) nafcillin or oxacillin 100 to 200 mg/kg per day, divided every 6 hours (maximum 12 g/day), PLUS (3) gentamicin 6 to 7.5 mg/kg per day, divided every 8 hours. If the

patient is allergic to penicillin, vancomycin in a dose of 30 mg/kg per day, divided every 12 hours (maximum of 2 g/day) can be used in combination with gentamicin. Patients with staphylococcal infection should be started on nafcillin and gentamicin. Patients with methicillin-resistant strains of staphylococcus or prosthetic heart valves should be started

on vancomycin, rifampin, and gentamicin.²⁷ Indications for surgical intervention include heart failure, an obstructed valve, perivalvular abscess, fungal endocarditis, and large vegetations (>10 mm).

Prophylaxis

Stratifying people in to high-, moderate-, and negligible-risk categories is helpful in order to identify which individuals need prophylaxis for endocarditis²⁰ (Table 64–3). Patients in the negligible-risk category have no greater risk of developing infective endocarditis than the general public, and therefore prophylactic antibiotics are not necessary. Individuals in the moderate and high risk categories require prophylaxis for various medical and dental procedures²⁸ (Tables 64–4 and 64–5).

Table 64–2 Dukes Criteria for Infective Endocarditis*

Major Criteria

1. Isolation of organisms from 2 blood cultures: must be typical organisms (viridans streptococci, *Streptococcus bovis*, HACEK group, or *Staphylococcus aureus*) or enterococci in absence of primary focus
2. Persistently positive blood culture: 2 or more positive blood cultures for same organism separated by 12 hr, or ≥3 positive blood cultures for same organism with 1 hr between first and last culture
3. Positive echocardiogram for oscillating intracardiac mass at sites where vegetations typically occur
4. Intracardiac abscess identified by echocardiogram
5. New partial dehiscence of prosthetic valve as identified by echocardiogram
6. New regurgitant murmur

Minor Criteria

1. Fever greater than 38° C
2. Predisposing heart condition or IV drug use
3. Vascular phenomena: Includes major arterial emboli, mycotic aneurysms, CNS hemorrhages, Janeway lesions, conjunctival hemorrhages, peripheral necrotic skin lesions
4. Immunologic phenomena: includes elevated rheumatoid factor, immune complex glomerulonephritis, Osler’s nodes
5. Echocardiogram findings consistent with endocarditis but not meeting major criterion: nonoscillating masses, nodular valve thickening

*Clinical diagnosis of definite infective endocarditis requires 2 major criteria, 1 major with 3 minor criteria, or 5 minor criteria. Abbreviations: CNS, central nervous system; HACEK, *Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*; IV, intravenous.

Table 64–3 Cardiac Conditions Requiring Prophylaxis against Endocarditis

Endocarditis Prophylaxis Recommended

High-risk category
 Presence of prosthetic valves
 Previous bacterial endocarditis
 Complex cyanotic heart disease
 Surgical systemic pulmonary shunts or conduits

Moderate-risk category
 Other congenital heart malformations
 Acquired valve dysfunction
 Hypertrophic cardiomyopathy
 Mitral valve prolapse with regurgitation or thickened leaflets

Endocarditis Prophylaxis Not Recommended

Negligible-risk category
 Isolated secundum atrial septal defect
 Surgically repaired atrial septal defect, ventricular septal defect, or patent ductus arteriosus
 History of coronary bypass graft surgery
 Mitral valve prolapse without regurgitation
 Physiologic, functional, or innocent murmurs
 History of Kawasaki disease without valve dysfunction
 History of rheumatic fever without valve dysfunction
 Cardiac pacemakers and implanted defibrillators

Table 64–4 Prophylaxis for Dental, Oral, Respiratory Tract, or Esophageal Procedures

Situation	Recommended Antibiotic	Dosing Regimen
Standard prophylaxis	Amoxicillin	50 mg/kg PO 1 hr prior to procedure, not to exceed 2 g
Unable to take oral medications	Ampicillin	50 mg/kg IM or IV within 30 min prior to procedure, not to exceed 2 g
Allergic to penicillin	Clindamycin	20 mg/kg PO 1 hr prior to procedure, not to exceed 600 mg
	Azithromycin or clarithromycin	15 mg/kg PO 1 hr prior to procedure, not to exceed 500 mg
Allergic to penicillin and unable to take oral medications	Clindamycin	20 mg/kg IV within 30 min before procedure, not to exceed 600 mg

Table 63–5 Endocarditis Prophylaxis for Genitourinary and Gastrointestinal Procedures

Situation	Recommended Antibiotic	Dosing Regimen
High-risk patients	Ampicillin and gentamicin	Ampicillin 50 mg/kg IM or IV, not to exceed 2 g, plus gentamicin 1.5 mg/kg IV, not to exceed 120 mg; 6 hr later, ampicillin 25 mg/kg IM/IV or amoxicillin 25 mg/kg PO
High-risk patients with penicillin allergy	Vancomycin and gentamicin	Vancomycin 20 mg/kg IV over 1–2 hours, not to exceed 1 g, plus gentamicin as above
Moderate-risk patients	Amoxicillin or ampicillin	Amoxicillin 50 mg/kg PO 1 hr prior to procedure, not to exceed 2 g; or ampicillin 50 mg/kg IV/IM within 30 min of procedure, not to exceed 2 g
Moderate-risk patients with penicillin allergy	Vancomycin	Vancomycin 20 mg/kg IV over 1–2 hours, complete within 30 min of procedure, not to exceed 1 g

Chapter 65

Hypertensive Emergencies

Todd Wylie, MD, MPH and Nazeema Khan, MD

Key Points

Hypertension in young children is most likely secondary hypertension of a renal etiology.

A hypertensive emergency is defined by the presence of end-organ damage in addition to hypertension, and is not defined by any specific number for the systolic or diastolic blood pressure.

The goal of therapy for hypertensive emergencies is to reduce the mean arterial blood pressure by 25% over the first 2 to 8 hours. Overly rapid reduction of the blood pressure can lead to cerebral hypoperfusion and neurologic complications.

Antihypertensive medications should be carefully selected based on the affected organ(s), suspected etiology of the hypertension, and other medications used by the patient, and should always be easily titratable, intravenous medications.

Introduction and Background

The prevalence of hypertension in the pediatric population ranges from 1% to 3%.¹ The prevalence varies based on age, genetic background, and body weight. Hypertension can be diagnosed by comparing the patient's blood pressure to standard values for age and gender (Tables 65–1 and 65–2). A normal blood pressure is defined as a systolic and diastolic blood pressure (SBP and DBP, respectively) less than the 90th percentile for age, gender, and height.² An SBP or DBP equal to the 90th percentile but less than the 95th percentile is designated as prehypertension.² An SBP or DBP level ranging from the 95th percentile to 5 mm Hg above the 99th percentile is defined as stage 1 hypertension, and SBP or DBP levels greater than 5 mm Hg above the 99th percentile are defined as stage 2 hypertension.²

Although the discovery of hypertension may not require immediate treatment in the ED, hypertensive emergencies in children demand rapid recognition and intervention to prevent further morbidity or even mortality. Importantly, a

hypertensive emergency is not defined by the degree of elevation of the blood pressure, but rather by the presence of end-organ damage in the setting of an elevated blood pressure. Involved organ systems may include the renal, cardiac, visual, neurologic, or pulmonary systems. Examples of end-organ damage include congestive heart failure, hypertensive encephalopathy, acute nontraumatic intracranial hemorrhage, acute renal failure, and retinopathy.

Recognition and Approach

Adolescents more commonly have essential hypertension (no identifiable cause) compared to younger children.^{3,4} Hypertension in the first decade of life may be due to essential hypertension, but is more likely to have an underlying cause (secondary hypertension).³ Renal disorders, such as glomerulonephritis, renal artery stenosis, systemic lupus erythematosus, renal transplantation, polycystic kidney disease, or reflux nephropathy, are the most common causes of hypertension in children⁵ (Table 65–3). A hypertensive emergency can be an acceleration of preexisting hypertension or can occur suddenly. Hypertensive emergencies commonly occur secondary to underlying renal disorders.⁶ Extrarenal causes of hypertensive emergencies include coarctation of the aorta, neuroblastoma, pheochromocytoma, and increased intracranial pressure.^{5,6} Drug ingestions such as corticosteroids, sympathomimetics, cocaine, or theophylline may also precipitate hypertensive crises.⁵

The pathophysiology of hypertensive emergencies is not completely understood. It is known that the vascular endothelium has a role in blood pressure homeostasis through the release of vasodilatory substances such as nitric oxide and prostacyclin.⁷ Generally, these substances are released by the endothelium as a compensatory mechanism to decrease vascular resistance in reaction to an initial increase in blood pressure. When the increase in blood pressure is prolonged, or of sufficient severity, these vasodilatory substances can no longer compensate, and increased vascular resistance and endothelial damage result. This leads to increased vascular resistance, increased blood pressure, and, ultimately, end-organ damage.

Clinical Presentation

Children with hypertension may be asymptomatic or present with nonspecific symptoms. Most adolescents with

hypertension are asymptomatic.⁴ Young children, infants, and neonates with chronic hypertension often have nonspecific signs and symptoms such as feeding difficulties, polydipsia, polyuria, nocturia, growth failure, irritability, listlessness, and confusion.^{4,8} Multiple other findings on the history and physical examination may exist and may be indicative of the underlying disorder causing hypertension. For example, tachycardia with thyromegaly may suggest hyperthyroidism as a secondary cause of hypertension. A

drop in the blood pressure from the upper to lower extremities may indicate coarctation of the aorta. Truncal obesity, moon facies, acne, and hirsutism may all indicate Cushing's syndrome. Tachycardia along with pallor, flushing, and diaphoresis may suggest pheochromocytoma. A malar rash in addition to joint swelling suggests systemic lupus erythematosus. Café-au-lait spots are found with neurofibromatosis. A bruit detected in the epigastric or flank area may indicate renal artery stenosis. An abdominal mass may be found with

polycystic kidney disease, Wilms' tumor, or neuroblastoma. Ambiguous genitalia or virilization should make one think of adrenal hyperplasia.

Signs and symptoms of a hypertensive emergency vary considerably. Clinical manifestations generally reflect the end-organs damaged. The most commonly affected organs include the eyes, the central nervous system, the heart, and the kidneys.⁹ In one study of children with hypertensive emergencies, the most common presenting complications

included hypertensive retinopathy, hypertensive encephalopathy, convulsions, left ventricular hypertrophy, facial palsy, visual symptoms, and hemiplegia.¹⁰

Hypertensive encephalopathy describes the transient cerebral dysfunction that ensues when blood pressure rapidly increases.¹¹ It is characterized by the triad of severe hypertension, altered mental status, and papilledema.¹² Headache, visual disorders, and seizures may occur. Hypertensive encephalopathy is more likely to occur in individuals with

previously normal blood pressures who suffer rapid onset of severe hypertension, such as children with acute glomerulonephritis or pregnant adolescents with preeclampsia or eclampsia.¹²

Congestive heart failure as the initial complication of a hypertensive emergency may have relatively nonspecific signs and symptoms depending on the age of the child. Common symptoms in infants include prolonged feeding times, poor feeding, excessive sweating, and increased respiratory rate and effort.^{13,14} The infant may also be described as fussy or irritable. Physical examination findings may include pallor, tachycardia, tachypnea, diaphoresis, hepatomegaly, and an S₃ gallop rhythm. Rales are not always heard on auscultation. Peripheral edema is uncommon in infants. Older children may present with poor exercise tolerance, fatigue, poor appetite, growth failure, and increased respiratory rate and effort.¹⁵ Signs of congestive heart failure in older children include tachycardia, tachypnea, rales, hepatomegaly, jugular venous distention, and peripheral edema.

Children with acute renal failure often have decreased urine output. There may also be a history of hematuria or edema. If there is significant solute retention, signs and symptoms of uremia may be present, such as vomiting, fetid odor, pruritus, fatigue, psychiatric disturbances, seizures, and coma.

Diagnostic Tests

The diagnostic evaluation of a child with a hypertensive crisis to some extent will be dictated by the presenting signs and symptoms. However, certain studies should be obtained in all cases of suspected hypertensive emergency. An electrocardiogram is helpful in detecting hyperkalemia, dysrhythmias,

and left ventricular hypertrophy. An echocardiogram is the recommended study to evaluate for left ventricular hypertrophy in hypertensive children,² but is generally not necessary in the initial ED evaluation of the patient. A complete blood count should be obtained in all suspected cases. Findings may include evidence of a microangiopathic hemolytic anemia, with schistocytes and other fragmented erythrocyte forms found on the peripheral smear. If the child has a history of chronic hypertension, an anemia consistent with chronic renal insufficiency may be present. A basic chemistry profile including electrolytes, blood urea nitrogen, creatinine, glucose, and calcium is mandatory. It is important to note that the blood urea nitrogen and creatinine levels may not reflect mild to moderate degrees of renal damage.¹⁶ Specifically, creatinine does not generally increase until the glomerular filtration rate has reached approximately 30% of the baseline value.¹⁶ A urinalysis is always indicated, and may show hyaline and granular casts, red cell casts, trace proteinuria, and microalbuminuria. Urine should also be sent for culture to evaluate for evidence of chronic infection. A urine drug screen may be useful in some instances. Other laboratory studies that may help identify secondary causes of hypertension include plasma and urine catecholamine studies, a plasma renin determination, thyroid function studies, or serum cortisol levels.

Radiologic studies in the ED should include a chest radiograph. A computed tomography (CT) scan of the head is indicated if there are any neurologic deficits, seizures, or change in mental status. If coarctation of the aorta or aortic dissection is suspected, a spiral CT scan of the chest or transesophageal echocardiogram is indicated. A renal ultrasound is helpful to identify congenital renal anomalies or scarring,

but is not needed in the ED in most cases. Renovascular imaging with techniques such as magnetic resonance angiography, intra-arterial angiography, digital subtraction angiography, or scintigraphy is helpful in identifying possible renovascular lesions.

Important Clinical Features and Considerations

Proper measurement of blood pressure is important in order to avoid incorrectly high or low results. Accurate measurement of a child's blood pressure requires an appropriately sized cuff for the upper arm. The cuff should have an inflatable bladder width that is at least 40% of the arm circumference at a point midway between the olecranon and the acromion.² The bladder length of the cuff should cover 80% to 100% of the circumference of the arm.² Confirmation of an elevated blood pressure in a child requires measurement of the blood pressure with a standard clinical sphygmomanometer, and a stethoscope placed over the brachial artery.² Noninvasive oscillometric (automated) blood pressure measurements are as accurate as auscultatory measurements with less interobserver variability in children.¹⁷ However, SBP can average as much as 10 mm Hg above that obtained by auscultation, while DBP measurements are 5 mm Hg higher in children.¹⁸ For this reason, standard blood pressure tables that define normal values for children may not apply to blood pressure measurements obtained by oscillometric methods.¹⁸

Management

Management of hypertensive emergencies in children requires prompt recognition and appropriate management to prevent further complications. Initial efforts should focus on the airway, breathing, and circulation as in other emergent situations. Vascular access should be obtained and the patient should be placed on continuous cardiac monitoring with frequent blood pressure measurements. The blood pressure and neurologic status of the patient must be monitored carefully and frequently throughout the duration of therapy. An arterial line may be indicated in children on certain potent intravenous antihypertensives requiring frequent monitoring and titration.

It is important to realize that the goal of treatment is not to rapidly reduce the blood pressure to a “normal” level. Such actions can result in hypoperfusion of end organs and subsequent renal failure, blindness, and permanent neurologic deficits.^{10,19,20} The presumed mechanism of action for these complications is a loss of vascular auto-regulation secondary to severe hypertension.⁶ Vessels are unable to accommodate rapid reductions in blood pressure, and end-organ perfusion is compromised.

To avoid complications, blood pressure should be gradually reduced in a controlled manner using an intravenous infusion of an antihypertensive medication under carefully monitored conditions. The goal is to reduce the mean arterial pressure (MAP) by less than 25% over the first 2 to 8 hours and gradually normalize the blood pressure over the next 24 to 48 hours.^{2,5} There are several available agents, and choice of a specific agent depends on the clinical presentation and current medical condition of the patient (Table 65–4).

Sodium Nitroprusside

Sodium nitroprusside is a rapidly acting parenteral agent with proven efficacy in children.^{10,21} It is contraindicated in pregnancy and should be used only with caution in patients with renal disorders. Nitroprusside is metabolized to nitric oxide, which causes both arterial and venous dilation. This effect is immediate and results in a decrease in both preload and afterload. This decrease in systemic vascular resistance generally results in a reflex tachycardia. Control of tachycardia with a β -blocker (e.g., esmolol) may be required in specific aortic hypertensive emergencies (e.g., dissection). Sodium nitroprusside has a very short half-life, and blood pressure will return to previous levels within 30 to 60 seconds of discontinuing the infusion.^{3,6}

The recommended dose range for nitroprusside is 0.5 to 10 mcg/kg per minute.² Nitroprusside is started at the lowest dose (0.5 mcg/kg per minute) and titrated to achieve the desired blood pressure.

A significant concern with the use of nitroprusside is the associated potential toxicity of its metabolites. Nitroprusside is initially metabolized to cyanide, which is then metabolized in the liver to thiocyanate, and finally cleared by the kidneys.²² Hepatic or renal impairment, or long-term infusions of nitroprusside, may lead to accumulation of these toxic

Table 65–4 Antihypertensive Medications for Use in Hypertensive Emergencies in Pediatric Patients

Medication	Drug Class	Dose	Onset of Action	Duration of Action
Sodium nitroprusside	Vasodilator	0.5–10 mcg/kg/min IV infusion	Immediate	30–60 sec
Esmolol	β -blocker	Initial loading dose of 100–500 mcg/kg over 1 min, then 25–200 mcg/kg/min IV infusion	Immediate	9–30 min
Nicardipine	Calcium channel blocker	0.5–3 mcg/kg/min IV infusion	<1 min	30–60 min
Labetalol	α - and β -blocker	0.2–1.5 mg/kg/hr IV infusion, or 0.2–1 mg/kg IV bolus (max. 20 mg single dose)	2–4 min	Up to 4 hr
Fenoldopam	Dopamine receptor agonist	0.2–2 mcg/kg/min IV infusion	5–15 min	8–10 min
Enalaprilat	Angiotensin-converting enzyme inhibitor	5–10 mcg/kg IV bolus (max. 1.25 mg/dose)	Up to 60 min	4–6 hr
Phentolamine	Competitive α -adrenergic blocker	0.05–0.1 mg/kg/dose (max. 5 mg/dose)	Immediate	30–60 min

metabolites. Signs of cyanide toxicity include an odor of bitter almonds, tachypnea, mydriasis, cardiac dysrhythmias, hypotension, seizures, apnea, and coma. An elevated serum lactic acid level and elevated anion gap metabolic acidosis are present. Signs and symptoms of thiocyanate toxicity include tinnitus, blurred vision, nausea, altered mental status, seizures, and coma.^{5,23}

Nicardipine

Nicardipine is a dihydropyridine calcium channel blocker that reduces blood pressure and peripheral vascular resistance by selectively dilating peripheral arteries. Multiple studies and case reports have shown nicardipine to be safe and effective in a variety of patients, including neonates, children with postoperative hypertension, and children with hypertensive crises.²⁴⁻³¹ It has also been used effectively in children with renal disease.²⁴ The onset of action is 1 to 2 minutes and the half-life is approximately 40 minutes.^{5,6} Nicardipine is metabolized in the liver.

Nicardipine can be started at a dose of 0.5 to 1 mcg/kg per minute and titrated to a maximum infusion rate of 3 mcg/kg per minute.²⁵⁻²⁸ Some studies have shown it to be safe at doses as high as 5 mcg/kg per minute.^{24,29,31}

Nicardipine can be given through a central venous or peripheral intravenous catheter, although superficial thrombophlebitis may occur following infusion through peripheral intravenous lines.^{24,25} Other side effects of intravenous nicardipine include tachycardia, palpitations, and flushing.^{27,29} Nicardipine is not recommended in the presence of space-occupying intracranial lesions due to the vasodilatory effects, which can increase intracranial pressure.³²

Esmolol

Esmolol is an easily titratable, ultra-short-acting cardioselective β -blocking agent given as an intravenous infusion. It has an elimination half-life of approximately 2 to 4 minutes in children.³³ Esmolol is metabolized by erythrocyte esterases to an inactive acid metabolite.^{34,35}

Esmolol is first given as a loading dose of 100 to 500 mcg/kg over 1 minute.^{2,5,36} This is followed by a continuous infusion of 25 to 200 mcg/kg per minute.⁸ Although higher infusion doses have been reported (to a mean dose of 700 mcg/kg per minute),³⁷ they have only been used in a small number of patients, and the safety of these higher doses cannot be confirmed.

Esmolol should be used cautiously in patients with asthma, high-degree heart block, bradycardia, and decreased left ventricular function. Side effects include nausea, vomiting, bronchospasm, and bradycardia.

Labetalol

Labetalol is a nonselective β -blocker as well as an α_1 -adrenergic receptor blocker. It reduces the blood pressure by decreasing both systemic vascular resistance and cardiac output. A parenteral infusion produces effects within 5 to 10 minutes. It is metabolized entirely in the liver via glucuronide metabolites, thus clearance is not affected by renal failure.³⁸

Labetalol can be given in a continuous infusion or as intermittent bolus doses. The recommended dose for a continuous infusion ranges from 0.2 to 1.5 mg/kg per hour.^{5,6,38} Alternately, an initial intravenous bolus dose of 0.2 mg/kg

per dose can be given. If ineffective, this dose can be doubled every 15 to 30 minutes to a maximum of 1 mg/kg per dose, with a maximum single dose of 20 mg.³⁸

Due to its β -blocking effects, labetalol should not be used in patients with asthma or obstructive lung disease. It should also be avoided in patients with decreased ventricular function or high-degree heart block. Other reported side effects include fatigue, nausea, vomiting, itching, rash, hepatotoxicity, and possibly hyperkalemia in renal transplant patients.^{5,38} Hypoglycemia may also occur in association with labetalol.

Fenoldopam

Fenoldopam is a direct vasodilator that acts at dopamine₁ receptors in the kidneys, mesentery, coronary system, and skeletal muscle, resulting in a decrease of MAP.^{39,40} It increases renal plasma flow, glomerular filtration rate, and urinary sodium excretion.⁴¹ Fenoldopam is primarily cleared through hepatic conjugation. Therefore, the dose need not be adjusted if renal pathology is present.³⁹ Its efficacy in controlling blood pressure in adults with hypertensive crisis has been demonstrated in several studies.⁴²⁻⁴⁴ Its effects have been compared to sodium nitroprusside without adverse renal effects, cyanide toxicity, or light sensitivity.⁴⁵ Infusion rates for pediatric patients range from 0.2 to 2 mcg/kg per minute.^{39,42} Side effects of fenoldopam include tachycardia, headache, dizziness, and skin flushing.^{39,40} Increased intraocular pressure has been reported.⁴⁶ Although fenoldopam appears to be safe in pediatric patients, experience is limited in this population. Its use should be restricted primarily to patients requiring potent titratable intravenous agents who have contraindications to the use of sodium nitroprusside.

Enalaprilat

Enalaprilat is an intravenous angiotensin-converting enzyme inhibitor. The recommended dose is 5 to 10 mcg/kg to a maximum of 1.25 mg per dose, given as an intravenous bolus every 8 to 24 hours as needed. It has been used safely for blood pressure control in pediatric patients.^{47,48} However, the effects can be variable, and individuals most likely to respond are those with high renin levels, renal artery stenosis, or a mass lesion of the kidney. In addition, enalaprilat may cause significant hypotension in volume-contracted patients, or may cause acute renal failure in patients with bilateral renal artery stenosis. Due to these potential side effects, the inability to titrate, and the potential for a delayed onset of action (up to 60 minutes), other medications are preferable to enalaprilat in the setting of a hypertensive emergency.

Phentolamine

Phentolamine is a competitive α -adrenergic blocking agent that has direct relaxant effects on vascular smooth muscle. It is only indicated in the specific setting of acute hypertensive crises secondary to excess circulating catecholamines from a pheochromocytoma, or reactions involving a monoamine oxidase inhibitor. The dose is 0.05 to 0.1 mg/kg intravenously up to a maximum of 5 mg per dose every 1 to 4 hours as indicated. Phentolamine should be used with caution if cerebral ischemia, renal impairment, arrhythmias, or significant cardiac disease is present. Adverse reactions include tachycardia, dysrhythmias, and hypotension.

Other Medications

Diazoxide and hydralazine have been used to treat hypertensive emergencies as bolus intravenous injections. However, bolus injection of these drugs has been reported to result in abrupt hypotension and irreversible neurologic damage.¹⁰ Multiple other intravenous medications that are easily titrated and more appropriate for treating most hypertensive emergencies are available. Hydralazine is still recommended for treating hypertension in patients with preeclampsia or eclampsia. Magnesium is used for seizure prophylaxis and treatment of seizures associated with eclampsia, but only temporarily decreases blood pressure during bolus injection. The dose of hydralazine for the treatment of hypertension associated with preeclampsia or eclampsia is 5 mg intravenously as an initial dose. This dose may be repeated every 30 minutes as needed to a maximum of 20 mg every 4 to 6 hours.

Nifedipine is a calcium channel blocker that can be administered orally or sublingually. This agent is not approved by the Food and Drug Administration for use in children, although many pediatric nephrologists use nifedipine routinely for severe hypertension.⁴⁹⁻⁵¹ In severe pediatric hypertension, retrospective studies show that up to 10% of patients develop hypoxia and 4% develop neurologic events, including stroke, seizures, and altered consciousness, following use of this agent.⁵¹ Moreover, dosing errors can easily occur since 10-mg capsules (29 mg/ml) and 20-mg capsules (44 mg/ml) require puncture and measurement of minute amounts to ensure administration of 0.25 to 0.5 mg/kg orally or sublingually.⁴⁹ The response to typical dosing is erratic, with an SBP drop of up to 63% and a DBP drop of up to 89% noted in some series.⁴⁹⁻⁵¹ Finally, management of hypertensive emergencies requires use of short-acting, easily titratable, reversible agents with predictable onset and peak effects, none of which is a feature of orally or sublingually administered nifedipine.

Summary

The goal of therapy for hypertensive emergencies is to reduce the MAP by less than 25% over the first 2 to 8 hours. Rapid reduction of the blood pressure can lead to cerebral hypoperfusion and neurologic complications. While multiple medications are available for treating hypertensive crises, other therapeutic interventions should be used to address specific end-organ damage. For instance, furosemide will improve pulmonary mechanics in patients with pulmonary edema, dialysis may be required for acute renal failure, magnesium will prevent seizures in preeclampsia, and pain management may diminish the requirement for antihypertensives in patients with severe pain. All children diagnosed with a hypertensive emergency should be admitted to a pediatric intensive care unit (PICU). If one is not available in the hospital in which the child is initially evaluated, the patient should be transferred to the nearest available hospital with a PICU after appropriate stabilization has been completed.

Chapter 66

Postsurgical Cardiac Conditions and Transplantation

Grace J. Kim, MD and Richard E. Chinnock, MD

Key Points

The typical presenting symptoms of congestive heart failure in children are dyspnea, tachypnea, tachycardia, sweating with feeding, and a palpable, enlarged liver edge on physical examination. Peripheral edema and rales are usually absent.

For children with intrathoracic cardiovascular shunts, dehydration can rapidly become life threatening as the shunt may begin to clot and fail.

Cardiac allograft vasculopathy is a leading cause of death in patients greater than 3 years posttransplantation.

Thrombolytic therapy and acute percutaneous angioplasty are not indicated for heart transplant recipients who are having acute myocardial infarctions.

dependent on the abnormal heart lesions and their hemodynamic effects on the patient. Treatments can vary from expectant waiting for trivial lesions to maintenance of relatively normal hemodynamics with medication, to palliative or definitive corrective cardiac surgery, including heart transplantation. When evaluating patients with a history of cardiac surgery, asking about each patient's baseline status (energy, oxygenation, feeding, weight) is imperative. Although emergency physicians do not need to know all possible complications from cardiac surgery and transplantation, knowledge about common and important postsurgical complications can aid in expediting the emergency department care of these patients (Table 66–1).

Clinical Presentation

Congestive Heart Failure

The term *congestive heart failure* (CHF) implies a physiologic condition in which there is decreased perfusion so that the blood flow is unable to meet the metabolic demands of the body. In infants, the signs and symptoms are nonspecific and include poor feeding, tachypnea, abnormal respiratory pattern, diastolic filling sound, and hepatomegaly. With increasing severity, hepatomegaly is more pronounced and perfusion decreases. In contrast to adults, children are less likely to have ventricular dysfunction as the pathophysiology of heart failure. Patients are more likely to be symptomatic on the basis of pulmonary congestion and volume overload resulting from a left-to-right cardiac shunt.³ However, the view of heart failure as purely a hemodynamic disorder is incorrect. There is a body of evidence suggesting neurohormonal mechanisms regulate CHF. Brain natriuretic peptide hormone (BNP) mediates arterial and venous vasodilation in response to ventricular wall tension and left ventricular filling pressures and is secreted by the ventricular myocytes. In children with CHF, the BNP level is elevated and correlates with the ejection fraction of the failing heart. Although studies are limited, measurement of BNP appears to be useful for diagnosing CHF in infants and children.⁴

With the chronic abnormal hemodynamic state, the renin-angiotensin system is activated and catecholamine levels are elevated.⁵ Traditional treatment of CHF in adults consists of furosemide and digoxin. Conflicting evidence suggests that

Introduction and Background

Since the mid-20th century, children with complicated heart conditions who would have died in the past are now living with the use of life-saving medications and with the advent of multiple palliative and definitive surgeries, including heart transplantation. Because of the increasing survival of these patients, all emergency physicians need to be familiar with these conditions.

Recognition and Approach

It is estimated that 1% of live-born infants have isolated congenital heart disease (CHD). The incidence increases if the heart defect is a characteristic of a syndrome or is associated with chromosomal abnormality.¹ Since most data are usually collected by a tertiary cardiology center, the reported incidence varies depending on the study methods. The incidence is 0.75% for all forms of CHD and 0.2% for moderate to severe CHD.² Care of infants and children with CHD is

Table 66–1 Specific Defect Repairs and Associated Complications

Disorder	Repair	Selected Complications
Atrial septal defect (ASD)	Patching or suturing ASD	Obstructed vena cava or pulmonary vein leading to pulmonary edema/hepatic congestion, atrial arrhythmias (especially atrial fibrillation/flutter)
Ventricular septal defect (VSD)	Patching or suturing VSD	Right bundle branch block
Atrioventricular (AV) septal (canal) defects	Multiple depending upon defects	Heart block, atrial arrhythmias, heart failure, residual VSD, AV valvular regurgitation, pulmonary hypertension
Cyanotic lesion (with ↓ pulmonary flow) temporizing for tetralogy of Fallot, tricuspid or pulmonary atresia	<i>Blalock Taussig (B-T) shunt</i> connecting subclavian artery and pulmonary artery (PA) <i>Potts and Watterson anastomosis</i> —aorta to PA	If shunt is too small, residual cyanosis may be present; if shunt is too large, pulmonary edema may result (up to 28% of B-T shunts) Thrombosis of shunt due to dehydration (especially with respiratory syncytial virus or rotavirus infection) with ↑ cyanosis Aneurysm of shunt
Left-to-right shunts (ASD, VSD, AV canal)	Pulmonary band to prevent pulmonary hypertension	Branch pulmonary artery stenosis or impingement with hypoxia Coronary artery compression, band loosening with CHF development
Tetralogy of Fallot	Patching VSD plus surgery to decrease pulmonary outflow tract obstruction (e.g., infundibulotomy)	Bundle of His injury with residual right bundle branch, bifascicular or complete AV block, sudden death, congestive heart failure, right ventricular dysfunction, pulmonary hypertension, pulmonary regurgitation
Coarctation of aorta	Resection with anastomosis, subclavian flap aortoplasty or synthetic aortoplasty	Acute postoperative hypertension, restenosis (up to 60% with direct anastomosis), sudden death from arrhythmias, left ventricular hypertrophy on electrocardiogram
Transposition of the great arteries (TGA)	<i>Mustard and Senning operations</i> —baffle is placed across atria to redirect flow into correct ventricle	Syncope, atrial/junctional arrhythmias (sudden death), thrombosis of pulmonary/systemic flow with superior/inferior vena cava syndrome, ascites, protein-losing enteropathy, and edema
TGA	<i>Arterial switch</i> —aorta and coronary arteries are switched to the left ventricle (LV) and the PA is switched to the right ventricle (RV)	Sudden death, pulmonary artery stenosis, left ventricular failure, inferior or superior vena cava thrombosis (syndrome), coronary artery stenosis and myocardial infarction, stenosis of anastomoses (PA to RV and aorta to LV)
TGA—if complexed with subpulmonary stenosis with VSD	<i>Rastelli procedure</i> —patch to shunt blood from LV across VSD and out aorta; ligate proximal PA with conduit from RV to PA	Right ventricular hypertension, ventricular arrhythmias and cardiac conduction abnormalities
Single-ventricle physiology (e.g., severe Ebstein's anomaly, hypoplastic left heart syndrome)	<i>Fontan procedure</i> —bypass RV to provide pulmonary blood flow (e.g., superior vena cava to right PA + inferior vena cava to RA, then into left PA)	Sudden death, thromboembolism, thrombosis, anastomotic stenosis, fluid retention, atrial arrhythmias, pulmonary effusions, pericardial effusions, protein-losing enteropathy, peripheral edema
Hypoplastic left heart syndrome (Tricuspid atresia)	1. <i>Norwood procedure</i> —create neo-aorta: disconnect branch pulmonary artery stenosis and perform B-T shunt; main PA used to construct aortic arch 2. <i>Glenn (hemi-Fontan) procedure</i> —connect superior vena cava to PA 3. (at 18 mo) Complete Fontan procedure so systemic venous blood drains directly to pulmonary system	See Fontan procedure complications above; increased cyanosis due to venovenous collaterals

digoxin is beneficial in some children with CHF and potentially detrimental in others depending upon baseline systemic and pulmonary resistance.^{6–8} In children with chronic CHF, β -blockers (e.g., propranolol and carvedilol) may improve symptoms.^{9–12}

Cardiac Shunt Thrombosis

The *Blalock-Taussig (B-T) shunt* is one of the most common pulmonary-to-systemic shunt procedures performed in children with cyanotic heart disease as a palliative therapy before a definitive correction is performed. The B-T shunt consists of an anastomosis of the subclavian artery to the ipsilateral pulmonary artery (Fig. 66–1). The classic B-T shunt sacrificed the subclavian artery for the procedure. The modified B-T utilizes a Gore-Tex conduit between the subclavian and

pulmonary artery. This procedure is performed in patients with tetralogy of Fallot (TOF), tricuspid atresia, pulmonary atresia, and right ventricular hypoplasia.^{13,14} Although the B-T shunt is generally well tolerated, it is not without complications. The presentation of B-T shunt complications is due to too much or too little flow to the pulmonary vasculature and results in a worsening of the patient's baseline oxygenation. Excessive pulmonary blood flow through the shunt is the most common complication, and causes pulmonary edema and liver congestion, while too little flow through the shunt will result in decreased pulmonary blood flow.¹⁴ Dehydration has been implicated as a probable cause for development of thrombosis in patients with synthetic conduits. Patients with inborn clotting disorders are also at increased risk for shunt thrombosis.^{15,16} Another complication, albeit uncommon, is

pseudoaneurysm of the shunt. Patients present with cough, fever, and cyanosis, with chest radiographs revealing right upper lobe consolidation (“shadowing”).¹⁷⁻¹⁹ Diagnosis of shunt occlusion can be made by transthoracic echocardiography, transesophageal echocardiography, and angiogram.

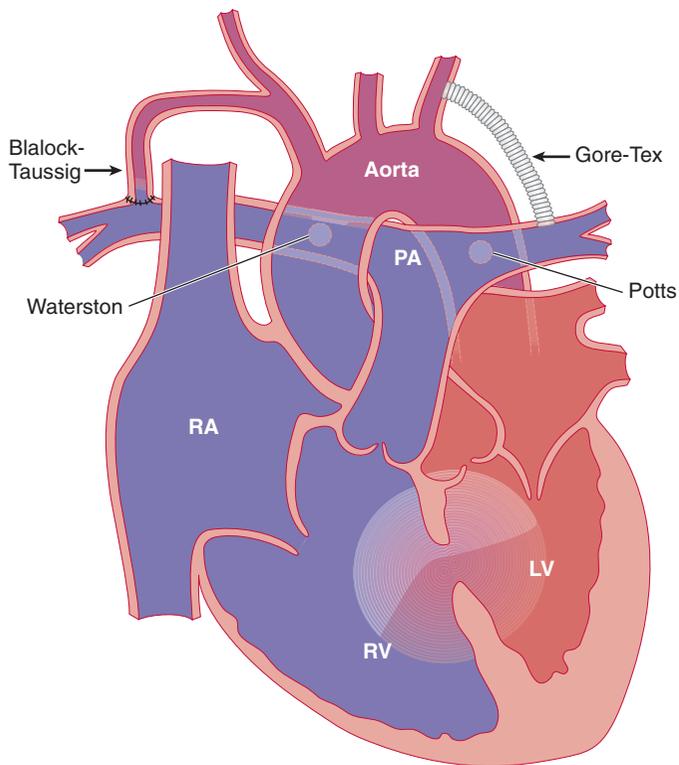

FIGURE 66-1. Pulmonary-to-systemic shunts with the classic and current Blalock-Taussig shunt. (From Park M: *Pediatric Cardiology for Practitioners*, 4th ed. St. Louis: Mosby, 2002.)

A *Fontan procedure* is performed in patients who have a single functional ventricle, such as those with tricuspid atresia, hypoplastic left heart syndrome, and pulmonary atresia with intact ventricular septum. The Fontan and its modification provides an atriopulmonary or cavopulmonary anastomosis so the systemic venous return can reach the pulmonary circulation, bypassing the ventricle²⁰ (Fig. 66-2). The complications of the Fontan procedure are thrombosis and thromboembolism (i.e., cerebrovascular accidents, systemic venous obstructive symptoms such as superior vena cava syndrome, pulmonary embolism, and emboli to extremities),²¹⁻²³ especially in the face of dehydration. Arrhythmias also may lead to thrombus formation.²¹ Hepatic congestion resulting in abnormalities in prothrombin time and galactose elimination are also noted following the Fontan procedure.²⁴ Protein-losing enteropathy occurs, possibly due to the chronically elevated systemic venous pressure. Infants and children present with peripheral edema and ascites, hypoproteinemia, lymphocytopenia, hypocalcemia, and low immunoglobulin concentrations.^{25,26}

Post-pericardiotomy Syndrome

Pericardial effusions develop in 23% to 53% of patients who undergo pericardiotomy, with 23% to 45% of these patients developing post-pericardiotomy syndrome (PPS).^{27,28} This disorder occurs due to an immune-mediated response to pericardial or direct myocardial injury.²⁹ PPS syndrome consists of fever, irritability, and poor feeding. The cardiac examination can reveal a friction rub and hepatomegaly. Other findings include chest pain, vomiting, and signs of cardiac tamponade with tachypnea, tachycardia, and hypotension.^{28,30} Chest radiographs may reveal an enlarged cardiac shadow, but the ultimate diagnosis is made by an echocardiogram that shows a pericardial effusion.^{27,28,30} PPS is typically a self-limiting condition and can be managed

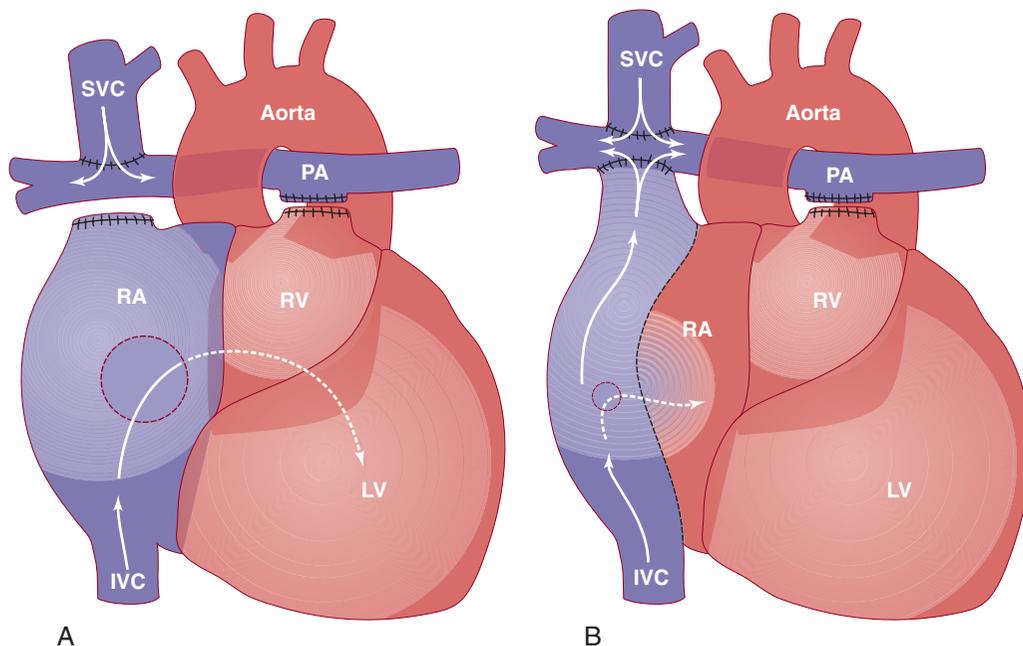

FIGURE 66-2. Modified Fontan operation. **A**, Bidirectional Glenn operation or superior vena cava (SVC)-to-right pulmonary artery anastomosis. **B**, Cavocaval baffle-to-pulmonary artery (PA) connection, with or without fenestration. (See text for description of these procedures.) Abbreviations: IVC, inferior vena cava; LV, left ventricle; RA, right atrium; RV, right ventricle.

medically with fluid restriction, diuretics (e.g., furosemide 1 mg/kg per dose), and nonsteroidal anti-inflammatory medications or glucocorticoids for severe or recurrent pericardial effusion. Glucocorticoids may contribute to faster resolution of symptoms but not to earlier hospital discharge. The recommended dose of prednisone is 2 mg/kg per day tapered over 14 days.³¹ Aspirin has been used widely but has not been proven effective.²⁷ Occasionally, this condition will progress to cardiac tamponade. If this complication occurs, pericardiocentesis in the emergency department will be required.³²

Viral Infections

Respiratory syncytial virus (RSV) infections are an important cause of morbidity in infants with congenital heart disease, postsurgical cardiac disorders, and cardiac transplants. Risk factors for severe disease include young age of patient, history of prematurity, chronic lung disease, CHD, and metabolic disorders.³³ High-risk patients have increased incidence of arrhythmias, hypotension or shock, and respiratory failure when infected with RSV.³⁴ Therefore, patients with risk factors for severe disease who have pneumonia, hypoxia, respiratory distress, or tachypnea will require admission. RSV testing can be obtained by any of the commercially available antigen detection kits, allowing for rapid diagnosis.³⁵ Multiple studies have evaluated the use of ribavirin in high-risk patients. Thus far, there is no significant difference in patients treated with ribavirin. Currently, the American Academy of Pediatrics states that ribavirin “may be considered in patients at high risk for complicated disease.”³⁶ For heart transplantation patients, high-risk factors for severe disease with RSV include age less than 1 year, increased immunosuppressive therapy (i.e., shortly after transplantation or recent allograft failure), or underlying lung disease. In patients with isolated upper respiratory infection who have no risk factors, only supportive care is recommended. If the posttransplantation patient has upper respiratory infection with risk factors or lower respiratory illness, treatment options to consider include aerosolized ribavirin in conjunction with RSV intravenous immune globulin (*Respi-Gam*) or palivizumab (*Synagis*).³⁷

Influenza A and B virus infection in the heart transplantation patient should prompt treatment with zanamivir or oseltamivir. Amantadine and rimantadine are not currently recommended due to high resistance. Patients who have respiratory symptoms such as tachypnea or hypoxia require admission. For severe lower respiratory illness, aerosolized ribavirin is an option.³⁸

Post-Cardiac Surgery Arrhythmias

Post-cardiac surgery arrhythmias occur in nearly half of all patients, especially in the early postoperative period spent in the intensive care unit.³⁹ Arrhythmias that occur weeks to years after cardiac surgery are attributed to multiple factors: scarring of the myocardium, the type of surgery performed, the natural history of the specific cardiac defect, history of preexisting arrhythmias, and the patient’s postoperative hemodynamic status (Table 66–2).⁴⁰ Intra-atrial reentrant tachycardias (IARTs) are seen in patients who have had atrial surgery and are thought to be due to the variable location of the suture lines. IATR is an atrial tachycardia (like atrial flutter) that uses a reentry circuit that does not involve the

Table 66–2 Post-Cardiac Surgery Arrhythmias

Arrhythmia	Heart Defect/Procedure
Sinus bradycardia	Transposition of the great arteries (TGA)
Right bundle branch block	Tetralogy of Fallot (TOF)
Complete heart block	TOF, TGA, aortic stenosis (AS)/Fontan procedure
Junctional rhythm	TGA/Fontan procedure
Atrial flutter	Atrial septal defect (ASD), TOF, TGA/Fontan procedure
IART	
Atrial fibrillation	
Supraventricular tachycardia	ASD, TGA/Fontan procedure
Ventricular tachycardia	TOF, AS/Fontan procedure, AV canal repair

Abbreviations: AV, atrioventricular; IART, intra-atrial reentrant tachycardia.

atrioventricular node.^{40–42} Isolated ventricular septal defect repair is not highly associated with arrhythmias, although reports of atrioventricular conduction defects exist. However, when the ventricular septal defect is a part of TOF, the incidence of arrhythmias is markedly increased. Surgery in patients with TOF ranges from palliation with B-T shunt to complete repair of the defects. Right bundle branch block, atrial fibrillation/flutter, ventricular arrhythmias, and complete heart block are associated with these repairs. The greatest risks for late morbidity and mortality are unpaced complete heart block and ventricular tachycardia.^{40,43} Correction of transposition of the great arteries has evolved over the years. The common surgeries, which involve an intra-atrial switch or intra-atrial baffle, are the Mustard and Senning repairs. Because of the extensive manipulation of the atrial muscle and sinus node, these repairs result in a high propensity for arrhythmias.⁴⁴ However, with arterial switch procedures, there is a significantly lowered incidence of arrhythmias, with 96% of patients manifesting sinus rhythm at follow-up to 8.5 years.⁴⁵ Catheter ablation therapy is used for patients who have life-threatening or drug-resistant arrhythmias, adverse drug reactions, or tachycardia-induced cardiomyopathy. It has also been performed on IART with good success.^{46,47} Implantable cardioverter-defibrillators can effectively manage dangerous, refractory ventricular arrhythmias in selected patients.⁴⁸ Management of dysrhythmias is discussed in Chapter 63 (Dysrhythmias). Importantly, adenosine should be avoided post-transplant as it can lead to permanent asystole.

Endocarditis

Endocarditis is a relatively uncommon disease that has high morbidity and mortality despite advances in antimicrobial therapies, diagnostic capabilities, and treatments. Patients at high risk for endocarditis include those with palliative shunts, conduit procedures, prosthetic valves, and indwelling catheters.⁴⁹ Those who are at moderate risk are patients with uncorrected ventricular septal defect, patent ductus arteriosus, primum atrial septal defect, coarctation of the aorta and bicuspid aortic valve, and mitral valve prolapse. Six months after successful surgical correction of congenital heart defects in the moderate-risk category, the patients are considered to have negligible risk for developing endocarditis, and do not need prophylactic antibiotics prior to invasive procedures.^{50,51} Patients with endocarditis present with indolent fevers lasting

from days to weeks. There are also nonspecific complaints of malaise, myalgia, arthralgia, weight loss, rigors, and diaphoresis. Development of CHF as a complication of endocarditis is a grave prognostic factor. It may develop acutely with valve perforation (aortic, mitral, or tricuspid), chordae rupture, valve obstruction from large vegetations, or development of intracardiac shunts from fistulous tracts or prosthetic dehiscence. It may also develop insidiously as a result of progressive worsening of the valvular insufficiency and resultant ventricular dysfunction.⁵² Occasionally, infants and children with endocarditis will present acutely with high fevers and rapid development of symptoms. Conditions that require cardiovascular surgical intervention include worsening CHF, valvular obstruction, perivalvular extension of infection, fungal endocarditis, and persistent bacteremia despite appropriate antibiotic therapy.⁴⁹ Antibiotics for endocarditis need to cover the gram-positive organisms that are the causative organisms. Antibiotic recommendations for native and prosthetic valve endocarditis are discussed in Chapter 64 (Pericarditis, Myocarditis, and Endocarditis). In general, antibiotic regimens for repaired cardiac defects should mirror these recommendations.

Heart Transplantation

In 2002, 359 pediatric patients received a heart transplant, with approximately 80 centers performing this procedure.⁵³ These patients are followed closely initially by the transplanting centers, then return home with scheduled follow-ups with decreasing frequency depending upon complications.

Posttransplantation Infection

Fever is a common reason for a heart transplantation patient to present to the emergency department. Infection following transplantation has three phases. During the first phase, in the first month after transplantation, the causes of infection are most commonly the underlying disease the recipient had prior to the transplantation, a contaminated allograft introducing infection, or the usual postoperative infections that can be found in all patients, although in an individual receiving a transplant, the episodes are accentuated.⁵⁴ Bacterial infections are the most common type of infection immediately posttransplantation, especially in infants younger than 6 months of age.⁵⁵ The majority of infections are in the blood and lungs.⁵⁴ The second phase is 1 to 6 months after transplantation. The major classes of infection are viral (cytomegalovirus [CMV], Epstein-Barr virus [EBV], hepatitis virus, and herpesvirus), and opportunistic infections such as *Listeria monocytogenes*, *Aspergillus fumigatus*, and *Pneumocystis jiroveci*. Greater than 6 months posttransplantation, the majority of patients who are stable in their maintenance immunosuppression are at the greatest risk from community-acquired viruses such as influenza virus, RSV, and parainfluenza virus.⁵⁴ Patients with CMV infection present with a “viral syndrome.” Patients may present with fever, malaise, hepatitis, pneumonitis, retinitis, or gastrointestinal disease. Leukopenia and thrombocytopenia may also be present. CMV infection is a risk factor for development of bacteremia or invasive fungal disease, and it has been implicated in posttransplantation lymphoproliferative disorder (PTLD) and cardiac allograft vasculopathy (CAV). Treatment is with ganciclovir 5 mg/kg per dose IV twice daily for 2 to 4 weeks.^{54,56} Patients with EBV infection can present similarly to those

with CMV infection. Primary EBV infection has been implicated in the development of PTLD.^{57,58} This is a lymphoproliferative disorder that ranges in severity from a relatively benign condition that improves with adjustment of immunosuppressive medication to lymphoma.⁵⁴

Acute Transplant Rejection

Acute transplant rejection occurs most frequently within the first year after heart transplantation. Presenting symptoms include poor feeding, irritability, low-grade fever, ileus, and dyspnea. Clinically, the patient may display tachycardia, tachypnea, hepatomegaly, gallop, or ventricular ectopy.⁵⁹ Thirty-eight percent of patients with heart transplants require therapy for arrhythmias. The most common arrhythmias are sinus bradycardia and atrial tachyarrhythmias.

The new onset of Wenckebach periodicity is associated with either rejection or coronary artery disease.⁶⁰ However, any new arrhythmia requires evaluation for rejection. Endomyocardial biopsy is the “gold standard” for diagnosing acute rejection.⁶¹ Because of its invasiveness, cost, and labor intensity, other less invasive methods for diagnosing rejection have been explored. In cardiac transplantation patients, initially the belief was that a decrease in the electrocardiogram (ECG) QRS voltages could be related to acute rejection.⁶² Studies in animals and humans suggest that there is great variability in voltage even in normal hearts, and that the ECG finding of decreasing voltage is not specific for rejection.^{63,64} However, ECG abnormalities that have been known to precede onset of cardiac failure include a decrease in voltage, axis deviation, arrhythmias, and conduction abnormalities.⁶⁵ Echocardiography of patients with acute rejection may show increased ventricular mass, decreased ventricular volume, or ventricular dysfunction. These findings do not correlate well with endomyocardial biopsies; therefore, they cannot be used solely to predict rejection.^{66,67} However, the positive predictive value (of these tests) is increased when patients are evaluated for change from baseline.⁶⁸ The BNP level is elevated in adult patients during acute cardiac allograft rejection,⁶⁹ but studies in children have not been definitive. Although BNP is elevated during graft rejection, levels cannot be used to gauge the severity of the episode.⁷⁰⁻⁷² Objective evaluation of patients in the emergency department with suspected acute rejection may include the combination of BNP level, ECG, and echocardiogram, then admission for further evaluation and management.

Cardiac Allograft Vasculopathy

CAV is one of the major limitations to long-term graft survival. It is the leading single cause of death in patients greater than 3 years posttransplantation.⁵³ It is a progressive form of atherosclerosis that is unique to the transplantation patient. CAV is caused by both immunologic and nonimmunologic mechanisms. Immunologic mechanisms include frequent and late (>1 year posttransplantation) acute rejection episodes.⁷³ Nonimmunologic mechanisms are those relating to the transplant itself or the recipient (donor age, smoking, obesity, history of diabetes, hyperlipidemia, or hypertension) and to side effects from immune suppression, such as CMV infection, which may impair endothelial function⁷⁴; nephrotoxicity; and new-onset diabetes.⁵⁶ CAV is different from atherosclerosis in that the narrowing of the arteries caused by proliferation of the intima is concentric, and involves the

length of the coronary arteries. This process involves vessels of all sizes. Ischemia often involves very small, patchy areas of the myocardium. Therefore, treatment with angioplasty or bypass surgery will not be as successful as it is in conventional atherosclerotic heart disease.^{75,76} There is some evidence that myocardial infarction and ischemia are usually silent and devoid of chest pain due to de-innervation of the heart. However, some re-innervation may occur post-transplant. In fact, the first clinical manifestations of myocardial infarction may be congestive heart failure, ventricular arrhythmias, or sudden death.^{77,78} A small number of transplantation patients may require pacemakers for arrhythmias. These patients present with dizziness and syncope. If these symptoms are present, an evaluation for CAV is required.⁷⁹ CAV is diagnosed by coronary angiography; however, intravascular ultrasound is even more sensitive at detecting early stages of coronary endothelial dysfunction, which leads to CAV.⁸⁰ The only current treatment for CAV is a new heart transplant.⁵⁶ However, there is evidence of vasculopathy regression after introducing sirolimus to the immunosuppressive regimen.⁸¹ Further trials are needed to determine the efficacy of this agent.

Posttransplantation Lymphoproliferative Disorder

PTLD is a heterogeneous entity found more frequently in children than in adults.⁵⁷ It is due to an abnormal proliferation of lymphoid cells. Severity of the disease may range from local, isolated lymphadenopathy to lymphoma. Symptoms vary, depending on the location of the lesions, from cough, dyspnea, or respiratory difficulty, including upper airway obstruction, with lung nodules, to gastrointestinal symptoms that include diarrhea, bleeding, abdominal pain, or masses. Constitutional symptoms such as fever, fatigue, and weight loss are also common.⁸² There are multiple risk factors for developing PTLD, including recurrent rejection episodes and primary infection with EBV after transplantation.⁸³ Diagnosis is confirmed by histopathologic evaluation of the involved tissues. Treatment ranges from withdrawal of immunosuppressive therapy to chemotherapy. There is a report of complete resolution of PTLD in a child treated with rituximab (an anti-CD20 monoclonal antibody) along with reduced immunosuppression, and treatment for an active EBV hepatitis with ganciclovir.⁸⁴

Transplantation Medication Side Effects

Several important side effects are associated with medications used to treat post-cardiac transplantation patients.⁸⁵⁻⁹³ These effects are listed by the affected organ systems in Table 66-3.

Important Clinical Features and Considerations

Nonspecific symptoms of poor feeding, irritability, lethargy, and tachypnea are common in children with post-cardiac surgery conditions, including CHF and acute rejection in heart transplantation patients. Patients with congenital heart disease who present with complaints of chest pain, dizziness, or syncope should be evaluated for arrhythmias with an ECG or Holter monitoring.

Dehydration in patients with intrathoracic cardiovascular shunts can be life-threatening if thrombosis ensues with

Table 66-3

Side Effects of Medications Used to Treat Posttransplantation Patients

Medication	Side Effects
Glucocorticoids	<i>Neurologic:</i> steroid psychosis, memory or cognitive dysfunction <i>Ocular:</i> cataracts, glaucoma <i>Endocrine:</i> decreased growth hormone, hypogonadism, osteopenia, diabetes, mellitus, Cushing's syndrome <i>Cardiovascular:</i> hypertension, dyslipidemia
Cyclosporin A (CSA) Tacrolimus	<i>Renal:</i> nephrotoxicity <i>Neurologic:</i> seizure, tremors, paresthesias, peripheral neuropathies <i>Cardiovascular:</i> hypertension, hyperlipidemia <i>Hepatic:</i> hepatotoxicity (CSA) <i>Endocrine:</i> Glucose intolerance and diabetes mellitus (tacrolimus)
Mycophenolate mofetil (MMF)	<i>Gastrointestinal:</i> discomfort, diarrhea <i>Hematologic:</i> leukopenia

resulting shunt failure. Patients will present with worsening baseline oxygen saturation, tachypnea, and malaise.

Cardiac troponins are elevated in CAV; however, this test is less useful as a predictor of acute transplant rejection. Creatine kinase is not useful for detecting acute rejection.⁹²

Management

Chronic management of CHF may include furosemide, digoxin, angiotensin-converting enzyme inhibitors or β -blockers. However, acute management is supportive, with semi-upright positioning, supplemental oxygen, and furosemide 1 mg/kg per dose for pulmonary edema. Inotropic support with dopamine or dobutamine is administered for severe low-output states in CHF or cardiogenic shock.⁹³

Shunt thrombosis can be evaluated and diagnosed (with increasing sensitivity) by transthoracic echocardiography, transesophageal echocardiography, or angiography.²⁰ Initial therapy includes correction of dehydration with intravenous fluids. Treatment of the thrombus can be accomplished through administration of heparin, balloon angioplasty,⁹⁴ catheter-directed infusion of low-dose alteplase²³ or stent replacement. Because of the choices available for treatment, a cardiologist should be consulted prior to starting heparin therapy.

Acute rejection is treated with methylprednisolone at 20 mg/kg per dose twice daily for eight doses. This agent should be given in consultation with a transplant team.

Therapy for specific infections (e.g., PTLD; bacterial, viral, and parasitic infections) may be required following evaluation for fever or nonspecific complaints.

Summary

Survival of patients with complex congenital heart disease is markedly improved by better surgical techniques and heart transplantation. Evaluating patients with these disorders can be challenging due to their intricate underlying physiology, complex past medical history, and unique medical regimens. Recognizing the many disorders that can occur in these patients is difficult and requires knowledge of common and

important complications, awareness of the utility of various diagnostic adjuncts, and an understanding of unique medications. When there is uncertainty about the management of a patient, the patient's transplant coordinator or the on-call cardiologist should be contacted.

Chapter 67

Valvular Heart Disease

Mark S. McIntosh, MD, MPH and Nazeema Khan, MD

Key Points

Asymptomatic children with murmurs that are not clearly innocent require nonemergent consultation by a pediatric cardiologist who will guide further testing (i.e., echocardiography).

Symptomatic children with pathologic murmurs require management of acute symptoms and emergent consultation.

The need for endocarditis prophylaxis must be evaluated in all patients with suspected valvular heart disease.

The clinician should confirm that children with a history of rheumatic fever are on antibiotic prophylaxis.

Introduction and Background

Valvular cardiac lesions of congenital or acquired causes are classified as valvular stenosis or valvular regurgitation. Valvular stenosis is characterized by mild or moderate obstruction of blood flow. Complete obstruction is termed *atresia* and is usually part of a complex structural cardiac defect. Valvular regurgitation occurs when blood leaks across the pathologically affected valve from a high-pressure region to one of low pressure. Patients with valvular heart disease often present with major systemic symptom complexes, including congestive heart failure, chest pain, palpitations, syncope, and acute neurologic deficits. However, patients with endocarditis or rheumatic heart disease may present with a more obscure clinical syndrome not immediately recognized as being due to valvular heart disease.

Recognition and Approach

Up to 72% of children will have a murmur noted at some point during their childhood.¹ Most of these children have innocent or benign murmurs rather than murmurs caused by structural cardiac disease. A stepwise approach can be

used to assess, diagnose, and plan treatment for patients presenting to the emergency department with signs and symptoms that may be indicative of valvular heart disease. Following the history and physical examination, the severity of the patient's condition and the murmur's grade (Table 67-1) and characteristics will dictate the need for supplemental data obtained from an electrocardiogram (ECG) and chest radiograph. At this point, the clinician will have acquired sufficient information to decide if the patient's condition suggests structural heart disease or is more likely due to an innocent murmur. This conclusion will guide plans for treatment, consultation, and final disposition.

Innocent and Pathologic Murmurs

Distinguishing innocent murmurs from pathologic murmurs resulting from significant structural heart disease is important for children with murmurs newly diagnosed in the emergency department (Table 67-2).

A *prenatal history* suggestive of exposure to infections (e.g., maternal rubella in the first trimester), medications known to have teratogenic cardiac effects (e.g., anticonvulsants, amphetamines), or maternal conditions with higher incidence of congenital heart disease (e.g., diabetes, collagen vascular disease) may alert the clinician to consider a cardiac lesion. *Family histories* of congenital heart disease, rheumatic fever, sudden death, or inherited disease are important to identify. *Signs or symptoms* of reduced cardiac output and pulmonary edema suggest a pathologic origin of a heart murmur. Shortness of breath, failure to thrive, easy fatigability, syncope, neurologic deficits, and chest pain are alarming in the context of a newly identified murmur.² Furthermore, physical examination findings suggestive of valvular pathology include obvious syndromal or chromosomal abnormalities, tachypnea, tachycardia, hyperdynamic precordium, cyanosis, clubbing caused by hypoxia, abnormal pulses, and hepatomegaly. A thorough, step-by-step auscultation evaluating heart sounds and systolic and diastolic murmurs is critical for distinguishing the innocent from the pathologic murmur^{3,4} (Table 67-3). Murmur location is an important determinant of the specific cardiac lesion present (Fig. 67-1).

The heart sounds in innocent murmurs are normal. Any abnormality of the first or second heart sound (S_1/S_2), including quality, abnormal splitting, or extra heart sound (click), is indicative of pathology. Innocent murmurs are typically grade I or II in intensity but rarely grade III. Innocent

Table 67–1 Grading of Murmurs

Grade	Characteristics
I	Very soft murmur only heard with careful auscultation
II	Soft murmur that is readily evident
III	Moderately intense murmur that is not associated with a palpable precordial thrill (vibration)
IV	Loud murmur with an associated precordial thrill
V	Loud murmur heard with a stethoscope partially placed on chest and a palpable precordial thrill
VI	Loud murmur that is audible when the stethoscope is lifted off of the chest and a palpable precordial thrill

Table 67–2 Key Risk Factors for Pathologic Murmurs^{2,3}**Historical Facts****Prenatal**

Maternal health history during pregnancy
Maternal exposure to infections, medications, illicit drug/tobacco/alcohol use

Postnatal or Past/Immediate History

Delivery complications, birth weight
Inappropriate development
Reported history of murmur
Genetic or chromosomal disorders
Cyanosis
Change in feeding pattern/respiratory pattern
Exercise intolerance
Chest pain
Syncope
Palpitations
Neurologic deficits or congestive heart failure

Family History

Congenital heart disease
Rheumatic fever
Sudden death
Hereditary disease

Physical Examination Findings

General appearance (note dysmorphic facial features suggesting syndromal abnormalities)
Signs of malnutrition
Observation of cyanosis/pallor
Precordial activity (thrills)
Respiratory activity (rate/retractions)
Clubbing
Hepatomegaly
Abnormal blood pressure
Character of pulse: Narrow pulse pressure (aortic valve stenosis), wide pulse pressure (aortic regurgitation)
Auscultation: Heart rate and regularity, cardiac heart sounds, murmurs

murmurs are characterized as systolic, or occasionally as continuous (venous hum), but never as isolated diastolic (Fig. 67–2). Patients with innocent murmurs should have a normal history and physical examination and be free of symptoms or signs suggestive of congenital or acquired heart disease^{3,5,6} (Table 67–4).

Electrocardiograms and radiographs are insensitive and nonspecific and rarely enhance the diagnostic accuracy of the clinician who needs to distinguish between pathologic and innocent murmurs of asymptomatic children.^{7,8} However there are classic ECGs and chest radiography findings that enhance the diagnostic accuracy when heart lesions are

Table 67–3 Characteristics of Pathologic Murmurs^{3,4}

Symptomatic presentation, including exertional chest pain, syncope, shortness of breath
Abnormal pulses (diminished or bounding)
Pan-systolic murmur
Diastolic murmur
Systolic murmur that is grade III–VI, or midsystolic or holosystolic
Cyanosis
Abnormal heart sounds (e.g., early/midsystolic click)
Harsh, loud murmur \geq grade III or thrill
Increase in murmur with standing
Abnormal chest radiograph
Abnormal electrocardiogram

present.⁹ Therefore, an emergency department ECG and chest radiograph are warranted when the clinician continues to consider underlying cardiac pathology as the source of the murmur.

Echocardiography is the primary test used for the diagnosis of structural heart disease and is the modality of choice for evaluating heart murmurs of uncertain etiology. Cardiac pathology will not always be evident by clinical examination even to the pediatric cardiologist.¹⁰ If there is any diagnostic uncertainty in the evaluation of an asymptomatic murmur, then prompt referral should be arranged for pediatric cardiology consultation or performance and interpretation of an echocardiogram by a laboratory with expertise in pediatric heart disease. Cost analysis studies suggest that most cases of innocent murmurs will be diagnosed without echocardiography by the pediatric cardiologist, resulting in an overall cost savings.^{11,12} However, the higher sensitivity for pathology achieved with a strategy of echocardiography in all cases of suspected pathologic murmur warrants a low threshold for using this test, especially in patients with any concerning clinical features.¹³

Clinical Presentation (Table 67–5)

Obstructive Cardiac Lesions to Ventricular Outflow

Obstructive valvular lesions to ventricular outflow include aortic stenosis (AS) and pulmonary stenosis (PS). As the outflow tract pressure gradient across the stenotic valve increases and becomes hemodynamically significant, the respective ventricle undergoes severe concentric hypertrophy. Ultimately, progression of this process results in ventricular dilation and decreased stroke volume and cardiac output. The reduction in cardiac output results from a combination of obstruction and impaired function. These patients will present with a combination of compromised ventricular function and pulmonary venous or systemic vascular congestion.

Aortic Stenosis

AS accounts for 3% to 6% of all congenital heart defects. Up to 85% of these stenotic valves are bicuspid. The stenosis is valvular, supralvalvular, or subvalvular, depending on its position in relation to the aortic valve. Infants with severe aortic stenosis generally present within the first few weeks to months of life. With critical AS, systemic blood flow

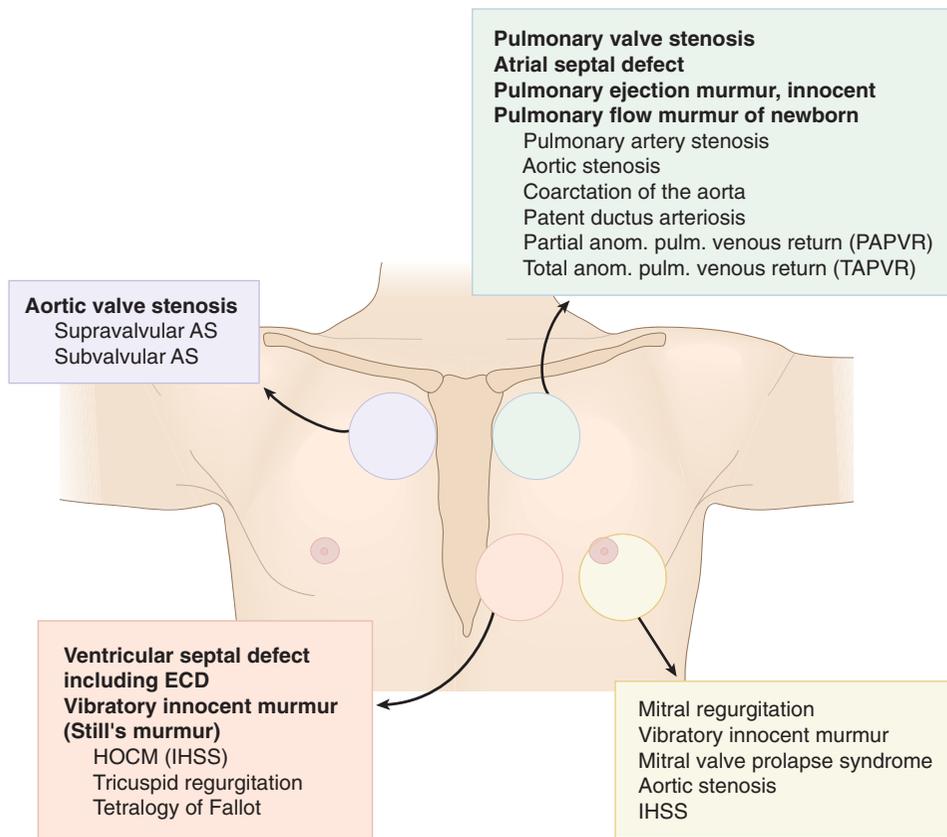

FIGURE 67-1 Diagram showing systolic murmurs audible at various locations. Less common conditions are shown in smaller type. Abbreviations: AS, aortic stenosis; ECD, endocardial cushion defect; HOCM, hypertrophic obstructive cardiomyopathy; IHSS, idiopathic hypertrophic subaortic stenosis. (From Park M: Basic tools in routine evaluation of cardiac patients: physical examination. *In* Pediatric Cardiology for Practitioners, 4th ed. St. Louis: Mosby, 2002, pp 19–23.)

Table 67-4 Pediatric Innocent Heart Murmurs ^{3,5,6}			
Innocent Heart Murmur	Description	Characteristics of Murmur	Child's Age at Diagnosis
Vibratory Still's murmur	Origin: pulmonary valves vibrate, resonance of flow across ventricular outflow tract and ascending aorta produces murmur	<i>Timing:</i> Systolic <i>Quality:</i> Vibratory, musical; low pitch <i>Location:</i> Left mid or lower sternal border	2–6 yr; can also hear as early as infancy and late as adolescence
Physiologic peripheral pulmonic stenosis murmur	Turbulent flow from main to branch pulmonary arteries Peripheral branch arteries are smaller and come off at sharp angles	<i>Timing:</i> Systolic <i>Quality:</i> Blowing, high pitch <i>Location:</i> Axillae, back, upper left sternal border	Birth–9 mo
Pulmonary flow murmur of newborn	Turbulent flow through relatively hypoplastic left and right pulmonary arteries at birth	<i>Timing:</i> Systolic <i>Quality:</i> Blowing, high pitch <i>Location:</i> Upper left sternal border, transmits to the left and right chest, axillae, and back	Neonates, especially low birth weight; disappears by 3–6 mo
Pulmonary flow murmur of childhood	Flow across pulmonary outflow tract	<i>Timing:</i> Systolic <i>Quality:</i> Blowing, high pitch <i>Location:</i> Upper left sternal border, transmits to chest, axillae, and back	8–14 yr
Supraclavicular murmur	Turbulent flow in the subclavian and carotid arteries	<i>Timing:</i> Systolic, very short and early <i>Quality:</i> Blowing, medium pitch <i>Location:</i> Over clavicle, neck and varies with extension of shoulders	Children, young adults
Venous hum	Turbulent flow from drainage of the internal jugular and subclavian veins into the intrathoracic veins	<i>Timing:</i> Continuous <i>Quality:</i> "hum" <i>Location:</i> Neck/clavicles; absent if supine, changes with rotation of neck	3–6 yr

Evaluation of Undiagnosed Cardiac Murmurs

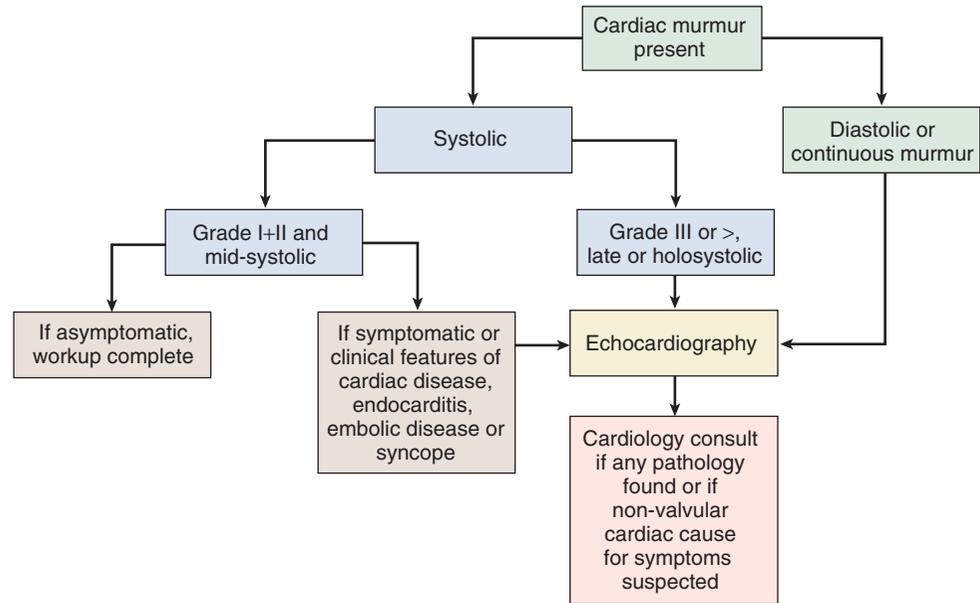

FIGURE 67-2 Evaluation of undiagnosed cardiac murmurs. (Adapted from Braunwald E, Perloff JK: Physical examination of the heart and circulation. In Zipes DP [ed]: Braunwald’s Heart Disease: A Textbook of Cardiovascular Medicine, 7th ed. Philadelphia: Elsevier, 2005, p 103.)

Table 67-5 Pathologic Murmurs ^{17-19,21-23,26}				
Valvular Lesion	Clinical Presentation	Physical Examination	Auscultation	ECG/CXR
Aortic stenosis	History of bicuspid valve <i>Infants:</i> CHF, shock <i>Older children:</i> Syncope, chest pain, sudden death, exercise intolerance	Acyanotic, pulmonary edema	Harsh, medium-pitched, crescendo-decrescendo systolic murmur; paradoxically split S ₂ , ejection click and S ₄ gallop	<i>ECG:</i> Left ventricular hypertrophy <i>CXR:</i> Dilated ascending aorta, cardiomegaly
Pulmonary stenosis	<i>Infants:</i> Cyanosis, poor feeding, tachypnea, cardiac shock <i>Children:</i> Exertional dyspnea, exercise intolerance, chest pain, right-sided heart failure	Cyanosis, tachypnea, dependent edema, and organomegaly (spleen, liver)	Harsh crescendo-decrescendo ejection systolic murmur heard best at the upper left sternal border, radiates to back or left infraclavicular area; ejection click, split S ₂	<i>ECG:</i> Right axis deviation, right ventricular hypertrophy <i>CXR:</i> cardiomegaly, prominence of the main and left pulmonary artery
Mitral stenosis	Dyspnea, rarely hemoptysis	Pulmonary edema	Low-pitched, rumbling, diastolic murmur over apex; opening snap	<i>ECG:</i> Left atrial enlargement, right ventricular hypertrophy <i>CXR:</i> Left atrial enlargement, prominent pulmonary vasculature, pulmonary congestion
Aortic regurgitation	Exercise intolerance, CHF, chest pain	Wide pulse pressure, bounding arterial pulses	Decrescendo mid-diastolic high-pitched murmur over the 3rd or 4th ICS; S ₁ diminished	<i>ECG:</i> Left ventricular hypertrophy in severe AR; PVCs <i>CXR:</i> Cardiomegaly, dilation of ascending aorta, pulmonary congestion
Mitral regurgitation	History of rheumatic fever	<i>Acute MR:</i> acute pulmonary edema and evidence of right-sided heart failure <i>Chronic MR:</i> minimal symptoms	High-pitched, blowing, pan-systolic murmur at the apex and radiating to left axilla; widely split S ₂	<i>ECG:</i> Left ventricular hypertrophy, left atrial enlargement <i>CXR:</i> Left ventricular hypertrophy, left atrial enlargement
Mitral valve prolapse	<i>Adolescents:</i> Palpitations, chest pain, syncope	Healthy appearing	Midsystolic click, late systolic murmur	<i>ECG:</i> Dysrhythmias—SVT, premature atrial or ventricular contractions

Abbreviations: AR, aortic regurgitation; CHF, congestive heart failure; CXR, chest radiography; ECG, electrocardiogram; ICS, intercostal space; MR, mitral regurgitation; PVCs, premature ventricular contractions; SVT, supraventricular tachycardia.

often depends on a left-to-right shunt across a patent foramen ovale and a right-to-left shunt across the patent ductus arteriosus.¹⁴ Infants with severe AS usually present with cardiomegaly, vascular congestion, or cardiogenic shock. The clinical picture may be difficult to distinguish from overwhelming sepsis with low cardiac output. Even asymptomatic infants with AS identified in the neonatal period may have rapid disease progression, which appears to occur independently of the severity of the initial obstruction.¹⁵ Children with mild to moderate AS are usually asymptomatic. However, valvular disease progression usually manifests with the unmasking or exacerbation of symptoms with exercise. Children with more severe AS present with exercise intolerance, chest pain, syncope, or even sudden death.¹⁶ Importantly, chest pain or syncope during exertion should always prompt consideration of AS or idiopathic hypertrophic subaortic stenosis (IHSS) in the differential diagnosis.

On physical examination, patients with valvular AS are acyanotic but may have signs of pulmonary edema. The murmur of AS is classically a harsh, medium-pitched, crescendo-decrescendo-shaped systolic murmur heard over the aortic valve area. Other heart sounds may include a diminished, paradoxically split S₂, an ejection click, and an S₄ gallop. The ECG can be normal or may reveal left ventricular hypertrophy. Chest radiography occasionally may show cardiomegaly, but the only abnormal finding may be dilation of the ascending aorta. As the child grows and cardiac output increases, the pressure gradient across the valve increases. This natural progression of disease eventually leads to ventricular dysfunction and congestive heart failure.^{17,18}

Supravalvular and subvalvular aortic stenosis are less prevalent. Patients with the idiopathic form of diffuse subaortic stenosis, also referred to as IHSS, will present with many symptoms similar to those with valvular aortic stenosis. Clinical and echocardiographic findings will distinguish these entities.

Pulmonary Stenosis

Lesions that cause PS also may be valvular, supravalvular, or subvalvular. Abnormalities of the pulmonary leaflets are the cause of valvular PS. Supravalvular PS is characterized by stenosis of the main pulmonary artery, while subvalvular PS involves the infundibulum and is often associated with tetralogy of Fallot. Infants with critical PS will depend on a patent ductus to provide pulmonary blood flow and an interatrial shunt to direct most of the systemic venous return. Clinically, during the postnatal period these infants will have varying degrees of cyanosis depending on the blood flow through the patent ductus and the interatrial shunt. They may have symptoms of poor feeding and tachypnea that can progress to cardiac shock as the ductus closes. Children with mild PS are generally asymptomatic, but as stenosis progresses, they may develop exertional dyspnea and increased exercise intolerance. Children with severe PS can have chest pain and heart failure. The harsh, medium-pitched, crescendo-decrescendo ejection-type systolic murmur of PS, best heard over the upper left sternal border, may be associated with an ejection click and split S₂. It radiates to the back or to the left infraclavicular area. The ECG may be normal in patients with mild PS, but with increased severity of stenosis, right axis deviation and right ventricular hypertrophy

develop. With progression of PS, chest radiography will reveal cardiomegaly and prominence of the main and left pulmonary artery due to post-stenotic dilation. On chest radiography, pulmonary vascular markings are normal or slightly diminished.^{18,19}

Obstruction to Flow Across the Atrioventricular Valves

Stenosis of the atrioventricular valves, as seen in mitral stenosis (MS) and tricuspid stenosis (TS), causes passive pulmonary and systemic vascular congestion without an effect on ventricular function. However, impaired filling of the left ventricle will lead to decreased cardiac output.

Mitral Stenosis

Congenital MS can occur as an isolated valvular lesion or in association with other congenital cardiac defects. Acquired MS, almost always due to rheumatic fever, is rare in the United States. Thickening of the leaflets, fusion of the commissures, or “parachute mitral valve” obstructs flow from the left atrium, resulting in increases in atrial pressure and eventually pulmonary venous congestion. The clinical presentation of MS includes the signs and symptoms of pulmonary edema and pulmonary hypertension, which reflect the severity of stenosis. Congenital MS is usually severe, presenting in early infancy. On physical examination, patients have a low-pitched, rumbling, diastolic murmur appreciated over the apex. A diastolic opening snap may rarely be heard. The ECG demonstrates left atrial enlargement and right ventricular hypertrophy. Atrial fibrillation as a manifestation of left atrial dilation and hypertrophy is rare in children. The chest radiograph shows left atrial enlargement and prominent pulmonary vasculature and interstitial edema reflective of pulmonary congestion.²⁰⁻²²

Tricuspid Stenosis

Congenital tricuspid valve disease is usually due to valvular atresia or Ebstein’s anomaly. Isolated congenital TS is rare. Tricuspid stenosis is almost always rheumatic in origin, and symptoms rarely present in childhood. Signs and symptoms of systemic venous obstruction due to TS include peripheral edema with passive congestion and enlargement of organs such as the liver and spleen.²³

Regurgitant Flow Across the Cardiac Valves

Cardiac valves that allow retrograde or regurgitant flow across the valve result in volume overload and dilation of the cardiac chamber or great vessel on either side of the valve. Significant chronic regurgitation or acutely developing regurgitation manifests clinically as congestive heart failure. Commonly recognized valvular regurgitant lesions are mitral regurgitation (MR) and aortic regurgitation (AR). Hemodynamically significant pulmonary and tricuspid regurgitation are much rarer clinical entities. Patients with late-stage obstructive or regurgitant valvular dysfunction will present to the emergency department with shock or pulmonary edema.

Aortic Regurgitation

AR in childhood is most commonly associated with a bicuspid valve. Incomplete closure or prolapse of the bicuspid valve may lead to isolated regurgitation or a combination of

stenosis and regurgitation.²⁴ AR is associated with many clinical entities, including dilation of the aortic root as seen in Marfan syndrome, destruction of the semilunar cusps due to endocarditis, ventricular septal defects, and rheumatic fever. Mild AR is generally asymptomatic, but disease progression can result in exercise intolerance and eventual congestive heart failure. Chest pain, multiple premature ventricular contractions, and congestive heart failure are ominous signs. However, these symptoms are usually not evident until well into adulthood. Acute AR, as seen in infectious endocarditis or trauma, presents with rapid onset of heart failure symptoms and even sudden cardiovascular collapse. The murmur of AR is a decrescendo, mid-diastolic, high-pitched murmur best heard at the third or fourth left intercostal space. S_1 is abnormally diminished. A wide pulse pressure and bounding arterial pulses are often present with severe chronic AR. In more severe AR, the ECG will show left ventricular hypertrophy. Chest radiographs may reveal left ventricular cardiomegaly, dilation of the ascending aorta, and pulmonary venous congestion.^{21,23}

Mitral Regurgitation

Congenital MR is most frequently diagnosed in the context of other congenital heart defects. Isolated congenital MR is extremely rare. MR is the common manifestation of valvular dysfunction in children with rheumatic heart disease.²⁵ Other major causes of MR include infectious endocarditis, collagen vascular disorders, primary abnormalities of the valve, myocardial ischemia (e.g., anomalous left coronary artery, Kawasaki disease), and cardiomyopathy. Patients with chronic MR are relatively asymptomatic until adulthood, when progression of disease leads to decreased cardiac output and eventually heart failure. Patients with acute MR, as seen in infectious endocarditis, acute dysfunction of the papillary muscle, or chordae tendineae, present with symptoms of acute pulmonary edema and right-sided heart failure. A regurgitant, high-pitched, blowing pan-systolic murmur is appreciated at the apex and radiates to the left axilla. The S_2 is widely split because the aortic valves close early, with the decreased stroke volume ejected from the left ventricle. The ECG may show left ventricular and left atrial hypertrophy. The chest radiograph may reveal left ventricular hypertrophy and left atrial enlargement in chronic MR and pulmonary edema in acute MR.^{21,23,26}

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is the most common valvular problem seen in practice and is the most common cause of MR in the United States. It is more commonly seen in adolescents. Most cases of MVP are considered a normal variant whereby the posterior or anterior leaflet bulges into the left atrium. MVP is often recognized in children with congenital heart defects, Marfan syndrome, or other connective tissue disorders. Children are usually asymptomatic but may present with palpitations, chest pain, or rarely syncope. The natural history of uncomplicated MVP is not well understood, and cardiovascular complication of arrhythmias, progression of MR, overt congestive heart failure, chordae tendineae rupture, and even sudden death have been described.^{16,27} On auscultation, patients with mitral regurgitation may have a midsystolic click followed by a late systolic murmur (click-murmur syndrome). ECG rarely may reveal

arrhythmias such as supraventricular tachycardias or premature atrial or ventricular contractions.²¹

Cardinal Systemic Manifestations of Valvular Heart Disease

Patients with valvular heart disease present with a constellation of systems determined by age and progression of valvular disease pathology. The cardinal symptoms of valvular heart disease include congestive heart failure, chest pain, palpitations, syncope, and neurologic deficits.

Congestive heart failure results from volume or pressure overload. Time of onset of congestive heart failure due to congenital heart disease can be reliably predicted. Severe pulmonary or tricuspid atresia will result in symptoms of volume overload at birth. Patients with critical AS or PS will likely become symptomatic during the first few weeks of life. However, complex congenital heart disease, episodes of supraventricular tachycardia, congenital heart block, hydrops fetalis, and bronchopulmonary dysplasia also cause congestive heart failure in the neonatal period and must be distinguished from isolated critical AS/PS. AR, MS, and MR leading to congestive heart failure will have highly variable presentations ranging from early childhood to late adulthood. The onset of acquired valvular heart disease will be less predictable and must be distinguished from other disease processes such as sepsis, viral myocarditis, infiltrative or hypertrophic cardiomyopathy, and recurrent bouts of “pneumonia.”²⁸

Children who present to the emergency department with *chest pain* rarely have serious valvular disease.²⁹ However, patients with severe valvular pathology (e.g., AS, IHSS) occasionally develop chest pain due to ventricular hypertrophy, increased wall stress, and resultant unmet oxygen demand. Similar to angina pectoris, patients may develop exertional chest pain that usually resolves with rest. Other conditions causing chest pain must be considered, including coronary artery anomalies, arrhythmias, cardiovascular disease, hypertrophic obstructive cardiomyopathy, cocaine abuse, pericarditis, and myocarditis³⁰ (see Chapter 62, Chest Pain).

Cardiac arrhythmias clinically perceived as *palpitations* are associated with all cardiac valvular lesions. Supraventricular rhythms (e.g., paroxysmal supraventricular tachycardia, atrial fibrillation, and atrial flutter) are frequently associated with MS and MR. In all patients presenting with palpitations, thorough evaluation for valvular causes is warranted. Specifically, MVP has been associated with atrial and ventricular premature contractions, paroxysmal supraventricular tachycardias, and ventricular tachyarrhythmias.³¹

Patients with severe obstructive cardiac lesions such as AS, PS, or IHSS may have *syncope* (see Chapter 61, Syncope). Clinically, these patients often present with exercise-induced syncope. The demand for cardiac output is not met, resulting in decreased cerebral perfusion and syncope. Furthermore, patients with valvular disease may experience syncope due to arrhythmias resulting from the underlying valve pathology.³²⁻³⁵

In the absence of signs and symptoms consistent with endocarditis, systemic embolization manifested as an acute *neurologic deficit* in a young patient warrants thorough investigation for left-sided valvular lesions or right-sided lesions associated with an interatrial communication³⁶ (see Chapter 44, Central Nervous System Vascular Disorders).

Important Clinical Features and Considerations

Endocarditis and Antibiotic Prophylaxis

Valvular heart disease causes significant pressure gradients and turbulent blood flow, which predispose to endothelial damage and thrombus formation. This environment of vascular damage and overlying thrombus formation produces a nidus for bacterial growth. Any focal infection (e.g., pyelonephritis, pneumonia, skin abscess) or procedures performed on patients can lead to bacteremia. This combination of factors produces the milieu for development of endocarditis. The onset of illness is usually insidious and is suspected when there are signs and symptoms of fever, chills, sweats, malaise, fatigue, and cardiac murmur. Endocarditis can be life-threatening. The emergency physician must be cognizant of the patient's underlying valve disease because special considerations need to be exercised to prevent development of infectious endocarditis. Recommended antibiotic prophylaxis regimens for endocarditis developed by the American Heart Association depend on the level of risk associated with the procedure and the cardiac lesions (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis).^{37,38}

Rheumatic Heart Disease

Acute rheumatic fever is a common cause of heart disease in underdeveloped countries, but is rarely seen in the United States except for occasional localized outbreaks.³⁹ Valvular lesions are believed to be caused by antibodies against the group A streptococcus that cross-react with antigen in various components of the heart. The revised Jones criteria are used to diagnose acute rheumatic fever (see Chapter 95, Musculoskeletal Disorders in Systemic Diseases). Carditis occurs in 50% of patients and invariably is associated with the murmurs of valvulitis (MR or AR).⁴⁰ Permanent damage to heart valves often results from the carditis, leading to chronic valvular disease affecting predominantly the aortic and mitral valves. Recurrent episodes of rheumatic fever increase the valvular pathology. Patients with a history of rheumatic fever must receive antibiotic prophylaxis.⁴¹

Management

The initial stabilization and management of the newborn with cardiac valvular disease is dictated by the underlying valvular pathology and severity of symptoms. The critically ill infant or child will require emergent medical treatment and coordination of management with the pediatric cardiac specialist (see Chapter 7, The Critically Ill Neonate; and Chapter 30, Congenital Heart Disease). Newborns with critical right-sided obstruction to pulmonary outflow, causing cyanosis, or left-sided obstruction to systemic outflow, causing shock, benefit temporarily from prostaglandin E₁ infusion, which reopens the ductus arteriosus. Vasodilators should be avoided in the treatment of ventricular failure due to AS, but their use should be considered in the treatment of MR to maintain the forward flow state. Symptoms of pulmonary venous congestion due to severe MS are treated with diuretics. The pediatric cardiologist will help coordinate further diagnostic procedures as indicated, including echocardiography (M-mode, two-dimensional, and Doppler

studies) and catheterization, the results of which will direct further management to include medical therapy, valvuloplasty, or surgery.

The asymptomatic child with potential cardiac valvular pathology requires referral to a pediatric cardiologist. The child with symptoms such as chest pain and syncope or symptoms suggestive of congestive heart failure will require an expedited evaluation. Indications and timing of interventions such as balloon valvuloplasty or surgery are based on the symptoms of the patient and evaluation of Doppler gradients across the affected valve, peak systolic pressure gradients, and calculated effective area of the valve orifice determined during echocardiography and catheterization.

Patients with valvular heart disease may experience complications resulting from their medical management. Drug interactions and potential toxicities of cardiac medications warrant consideration. Patients presenting to the emergency department with problems unrelated to their valvular disease may need endocarditis prophylaxis for conditions or procedures that may cause bacteremia (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis). These patients may also be more susceptible to other illnesses such as gastrointestinal bleeding or pulmonary infections.^{18,21,42}

Summary

One of the most important roles of the emergency physician in caring for pediatric patients with valvular heart disease is to first consider the diagnosis. A thorough history and physical examination with minimal testing will enable the physician to guide management and disposition. Patients with findings consistent with innocent murmurs can appropriately be followed by the primary physician. Asymptomatic patients who potentially have a pathologic murmur can usually be referred for outpatient evaluation by the pediatric cardiologist. Symptomatic patients will require acute management and disposition by the emergency physician augmented by a pediatric cardiologist. If an infant or child with known valvular heart disease presents to the emergency department, the clinician must consider whether symptoms are suggestive of complications of the valvular disease or if antibiotic prophylaxis is needed to prevent complications such as endocarditis.

Bacteremia

Elizabeth R. Alpern, MD, MSCE

Key Points

Occult bacteremia is the risk of bacteremia in a well-appearing young child with a fever without an identifiable source of infection.

Recent immunization innovations have drastically changed the etiology and lowered the prevalence of occult bacteremia.

Risk of serious invasive disease associated with occult bacteremia is present but extremely low in an immunized child.

Bacteremia may be associated with identifiable focal bacterial infections common in childhood, such as pneumonia, but is a different clinical entity than that of occult bacteremia.

Introduction and Background

Occult bacteremia is the presence of pathogenic bacteria in the blood of a well-appearing febrile child who lacks a focal bacterial source of infection. Occult bacteremia carries a risk of progressing to focal infection, meningitis, or sepsis; therefore, a patient's risk, methods for early identification, and treatment options for this entity have been widely studied. The population at risk has been identified as those children 2 to 24 months of age (some studies included children up to 36 months of age) with fever. It is an important concept for the emergency physician to differentiate children at risk for occult bacteremia from those children at risk for "nonoccult" bacteremia. Certainly young children with signs or symptoms of invasive disease, underlying immunodeficiencies, or evidence of systemic infection stemming from focal bacterial infections have an important and known risk of bacteremia. This bacteremia is not *occult* and therefore is a different entity from that described in this chapter.

Recognition and Approach

As with every clinical entity, identification of the at-risk population is the first step to diagnosis and treatment. Occult

bacteremia, by definition, affects healthy, well-appearing children from 2 to 24 or 36 months of age.¹⁻⁸ This chapter is thus limited to those healthy children considered immunocompetent hosts. In most cases, the patient's medical history will establish this prerequisite condition, which is vitally important to ascertain. The patient should not have a known underlying oncologic process, acquired or inborn immunodeficiency, sickle cell anemia, congenital heart disease, or indwelling medical device. Children who fall into those categories are certainly at risk for bacteremia; however, this is not the population that comprises those at risk for occult bacteremia. In addition, immunization status and concurrent antibiotic use may influence the risk of occult bacteremia (as discussed later in detail), and therefore should be identified. Although fever is typically recognized as a temperature above 38.5° C, for purposes of population definition, most studies use 39° C as a cutoff for fever in children at risk for occult bacteremia.^{2-5,7,8}

Another prerequisite condition for considering the diagnosis of occult bacteremia is a well-appearing child without evidence of focal bacterial infection (other than otitis media) that may predispose to bacteremia, such as pneumonia or urinary tract infections (see Chapter 33, Urinary Tract Infection in Infants; Chapter 58, Pneumonia/Pneumonitis; and Chapter 86, Urinary Tract Infections in Children and Adolescents). Some researchers believe that, if a child appears ill enough to warrant assessment with a lumbar puncture based on physical examination at initial evaluation, then he or she should not be included in the at-risk population for occult bacteremia, though he or she may certainly be at risk for nonoccult bacteremia.³

Historically, the most common etiologic organisms for occult bacteremia were *Streptococcus pneumoniae* and *Haemophilus influenzae* type b.^{2,4,6,7} Other common causative organisms included *Salmonella* species, *H. influenzae* non-type b, group A streptococci, *Enterococcus* species, and *Neisseria meningitidis*.^{3,5} Recent innovations in childhood immunizations have had the opportunity to dramatically change the prevalence and causative organisms of occult bacteremia. The *H. influenzae* type b (Hib) vaccine was introduced in 1987. Since that time, in the population at large, there has been a 94% decrease in the incidence of Hib meningitis and a shift in the median age of Hib meningitis from 15 months to 25 years of age.^{9,10} Prior to the licensure of the Hib vaccine, studies reported the prevalence of occult bacteremia to be between 3% and 11%.^{2,4,6,11,12} However, since the

widespread use of the Hib vaccine, two studies have reported the overall rate of occult bacteremia to be between 1.6% and 1.9%.^{3,5} The conjugate pneumococcal vaccine was licensed in 2000, with subsequent impressive declines in invasive pneumococcal disease.¹³⁻¹⁶ There are 90 pneumococcal serotypes, and the current conjugate pneumococcal vaccine licensed in the United States is a heptavalent vaccine. The seven serotypes covered by the current vaccine, however, accounted for 98% of cases of occult pneumococcal bacteremia in a recent study.¹⁷ The results of a single study since the introduction of the conjugate pneumococcal vaccine indicate that the overall prevalence of the disease has decreased to less than 1% of children at risk.⁸

Occult bacteremia is of concern to the clinician due to the risk of possible progression from bacteremia to sepsis or death via hematogenously spread focal infection. This risk of invasive disease associated with occult bacteremia is dependent on the causative organism of the bacteremia. Prior to the Hib vaccine era, the risk of invasive disease associated with identified *H. influenzae* type b bacteremia was 25% to 44%.^{2,18} However, occult pneumococcal bacteremia is associated with a significantly decreased risk of invasive disease, estimated at less than 1%.^{2,18} Subsequent to the use of Hib vaccine, but prior to the introduction of the conjugate pneumococcal vaccine, the risk of meningitis or death in children considered to be at risk for occult bacteremia was approximately 0.03%.³

Clinical Presentation

The diagnosis of occult bacteremia is dependent upon a complete history, including immunization status, and a thorough physical examination. There are several findings on the physical examination of the at-risk child that influence the probability that the patient has occult bacteremia. The incidence of occult bacteremia remains constant between 6 and 24 months of age.^{3,5,19} There is a lower incidence from 3 to 6 months of age hypothesized to be due to presence of maternal antibody after birth. However, selection bias in the studies performed (i.e., younger children may have undergone more invasive evaluations, and focal infections were identified at a higher rate) may have influenced results. The risk of occult bacteremia increases with increasing temperature and is more than two times the risk once temperature rises above 40° C.^{3,19} However, a patient's response to antipyretics does not reflect the risk of underlying occult bacteremia; a patient whose appearance improves after antipyretics does not have a lowered risk of bacteremia.²⁰⁻²²

The risk of occult bacteremia with certain concomitant diseases has also been studied. Children with identified otitis media have the same overall risk of occult bacteremia as those without ear infections.^{3,18} Children presenting with simple febrile seizures without focal identifiable infections also have rates of occult bacteremia comparable to those of all children at risk.²³ Children with particular viral illnesses, such as bronchiolitis, croup, and stomatitis, however, have a lower risk of occult bacteremia associated with those febrile illnesses.^{7,24,25}

The final diagnosis of occult bacteremia is contingent upon a positive blood culture. However, an inherent limitation of this test is the delay until growth of the organism indicating a positive culture. In a continuously monitored

carbon dioxide detection pediatric blood culture system, approximately 94% of pathogenic cultures became positive within 18 hours.^{3,26} The majority of contaminated cultures are not positive until after that time point. As the rate of occult bacteremia declines due to improved immunization practices, the rate of truly positive pathogenic cultures approximates that of contaminated cultures.^{3,8}

Many laboratory studies have been evaluated as screening tools for the identification of occult bacteremia. However, due to the overall low rate of occult bacteremia, their usefulness for the emergency medicine physician is limited by their positive predictive value. The complete blood count is the most widely studied laboratory screening test for occult bacteremia.^{2,5,6,8,12,19,27} If a white blood cell count of 15,000/mm³ or greater is used for a “positive” screen for occult bacteremia, the current positive predictive value of that test is between 3% and 5%.^{5,8} In other words, approximately 3% of children with white blood cell counts \geq 15,000/mm³ will have occult bacteremia. An absolute neutrophil count of \geq 10,000/mm³ has predicted approximately 8% of patients with occult bacteremia.¹⁹ Therefore, although an increased white blood cell count or neutrophil count is associated with an increased risk of occult bacteremia, the vast majority of patients with a “positive” screen will not have occult bacteremia. The emergency physician must balance the risk of not identifying a small percentage of cases of occult bacteremia with the ubiquitous use of screening tests that add time and invasive testing to the emergency department (ED) visit of a young child.

C-reactive protein has also been studied as a screen for serious bacterial infections, including pneumonia, urinary tract infections, and occult bacteremia.^{28,29} The positive predictive value of C-reactive protein, depending on the cutoff for positivity, is between 30% and 65% for identification of all patients at risk for “serious bacterial infections.”^{28,29} However, when applied solely to patients with occult bacteremia, approximately 3% of at-risk children with a C-reactive protein level \geq 4.4 have occult bacteremia. Thus the same considerations apply to the use of C-reactive protein as a screening tool for occult bacteremia.

The risk of occult urinary tract infection far outweighs the risk of occult bacteremia in some at-risk children, especially febrile well-appearing boys under 6 months of age and uncircumcised boys or any girls prior to toilet training. Therefore, assessment for occult urinary tract infections is extremely important (see Chapter 33, Urinary Tract Infection in Infants; and Chapter 86, Urinary Tract Infections in Children and Adolescents).

Important Clinical Features and Considerations

There are several important misconceptions or problem areas regarding the evaluation and treatment of occult bacteremia. Emergency physicians must be aware of these issues so the correct strategy is applied to febrile children who are at risk for both occult and nonoccult bacteremia (Table 68–1).

The evaluation and treatment of young, febrile, well-appearing children at risk for occult bacteremia has long been a topic of controversy in pediatrics and emergency medicine. In response to one of the many studies of occult

Table 68–1 Misconceptions or Problem Areas Regarding the Evaluation and Treatment of Occult Bacteremia in Children

Misconception/Problem Area	Clarification/Appropriate Action
Applying the approach to the wrong population (i.e., those who are not at risk for occult bacteremia)	Identify host factors and exclude those children with oncologic process, immune disorders, sickle cell disease, congenital heart disease, or indwelling medical device.
Performing a lumbar puncture on an ill-appearing child and, if normal, considering the child to be at risk for occult bacteremia	If a child appears ill enough to warrant a lumbar puncture, then he or she should not be included in the at-risk population for occult bacteremia; however, he or she may still be at risk for nonoccult bacteremia.
Believing that screening tests will be able to identify patients at greater risk of occult bacteremia	Due to the overall low prevalence of occult bacteremia, screening tests have been shown to have a very low positive predictive value in these patients.
Failure to appreciate the risk or prevalence of occult urinary tract infection	The risk of occult urinary tract infection far outweighs the risk of occult bacteremia in selected populations; therefore, screening for urinary tract infection in young febrile children is extremely important.
Failure to arrange close outpatient follow-up	Follow-up care is imperative for any child with persistent fever or other symptoms regardless of emergency department evaluation as focal bacterial sources may become evident at a later date.
Failure to understand the laboratory methods used to identify positive blood cultures and their impact on the interpretation of the culture result	In a continuously monitored system, the vast majority of pathogenic blood cultures will turn positive within 18 hr; the vast majority of contaminants will turn positive after that time point.

infections in young children, an insightful editorial summarized this controversy as follows.³⁰ Physicians typically approach the workup and treatment of the young child at risk for occult bacteremia in one of two basic ways: as a “risk-minimizer” or a “test-minimizer.”³⁰ If the physician leans more toward minimizing any possible risk of adverse outcome, then a “structured, methodical, laboratory intensive” strategy, including obtaining a blood culture, is often used to identify and treat all patients at risk for occult bacteremia (risk minimizer).³⁰ Alternatively, if the physician leans toward “careful clinical examination, close follow-up, and avoiding invasive testing” (test minimizer), then he or she likely believes that the risk of adverse outcome is so low as to not justify broad-spectrum antibiotics in all possible patients at risk.³⁰ Physicians in this group are likely to avoid ordering blood cultures on patients at risk for occult bacteremia. Recognition of where one stands on this continuum at different points in one’s career as a physician is as important as understanding the studies of possible evaluation and treatment strategies of children at risk for occult bacteremia.

Management

Due to the difficult nature of the process of diagnosing occult bacteremia without some delay in test results, expectant antibiotic use has been advocated by some to decrease the risk of adverse outcomes such as meningitis or sepsis. However, as the risk of occult bacteremia and subsequent adverse sequelae have changed due to immunization innovations, with resultant changes in causative organisms, many advocate treating only patients identified to have documented bacteremia, not all those at risk. There are also risks associated with expectant antibiotic therapy, including adverse and allergic reactions and increasing the prevalence of drug-resistant organisms.

Several large studies have evaluated the benefits of expectant antibiotics. In the pre-Hib vaccine era, three studies evaluated antibiotic treatment of patients at risk for occult bacteremia.^{2,4,12} In a trial of amoxicillin versus placebo, there

was no statistical difference between the antibiotic group and the placebo group in the incidence of major infectious morbidity.⁴ In a study of amoxicillin/clavulanate versus ceftriaxone, there was no difference in serious adverse outcomes in patients treated with either drug.¹² The third study examined the difference in risk of focal infections of patients treated with ceftriaxone versus amoxicillin.² Ceftriaxone was noted to decrease the risk of “definite” focal infections but was not effective in decreasing the risk of acquiring a “definite or probable” focal infection.^{2,31} In this particular study, *H. influenzae* and *Salmonella* species were the only causes of subsequent meningitis in patients with occult bacteremia. Several meta-analyses have also evaluated expectant antibiotic treatment of patients at risk for occult bacteremia.^{32–34} These studies concluded that expectant antibiotics do not prevent serious bacterial infections in all children at risk for occult bacteremia, especially in light of the extremely low risk of meningitis or death associated with pneumococcal bacteremia.^{32–34}

A review of the risk of serious bacterial illness associated with occult bacteremia when antibiotics are reserved for only culture-proven bacteremia showed that the risk of adverse outcome associated with reserved treatment was exactly the same as the risk associated with treatment with expectant antibiotics published in prior literature.³⁵ In addition, a cost-effectiveness analysis indicated that, as the rates of occult bacteremia and meningitis decline with epidemiologic changes, empirical testing with complete blood counts and use of expectant antibiotic will become significantly less cost effective.³⁶ Whichever treatment plan is instituted for an individual patient, follow-up within 24 to 36 hours with the child’s primary care provider or alternative site of care is imperative for any child with persistent fever or other symptoms as focal bacterial infections may become evident after the ED visit.

The emergency physician is likely to see children return or referred to the ED for evaluation and treatment following a “positive” blood culture obtained at a prior visit to the ED or primary care provider. If the blood culture becomes

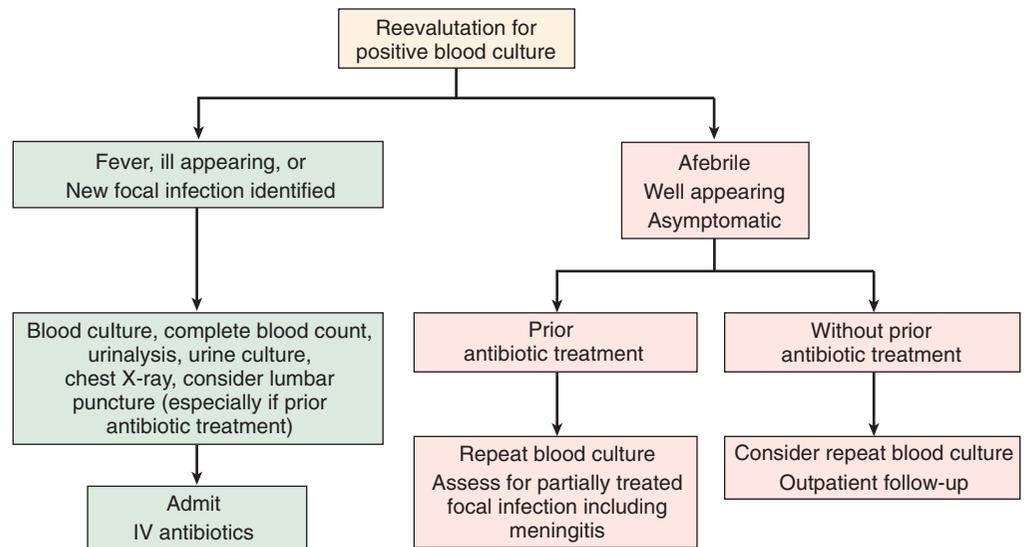

FIGURE 68-1. Reevaluation for positive blood culture.

positive within 18 to 24 hours utilizing a continuously monitored carbon dioxide detection system, the risk that this represents a true pathogenic culture is high.^{3,26} Cultures that become positive after this time period are most probably contaminants; however, they still have a small risk of representing more uncommon pathogens. Although *S. pneumoniae* is currently the most common causative organism of occult bacteremia and has a very high spontaneous resolution rate, there is still a risk of seeding deep infection. Therefore, a systematic approach to the patient who returns or is “recalled” due to a positive blood culture is recommended.³⁷

Patients with a positive blood culture and resolution of fever and lack of signs or symptoms of focal infection on reevaluation can be safely treated as outpatients after a repeat blood culture is obtained (Fig. 68-1). However, patients with positive cultures who are persistently febrile and/or ill appearing need a full evaluation to assess for new focal infections, including meningitis. If no prior antibiotics have been prescribed, physical examination by an experienced practitioner may reliably indicate the presence or absence of a focal infection. Complete blood count, urinalysis and culture, chest radiograph, and lumbar puncture should all be considered in the ill-appearing febrile child with known occult bacteremia. Admission and broad-spectrum intravenous antibiotic treatment are indicated.

Summary

Occult bacteremia is an entity that affects well-appearing febrile children without an identifiable focus of infection. The prevalence of and risks associated with occult bacteremia have changed significantly over the past decades as immunizations have targeted the most common etiologic organisms. Although there is a risk of serious bacterial illness associated with occult bacteremia, now that *S. pneumoniae* is the most common cause, this risk has greatly decreased. The impact of the pneumococcal conjugate vaccine is yet to be fully determined. Due to the decreasing prevalence of the disease, evaluation of children at risk for occult bacteremia with complete blood counts and treatment with

expectant antibiotics now has limited impact. Outpatient follow-up for all persistently febrile children is also a crucial step in the management of patients at risk for occult bacteremia.

Human Immunodeficiency Virus Infection and Other Immunosuppressive Conditions

Marina Catalozzi, MD

Key Points

Human immunodeficiency virus infection and acquired immunodeficiency syndrome have different manifestations in children and adults.

Early anticipation and aggressive management of overwhelming postsplenectomy infection are vital to outcome.

Patients with asplenia of any etiology should be considered at high risk for invasive and life-threatening bacterial and parasitic infection and should be managed aggressively.

Neutropenic patients can present with severe infections without localizing signs or symptoms.

Since it is not possible to determine which immunocompromised patients are or are not infected on presentation to the emergency department, empirical antibiotics should be given to all such patients.

Selected Diagnoses

Human immunodeficiency virus and acquired immunodeficiency syndrome
Asplenia: congenital, splenectomy, and functional
Primary immunodeficiencies
Immunosuppression

Discussion of Individual Diagnoses

Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

The perinatally acquired human immunodeficiency virus (HIV) epidemic peaked in the 1980s and 1990s. The United

States has seen a dramatic decrease in the number of new cases of perinatal HIV transmission since 1995, when voluntary HIV testing in pregnant women and antiretroviral therapy for HIV-positive women during pregnancy and delivery became routine. Reducing mother-to-child HIV transmission, institution of appropriate prophylaxis of opportunistic infections (OIs), and offering antiretroviral therapy when indicated have all contributed to decreases in OIs in children with HIV and/or acquired immunodeficiency syndrome (AIDS).¹ However, in 2005 there were still an estimated 68 cases of AIDS reported in children under age 13, and 9112 estimated cumulative cases of AIDS in children under 13.² Thus, OIs are still a cause for concern in the pediatric HIV-infected population. Additionally, HIV-positive women with OIs are more likely to transmit infections congenitally to both HIV-exposed but uninfected children and those with HIV infection.³ In contrast to OIs in adults, children do not have reactivation of latent pathogens, but primary infection with pathogens. Thus clinicians should be aware that the clinical manifestations and treatment differ from that in adults with OIs.

The Centers for Disease Control and Prevention estimates that approximately half of all new HIV infections in the United States are among people less than 25 years of age.² A disproportionate number of 13- to 24-year-olds with newly diagnosed HIV infection are racial and ethnic minorities, and most are infected sexually, either young men who have sex with men or young women who have sex with men. In 2005, there were an estimated 2546 new cases of AIDS and a cumulative estimated 41,311 cases of AIDS in 13- to 24-year-olds.² In seeing patients in this age group, clinicians must be aware of the acute seroconversion syndrome in people at risk for acquiring HIV, and presentations of illness in those who do and do not know their HIV status. Many 13- to 24-year-olds infected with HIV are unaware of their status. Additionally, not all patients who are prescribed antiretroviral therapy have a good response to therapy. Reasons for this include poor adherence to regimens, drug toxicity, drug interactions, and initial infection with resistant HIV. Thus OIs in the HIV-infected adolescent must be considered.⁴

Clinical Presentation

Children and adolescents with HIV with signs and symptoms of acute illness will most commonly have OIs. These infections cause a varied array of clinical findings, including most commonly fever, respiratory distress, gastrointestinal symptoms, mucocutaneous manifestations, and neurologic syn-

dromes. Table 69–1 presents the differential diagnosis to consider, clinical manifestations to recognize, and diagnostic tests to order when approaching these patients.

For children and adolescents on antiretroviral therapy, drug toxicity must also be considered, with the most common presentations including rash, gastrointestinal symptoms, and fever. Additionally, pain is a common complaint in children

Table 69–1 Differential Diagnosis of Acute Illness in Children and Adolescents with HIV/AIDS

Diagnosis	Clinical Presentation	Diagnostic Tests
Bacterial infections, invasive	<i>Children:</i> febrile illness, pneumonia, meningitis, sepsis, UTI, sinusitis, otitis osteomyelitis, septic arthritis, abscess <i>Adolescents:</i> pneumonia with fever, chest pain, productive cough	Blood culture, urine culture, CBC, CXR, LP if indicated; radiologic testing based on localizing signs Blood culture, CXR, sputum culture
<i>Candida</i> infections	<i>Children:</i> oral thrush, diaper dermatitis, esophagitis; rarely invasive but more common in those with advanced disease, central lines <i>Adolescents:</i> oral thrush, esophagitis, vulvovaginitis	Physical exam, KOH prep, fungal culture, barium swallow or endoscopy, blood culture; if fungemic, retinal exam, abdominal CT or US, bone scan if osteomyelitis suspected
Coccidiomycosis	<i>Children:</i> fever, respiratory distress, lymphadenopathy, headache, wasting <i>Adolescents:</i> disseminated disease (fever, lymphadenopathy, skin manifestations), meningitis	Blood culture, sputum culture, LP for CSF culture, serum antibody testing
Cryptococcosis	<i>Children:</i> meningoenzephalitis (fever, headache, altered mental status more common than meningismus, photophobia, focal neurologic signs), disseminated cryptococcosis (cutaneous lesions resembling molluscum), pulmonary cryptococcosis (fever, nonproductive cough, mediastinal lymphadenopathy) <i>Adolescents:</i> meningitis (can see clinical presentation of meningitis), meningoenzephalitis	Cryptococcal antigen (serum and CSF), LP (for cell count, glucose, protein, opening pressure); fungal cultures of CSF, sputum, and blood; BAL; biopsy of pulmonary or skin lesions
Cryptosporidiosis/ Microsporidiosis	<i>Children:</i> fever and vomiting, nonbloody watery diarrhea, dehydration, weight loss; presents as any other acute gastroenteritis; can present with fever, right upper quadrant pain if infects the bile duct <i>Adolescents:</i> watery diarrhea, abdominal cramping; can see nausea & vomiting; cholangitis, and pancreatitis; in rare cases, microsporidia can cause eye infections, encephalitis, and disseminated infection	Stool for ova and parasites; endoscopy if indicated
Cytomegalovirus (CMV)	<i>Children:</i> febrile illness, retinitis, mono-like illness, colitis, pneumonitis, encephalitis, congenital manifestations <i>Adolescents:</i> retinitis, colitis, esophagitis	Dependent on presentation, CMV serum and urine antigen, CMV antibody titers, CMV PCR, endoscopy, CXR, LP, head imaging, eye exam
Hepatitis B and C	<i>Children:</i> asymptomatic or clinical hepatitis <i>Adolescents:</i> asymptomatic or clinical hepatitis (fever, nausea, vomiting, jaundice)	Hepatitis B surface antigen, hepatitis C virus PCR, LFTs
Herpes simplex virus (HSV)	<i>Congenital:</i> disseminated multiorgan disease; localized CNS, skin, eye, or mouth disease <i>Children:</i> orolabial disease with dissemination and visceral involvement in severely immunocompromised; esophagitis, genital <i>Adolescents:</i> skin, eye, or mouth disease, genital lesions	Clinical diagnosis based on seeing vesicles and ulcers, viral culture from lesions, direct immunofluorescence for HSV antigen from lesions; Tzanck preparation from lesions no longer recommended because nonspecific; CSF for HSV PCR if indicated
Histoplasmosis	<i>Children:</i> fever, fatigue, weight loss, nonproductive cough, cutaneous nodules <i>Adolescents:</i> interstitial pneumonitis, meningitis	Blood culture (takes up to 6 wk to grow); antigen in serum, urine, CSF, BAL
<i>Mycobacterium avium</i> complex disease	<i>Children:</i> recurrent fever, weight loss, night sweats, diarrhea, abdominal pain, lymphadenopathy <i>Adolescents:</i> usually disseminated disease with fever, night sweats, weight loss, diarrhea	Blood culture (for AFB, can take up to 6 wk to grow), biopsy specimens, CBC (neutropenia, anemia, thrombocytopenia), LFTs (evidence of infiltrative liver disease)
<i>Mycobacterium tuberculosis</i>	<i>Neonates:</i> congenital, nonspecific, failure to thrive, symptoms, pneumonia, meningitis <i>Children:</i> no symptoms or nonspecific, fever, failure to thrive, acute pneumonia, extrapulmonary disease <i>Adolescents:</i> fever, cough, wasting, lymphadenopathy	CXR, skin testing (anergy testing not indicated), history of contact with infected adult, AFB stain of morning gastric aspirate (children), sputum, or BAL
<i>Pneumocystis jiroveci</i>	<i>Children:</i> fever, respiratory distress, cough, hypoxia <i>Adolescents:</i> fever, SOB, cough, hypoxia	Low alveolar-arterial oxygen gradient on arterial blood culture, elevated lactate dehydrogenase; CXR can appear normal (early on) or have diffuse parenchymal infiltrates; visualization of the organism on histopathology or direct fluorescent antibody of BAL or sputum (in adolescents)

Table 69–1 Differential Diagnosis of Acute Illness in Children and Adolescents with HIV/AIDS (Continued)

Diagnosis	Clinical Presentation	Diagnostic Tests
Progressive multifocal leukoencephalopathy	Focal neurologic signs, seizures, cognitive dysfunction	Radiographic findings (demyelination) on CT or MRI, CSF, or PCR for JC virus support diagnosis; brain biopsy may be indicated
Syphilis	<i>Congenital:</i> if no symptoms at birth, can see symptoms within the first 6 mo of life; organomegaly, jaundice, rash, nasal discharge, mucocutaneous lesions, anemia, pseudoparalysis <i>Adolescents:</i> primary (painless genital ulcer), secondary (skin lesions—generalized and on palms and soles, lymphadenopathy, fever, HA, aseptic meningitis), late syphilis (dementia, aortitis)	In infants, cannot rely on antibody testing because reflects mother's immunoglobulins; diagnosis made by combination of physical, radiologic, serologic, and direct microscopic exam; CBC, CSF for VDRL; if indicated can check CXR, long bone radiograph, eye exam Nontreponemal antibody tests (VDRL or RPR), treponemal tests if former are positive (DFA-TP or FTA-ABS). LP should be considered in HIV-positive patients with serologic evidence of syphilis to rule out neurosyphilis; consider diagnosis if high-risk sexual activity (MSM, other STDs)
Toxoplasmosis	<i>Congenital:</i> maculopapular rash, lymphadenopathy, organomegaly, jaundice, pancytopenia, CNS disease (seizures, microcephaly, hydrocephalus) <i>Children:</i> fatigue, fever, sore throat, mono-like syndrome, rash, cervical lymphadenopathy <i>Adolescents:</i> fever, headache, confusion, seizures, encephalitis	Toxo-specific serum IgM, IgA, IgE, IgG (after 6 mo), head imaging (CT with multiple ring-enhancing lesions)
Varicella-zoster virus (VZV)	<i>Congenital:</i> skin scarring, lymph hypoplasia, neurologic manifestations (seizures, microcephaly, etc.) <i>Children:</i> generalized pruritic vesicular rash, fever; zoster with typical dermatomal distribution, but can see more disseminated rash; retinitis; encephalitis <i>Adolescents:</i> zoster/shingles (dermatomal, rarely disseminated if immunocompromised); retinal necrosis	Clinical diagnosis based on typical appearance of generalized vesicular rash and fever or painful vesicular rash in dermatomal pattern; direct immunofluorescence for VZV antigen on cells collected from skin, conjunctiva, or mucosa. Tzanck preparation is nonspecific (see giant cells with HSV as well). VZV isolation from culture of vesicular fluid; eye exam

Abbreviations: AFB, acid-fast bacilli; BAL, bronchoalveolar lavage; CBC, complete blood count; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; CXR, chest radiograph; DFA-TP, direct fluorescent antibody–treponemal test; FTA-ABS, fluorescent treponemal antibody absorption test; HA, headache; HIV, human immunodeficiency virus; Ig, immunoglobulin; KOH, potassium hydroxide; LFTs, liver function tests; LP, lumbar puncture; MRI, magnetic resonance imaging; MSM, men who have sex with men; PCR, polymerase chain reaction; RPR, rapid plasma reagent test; SOB, shortness of breath; STDs, sexually transmitted diseases; US, ultrasound; UTI, urinary tract infection; VDRL, Venereal Disease Research Laboratory test.
Adapted from Mofenson LM, Oleske J, Serchuck L, et al.³ and Benson CA, Kaplan JE, Masur H, et al.⁴

with HIV infection secondary to systemic manifestations such as cardiomyopathy, myositis, drug reactions, and other secondary infections.⁵

In adolescents engaging in high-risk behaviors (unprotected sex, young men who have sex with men, history of a sexually transmitted disease, known HIV-positive sexual contact or forced sex within the 4 weeks prior to presentation), a diagnosis of acute HIV seroconversion must be considered when patients present with symptoms such as fever, fatigue, lymphadenopathy, pharyngitis, generalized rash, or, in general, a mononucleosis-like syndrome. While HIV antibody testing is not helpful in this acute setting, a baseline test should be obtained. Diagnostic testing should include a measurement of plasma viremia (by HIV polymerase chain reaction), with viral loads of greater than 50,000 copies/ml diagnostic of HIV seroconversion in the setting of a negative HIV antibody test.^{6–8}

In the acute setting, the most common diagnoses to recognize in HIV-infected children and adolescents include invasive bacterial infections (bacteremia and pneumonia in particular), *Pneumocystis jirovecii* (PCP; formerly *Pneumocystis carinii*) pneumonia, herpes zoster, esophageal candidiasis, and disseminated *Mycobacterium avium* complex. Studies of opportunistic infections in perinatally infected children prior to antiretroviral therapy showed that bacterial infec-

tions were the most common infections, with pneumonia, bacteremia, and urinary tract infections the most common manifestations.³ One explanation for this finding is that, in children, infection with HIV occurs before primary immune function against common bacterial infections develops (specifically B-cell and humoral responses). While *Streptococcus pneumoniae* was found to be the most important bacterial pathogen in this group, this pattern may change given the institution of pneumococcal conjugate vaccinations as part of the primary vaccine series. While bacteremia with gram-positive organisms is more common than gram-negative bacteremia, gram-negative bacteremia is observed in children with advanced disease, those with central lines, and those less than 5 years of age with less severe immunosuppression.⁹ Typical gram-negative organisms include *Pseudomonas aeruginosa*, nontyphoidal salmonellae, *Escherichia coli*, and *Haemophilus influenzae*.

In the absence of bacteremia, acute pneumonia is presumed to be bacterial in the setting of a febrile child with pulmonary symptoms and an abnormal chest radiograph. Lymphoid interstitial pneumonitis (LIP) is common in pediatric AIDS. LIP or any underlying chronic lung disease makes development of acute pneumonia more likely.¹⁰ The clinical presentation of bacterial infections is based on the type of infection, as HIV-infected children will most likely present

with signs and symptoms similar to those of children without HIV (fever, increased white blood cell count). However, severely immunocompromised patients may not be able to produce either fever or an elevated white blood cell count.

PCP is still the most common AIDS-defining disease in the pediatric population, with the incidence peaking in the first year of life, between 3 and 6 months. In contrast to children over 1 year of age and to adults, in whom PCP occurs when CD4 cell counts are less than 200/mm³, low CD4 cell counts are not a risk factor for disease in infants as many infected with PCP have CD4 counts over 1500/mm³. This is why PCP prophylaxis is recommended in infants of HIV-positive mothers until the absence of HIV infection is proven. As in adults, the presentation of PCP can be either sudden, with classic symptoms of fever, tachypnea, and cough, or more subtle, with mild cough, dyspnea, and poor feeding.^{3,11}

Mucocutaneous manifestations and infections that are rare in immunocompetent children are more common in perinatally infected HIV-positive children with moderate (defined as CD4 percentage of 15 to 24) and severe (defined as CD4 percentage of 1 to 14) immunosuppression. One study found that fungal infections were most common, notably oral candidiasis with *Candida albicans*. Viral infections were the second most common. As in HIV-infected adults, herpes zoster is more common in children with AIDS than in uninfected children. Herpes simplex virus (HSV) stomatitis occurs with greater frequency and severity. Presentations can be atypical, and more than one mucocutaneous manifestation can present in the same patient.¹²

Management

When invasive bacterial infection is suspected in the emergency department (ED), treatment regimens should take into consideration local resistance patterns to common infectious agents (e.g., penicillin-resistant *S. pneumoniae* or methicillin-resistant *S. aureus*) and any recent use of prophylactic or therapeutic medications by the patient. HIV-infected children who are severely immunocompromised require broad-spectrum antibiotic treatment for a range of organisms (resistant and nonresistant); those who are neither immunocompromised nor neutropenic can be treated as HIV-negative patients. An HIV-infected pediatric patient (non-neonatal) with suspected bacteremia, bacterial pneumonia, or meningitis should be treated with broad-spectrum cephalosporins such as ceftriaxone (80 to 100 mg/kg in one or two divided doses with a maximum dose of 4 g daily) or cefotaxime (200 mg/kg divided in three or four doses with a maximum dose of 8 to 10 g daily) until an organism can be identified. In HIV-infected pediatric patients with fever and an indwelling catheter, both gram-negative and gram-positive organisms should be treated with a regimen with pseudomonal and methicillin-resistant *S. aureus* coverage, such as ceftazidime and vancomycin.^{3,4}

Treatment for PCP should be initiated if the diagnosis is suspected, and not withheld pending the diagnosis. Bronchoalveolar lavage is positive for at least 72 hours after PCP treatment has been initiated. In the absence of allergy, trimethoprim-sulfamethoxazole (TMP-SMX) can be started at 15 to 20 mg/kg of body weight per day (TMP component; 75 to 100 mg/kg of SMX) in three to four divided doses for patients older than 2 months of age and adults. It should be given

intravenously (IV) over 1 hour. Once the acute phase has passed, the TMP-SMX can be administered orally in the same dose to complete the 21-day course of treatment. If patients are not able to take TMP-SMX, pentamidine may be given (4 mg/kg as a single daily dose given IV over 60 to 90 minutes for 14 to 21 days). If pentamidine cannot be used, alternative oral regimens can be initiated, but are poorly studied in children.

Early initiation of corticosteroids (within 72 hours of diagnosis) can be beneficial in moderate or severe cases of PCP. This is usually defined as the presence of hypoxemia with a partial pressure of arterial oxygen less than 70 mm Hg or an alveolar-arterial gradient greater than 35 mm Hg. Recommended initial doses include prednisone 40 mg twice a day, prednisone or IV methylprednisolone 1 mg/kg twice a day, or IV methylprednisolone 1 mg/kg every 6 hours.^{3,4,11}

Uncomplicated oropharyngeal candidiasis can usually be treated with topical therapy such as clotrimazole troches used at 10 mg orally four to five times a day for 14 days or regimens utilizing nystatin suspension at 400,000 to 600,000 U/ml four times daily for 7 to 14 days. Since many of the topical therapies fail, some providers choose to begin therapy with an oral azole in severe cases, either fluconazole (best tolerated and most effective; 3 to 6 mg/kg by mouth once a day for 14 days), itraconazole, or ketoconazole. The patient's liver function should be assessed prior to beginning this therapy. Interactions with other medications (particularly antiretrovirals) that utilize the cytochrome P-450 system should also be considered.^{3,4}

Acyclovir is the first-line treatment for HIV-infected children with primary varicella and zoster. With primary varicella, IV acyclovir is recommended because of the risk of disseminated and life-threatening illness (fever, numerous or deep and hemorrhagic skin lesions, moderate or severe immunosuppression). Neonatal HSV disease should be treated with high-dose IV acyclovir (20 mg/kg of body weight per dose three times daily) administered for 21 days for central nervous system and disseminated disease and for 14 days for skin, eye, and mouth disease. The dose for children less than 1 year of age is 10 mg/kg over 1 hour every 8 hours for 21 days. Oral acyclovir at 20 mg/kg per dose given four times a day should be reserved for children with normal CD4 counts or for those with very mild disease. Acyclovir is also first-line treatment for HIV-infected children with zoster. Intravenous acyclovir should be used in children who are very immunosuppressed if there is risk of eye involvement (trigeminal nerve distribution), or multidermatomal distribution. Renal function should be checked with a baseline serum creatinine so the dose can be adjusted for renal impairment if necessary.³

Asplenia: Congenital, Splenectomy, and Functional

Patients without a spleen or with functional hyposplenism are at risk for life-threatening infection. Congenital asplenia is associated with very low survival rates past 1 year of age and usually seen in conjunction with cardiac abnormalities and biliary atresia. Surgical splenectomies are performed secondary to trauma, cysts, malignancy, or other hematologic conditions (Hodgkin's disease, hemolytic anemia, and idiopathic thrombocytopenic purpura).¹³ While some surgeons attempt to retain splenic tissue or autotransplant splenic

tissue, there is no good evidence that this helps to preserve splenic function. Functional asplenia occurs from other primary medical conditions that result in degrees of hyposplenism: sickle cell disease (hemoglobin SC, hemoglobin SE, β -thalassemia), thrombocytopenia, malignant histiocytosis, gastrointestinal causes (celiac disease, dermatitis herpetiformis, ulcerative colitis), liver disease (portal hypertension), immunologic disorders (systemic lupus erythematosus, rheumatoid arthritis, Graves' disease, polyarteritis nodosum), infiltrative diseases (amyloidosis, sarcoidosis), and other miscellaneous causes (Bartonella infection, HIV infection, graft-versus-host disease, post-bone marrow transplantation, total parenteral nutrition, cancer therapy that includes either high-dose steroids or splenic irradiation).¹³

Important Clinical Features and Considerations

The spleen plays a critical role in responding to antigens both by antigen clearance and antibody production, as well as through filtering, phagocytosis, and opsonization of cells. This places asplenic patients at higher risk for sepsis caused by bacteria, particularly encapsulated organisms such as *Strep. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*. While *Strep. pneumoniae* is the most common pathogen, other important causes of infection include gram-negative bacteria (associated with high mortality rates) such as *E. coli* and *P. aeruginosa*. Other bacteria include group B streptococcus, *Staphylococcus aureus*, Salmonella species, Enterococcus species, Bacteroides species, Bartonella, and Plesiomonas. Unusual organisms such as *Capnocytophaga carnimorsus* (also implicated after dog bites) and protozoa (e.g., those causing babesiosis, malaria, and ehrlichiosis) have also been implicated in asplenic patients. These infections must be considered in patients with asplenia with recent travel.^{14,15}

Overwhelming postsplenectomy infection (OPSI) risk is thought to be highest in children, people undergoing splenectomy for hematologic conditions, and patients who are immunosuppressed for other reasons. While the risk of infection has been found to be highest in the first 2 years after splenectomy, lifetime risk of OPSI remains at 5% and carries a mortality rate of 38% to 69%.¹⁵ Despite preventive measures to reduce the risk of OPSI—immunization against *Strep. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*; prophylactic antibiotics; standby antibiotics (to be used if the patient becomes acutely febrile or ill and does not have quick access to a medical center)—asplenic patients remain at risk for OPSI, and no studies have specifically shown the efficacy of these measures. Also, it cannot be assumed that asplenic patients have been counseled regarding the risk of infection or the importance of compliance with daily prophylaxis.¹⁴

Streptococcus pneumoniae is the most important pathogen in asplenic pediatric patients, and has been implicated in over 50% of invasive infections.¹⁴ Prior to the institution of vaccination with conjugate pneumococcal vaccine, the median time to come to medical attention was 24 hours. Presenting signs and symptoms include fever, shock, petechiae or purpura, disseminated intravascular coagulopathy, and respiratory distress. Types of illnesses in these children include bacteremia (with or without other focal infections), meningitis, and osteomyelitis. While there are studies to support an overall decline in invasive pneumococcal disease after the introduction of the conjugate vaccine, approxi-

mately 19% of invasive pneumococcal disease has been caused by serotypes not included in the conjugate pneumococcal vaccine. Thus protection against pneumococcus cannot be presumed.^{16,17}

OPSI does not always have a focus of infection. One possible explanation for the lack of localizing findings is that nasal carriage and colonization may lead to later invasive infection.¹³ Patients may present with septic shock, but often the presentation is more protean—viral-type symptoms such as fever, fatigue, headache, vomiting, and abdominal pain. OPSI must be suspected and therapy must be instituted very early as the disease can progress very quickly. The overall mortality rate of OPSI is between 50% and 70%. Other morbidities can include hearing loss, gangrene, skin grafts, and amputations. Early anticipation of OPSI and aggressive management are vital.^{13,16}

Management

The best way to improve survival is to recognize the risk for the illness before the full clinical picture of sepsis emerges. Sepsis should be aggressively treated, and empirical therapy should take precedence over any diagnostic testing. Ideally, blood cultures would be drawn prior to the administration of antibiotics, but should never delay treatment. Even though Pneumococcus is the most common pathogen, IV antibiotics should be administered that cover the spectrum of possible bacterial etiologies. Combination antibiotics should cover penicillin-resistant pneumococci, gram-negative organisms, β -lactamase-resistant organisms, and any other local resistance issues. Consultation should be sought with infectious disease specialists in areas where both penicillin and cephalosporin resistance is known, or when patients have multiple allergies. Proposed regimens include ceftriaxone (50 to 75 mg/kg IV per dose every 12 hours; adult dose 2 g IV per dose every 12 to 24 hours) or cefotaxime (25 to 50 mg/kg IV per dose every 6 hours; adult dose 2 g IV per dose every 8 hours) plus gentamycin (2.5 mg/kg IV per dose every 8 hours; adult dose 5 to 7 mg/kg IV per dose every 24 hours) or vancomycin (10 to 15 mg/kg per dose every 6 hours; adult dose 2 to 3 g per day in divided doses every 6 to 12 hours). Some authors also suggest the addition of rifampin in initial management.^{13,14} While some authors suggest steroids or immunoglobulin, there are no clear recommendations or data to support these measures. Patients with asplenia or splenectomy are at high risk for OPSI after animal or bite wounds and should be treated with prophylactic antibiotics, either ampicillin-sulbactam or amoxicillin-clavulanic acid by mouth depending on the severity of the wound. Particular attention to the possibility of malaria (whether or not the patient was on prophylaxis), babesiosis, or ehrlichiosis should be considered in asplenic patients who travel to endemic regions.¹⁴

Diagnostic workup (before or after the initiation of IV antibiotics), depending on the clinical scenario, should include blood culture, urine culture, sputum culture (in older children and adolescents), lumbar puncture if indicated, complete blood count, chemistry, and chest radiograph.

Primary Immunodeficiencies

Primary immunodeficiencies (PIs) are a group of disorders in which the primary defect is intrinsic to one or more of the

four components of the immune system: B lymphocytes, T lymphocytes, phagocytes, and complement. The World Health Organization classifies PIs on a molecular basis as T- and B-cell immunodeficiencies; predominantly antibody deficiencies; other well-defined immunodeficiency syndromes; diseases of immune dysregulation; congenital defects of phagocyte number, function, or both; defects in innate immunity; autoinflammatory disorders; and complement deficiencies. For the purposes of this chapter, PIs are discussed in terms of the components of the immune system affected.^{18,19}

Clinical Presentation

In the ED, children with PIs may present with known diagnoses, as overwhelming infections representing the first sign of a PI, or with recurrent infections indicating an underlying PI. It is helpful to approach the disorders in terms of types of infections with which they are likely to present.^{18,19}

B-lymphocyte defects are the most common PIs (approximately 70%) and manifest as an impaired antibody response.^{20–22} Those patients affected are more susceptible to bacterial infections, particularly encapsulated pyogenic bacteria such as *H. influenzae*, *Strep. pneumoniae*, and staphylococci, but also infections with other bacteria (*P. aeruginosa*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*) as well as enteroviruses. Most of the B-lymphocyte defects (except common variable immunodeficiency, which presents between 20 and 30 years of age) present after 3 to 6 months when maternal antibodies wane. Types of bacterial infection include pneumonia, otitis, sinusitis, and bacteremia.^{20–22}

T-lymphocyte defects usually present at birth or in early infancy. While T-cell disorders are thought of as cellular immunodeficiencies, these patients are also at risk for pneumococcal disease because of impaired antibody

responses.^{20,21,23} Patients with T-cell defects are primary thought to be at high risk for OIs secondary to viruses (severe respiratory infections caused by parainfluenza or respiratory syncytial virus; herpesvirus infections such as HSV, varicella-zoster virus, or cytomegalovirus), and PCP. They may also be at risk for infections with bacterial pathogens as seen in B-lymphocyte defects. These children are also more prone to fungal and mycobacterial disease.^{20,21,23}

Phagocyte defects (affecting neutrophils and macrophages) present in early childhood and display very specific infections with pyogenic bacteria (*Pseudomonas*, *Serratia marcescans*, *Staph. aureus*) and fungi (*Aspergillus fumigatus* and *Candida*). They do not typically cause infection with PCP, pneumococcus, or viruses. Infections of the skin and reticuloendothelial system frequently occur.^{21,24}

Complement defects are rare, but can occur in nearly every component of the complement system—the classical pathway, alternative pathway, and membrane attack complex. This defect predisposes patients to encapsulated bacterial infections, most notably pneumococcal infections. Clinical presentations include bacteremia or meningitis. Defects of the terminal components (C5 to C9) predispose to infection with *Neisseria* species.^{20,21} Table 69–2 contains examples of primary immunodeficiencies in each part of the immune system.

Management

Whether or not the underlying immunologic defect is known, acute management should be guided by the patient's clinical situation. In the ED, supportive and resuscitative management and coverage with broad-spectrum antibiotic therapy are always appropriate until further diagnostic workup can be pursued. PIs are an important group of disorders in the pediatric population. Careful attention to overwhelming or recurrent infection is the key to guiding diagnosis and man-

Table 69–2 Examples of Primary Immunodeficiencies^{20–23}

Affected Part of the Immune System	Examples	Typical Presentation
B lymphocytes	X-linked agammaglobulinemia Autosomal recessive agammaglobulinemia Hyper-IgM syndrome IgA deficiency Common variable immunodeficiency IgG subclass deficiencies Selective antipolysaccharide antibody deficiencies	First year of life with infection from encapsulated bacteria such as <i>Pneumococcus</i> , <i>Giardia</i> , or enteroviruses
T lymphocytes	DiGeorge syndrome Purine nucleoside phosphorylase deficiency	Thymic hypoplasia, hypocalcemia secondary to hypoparathyroidism, and congenital cardiac anomalies; classic facies associated
Combined B and T lymphocytes	Severe combined immunodeficiency Wiskott-Aldrich syndrome (X-linked recessive) Ataxia-telangiectasia (autosomal recessive) Progressive cerebellar ataxia Oculocutaneous telangiectasia Recurrent lung infections	Failure to thrive, chronic diarrhea, oral thrush, skin rash, pneumonia, sepsis, PCP, severe pneumonias due to several possible etiologies; fatal without intervention, bone marrow transplantation
Phagocytes	Chronic granulomatous disease (defect of the nicotinamide adenine dinucleotide phosphatase oxidase pathway) Leukocyte adhesion defect Chédiak-Higashi syndrome	Eczema, thrombocytopenia, and recurrent infections Recurrent and often life-threatening infection with catalase-positive bacteria and fungi most often in the skin, lung, lymph nodes, and liver; excessive granuloma formation

Abbreviations: Ig, immunoglobulin; PCP, *Pneumocystis jiroveci* pneumonia.

agement. Knowledge of an already diagnosed PI also helps to guide therapy.

Immunosuppression

Immunodeficiencies can be either primary or secondary and can affect any component of the immune system. Causes of secondary immunosuppression include cancer and transplantation (bone marrow or solid organ). Risk of infection in cancer is high because of the underlying disease process or organ involved, chemotherapeutic agents utilized in treatment, degree of neutropenia, alteration of mucosal immunity, and frequent need for an indwelling catheter. Infection risk in bone marrow transplantation is high for the reasons mentioned, and because of the need for immunosuppressive medications, risk of infection with cytomegalovirus, and graft-versus-host disease. Solid organ transplantation is associated with infection risk at the site of the transplanted organ, an underlying disease process for which the patient received the transplant, poor nutritional status of the patient prior to transplantation due to chronic disease, and the need for immunosuppressive medications. All of these factors make the initial evaluation and treatment of the immunosuppressed patient crucial to outcome.²⁵

Clinical Presentation

Fever can often be the only sign of a serious infection in an immunocompromised patient. Half of febrile neutropenic patients with cancer have an occult infection.²⁵ The Infectious Diseases Society of America Fever and Neutropenia Guidelines Panel defines fever as a single oral temperature of greater than 38.3°C (101°F) or a temperature of greater than 38.0°C (100.4°F) for more than 1 hour. They define neutropenia as a neutrophil count of less than 500 cells/mm³ or a count of less than 1000 cells/mm³ with the likelihood that the count will decrease to less than 500 cells/mm³. Increased risk of infection is associated with lower neutrophil count, prolonged neutropenia, and a low nadir of neutrophil count.^{25,26}

If pathogens are able to be isolated, bacteria are most common and include gram-positive, gram-negative, and anaerobic organisms. Fungi are common in patients with a history of exposure to broad-spectrum antibiotics. Neutropenic patients can present with severe infections without localizing signs or symptoms (i.e., induration, erythema) due to lack of ability to mount a local inflammatory response. Body fluids may not always reflect a pleocytosis.^{25,26}

A careful history and physical examination is paramount, and attention should be focused on common sites of infection—the oral cavity, including the teeth, gums, and oropharynx; the lungs; the gastrointestinal tract (with special attention to the perineum and anus); the eyes and fundi; the skin (focus on any access sites, bone marrow aspirate sites), and soft tissue (particularly around the nails).^{25,26}

If the patient is hemodynamically stable, the following diagnostic evaluation should be obtained prior to empirical treatment with antibiotics: blood culture (from both the peripheral vein and catheter lumen) for bacterial and fungal culture; Gram stain and culture (for bacteria, fungi and, if the lesion is chronic, mycobacteria) of any fluid draining from the indwelling catheter site; urinalysis and urine culture; and chest radiograph. Other studies (such as cerebrospinal fluid) are dependent on the patient's clinical status.

A complete blood count and serum chemistry (electrolytes, blood urea nitrogen, creatinine, liver function tests) should also be obtained. Workup for fungal infection can be pursued at a later date or if the patient does not respond to initial antimicrobial therapy.^{25,26}

Management

As with patients with asplenia, infection in neutropenic patients can progress rapidly, and all febrile and neutropenic patients should be presumed to have an invasive infection until proven otherwise. Empirical therapy should include coverage for both gram-positive and gram-negative bacteria. The antibiotic choice should be dependent on the susceptibility and resistance patterns of a given institution as well as the patient's allergies or organ impairment. Suggested management can include monotherapy with a third- or fourth-generation cephalosporin (cefepime, ceftazidime), or carbapenem, or two-drug therapy (an aminoglycoside *and* either an antipseudomonal penicillin *or* cefepime, ceftazidime, or carbapenem).^{25,26} Vancomycin should be added if local rates of gram-positive infections are high, if the infection is suspected to be catheter related, if the patient is known to be colonized with resistant bacteria, if the patient was recently treated for gram-positive bacteremia, if the patient received chemotherapy that is known to cause severe mucosal impairment, or the patient is hypotensive or clinically unstable.^{25,26} Other coverage should be based on the patient's clinical examination and findings. Empirical antifungal coverage is almost never initiated in the ED unless the patient is known to have fungal disease. Central indwelling catheters should stay in place unless there is a clear indication for removal (tunnel infection, recurrent infections), and that decision is usually not made in the ED. For well-appearing low-risk patients, some institutions manage fever and neutropenia in the outpatient setting with oral antibiotics, but this must be in consultation with the oncologist and with assurance that the patient has a reliable social situation, ability to return to the hospital for worsening status, and prearranged close follow-up.^{25,26}

Fever is a common presenting symptom in immunocompromised, neutropenic patients and is usually indicative of an underlying infection. Since it is not possible to determine which patients are or are not infected on presentation to the ED, empirical antibiotics should be given to all such patients.

Sexually Transmitted Infections

Cynthia J. Mollen, MD, MSCE

Key Points

Evaluation for sexually transmitted diseases in adolescent females can often be done without the speculum examination, if nucleic acid amplification techniques are available for organism identification

Empirical treatment is generally recommended when suspicion of a sexually transmitted infection (STI) is high, in order to reduce the risk of complications and shorten infectivity.

Confidentiality and consent issues should be considered for all adolescent patients presenting for evaluation of a possible STI.

Selected Diagnoses

- Pelvic inflammatory disease
- Cervicitis
- Vaginitis
- Genital ulcers
 - Herpes genitalis
 - Syphilis
 - Lymphogranuloma venereum
 - Chancroid
- Genital growths
 - Human papillomavirus
 - Molluscum contagiosum
- Urethritis and epididymitis
- Neonatal infections

Discussion of Individual Diagnoses

The rates of many sexually transmitted infections (STIs) are highest among adolescents, due at least in part to increased frequency of unprotected intercourse when compared to adults. In addition, adolescents are biologically more susceptible to infection, often have short-term serial relationships, and may have barriers to access to health care. Clinicians can make an impact on future acquisition of STIs by discussing risk factors and healthy sexual behaviors with the adolescent

patient. Of paramount importance is obtaining an accurate sexual history in private, in a nonjudgmental fashion, in order to assess risk for the infections discussed in this chapter.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is a polymicrobial infection of the upper genital tract, and is one of the most common infections in sexually active young women. A range of inflammatory disorders can be classified as PID, including endometritis, salpingitis, oophoritis, perihepatitis, and tubo-ovarian abscess (TOA). Adolescents are at approximately 10-fold higher risk for acquiring PID when compared to adult women (women under 25 years old account for 70% of cases); this increased risk is due to a number of factors, including lower levels of secretory immunoglobulin A in adolescents and differences in the epithelial cells of young women when compared to adults, which allow pathogens to cause infection more easily. In addition, adolescents may be more likely to be exposed to bacterial and viral causes of STIs as they tend to have short-term serial intimate relationships and most likely are less effective users of condoms than adults.^{1,2}

PID usually begins as an STI, often caused by *Neisseria gonorrhoeae* or *Chlamydia trachomatis*. However, PID is a polymicrobial infection that often involves other organisms as well, including anaerobes. Once the lower genital tract is infected, bacteria ascend to the upper genital tract and cause symptoms of PID.¹ In addition to age, other risk factors for PID include previous episodes of PID, use of an intrauterine device, vaginal douching, and bacterial vaginosis. The use of condoms and oral contraceptives is a protective factor; oral contraceptives cause thickening of the cervical mucus and decrease cervical dilation, uterine contraction, and blood flow during menses, all of which are mechanisms that support ascension of bacteria to the upper genital tract.²

Clinical Presentation

Patients can present with a wide variety of symptoms and signs, and the presentation can be subtle, particularly with mild disease. Therefore, it is important to consider PID in the differential of any young women presenting to the emergency department (ED) with the complaint of abdominal pain. The clinical diagnosis of PID is imprecise; studies suggest that the clinical diagnosis of symptomatic PID has a positive predictive value for salpingitis of only 65% to 90% when compared to laparoscopy, which is considered to be the best diagnostic tool for PID.^{3,4} Clearly laparoscopy is not

Table 70–1 Diagnosis of Pelvic Inflammatory Disease

Minimum Criteria (at least one)	Additional Supporting Criteria
Uterine tenderness Adnexal tenderness Cervical motion tenderness	Oral temperature >101° F (38.3° C) Abnormal cervical or vaginal mucopurulent discharge Elevated erythrocyte sedimentation rate Elevated C-reactive protein Laboratory documentation of cervical infection with <i>N. gonorrhoeae</i> or <i>C. trachomatis</i> Presence of abundant numbers of WBC on saline microscopy of vaginal secretions

From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Recomm Rep 55(RR-11):1–100, 2006.

indicated for the majority of patients with suspected PID, so a clinical diagnosis is usually necessary (Table 70–1).

Most patients presenting with PID will complain of abdominal pain, abnormal vaginal bleeding, or vaginal discharge. Patients may report a history of fever, and may complain of nausea and vomiting, although gastrointestinal symptoms are usually not the primary complaint. Major diagnoses to consider in adolescent patients presenting with abdominal pain, in addition to PID, include appendicitis, constipation, cholecystitis, ovarian torsion, ovarian tumor, pregnancy and associated complications, pyelonephritis, and nephrolithiasis.

When assessing an adolescent for the possibility of PID, it is crucial to obtain an accurate social history. This is best obtained by interviewing the patient alone. One approach is to establish a practice of interviewing all adolescents without a parent present, in order to maintain consistency and limit the possibility of missing important information. This approach will also minimize the possibility of missing the diagnosis of PID in a patient who “seems” unlikely to be sexually active, such as the patient with a chronic medical condition or special health care needs. It is important to outline the limits of confidentiality for both the parent and the patient (suicidal or homicidal ideation, or an indication of abuse) (see also Chapter 151, Issues of Consent, Confidentiality, and Minor Status).

Because there is no laboratory or radiologic test that can make a definitive diagnosis of PID, the physical examination is of the utmost importance. In addition to a general physical examination, the pelvic examination provides key information. The pelvic examination, which consists of three traditional components (external inspection, speculum examination, and bimanual examination), is generally associated with a significant amount of anxiety for the adolescent patient.⁵ According to the Centers for Disease Control and Prevention (CDC) 2006 Sexually Transmitted Diseases Treatment Guidelines, the diagnosis of PID should be considered in all patients at risk for an STI who have either uterine or adnexal or cervical motion tenderness on physical examination, if no other explanation for the findings can be found.³ Furthermore, a recent study suggests that the most sensitive physical examination finding for diagnosing PID is adnexal tenderness.⁶ Both of these physical examination criteria can

be assessed through the bimanual examination, without the use of a speculum. In addition, recent advances in diagnostic testing techniques for *N. gonorrhoeae* and *C. trachomatis* have helped pave the way for a reduction in the use of the speculum.⁷ Urine-based and vaginal swab nucleic acid amplification techniques have been shown to be at least as sensitive as endocervical culture. Cervical culture for gonorrhea has a sensitivity of 87% to 94%, compared with a sensitivity of 92% to 96% for urine-based tests and up to 100% for vaginal swab-based tests. Similarly, while cervical culture for chlamydia has a sensitivity of only 77% to 84%, urine-based tests have a sensitivity of 88% to 95%, and vaginal swab-based tests have a sensitivity of 91% to 93%. Furthermore, urine-based and vaginal swab-based tests for both organisms have specificities of 100%.^{8–16} Therefore, in healthy, nonpregnant adolescents being evaluated in the ED for possible PID, a speculum examination can be avoided in most cases. A key exception to this is the patient with profuse vaginal bleeding.

A variety of symptoms, signs, and laboratory values support the diagnosis of PID (see Table 70–1). None of these criteria requires the use of a speculum. The presence of a cervical discharge is not necessary for the diagnosis; the presence of a mucopurulent discharge in the vagina, whether originating from the cervix or the vagina, is an adequate supportive finding. Most patients with PID have either a mucopurulent discharge or evidence of white blood cells (WBCs) on microscopic evaluation of a saline preparation of vaginal fluid; if neither of these findings is present, another explanation for the patient’s findings should be sought. Transvaginal ultrasound may be helpful in diagnosing some patients.¹⁷

Patients with suspected PID should have urine or vaginal swabs sent for detection of *N. gonorrhoeae* or *C. trachomatis*. Vaginal swabs should be sent for a wet preparation to evaluate for *Trichomonas vaginalis* and a Gram stain. To obtain adequate specimens, two Dacron-tipped specimen swabs should be simultaneously inserted about 1 inch into the vagina, and remain for approximately 30 seconds. In addition, a complete blood count, erythrocyte sedimentation rate, and C-reactive protein level can all be helpful in making the diagnosis. Depending on the local prevalence of syphilis, a rapid plasma reagin test may be done as well.

Important Clinical Features and Considerations

An important consideration for the patient diagnosed with PID is the concern for the presence of a TOA, which is the most serious acute complication of PID. Studies suggest that the prevalence of TOA among hospitalized patients may approach 20%, and that it is difficult to assess clinically whether or not a patient has a TOA.^{18–20} Based on these findings, some adolescent experts recommend pelvic ultrasound (the most specific and sensitive test for TOA) for all patients diagnosed with PID. To date, there are no clear guidelines to indicate which patients are at highest risk of TOA. A review of the literature suggests that, at a minimum, ultrasound should be obtained on patients in whom other diagnoses cannot be excluded (such as appendicitis), patients who are ill appearing or have elevated inflammatory markers, or patients who are not responding to therapy. Decisions about imaging should be based on the individual patient, and should take into account the patient’s ability to follow up with a health care provider within a few days.

Perihepatitis (Fitz-Hugh–Curtis syndrome) is another complication of salpingitis. Signs and symptoms include right upper quadrant pain and tenderness, fever, nausea, and vomiting. Signs and symptoms of salpingitis are usually present, but not in all cases.

The ED physician should remember to keep PID on the differential diagnosis list of any adolescent female presenting with abdominal pain; it is important to treat mild disease, so therapy should be instituted even if the diagnosis is not certain. One common misperception is that patients with cervicitis (discussed later) can have abdominal pain; this is generally not the case, so if a patient with vaginal discharge also has abdominal pain that is not explained by an additional diagnosis, the patient should be treated for PID rather than cervicitis. Other complications of PID include ectopic pregnancy, infertility, recurrent and chronic PID, chronic abdominal pain, and pelvic adhesions.

Management

Any patient meeting the minimum criteria for the diagnosis of PID (see Table 70–1), if no other diagnosis is apparent, should be treated empirically (Table 70–2). Up-to-date treatment recommendations can be found on the CDC website (<http://www.cdc.gov/STD/>). Of note, single-dose therapy of azithromycin has not been shown to be adequate treatment for PID.³ The decision about whether or not to admit a patient for inpatient therapy can be difficult. The CDC recommends inpatient treatment for patients in whom surgical emergen-

cies cannot be excluded; for pregnant patients; for patients not responding to oral therapy or who are unable to follow or tolerate an outpatient oral regimen; for patients with severe illness, nausea and vomiting, or high fever; and for patients with TOA. In addition, many adolescent experts recommend hospitalizing patients who are 14 years old or younger and patients for whom follow-up within 72 hours cannot be arranged. One randomized, controlled trial comparing inpatient to outpatient therapy for mild to moderate PID has been performed,²¹ which concluded that there was no difference in reproductive outcomes between women treated as inpatients compared with those treated as outpatients. However, that trial did not involve many adolescents, making it difficult to generalize the results to that population. Any patient treated as an outpatient should have clinical follow-up 3 days after beginning treatment. For adolescents, who may have issues with particular compliance or access to health care, it is important to ensure that the prescribed regimen will be completed and that follow-up can be arranged. In addition, male sex partners should be treated if they have had sexual contact with the patient within 60 days of the onset of symptoms. Options for partner treatment include self-referral and patient-delivered treatment.

When determining the best treatment strategy for the adolescent with PID, it is important to keep issues of confidentiality in mind. Patients under the age of 18 years are able to seek care for treatment of sexually transmitted diseases without parental consent.²² It is important to engage the adolescent in a discussion about disclosing the diagnosis, and, whenever possible, it is helpful to involve the parent in treatment plans in order to improve compliance and follow-up. However, the patient has the right to confidential treatment, although some states allow the physician to notify the patient's parents.²³ If the patient chooses not to inform a parent, it can be helpful to obtain private numbers (such as a cell phone or beeper number) in order to communicate culture results or to follow up the patient's clinical status.

Summary

PID is a difficult clinical diagnosis. It is important to consider the diagnosis of PID in any adolescent patient at risk for an STI in whom the minimum clinical criteria are met. All patients diagnosed with PID who are treated on an outpatient basis should have follow-up arranged within 72 hours. Adolescents may require more intensive education and follow-up than adult patients. Therefore, treatment decisions should be individualized and should take into account follow-up options, support systems at home, and the resources available on an outpatient or inpatient basis.

Cervicitis

Gonorrhea and chlamydia are among the most frequently reported infectious diseases in the United States. In fact, chlamydia is the most commonly reported bacterial STI, with 834,555 cases reported in 2002²⁴; because patients are often not tested before being treated, and because underreporting remains a problem, the CDC estimates that 2.8 million Americans are infected with chlamydia each year. The CDC estimates that there are approximately 700,000 people newly infected with gonorrhea yearly.²⁵ While both of these infections are often asymptomatic, they can both present with mucopurulent cervicitis (MPC).

Table 70–2 Treatment of Pelvic Inflammatory Disease

Parenteral Regimen A*	Outpatient Regimen A
Cefotetan 2 g IV q12h <i>or</i>	Ofloxacin [†] 400 mg orally bid × 14 days <i>or</i>
Cefoxitin 2 g IV q6h	Levofloxacin [†] 500 mg orally qd × 14 days
<i>Plus</i>	<i>With or without</i>
Doxycycline 100 mg orally q12h	Metronidazole 500 mg orally bid × 14 days
Parenteral Regimen B	Outpatient Regimen B
Clindamycin 900 mg IV q8h	Ceftriaxone 250 mg IM once <i>or</i>
<i>Plus</i>	Cefoxitin 2 g IM once <i>and</i> probenecid 1 g orally once
Gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose (1.5 mg/kg) q8h	<i>Plus</i> Doxycycline 100 mg orally bid × 14 days
	<i>With or without</i> Metronidazole 500 mg orally bid × 14 days

*Parenteral therapy can be discontinued 24 hours after clinical improvement, and the patient should complete a 14-day course of doxycycline (100 mg twice daily). When tubo-ovarian abscess is present, clindamycin or metronidazole is used with doxycycline to provide more effective anaerobic coverage.

[†]Fluoroquinolones are not recommended for use in patients younger than 18 years old; however, no joint damage has been observed in patients treated with prolonged courses of ciprofloxacin, so the CDC has stated that children who weigh more than 45 kg can be treated with any regimen.

Abbreviations: IM, intramuscularly; IV, intravenously. From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Recomm Rep 55(RR-11):1–100, 2006.

Clinical Presentation

MPC is characterized by a purulent endocervical discharge, which is often noted by the patient as a thick vaginal discharge. Patients with uncomplicated lower genital tract infection will not have abdominal pain or adnexal or cervical motion tenderness; conversely, patients who present only with vaginal discharge may have subclinical upper genital tract infection.^{26,27} Patients may complain of dyspareunia or postcoital spotting. Differential diagnoses to consider for the patient presenting with vaginal discharge include vaginitis (described later); cervicitis due to organisms other than *N. gonorrhoeae* and *C. trachomatis*, such as *Candida* species or herpes simplex virus; foreign body; and physiologic discharge. Laboratory testing for patients with vaginal discharge should include testing for *N. gonorrhoeae* and *C. trachomatis*. As mentioned earlier, vaginal swab-based and urine-based tests are sensitive and specific, and may obviate the need for a speculum examination in the adolescent patient. Additional testing includes vaginal swabs for Gram stain and wet preparation, as described previously. Recent studies suggest that women with vaginal polymorphonuclear cells (PMNs) noted on examination of their vaginal discharge are more likely to have subclinical PID; therefore, the finding of many PMNs on Gram stain may alter treatment.^{26,27} However, there are no clear guidelines as to whether or not these women need to be treated similarly to patients with clinical PID.

The diagnosis of cervicitis is fairly straightforward, and should be considered in any patient with an abnormal vaginal discharge. Although it can be difficult to distinguish with certainty between cervicitis and vaginitis without a speculum examination, because most etiologies of vaginitis can be diagnosed quickly with laboratory tests (as described later) the clinician can usually determine which patients are likely to benefit from empirical treatment for infection with *N. gonorrhoeae* and *C. trachomatis*. In many cases of MPC, neither organism is identified.

Other infections in females caused by *N. gonorrhoeae* include urethritis, which is characterized by dysuria, urinary frequency, exudate from the urethra or periurethral glands, and suprapubic pain; Bartholinitis and Bartholin gland abscess; pharyngitis, which usually resolves spontaneously; rectal infection; conjunctivitis; and otitis externa. Although pharyngeal infection is generally self-limited, patients should be treated to limit the spread of the organism and to limit the possibility of dissemination.²⁸ Patients with gonorrheal infection can also develop disseminated disease, characterized by arthritis/arthralgia, tenosynovitis, and dermatitis. Other sites of disseminated disease include perihepatitis, meningitis, myopericarditis, endocarditis, osteomyelitis, and pneumonia. *C. trachomatis* can also cause urethritis, which is often asymptomatic but can be associated with dysuria. Newborns of infected mothers are at risk for ophthalmia neonatorum, scalp abscess at the site of fetal monitors, rhinitis, pneumonia, and anorectal infections.

Management

The CDC recommends that patients suspected of being infected with *N. gonorrhoeae* and *C. trachomatis* should be treated empirically if the prevalence of these infections is high in the patient population, and if the patient might be difficult to locate for treatment after test results are available.

Table 70-3 Treatment of Cervicitis

Chlamydial Infection	Gonococcal Infection
Azithromycin 1 g orally once <i>or</i> Doxycycline 100 mg orally bid × 7 days	Cefixime 400 mg orally once <i>or</i> Ceftriaxone 125 mg intramuscularly once <i>or</i> Ofloxacin 400 mg orally once <i>or</i> Levofloxacin 250 mg orally once
Erythromycin base 500 mg orally qid × 7 days Erythromycin ethylsuccinate 800 mg orally qid × 7 days Ofloxacin* 300 mg orally bid × 7 days Levofloxacin* 500 mg orally qd × 7 days	Treatment for chlamydia if chlamydia infection not ruled out

*For quinolones, children who weigh more than 45 kg can be treated with any regimen recommended for adults.
From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Recomm Rep 55(RR-11):1–100, 2006.

For most adolescents, empirical treatment is warranted because of the difficulty with locating teenagers after an ED visit combined with potential problems with maintaining confidentiality once the patient has left the ED.

Patients should be treated for both gonorrhea and chlamydia infections (Table 70-3). For chlamydial infection, single-dose azithromycin therapy has been shown in randomized, controlled trials to be equally efficacious when compared with 7 days of doxycycline.²⁹ Although treatment with azithromycin is more expensive, this should be weighed against the benefit of providing complete treatment during the ED visit. Ofloxacin is also efficacious, but is not recommended as first-line therapy because of increased cost. Although erythromycin is an alternative treatment, it is not as effective as the others and the gastrointestinal side effects can affect compliance. In order to maximize compliance, particularly with the adolescent population, it can be useful to dispense the entire treatment course at the time of the ED visit and to observe the first dose. All sex partners within 60 days should be treated, and the most recent sex partner should be evaluated even if the most recent contact was more than 60 days prior to the patient's presentation. Patients should abstain from sexual intercourse until 7 days after the onset of treatment. Currently, there is no need for a patient to be retested once therapy is complete. For pregnant patients, azithromycin is thought to be safe and effective.

The preferred treatment for gonococcal infection is ceftriaxone.³⁰ Strains of *N. gonorrhoeae* resistant to quinolones are becoming more common. In fact, the CDC recommends that patients with gonorrhea who live in Hawaii and California not be treated with a quinolone; in addition, there have been recent increases in fluoroquinolone-resistant gonococci in Massachusetts, Michigan, New York City, and Seattle.³¹ In areas where resistance is a concern, ceftriaxone should be used as primary therapy. With the exception of cefixime, which at present is available sporadically and only as an oral suspension, other oral cephalosporin regimens have not been shown to be effective for the treatment of *N. gonorrhoeae*. Similarly, a 1-g dose of azithromycin is also not effective;

although a 2-g dose of azithromycin is effective, due to cost and a high frequency of gastrointestinal side effects it is also not a recommended treatment.³ Pregnant patients can be treated with ceftriaxone or spectinomycin intramuscularly (a single 2-g dose).

Patients with isolated cervicitis can be treated as outpatients, with follow-up within 5 to 7 days to assess for resolution of symptoms. Patients being treated for cervicitis should be counseled about the signs and symptoms of PID. In addition, patients with persistent symptoms after appropriate therapy should be rescreened for infection, as in most situations this represents a new infection rather than treatment failure. Some experts recommend that adolescents be screened every 3 to 4 months, even if asymptomatic, because of the risk of acquiring a new chlamydia infection. For the treatment of sex partners, one study suggests that patient-delivered treatment is comparable to self-referral, and so should be considered for some patients.³²

Vaginitis

The three most common infectious causes of vaginitis are *Candida albicans*, *Trichomonas vaginalis*, and bacterial vaginosis (BV). Herpes simplex virus can also cause vaginitis; it is discussed in detail later. It is estimated that up to 75% of women will experience at least one episode of vulvovaginal candidiasis (VVC) in their lifetimes.³³ Patients at particularly high risk include pregnant women, patients using corticosteroids or broad-spectrum antibiotics, and patients with diabetes mellitus. Although VVC is generally due to overgrowth of a patient's own organisms, the infection can be sexually transmitted. Approximately 15% of asymptomatic women may harbor *Candida* species during their reproductive years.³⁴ *T. vaginalis* is the most common treatable STI. The CDC estimates there are approximately 7.4 million new cases of trichomoniasis diagnosed each year in women and men.³⁵ Women can contract trichomoniasis from penis-vagina contact or from vulva-vulva contact; men usually contract trichomoniasis from infected women.³⁶

BV is the most common cause of vaginal discharge in women of childbearing age, and is diagnosed in approximately 15% of pregnant women in the United States.³⁷ The infection is characterized by an overgrowth of predominantly anaerobic organisms (*Gardnerella vaginalis*, *Mycoplasma hominis*, and *Prevotella* and *Mobiluncus* species), which replace the normal lactobacilli and increase the vaginal pH from less than 4.5 to as high as 7.0. It is more common in black women, in those who smoke, and in those who use intrauterine devices. Although sexual activity, particularly with multiple partners, is a risk factor for BV, it is unclear what role sexual activity plays in acquiring the infection. Studies suggest that exposure to a new sexual partner is a more important risk factor than frequency of sexual encounters^{38,39}; however, questions remain about the role of sexual activity in the acquisition of BV, particularly because partner treatment shows no benefit. It is thought that frequent episodes of BV are more likely to be relapsed infections rather than reinfection.³⁹

Clinical Presentation

Women with vaginitis generally present with some combination of vulvar irritation and itching, edema or erythema of the genitalia, and excessive or malodorous vaginal discharge. VVC, trichomoniasis, and BV all have specific clinical characteristics that can help narrow the differential diagnosis and guide laboratory evaluation (Table 70–4). Thick, curdy discharge, the classic description of vaginal discharge caused by VVC, is a specific but not very sensitive finding.³⁵ The classic frothy yellow discharge occurs in approximately 10% to 30% of women with *Trichomonas*.³⁶ Studies suggest that trichomoniasis infection is generally not associated with lower abdominal pain and dysuria.⁴⁰ BV is asymptomatic in up to 50% of infected women; symptomatic women generally present with a homogeneous white discharge without signs of inflammation.³⁷

Adolescents presenting with an abnormal vaginal discharge should have a Gram stain of the vaginal discharge as

Table 70–4 Common Causes of Vaginitis

Etiology	Vulvovaginal Candidiasis	Trichomoniasis	Bacterial Vaginosis
Symptoms/Signs	Vulvar itching and soreness Vaginal discharge Superficial dyspareunia Vulvar erythema, edema Fissures, excoriations Satellite lesions	Yellow or purulent vaginal discharge Vulvar itching Vulvar erythema Vaginal erythema	Vaginal discharge No signs of inflammation
Diagnosis	Saline microscopy 10% KOH microscopy Gram stain Culture if previously treated, question about species	Saline microscopy Rapid test (some labs) Culture pH > 4.5	Amsel criteria (at least 3) • homogeneous, white d/c • clue cells • fishy odor with 10% KOH • pH > 4.5
Treatment	Fluconazole 150 mg orally once (not in pregnant patients) or Multiple topical azoles; 1-, 3-, and 7-day treatment options	Metronidazole 2 g once or Metronidazole 500 mg bid × 7 days	Metronidazole 500 mg orally bid × 7 days or Metronidazole gel 0.75%, one full applicator (5 g) intravaginally qd × 5 days or Clindamycin cream 2%, one full applicator (5 g) intravaginally at bedtime for 7 days
Partner Treatment	No, unless partner symptomatic	Yes	No

well as microscopy to help distinguish between the likely causative agents. Symptoms alone should not be used to guide therapy.⁴¹ Gram stain has a sensitivity of 65% for detecting pseudohyphae; microscopy with 10% potassium hydroxide (KOH) has a sensitivity of 70%.³⁴ Of note, KOH is toxic to *T. vaginalis*, so additional microscopy with saline is necessary to detect trichomonads. The saline wet preparation has a sensitivity of 60% to 80% for detecting trichomoniasis. The use of spun urine can improve the detection of *T. vaginalis* in patients with suspected trichomoniasis who have negative wet preparations,⁴² and some laboratories can perform a rapid nucleic acid detection test. If necessary, culture for *T. vaginalis* can be performed, which has a sensitivity of approximately 95%.³⁶ Determining the pH of the vaginal fluid can also be helpful, as both trichomoniasis and BV are associated with a pH greater than 4.5. Culture of vaginal discharge is generally not helpful, with the exception of cases of recurrent VVC or to definitively diagnose a suspected case of trichomoniasis in the setting of a negative wet preparation.

BV can be diagnosed using clinical criteria (proposed by Amsel et al.)⁴³ or by Gram stain (using a scoring system introduced by Nugent et al.).⁴⁴ The two diagnostic methods have been shown to be relatively similar; in a multicenter study comparing Gram stains of vaginal smears to the standard criteria of Amsel et al. for the diagnosis of BV, the sensitivity of the Gram stain method was 89%, with a specificity of 83%.⁴⁵ Although the Gram stain method is more objective, the clinical criteria are more practical in many settings. The clinical criteria require three of the following: (1) a homogeneous, white, noninflammatory discharge that smoothly coats the vaginal walls, (2) the presence of clue cells on microscopic examination (clue cells are irregularly bordered squamous epithelial cells whose cell outlines are obliterated by sheets of small bacteria; they are seen in saline, not KOH, preparations), (3) a vaginal fluid pH of greater than 4.5, and (4) a fishy odor of vaginal discharge before or after addition of 10% KOH. Definitive diagnosis can be made by Gram stain demonstrating few or no lactobacilli with a predominance of *Gardnerella vaginalis* plus other organisms resembling gram-negative *Bacteroides* species, anaerobic gram-positive cocci, or curved rods.

The differential diagnosis for patients with vaginitis includes urinary tract infection and cervicitis, as well as non-infectious irritation of the vulva (e.g., mechanical, chemical, or allergic). In patients at risk for an STI who are diagnosed with vaginitis, it is important to consider concomitant treatment for cervicitis after specimens are sent for *N. gonorrhoeae* and *C. trachomatis*. If these specimens can be obtained without a speculum examination (i.e., urine or vaginal swab), there is generally no indication for a speculum examination in adolescents with vaginitis.⁴⁶

Important Clinical Features and Considerations

It is important to consider the diagnosis of VVC in any patient with vaginal discharge and irritation, even if the discharge is not described as the “classic” thick, curdy discharge. Patients who have four or more episodes of VVC a year are defined as having recurrent VVC; the pathogenesis of this is not well understood, and most women with recurrent VVC do not have an apparent predisposing condition. Vaginal cultures should be obtained in these patients to identify unusual

species.^{3,34} Patients can also present with severe VVC, characterized by extensive vulvar erythema, edema, excoriation, and fissure formation.³ VVC during pregnancy is associated with an increased risk of neonatal oral thrush. Other potential complications of vaginitis include recurrent infections as well as pregnancy-related complications, such as chorioamnionitis, particularly with trichomonas and BV. BV is also associated with premature rupture of membranes, preterm labor, and postpartum endometritis. Finally, BV is associated with an increased risk of infection with *N. gonorrhoeae* and *C. trachomatis*, as well as upper genital tract infection.^{47,48}

Patients who are at risk for an STI can present with more than one infection, so all causes of vaginitis should be considered for every sexually active adolescent. It is possible for patients to be diagnosed with any combination of VVC, trichomoniasis, and BV; therefore, regardless of the characteristics of the vaginal discharge, laboratory evaluation for all three infections should be included as standard workup for the sexually active adolescent presenting with vaginal discharge.

Management

Patients with VVC can be treated either orally, with a single dose of fluconazole,⁴⁹ or with a variety of topical azole therapies (see Table 70–4). For patients with recurrent VVC, although each individual episode usually responds well to short-term azole therapy, experts generally recommend a longer course of topical therapy (7 to 14 days) or, if treating orally, repeating a 150-mg dose of fluconazole on day 3. Patients with recurrent VVC benefit from suppressive maintenance therapy, which is usually continued for 6 months. Similarly, patients with severe VVC should also be treated with a 7- to 14-day course of topical therapy or two doses of oral fluconazole, 72 hours apart.

Infection with *T. vaginalis* is treated with metronidazole, either as a single dose or a 7-day course. Because of compliance issues, most adolescents should be treated with the single dose. Metronidazole gel is not recommended because, as a topical preparation, it is unlikely to achieve therapeutic levels in the urethra or perivaginal glands.³ Some strains of *T. vaginalis* have decreased susceptibility to metronidazole; however, these strains usually respond to higher doses, so patients who remain symptomatic after either regimen should be treated with 500 mg twice a day for 7 days. A third course of antibiotics, using 2 g daily for 3 to 5 days, can also be used. If the patient remains symptomatic after three courses of metronidazole, the CDC recommends consultation with a specialist; CDC specialists can be reached by telephone (770-488-4115).

All women with symptomatic BV should be treated, with the goal of relieving vaginal symptoms and signs of infection and to reduce the risk for other infections, such as human immunodeficiency virus (HIV) and PID.³⁸ In the pregnant patient, treatment of BV is particularly important. Recommended treatment for BV is with oral metronidazole for 7 days, intravaginal metronidazole gel, or intravaginal clindamycin cream; the clindamycin cream is thought to be less effective than the metronidazole regimens. Other alternative treatments include metronidazole in a single 2-g dose and oral clindamycin for 7 days; these regimens are also less effective than the other metronidazole regimens. Intravaginal preparations are not recommended for pregnant patients.

Patients with isolated vaginitis generally do very well with appropriate therapy. Follow-up for uncomplicated VVC, trichomonas, and BV is unnecessary for patients unless symptoms persist. Nucleic acid amplification tests are under development for *Trichomonas*, which may in the future aid in diagnosis. BV is a difficult diagnosis, particularly in the acute care setting; if uncertainty about the diagnosis exists and the patient is not pregnant, it is appropriate to arrange follow-up without providing treatment.

Genital Ulcers

Herpes Genitalis

Genital herpes, caused by either herpes simplex virus type 1 (HSV-1) or type 2 (HSV-2), is the second most prevalent STD in the United States, affecting at least 50 million people.⁵⁰ HSV-2 is believed to be the most common cause of genital herpes, although recent studies suggest that HSV-1 may account for more than the 30% of infections previously attributed to HSV-2, particularly in certain populations. Specifically, sexually acquired HSV-1 is more common in younger age groups, in women, and in men who have sex with men.⁵¹ The two strains of herpesvirus have very different natural histories, so determining the particular type of infection can be important for treatment and counseling.⁵² HSV initially causes epithelial infection, and then establishes latency in sacral neuronal ganglia. Once latency is established, there is no cure for the disease, and reactivation of the virus causes recurrent disease.

CLINICAL PRESENTATION

Patients with either type of HSV usually present with multiple painful 1- to 2-mm vesicles on an erythematous base. The eruption of ulcers is often preceded by paresthesias or burning sensations in the genital area. The early lesions then erode to become shallow ulcers, and may coalesce. Patients are at risk for secondary infection as well. Primary infections tend to be more severe than recurrences, and patients with a primary infection can also present with systemic symptoms such as fever, malaise, and myalgias. In addition, patients may complain of dysuria, urinary retention, and dyspareunia. Systemic symptoms peak within 3 to 4 days and then improve; pain and irritation are maximal between days 7 and 11, and lesions can persist for about 2 weeks. The total duration of a primary episode, including healing, is about 3 weeks. In contrast, recurrent infections generally present with fewer lesions that are smaller in size, with a total duration from onset to resolution of about 1 week. After the first year, recurrences tend to decrease in frequency, and recurrence of disease caused by HSV-1 is much less common than recurrence of disease caused by HSV-2. In fact, some studies suggest that the recurrence rate of HSV-1 is just 20% of the rate of HSV-2, and that recurrence after the first year with HSV-1 is very uncommon.⁵²

The differential diagnosis of patients presenting with genital ulcers includes early syphilis, chancroid, lymphogranuloma venereum (LGV), contact dermatitis, molluscum contagiosum, and genital lesions of Behçet's syndrome.

Because the prognoses for infection with HSV-1 and HSV-2 differ dramatically, most experts recommend testing both to confirm the diagnosis of herpes genitalis and to identify the viral serotype. Multiple testing strategies for HSV exist.^{53,54}

Isolation of HSV in cell culture is the preferred test, although the sensitivity of culture declines as lesions begin to heal. A culture specimen can be obtained when intact vesicles are present by aspirating the vesicle fluid using a fine-gauge needle, or unroofing a vesicle and swabbing the fluid using a cotton or Dacron swab. If pustules are present, a specimen can be obtained by unroofing the pustule, washing away purulent material with sterile saline, and swabbing the base of the lesion. For ruptured vesicles or ulcers, or for crusted lesions, a specimen can be obtained by washing away any necrotic material with sterile saline and swabbing the base of the lesion. Cervical Papanicolaou smears and Tzanck tests of genital lesions are both insensitive (30% to 70%) and non-specific, and so should not be used routinely. Immunofluorescence techniques can differentiate between the two serotypes, and are very sensitive and specific, and rapid. Because of the possibility of false-positive tests, repeat or confirmatory testing (with an immunoblot assay) may be indicated in some patients.⁵⁵

Although the classic presentation of herpes genitalis is unmistakable, many patients present with less classic symptoms. Therefore, it is important to consider other causes of genital ulcers in most patients. Complications of infection with HSV include significant psychological distress; local complications such as secondary bacterial infection, phimosis, labial adhesions, urinary retention, and constipation; proctitis, particularly in men who have sex with men; herpes keratitis; and encephalitis and meningitis. Furthermore, infants born to women with genital herpes infection are at risk for neonatal infection.

MANAGEMENT

Sitz baths or tap water compresses can provide some symptomatic relief, and petroleum jelly may also relieve some discomfort from crusting and fissuring. Three systemic antiviral medications have been shown in randomized, controlled trials to provide clinical benefit for first clinical episodes, for recurrent episodes, and as suppressive therapy: acyclovir, valacyclovir, and famciclovir.⁵⁵⁻⁵⁸ Topical antiviral therapy has little proven benefit and is not recommended.³ For the first clinical episode, antivirals used within 6 days of the onset of lesions have been shown to shorten viral shedding by 10 days, to dramatically reduce the number of new lesions, to decrease pain by about 25%, and to reduce time to healing by 4 to 9 days. Episodic therapy for recurrences reduces viral shedding and healing time by about 1 day; a more dramatic effect in healing time has been noted when patients initiate therapy early in the recurrence. In order to be effective, therapy should begin within 1 day of lesion onset. Suppressive therapy can reduce the frequency of recurrent infections by more than 75% in patients with six or more recurrences per year.^{59,60} All three medications have an excellent safety profile and are well tolerated. For patients with severe disease or complications that require hospitalization, such as disseminated infection, pneumonitis, hepatitis, encephalitis, or meningitis, intravenous acyclovir should be used³ (Table 70-5).

The safety of systemic acyclovir, valacyclovir, and famciclovir therapy in pregnant patients has not been well established, although studies suggest that there is not an increased risk for major birth defects compared with the general population for women exposed to acyclovir during the first

Table 70–5 Treatment for Herpes Genitalis

First Clinical Episode Treat for 7–10 days, longer if healing incomplete	Acyclovir 400 mg orally tid <i>or</i> Acyclovir 200 mg orally 5 times a day <i>or</i> Famciclovir 250 mg orally tid <i>or</i> Valacyclovir 1 g orally bid
Recurrent Episodes Treat for 5 days, unless using valacyclovir 500 mg orally twice a day; then 3 days is sufficient	Acyclovir 400 mg orally tid <i>or</i> Acyclovir 200 mg orally 5 times a day <i>or</i> Acyclovir 800 mg orally bid <i>or</i> Famciclovir 125 mg orally bid <i>or</i> Valacyclovir 500 mg orally bid <i>or</i> Valacyclovir 1 g orally qd
Suppressive Therapy Valacyclovir 500 mg regimen may be less effective than the other regimens in patients with ≥10 episodes per year	Acyclovir 400 mg orally bid <i>or</i> Famciclovir 250 mg orally bid <i>or</i> Valacyclovir 500 mg orally qd <i>or</i> Valacyclovir 1 g orally qd

From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Recomm Rep 55(RR-11):1–100, 2006.

trimester. Some experts recommend acyclovir therapy, particularly late in pregnancy, in order to reduce the risk of recurrences.

Approximately 90% of patients with HSV-2 will experience at least one recurrence; up to 40% can have at least six recurrences in the first year. Recurrence with HSV-1 infection is much less likely. Patients should refrain from sexual intercourse until the lesions are healed, and should be counseled that transmission can occur even in the absence of symptoms. Counseling about the disease is an important aspect of treatment, although many patients benefit more from counseling once the acute episode has resolved. The CDC has a National STD/HIV Hotline (800-227-8922), and a useful website is <http://www.ashstd.org>. Follow-up in 1 week is recommended, particularly to reinforce the implications of the diagnosis and to address psychological concerns. Vaccines for HSV are currently under development.⁶¹

Syphilis

Syphilis, a systemic disease caused by *Treponema pallidum*, is becoming much less common in the United States, due at least in part to the fact that in 1998 the CDC launched a national plan to eliminate the disease. However, despite an 80% decrease in the number of cases of syphilis reported to the CDC since 1990, syphilis continues to be among the top 10 reportable diseases, and in 2000 affected almost 6000 people.⁶² In adolescents, syphilis is more common among females. The disease in adolescents has been linked to cocaine use and drug-related sexual behavior. Real and perceived barriers to health care access likely also contribute to the rate of syphilis in this population due to delayed treatment and prolonged infectivity.⁶³

CLINICAL PRESENTATION

Syphilis can be divided into three stages: primary, secondary, and tertiary. In addition, latent infections (which can be early or late) are detected by serology in the absence of clinical symptoms. Primary syphilis presents with an ulcer or chancre at the infection site. The site of infection is usually the ano-

genital area or the mouth; breasts and fingers are less common sites. In fact, 95% of chancres are located on the external genitalia. Single lesions are common, but multiple lesions do occur; lesions that touch each other across folds of skin are referred to as “kissing lesions.” The chancre is usually 1 to 2 cm in diameter, and begins as a painless papule that erodes into an indurated, painless ulcer. Regional firm, nontender lymphadenopathy can accompany the lesion.

Secondary syphilis develops about 4 to 10 weeks after the chancre, and is characterized most commonly by a general skin eruption with a predilection for the palms and soles. The eruption involves mucous membranes, is bilateral and symmetric, and tends to follow lines of cleavage. Individual lesions are sharply demarcated, up to 2 cm in diameter, and have a reddish brown hue. The rash is usually macular, papular, or papulosquamous; vesicular and pustular rashes are rare. The eruption may last anywhere from several weeks to up to a year. Other manifestations of secondary syphilis include general or regional lymphadenopathy (nonpainful, rubbery, discrete nodes) and a flulike syndrome, most often with sore throat and malaise but also with headaches, lacrimation, nasal discharge, arthralgias, weight loss, and fever. Other rare manifestations of secondary syphilis include syphilis alopecia (moth-eaten appearance of the scalp and eyebrows), arthritis or bursitis, hepatitis, iritis and anterior uveitis, and glomerulonephritis.

Tertiary syphilis, which occurs 2 to 10 years after initial exposure in untreated patients, is rare in adolescents. Tertiary syphilis presents with cardiovascular symptoms (usually 10 to 30 years after exposure) and with gummas, which are granulomatous lesions that involve skin, soft tissue, viscera, or bones. The lesions are few in number, asymmetric, and not contagious.

Neurosyphilis is also rare in adolescents; most cases in this age group are asymptomatic or present as acute syphilitic meningitis. Acute syphilitic meningitis has signs and symptoms similar to those of other causes of acute meningitis, including fever, headache, photophobia, and meningismus. Cranial nerve palsies are present in about 40% of cases.

DIAGNOSIS

The differential diagnosis of primary syphilis includes sexually transmitted causes of genital ulcers, such as herpes, chancroid, and LGV, as well as non-sexually transmitted causes of ulcers, including traumatic lesions, fixed drug reaction, Candida, Behçet’s syndrome, psoriasis, lichen planus, and erythema multiforme. Also in the differential diagnosis is cancer, which is very rare in adolescents. Other etiologies with presentations similar to secondary syphilis include pityriasis rosea, drug eruptions, tinea versicolor, lupus erythematosus, scabies, pediculosis, rosacea, infectious mononucleosis, and condyloma acuminatum. Although the clinical history and appearance of the lesions can often distinguish these etiologies, serology tests for syphilis should be performed if there is any doubt about the diagnosis.

Darkfield microscopic examination and direct fluorescent antibody (DFA) tests of lesion exudate or tissue are the definitive methods for diagnosing primary syphilis, according to the CDC. Darkfield examination is simple and fairly reliable, with a sensitivity of 73% to 79%.⁶⁴ Some experts recommend repeating the examination on 3 separate days before determining that the test is negative. Failure to detect the organ-

ism using this technique does not ensure that the patient does not have syphilis; in addition, technical factors, such as too little or too much fluid on the slide, can affect the results. Darkfield microscopy should not be performed on samples of lesions on the mouth or anus, areas where nonpathogenic treponemes are often present. DFA is performed at some reference laboratories and some state health departments, and has a slightly better sensitivity than darkfield microscopy (73% to 100%).⁶⁴

A presumptive diagnosis of syphilis can be made using two types of serologic tests: (1) nontreponemal tests, including the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests; and (2) treponemal tests, including the fluorescent treponemal antibody, absorbed (FTA-Abs) and the *T. palladium* particle agglutination (TP-PA) tests.^{64,65} Nontreponemal tests are used for screening and to monitor therapy. The VDRL is the test of choice for evaluating for neurosyphilis, and has a slightly higher specificity when compared to the RPR (96% to 99% compared to 93% to 99%), resulting in fewer false-positive tests. However, the RPR has a slightly better sensitivity (86% compared to 78% for primary syphilis), and so is most often used for screening. Both tests have 100% sensitivity for secondary syphilis; the RPR is slightly more sensitive than the VDRL for detecting tertiary syphilis (73% vs. 71%) and latent syphilis (98% vs. 95%). Many disorders can result in false-positive nontreponemal tests, including acute infections (such as viral infections, chlamydial infections, Lyme disease, *Mycoplasma* infections, and nonsyphilitic spirochetal infections), autoimmune diseases, narcotic addiction, sarcoidosis, lymphoma, cirrhosis, and aging. Therefore, all positive nontreponemal tests need to be confirmed with a treponemal test.

Presumptive diagnosis of primary or secondary syphilis can be made based on a positive nontreponemal test with a titer of at least 1:8 (for primary syphilis) or a titer that rises more than two dilutions, combined with a positive treponemal test. Adolescents with a positive darkfield examination should be treated, as well as adolescents with a typical lesion and a positive serologic test. Routine lumbar puncture is not indicated for patients with primary syphilis; this test should be limited to patients with clinical signs and symptoms of neurologic involvement. Adolescents suspected of having secondary syphilis who have atypical findings or a nontreponemal titer of less than 1:16 should have a second nontreponemal test and a treponemal test performed. The titer results of an RPR and a VDRL cannot be compared.

The diagnosis of neurosyphilis can be difficult, because although the cerebrospinal fluid (CSF) VDRL is highly specific, it is somewhat insensitive (60% to 70%).^{3,64} Other laboratory findings in neurosyphilis include an elevated CSF leukocyte count (>5 WBCs/mm³) and increased CSF protein. The CSF FTA-Abs is less specific than the CSF VDRL, but is much more sensitive; some experts believe that a negative CSF FTA-Abs excludes neurosyphilis. In addition to patients with neurologic symptoms, evaluation for neurosyphilis should be performed in patients with ophthalmologic symptoms (e.g., uveitis), in patients who have treatment failure, in patients who have serum nontreponemal test titers of $\geq 1:32$ unless disease duration is known to be less than 1 year, and in patients in whom nonpenicillin therapy is planned, unless disease duration is known to be less than 1 year.

If latent syphilis is a concern, both an RPR/VDRL and an FTA-Abs test should be performed, because the nontreponemal tests have a sensitivity of about 70%. The adolescent should be treated if the FTA-Abs is positive and there is no documentation of prior treatment.

The diagnosis of syphilis should be considered in any sexually active patient with a genital ulcer or a generalized rash. The clinical presentation of syphilis can manifest in many different ways, and can mimic other diagnoses such as pityriasis rosea. One of the most difficult aspects of diagnosing syphilis is interpreting the various serologic tests. As mentioned earlier, many other disorders can result in a false-positive nontreponemal test. False-negative nontreponemal tests can occur in early or late syphilis. False-negative and false-positive treponemal tests are rare. However, both types of tests can be negative if sexual contact with an infected individual occurred within the preceding 90 days. Most treated patients continue to have positive treponemal tests for life; persistently positive nontreponemal tests usually indicate inadequately treated disease. The complications of syphilis, which result from untreated early disease, can be prevented with timely therapy.

MANAGEMENT

The treatment of choice for syphilis is penicillin G, administered parenterally (Table 70–6). Penicillin is the only proven therapy for neurosyphilis and syphilis during pregnancy. Penicillin-allergic patients in these categories should undergo desensitization prior to treatment. Although there are some data indicating that oral azithromycin may prove to be an effective therapy, currently that drug is not recommended.⁶⁶

The Jarisch-Herxheimer reaction occurs within 2 hours after treatment in 50% of patients with primary syphilis, 90% of patients with secondary syphilis, and 25% of patients with early latent syphilis. Fever and chills, myalgias, headache, elevated neutrophil count, and tachycardia characterize the reaction. The symptoms last 12 to 24 hours, and treatment is reassurance, bed rest, and antipyretics. The reaction can produce uterine contractions in pregnant women; however, this is not a contraindication to treatment.³

Syphilis is spread from person to person only when mucocutaneous lesions are present, which are rare after 1 year of infection. However, anyone who has been exposed sexually to a patient with syphilis should be evaluated. Patients exposed to someone with primary, secondary, or latent syphilis within the last 90 days should be treated presumptively; if exposure occurred more than 90 days ago but follow-up is uncertain, the patient should also be treated presumptively. For the purposes of partner notification and presumptive treatment, patients with syphilis of unknown duration who have high nontreponemal serologic test titers (i.e., at least 1:32) can be considered to have early syphilis. However, the titer should not be used to differentiate early from late latent syphilis for the purposes of treatment. Long-term sex partners of patients with latent syphilis should be evaluated clinically and serologically; treatment can be based on the results of this evaluation.

Adolescents diagnosed with syphilis require close follow-up to monitor the results of therapy. Some experts recommend HIV testing for all patients diagnosed with syphilis. Consultation with an infectious disease expert should be considered.

Table 70–6 Treatment for Syphilis

	Primary/Secondary	Early Latent	Late Latent	Tertiary	Neurosyphilis
Recommended	Benzathine PCN G 2.4 million units IM once	Benzathine PCN G 2.4 million units IM once	Benzathine PCN G 2.4 million units IM weekly × 3 doses	Benzathine PCN G 2.4 million units IM weekly × 3 doses	Aqueous PCN G 3–4 million units IV q4h × 10–14 days <i>or</i> Procaine PCN 2.4 units IM qd <i>plus</i> probenecid 500 mg orally qid × 10–14 days Ceftriaxone 2 g qd × 10–14 days
Possible alternatives (nonpregnant patients)	Doxycycline 100 mg orally bid × 14 days <i>or</i> Tetracycline 500 mg qid × 14 days	Doxycycline 100 mg orally bid × 14 days <i>or</i> Tetracycline 500 mg qid × 14 days	Doxycycline 100 mg orally bid × 14 days <i>or</i> Tetracycline 500 mg qid × 14 days		
Potentially effective (close follow-up necessary)	Ceftriaxone 1 g qd IM or IV × 10 days <i>or</i> Azithromycin 2 g orally once				

Abbreviations: IM, intramuscularly; IV, intravenously; PCN, penicillin.

Lymphogranuloma Venereum

LGV is rare in the United States; there were 113 known cases in 1997, although this number likely represents a falsely low prevalence due to underreporting and misdiagnosis. LGV is caused by serovars L1, L2, and L3 of *C. trachomatis*. The peak incidence of the disease is in people ages 15 to 40 years, and males account for about 75% of cases.

CLINICAL PRESENTATION

After an incubation period of 3 to 30 days, the primary stage of LGV is characterized by a small, painless papule at the site of the inoculation. The lesion may ulcerate, and is self-limiting. It is often not noticed by the patient. An associated mucopurulent discharge of the urethra or cervix can also be present. The secondary stage occurs several weeks later, and chiefly involves the inguinal lymph nodes; the anus or rectum can also be involved, particularly in women or in men who have sex with men. In women, the deep iliac or perirectal nodes can be involved, which may result in low back pain or abdominal pain. Painful regional adenopathy is the most common manifestation of secondary disease; nodes are typically enlarged and unilateral, and can become infected and develop necrotic abscesses. The characteristic bubo is produced when the lymph nodes become matted and fluctuant. The buboes may rupture in as many as one third of patients, but most buboes heal without problems. Most men present during this phase, but only one third of women do, since women tend not to develop inguinal lymphadenopathy. Patients may also complain of constitutional symptoms such as headache, fever, chills, and myalgias. The third phase is a genitoanorectal syndrome, which is uncommon but occurs more commonly in women who were asymptomatic earlier in the disease.⁶⁷

Differential diagnosis considerations for a genital-inguinal lesion include syphilis, HSV, chancroid, granuloma inguinale, pyogenic infection, and cat-scratch fever. For patients

with rectal fistulas, inflammatory bowel disease, chronic rectal infections such as gonorrhea and amebiasis, and granuloma inguinale should be considered. The diagnosis of LGV is made serologically and by excluding other causes of inguinal lymphadenopathy or genital ulcers.

Clinically, it can be difficult to distinguish LGV from chancroid. It is important to keep LGV in the differential diagnosis for patients presenting with genital ulcers or inguinal adenopathy, particularly if the patient has had sexual contact with a person in or from Asia or Africa, where the disease is much more common. Late-stage disease can be complicated by elephantiasis of the genitalia, rectal strictures, and rectal fissures.

MANAGEMENT

The preferred treatment is doxycycline 100 mg orally twice a day for 21 days. Alternatively, erythromycin base, 500 mg orally four times a day for 21 days, can be used. Buboes may require aspiration or incision and drainage to prevent the formation of inguinal/femoral ulcerations. Sexual contacts within 30 days before the onset of the patient's symptoms should be examined, tested for urethral or cervical chlamydial infection, and treated. Pregnant women should be treated with erythromycin.^{3,67}

Treatment cures the infection and prevents ongoing tissue damage, although scarring can result from tissue reaction. Rectovaginal fistulas, bowel obstruction, and extensive genital destruction require surgical treatment. Patients should be followed clinically until signs and symptoms have resolved.

Chancroid

Chancroid is a genital ulcer infection caused by *Haemophilus ducreyi*. It is endemic in some parts of the United States, and occurs in discrete outbreaks as well. In 2000, 78 cases of chancroid were reported to the CDC; like LGV, however,

chancroid is likely very underreported because of the difficulty of culturing the organism as well as the fact that the diagnosis is not often considered.⁶⁸ Using new DNA amplification methods, the CDC has identified this infection in cities where it was previously not diagnosed. About 10% of patients in the United States with chancroid are co-infected with *T. pallidum* or HSV, and chancroid is a cofactor for transmission of HIV.³

CLINICAL PRESENTATION

After an incubation period of 3 days to 2 weeks, a small inflammatory papule or pustule develops at the inoculation site. Within days the papule erodes to form a very painful, deep ulceration, usually 3 to 20 mm in diameter, that is soft, friable, and nonindurated. A foul-smelling, yellow-gray exudative covering is usually present, along with surrounding erythema. Men often have a single ulcer, while women often have several. Within several weeks, up to 60% of patients will develop unilateral, painful inguinal lymphadenopathy, which can develop into a suppurative bubo. Fever and malaise may occur. Extragenital sites are rare. Other forms include transient chancroid, which consists of an ulcer that rapidly resolves in less than a week and is followed by suppurative inguinal lymphadenitis; follicular chancroid, which has ulcerations in hair-bearing areas; the dwarf variety, which manifests as one or more herpetiform ulcerations; and giant chancroid, which consists of multiple small ulcerations that rapidly expand and coalesce to form a single large ulceration. A painful ulcer and tender inguinal adenopathy, combined with suppurative inguinal adenopathy, is almost pathognomonic for chancroid.⁶⁹

The differential diagnosis is similar to that for LGV: herpes genitalis, primary syphilis, Behçet's syndrome, traumatic lesions, or fixed drug eruptions. In adolescents, the most common causes of ulcerative lesions are, in descending order, herpes, nonspecific trauma, syphilis, and chancroid. A definitive diagnosis of chancroid can be made using a special culture medium for *H. ducreyi*; however, this medium is not widely available, and culture has a sensitivity of only 80%.⁷⁰ A probable diagnosis can be made if all of the following criteria are met⁶⁹: (1) the patient has one or more painful genital ulcers, (2) the patient has no laboratory evidence of syphilis at least 7 days after the onset of the ulcers, (3) the clinical presentation is consistent with chancroid, and (4) a test for HSV performed on ulcer exudate is negative. It is important to keep chancroid in the differential for patients with genital ulcers; the diagnosis can be easily missed because it is not very common.

MANAGEMENT

Recommended treatments are azithromycin 1 g orally in a single dose; ceftriaxone 250 mg intramuscularly (IM) in a single dose; ciprofloxacin 500 mg orally twice a day for 3 days; or erythromycin base 500 mg orally three times a day for 7 days. Ciprofloxacin should not be used in pregnant or lactating women.^{69,71}

Treatment cures the infection, leads to resolution of clinical symptoms, and prevents transmission to others. Patients who are uncircumcised or who have HIV infection may not respond as well as other patients to therapy. The CDC recommends that all patients diagnosed with chancroid be tested for HIV, and retested for syphilis and HIV 3 months after the

diagnosis if initial tests are negative. Patients should be reexamined 3 to 7 days after initiation of therapy; ulcers generally improve symptomatically within 3 days and objectively within 7 days. Sex partners should be examined and treated if they had contact with the patient within the 10 days preceding the onset of symptoms.

Genital Growths

Human Papillomavirus

Human papillomavirus (HPV) is the most prevalent STI in the United States among adolescent and young adult women. More than 30 types of HPV can infect the genital tract; most infections are asymptomatic, subclinical, or go unrecognized. HPV types 6 and 11 are the usual etiologies for visible genital warts and can cause respiratory papillomatosis in infants and children, although the risk is less than 0.04%.

Major risk factors are related to sexual behavior, and include multiple sex partners, first intercourse within 18 months after menarche, increased frequency of sexual intercourse, and, for men, failure to use a condom.^{72,73} The relationship between condom use and the acquisition of HPV by women is less clear.

CLINICAL PRESENTATION

There are four major types of warts caused by HPV. Condylomata acuminatum is the classic cauliflower-shaped growth with a granular surface. Papular warts are flesh-colored, smooth, dome-shaped papules that are 1 to 4 mm in size. Keratotic warts have a thick, crustlike layer, and resemble common skin warts. Flat-topped warts are macular or slightly raised and are invisible to the naked eye. The lesions occur most commonly on the cervix of women (70%) and the inner surface of the prepuce of men (70%); circumcised males are more likely to have involvement of the shaft of the penis. Other sites include the vulva (25%), the anus (20%), the vagina (10%), and the urethra (5%) for women. Up to 25% of males can have involvement of the urethral meatus. Lesions are usually asymptomatic, but can cause itching, burning, fissuring, pain, or bleeding.

The differential diagnosis for HPV includes condylomata lata (secondary syphilis), molluscum contagiosum, granuloma inguinale, seborrheic keratosis, neoplasia, and, in males, pink pearly papules (parallel rows of lesions at the corona of the penis that are normally present in about 15% of the population).

In most cases, external genital warts can be diagnosed clinically. If the diagnosis is uncertain, if the lesions do not respond to therapy, or if the disease worsens during therapy, biopsy can be used to confirm the diagnosis. All women with external genital warts should undergo a speculum examination to look for the presence of disease internally.

Although genital HPV is sexually transmitted, it is possible to contract external condylomata by autoinoculation or inoculation with HPV from skin warts. In addition, virus can be passed to an infant during delivery. The HPV types that cause skin warts can be transmitted by fomites, and virus has been recovered from sauna benches, underwear, examination gloves, and tanning couches. It is unclear whether or not fomites are an important source of infection for transmission of genital HPV. Any pediatric patient presenting with genital warts should be evaluated for evidence of sexual abuse.

MANAGEMENT

The primary goal of treating visible warts is symptomatic treatment, although some patients with asymptomatic lesions will want to be treated for cosmetic or psychological reasons. If left untreated, some warts will resolve spontaneously, although there is no way to predict which patients will experience spontaneous resolution. Some patients may choose to wait and see how the lesions progress prior to initiating therapy. Current data suggest that treating warts may reduce infectivity, but probably does not completely eliminate it. There are quite a few acceptable treatment regimens; selection of treatment should be based on the preference of the patient, the available resources, and the experience of the health care provider (Table 70–7).

All therapies are cytotoxic, except for topical 5% imiquimod cream and intralesional interferons, which are immunotherapies. Treatments are rarely administered in the ED. Patients should be referred to a gynecologist or primary care physician for definitive therapy. Complications from therapy are rare when the treatments are employed properly. Persistent hypo- or hyperpigmentation is common after ablation. Other complications include depressed or hypertrophic scars or, rarely, chronic pain syndromes. Local inflammatory reactions are common with the use of podofilox and imiquimod. Pain and sometimes necrosis and blistering can occur after application of liquid nitrogen. Imiquimod, podophyllin, and podofilox should not be used during pregnancy.

Patients should be counseled that recurrences, particularly within the first 3 months, might occur. Sex partners of patients with genital warts should be examined, because self- or partner examination has not been evaluated as a diagnostic method, and patients may miss lesions. However, there is no indication for treating in order to prevent future transmission, since the role of treatment in affecting infectivity is unknown. In addition, there is no indication that reinfection plays a role in recurrences. Many young women will become negative for HPV within 24 months of diagnosis.⁷³ There is no evidence that the presence of external genital warts is associated with the development of cervical cancer.

Molluscum Contagiosum

Molluscum contagiosum is a viral infection that is becoming increasingly common in sexually active adolescents. In ado-

lescents and adults, molluscum is most commonly transmitted by sexual contact, although it can be transmitted by casual contact, fomites, or self-inoculation.⁷⁴ In sexually active adolescents, the lesions are commonly seen on the genital and pubic areas. The lesions are firm, flesh-colored, waxy, dome-shaped, globular nodules with central umbilication. There are usually between 1 and 20 lesions between 3 and 7 mm in diameter, which occur in clusters. The lesions are usually asymptomatic, although inflammatory changes can occur. Some patients may experience pruritis or tenderness.

Differential diagnosis includes condylomata acuminata and vulvar syringoma for multiple small lesions, and squamous or basal cell carcinoma for large, solitary lesions. The diagnosis is usually made clinically, although several techniques can aid in the diagnosis. For example, spraying the lesion with ethyl chloride produces a distinct central area of darkness that is not found in warts, and unroofing the lesion with a 27-gauge needle reveals the presence of a white “pearl.” Biopsy is rarely necessary.

Most molluscum lesions will resolve spontaneously, although this process can take 6 months to 5 years. Many experts recommend treatment of genital molluscum lesions to reduce the risk of transmission and to prevent auto-inoculation, as well as to improve the patient’s quality of life. Treatment modalities are similar to those for external genital warts, and include physician-administered (electrosurgery, curettage, cryosurgery, trichloroacetic acid [TCA] application, and podophyllin) and patient-administered (podofilox, retinoic acid, and imiquimod 1% or 5% cream) modalities. The physical and chemical ablation techniques are associated with pain, irritation, and mild scarring; because of the caustic nature of TCA and podophyllin, only a small area can be treated at one time. Several open-label and randomized, controlled trials indicate that imiquimod cream is well tolerated and effective for the treatment of molluscum lesions, providing a novel treatment, particularly for patients who do not tolerate other therapies or in whom other therapies are not effective.^{3,74–76}

Patients should be followed up in 30 days in order to assess for new lesions that may have been incubating at the time of treatment. Sex partners require treatment only if lesions are present.

Table 70–7 Treatment of Genital Warts

Patient Administered	Provider Administered
Podofilox 0.5% solution or gel, applied with a cotton swab (solution) or finger (gel) to warts twice a day for 3 days, then no therapy for 4 days. Can repeat for up to 4 cycles. Limit to 10 cm ² of area and 0.5 ml of podofilox. Imiquimod 5% cream, applied once daily at bedtime, 3 times a week for up to 16 weeks. The treatment area should be washed 6–10 hr after the application.	Cryotherapy; can repeat every 1–2 wk. Podophyllin resin 10%–25% in a compound tincture of benzoin, applied to each wart and allowed to air dry. Can repeat weekly. Limit to 10 cm ² of area and ≤0.5 ml of podophyllin. BCA/TCA 80%–90%, with a small amount applied only to warts. A white “frosting” will develop. If excess acid is applied, remove with talc, baking soda, or liquid soap. Can repeat weekly. Surgical removal with tangential scissor excision, tangential shave excision, curettage, or electrosurgery.

Abbreviations: BCA, bichloroacetic acid; TCA, trichloroacetic acid.

Urethritis and Epididymitis

STIs in males include urethritis, epididymitis, and orchitis. Orchitis is discussed in Chapter 89 (Penile/Testicular Disorders). Urethritis is the most common manifestation of *N. gonorrhoeae* and *C. trachomatis* infection in males. Other etiologies of nongonococcal urethritis include *Ureaplasma urealyticum* and *Mycoplasma genitalium*, as well as *T. vaginalis* and HSV.

Clinical Presentation

Urethritis presents with urethral discharge and inflammation. Spontaneous discharge is often noted in the morning, after holding urine overnight. Dysuria and pruritis can also be present. Infection with *C. trachomatis* is often asymptomatic; when symptoms are present, they tend to be more mild than those associated with gonococcal infection. Even without symptoms, however, males infected with *C. trachomatis* usually have evidence of urethral inflammation on laboratory evaluation of secretions or urine.⁷⁷⁻⁷⁹

The presence of mucopurulent urethral discharge is adequate to make the diagnosis of urethritis; if in doubt, a Gram stain of the urethral secretions demonstrating ≥ 5 WBCs per oil immersion field can confirm the diagnosis. Gram stain is the preferred diagnostic test, because it has high sensitivity and specificity, and can also identify gonococcal infection by the presence of intracellular diplococci. Alternatively, a positive leukocyte esterase test on first-void urine or microscopic examination of first-void urine demonstrating ≥ 10 WBCs per high-power field supports the diagnosis. Definitive tests for *N. gonorrhoeae* and *C. trachomatis* should also be sent; either cultures from the urethra or nucleic acid amplification tests, using a urine specimen, are appropriate.⁸⁰ Testing for *T. vaginalis* is generally reserved for patients who do not respond to therapy, or to patients with a known infected contact. The differential diagnosis of urethritis includes the

infectious etiologies noted previously, as well as allergic inflammation, trauma, and foreign body.

Gonococcal infection can spread and cause prostatitis, epididymitis, seminal vesiculitis, and infection of Cowper's and Tyson's glands. Epididymitis is characterized by urethral discharge, dysuria, scrotal pain and tenderness that is usually unilateral, scrotal swelling and erythema, pain/tenderness/swelling of the lower pole of the epididymis, and swelling and pain of the spermatic cord. Prostatitis can be asymptomatic; when symptoms are present, they include chills, fever, malaise, rectal pain, lower back pain, lower abdominal pain, and urinary symptoms such as dysuria, frequency, and acute urinary retention. Like females, males are also at risk for pharyngitis, rectal infection, conjunctivitis, otitis externa, and disseminated disease. Proctitis has become much less common over the last decade, but is still important to consider in the differential of any sexually active patient with gastrointestinal symptoms.

Chlamydial infection can also cause epididymitis, which is often a more indolent infection than that caused by *N. gonorrhoeae*. Other complications include proctitis as well as Reiter's syndrome, which is characterized by conjunctivitis, dermatitis, urethritis, and arthritis. Some patients can have isolated arthritis or reactive tenosynovitis without the other characteristics of Reiter's syndrome. The role of *C. trachomatis* in prostatitis is unclear.

Management

Patients with confirmed uncomplicated gonococcal infection of the urethra or rectum should be treated with ceftriaxone or a fluoroquinolone, preferably administered during the ED visit (Table 70–8). Although there has been some concern about the use of fluoroquinolones in children younger than 18 years, the CDC has stated that, because no joint injury has been documented in children treated with prolonged

Table 70–8 Treatment for Other Gonococcal* and Chlamydial Infections

Infection	Treatment [†]
Uncomplicated gonococcal infection of the urethra or rectum	Ceftriaxone 125 mg IM once <i>or</i> Ciprofloxacin 500 mg orally once <i>or</i> Ofloxacin 400 mg orally once <i>or</i> Levofloxacin 250 mg orally once
Nongonococcal urethritis	Azithromycin 1 g orally once <i>or</i> Doxycycline 100 mg orally bid \times 7 days
Recurrent/persistent urethritis	Metronidazole 2 g orally once <i>plus</i> erythromycin base 500 mg orally qid for 10 days
Epididymitis	Ceftriaxone 250 mg IM once <i>plus</i> doxycycline 100 mg orally bid \times 10 days <i>Or, if allergy</i> Ofloxacin 300 mg orally bid \times 10 days <i>or</i> Levofloxacin 500 mg orally qd \times 10 days
Uncomplicated gonococcal infections of the pharynx	Ceftriaxone 125 mg IM once <i>or</i> Ciprofloxacin 500 mg orally once
Gonococcal conjunctivitis	Ceftriaxone 1 g IM once; saline lavage of the affected eye(s)
Disseminated gonococcal infection: therapy should continue for 24–48 hr after improvement; then be switched to oral therapy to complete 7 days treatment	Ceftriaxone 1 g IM q24h <i>or</i> Ciprofloxacin 400 mg IV q12h <i>or</i> Levofloxacin 250 mg IV daily
Gonococcal meningitis or endocarditis	Ceftriaxone 1–2 g q12h for 10–14 days (meningitis) or at least 4 wk (endocarditis)

*Patients with gonococcal infections should generally be treated for concomitant chlamydial infection.

[†]The reader is referred to the CDC Sexually Transmitted Diseases web site (<http://www.cdc.gov/STD/>) for additional regimens.

Abbreviation: IM, intramuscularly.

From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Recomm Rep 55(RR-11):1–100, 2006.

ciprofloxacin regimens, any patient weighing over 45 kg can be treated with any of the recommended regimens. Treatment for gonococcal pharyngitis is either ceftriaxone 125 mg IM in a single dose, or ciprofloxacin 500 mg orally in a single dose. Patients with gonococcal conjunctivitis should be treated with ceftriaxone 1 g IM once, as well as one lavage of the eye with normal saline. Patients with epididymitis can usually be treated as outpatients, although hospitalization is recommended when severe pain suggests other diagnoses, such as torsion, or if the patient is febrile. For all infections, if chlamydial infection is not ruled out, dual therapy is recommended.³ Patients with disseminated gonococcal infection should be hospitalized for treatment, particularly if compliance is questionable, the diagnosis is uncertain, or purulent synovial effusions or other complications are present.

Cure rates for uncomplicated gonococcal and chlamydial infections are high. If symptoms recur, patients should be re-treated with the original regimen if compliance is in doubt or if the patient has been reexposed to an infected partner. Patients with nongonococcal urethritis that is not due to *C. trachomatis* have relapse rates of up to 50% after 2 months; some cases are caused by tetracycline-resistant *U. urealyticum*. Patients with gonococcal infection who have persistent symptoms after treatment should be evaluated by culture in order to assess sensitivities of the organism.³ Patients with epididymitis who do not improve after 3 days of therapy should be re-evaluated to assess for other causes, such as tumor, abscess, infarction, tuberculosis, and fungal infection. All sex partners within 60 days, as well as the patient's most recent sex partner if more than 60 days ago, should be treated whether or not they are symptomatic. Patients should refrain from sexual intercourse for 7 days after treatment is completed and until symptoms have resolved.

Neonatal Infections^{3,81,82}

Both *N. gonorrhoeae* and *C. trachomatis* can cause ophthalmia neonatorum, which generally presents in patients less than 30 days old. Prophylaxis with erythromycin eye drops helps prevent gonococcal disease, but does not affect the incidence of chlamydia.³ Therefore, gonococcal ophthalmia should be considered in patients who did not receive prophylaxis and in children of mothers who did not receive prenatal care or who have a history of STIs. Other gonococcal infections include scalp abscess and disseminated disease with bacteremia, arthritis, or meningitis. *C. trachomatis* can also cause pneumonia.

Clinical Presentation

Infants born to mothers with a history of HSV can present with a variety of clinical syndromes; in addition, neonatal herpes can be present in infants born to mothers without a clear history of HSV, as well as in infants born via cesarean section. Infections have been documented despite presumed intact membranes. The risk to an infant born to a mother with a primary HSV infection is 33% to 50%; risk to infants of mothers with reactivated infection is less than 5%.⁸³ Infections usually present within the first 4 weeks of life. Most cases of congenital syphilis are diagnosed through routine prenatal and antenatal screening of the mother. However, a small number of patients may present to the ED during the neonatal period.

Infants with gonococcal ophthalmia generally present with a hyperpurulent eye discharge and very injected conjunctivae, although symptoms can be more subtle. Other causes of conjunctivitis in this age group include chemical conjunctivitis (often from prophylactic eyedrops, which presents in the first 3 days of life), other bacterial causes, and viral causes. Any infant with a purulent eye discharge should have a Gram stain of the discharge to evaluate for intracellular diplococci, as well as a viral culture of conjunctival cells (obtained via conjunctival scraping with a Dacron-tipped swab) to evaluate for Chlamydia. Culture of the eye discharge alone is not adequate to diagnose chlamydial infection. A limited number of nonculture tests are licensed by the Food and Drug Administration for conjunctival specimens.⁸⁴ Patients with intracellular diplococci on Gram stain should be treated presumptively for gonococcal infection until culture results are available. Culture is important for definitive diagnosis because other species of *Neisseria* can be indistinguishable from *N. gonorrhoeae* on Gram stain. Blood cultures and lumbar puncture can be reserved for patients with other signs of systemic disease, such as fever.

Infants with chlamydia pneumonia generally present with a staccato cough, tachypnea, and hyperinflation and bilateral diffuse infiltrates on chest radiograph. Specimens for Chlamydia testing should be obtained from the nasopharynx.

Neonatal HSV can present with disseminated disease, most often involving the lung and the liver; with localized central nervous system disease, with meningitis and focal seizures; or with disease localized to the skin, eyes, and mouth. Infants with HSV often present without skin lesions. Lesions can be evaluated for HSV as described earlier; if CSF is obtained, an HSV polymerase chain reaction test is available in many laboratories. In addition, serum can be sent for culture for the systemically ill infant.

Infants with congenital syphilis who are symptomatic can present with hepatosplenomegaly, snuffles, lymphadenopathy, mucocutaneous lesions, edema, rash, hemolytic anemia, or thrombocytopenia. Testing for syphilis in the neonate is similar to that described earlier; diagnosis is likely if the patient has clinical features consistent with syphilis and either a serum quantitative nontreponemal serologic titer that is fourfold greater than the mother's titer, or a positive darkfield or FTA-Abs test of body fluids. Patients with proven or highly probable disease should have a lumbar puncture and a complete blood count, and other tests, such as long-bone radiographs and liver function tests, as clinically indicated.

Important Clinical Features and Considerations

Because of the severe sequelae of gonococcal ophthalmia, infants with eye discharge should be assumed to have this infection until proven otherwise. Untreated, the infection can progress to corneal ulceration and to globe rupture within 24 hours of infection. Topical therapy is not adequate for either gonococcal or chlamydial ophthalmia neonatorum.

Given the high morbidity and mortality of neonatal herpes infection, this should be considered in any neonate with fever, irritability, and abnormal CSF results. A careful physical examination is necessary to identify skin lesions, particularly in the scalp and near the eyebrows.

Evaluation for congenital syphilis in the ED setting is limited to patients with clinical symptoms. There is no indication for routine screening in this setting.

Management

Patients with presumed gonococcal ophthalmia should be treated with ceftriaxone, 25 to 50 mg/kg intravenously (IV) or IM in a single dose (maximum 125 mg), and should be admitted to the hospital for frequent saline lavage of the eye until the discharge clears. These patients should be evaluated by an ophthalmologist. Patients with scalp abscesses or disseminated infection should be treated for 7 days, or for 10 to 14 days if meningitis is present. Patients with chlamydial ophthalmia neonatorum or pneumonia should be treated with erythromycin base or ethylsuccinate 50 mg/kg per day orally, in four divided doses, for 14 days. Infants treated with erythromycin for chlamydial infection should be followed up to determine treatment effectiveness; about 20% of these patients fail initial therapy and require a second course.

Infants with HSV should be treated with acyclovir 20 mg/kg IV every 8 hours for 14 days for skin disease, and for 21 days for meningitis. Infants with ocular involvement should also receive a topical ophthalmic drug, such as 1% to 2% trifluridine, and be evaluated by an ophthalmologist.

Infants with symptomatic congenital syphilis should be treated with aqueous penicillin G 50,000 units/kg per dose IV every 12 hours for the first 7 days of life and every 8 hours thereafter, for a total of 10 days, or procaine penicillin G 50,000 units/kg per dose IM daily for 10 days. All infants with congenital syphilis require close follow-up and repeat testing.

Chapter 71

Selected Infectious Diseases

Robert P. Olympia, MD

Key Points

Lyme disease, the leading cause of vector-borne infectious illness in the United States, is associated with three distinct clinical stages: early localized, early disseminated, and late disseminated.

“Food-borne illness” refers to an acute onset of symptoms, ranging from vomiting, diarrhea, and abdominal pain/cramping to potential life-threatening complications, caused by the ingestion of contaminated food. Onset and duration of symptoms vary, depending on the specific cause.

Distinguishing between diseases associated with foreign travel can be difficult since many present with fever associated with constitutional symptoms such as headache, myalgias, malaise, anorexia, and vomiting/diarrhea.

Young children with infectious mononucleosis are often asymptomatic, although they may present with low-grade fever, pharyngitis, lymphadenopathy, splenomegaly, malaise, rash, headache, anorexia, nausea, chills, and myalgias.

2002. It is caused by the spiral-shaped bacterium *Borrelia burgdorferi*. The bacterium is transmitted to humans via the bite of an infected deer tick, of which there are two types: the western black-legged tick (*Ixodes pacificus*), causing disease on the Pacific coast, and the black-legged tick (*Ixodes scapularis*), causing disease in the northeastern and north-central United States. The reservoirs for these ticks are the white-footed mouse and deer. Transmission is based on the length of attachment of the tick, with low risk of transmission associated with less than 24 to 48 hours of attachment. Lyme disease is commonly found in the northeastern mid-Atlantic and midwestern portions of the United States, as well as several counties in northwestern California. Outside the United States, the disease can be found in Spain, France, Austria, Germany, Russia, and Japan. Clinical manifestations of Lyme disease may present year-round, with a higher incidence during late spring to summer (May to August).

CLINICAL PRESENTATION

Lyme disease is associated with three distinct clinical stages: early localized, early disseminated, and late disseminated (Table 71–1). Clinical findings are based on time from the initial exposure (bite of the infected tick). The classic rash of Lyme disease is erythema migrans (EM), commonly found on the head or neck in young children or the extremities of older children. The lesion begins as a small red maculae or papule at or adjacent to the site of the bite, which enlarges in an annular centrifugal fashion to approximately 10 to 15 cm in diameter, resembling a “bull’s eye.” EM is commonly associated with nonspecific symptoms such as fever, fatigue, malaise, headache, myalgias, and arthralgias. EM, found in only two thirds of humans bitten by an infected tick, appears typically 14 days after the initial exposure. The rash and constitutional symptoms are typically self-limited and not dependent on treatment with antibiotics.

If untreated, early disseminated Lyme disease may occur weeks to months following initial exposure. Of those cases that progress, 20% develop neurologic manifestations (cranial neuropathy, radiculoneuropathy, aseptic meningitis/encephalitis),¹ 10% develop cardiac manifestations (myopericarditis, atrioventricular [AV] block, or cardiomyopathy), and 20% develop multiple EM. The most common cranial neuropathy associated with Lyme disease is Bell’s palsy (peripheral VII nerve palsy), which may be unilateral or bilateral. While commonly confused with viral meningitis, Lyme meningitis is more often associated with Bell’s palsy,

Selected Diagnoses

- Tick-borne illnesses
 - Lyme disease
 - Ehrlichiosis
- Food-borne illness
- Diseases associated with foreign travel
- Infectious mononucleosis
- Severe acute respiratory syndrome

Discussion of Individual Diagnoses

Tick-borne Illnesses

Lyme Disease

Lyme disease is the leading cause of vector-borne infectious illness in the United States, with 23,000 cases reported in

Table 71-1 Clinical Findings and Treatment* in Lyme Disease

Stage (Time from Initial Exposure)	Treatment [†]
Early Localized (7–14 days)	
Erythema migrans	Amoxicillin 50 mg/kg/day divided bid <i>or</i> Doxycycline [‡] 100 mg bid × 14–21 days
Early Disseminated (days to weeks)	
Multiple erythema migrans	Amoxicillin (as above) × 21–28 days
Neurologic	
Cranial neuropathy (Bell's palsy)	Amoxicillin (as above) × 21–28 days
Radiculoneuritis	Amoxicillin (as above) × 21–28 days
Aseptic meningitis/encephalitis	Ceftriaxone 75–100 mg/kg/day × 14–28 days or 30–60 days depending on clinical response
Cardiac	
Myopericarditis	Ceftriaxone (as above) × 14–21 days
Atrioventricular block	Cardiology consult
Cardiomegaly	Cardiology consult
Musculoskeletal	
Arthralgias	Supportive care
Myalgias	Supportive care
Late Disseminated (weeks to months)	
Arthritis	Amoxicillin (as above) × 28 days
Chronic polyneuropathy	Supportive care
Chronic encephalopathy [§]	Supportive care

*Treatment for Lyme disease may have different recommendations from different sources; consultation with an infectious disease expert should be considered.

[†]Cefuroxime axetil or erythromycin can be used for penicillin-allergic patients.

[‡]Only in children 8 years or older.

[§]Sleep disturbance, fatigue, mood changes, concentration difficulty, and memory loss.

papilledema, longer duration of symptoms prior to lumbar puncture, lack of fever at time of diagnosis, and cerebrospinal fluid (CSF) pleocytosis (especially neutrophils).²

Late disseminated Lyme disease is associated with oligoarthritis (most common manifestation), chronic polyneuropathy, and chronic encephalopathy (commonly manifesting as sleep disturbance, fatigue, mood changes, concentration difficulty, memory loss).³ The arthritis associated with late disseminated disease is often limited to large weight-bearing joints.⁴

The diagnosis of Lyme disease can be made clinically, serologically, or by polymerase chain reaction (PCR) (Table 71-2). The clinical diagnosis can be made simply by identifying the classic EM rash, or by identifying one clinical manifestation (arthritis, cranial neuropathy, AV block, aseptic meningitis, or radiculoneuritis) and isolation of or serologic evidence of *B. burgdorferi* infection. Enzyme-linked immunosorbent assay (ELISA) or Western blot techniques, both of which detect immunoglobulin M (IgM) and immunoglobulin G (IgG), are serologic tests that can confirm the diagnosis. In Lyme disease, IgM peaks approximately 4 weeks and IgG approximately 6 weeks after initial exposure. The Centers for Disease Control and Prevention recommends the use of ELISA as the initial screening test, and confirmation with the Western blot if the ELISA is positive (due to cross reactivity

Table 71-2 Diagnosis of Lyme Disease

Erythema migrans *or* at least one manifestation (arthritis, cranial neuropathy, AV block, aseptic meningitis, radiculoneuritis) and isolation or serologic evidence of *Borrelia burgdorferi* infection

Serologic evidence

 Perform enzyme-linked immunosorbent assay (ELISA) first

 If positive, confirm with Western immunoblot

 Polymerase chain reaction (PCR)—may be used on blood, CSF

 fluid, or synovial fluid

Supportive

 Elevated WBC count, sedimentation rate, AST, complement

 C3/C4

 Joint fluid with 25,000–125,000 WBCs/mm³ with

 polymorphonuclear predominance

 CSF with mild pleocytosis (<1000 cells) and neutrophil

 predominance

on ELISA of Epstein-Barr virus [EBV], parvovirus, syphilis, systemic lupus erythematosus, and juvenile rheumatoid arthritis).⁵ PCR may also be used to amplify DNA of *Borrelia burgdorferi* in blood, CSF fluid, and synovial fluid. Other laboratory tests, such as complete blood count, erythrocyte sedimentation rate, aspartate aminotransferase (AST), and complement factors (C3/C4), may help to support the diagnosis of Lyme disease. The differential diagnosis of Lyme disease can be found in Table 71-3.

MANAGEMENT

Early localized Lyme (EM) can be treated with oral antibiotics for 14 to 21 days (see Table 71-1). Children from an endemic area presenting with constitutional symptoms

without EM and a documented tick bite may be tested for Lyme and treated prophylactically. While most experts do not recommend performing a lumbar puncture on children with Bell's palsy and suspected Lyme disease who are otherwise well appearing, clinical evidence of meningitis or encephalitis does warrant a lumbar puncture, with cerebrospinal fluid sent for PCR analysis, hospitalization of the child, and intravenous antibiotics for 30 to 60 days. Cardiac manifestations of Lyme disease require hospitalization of the child, intravenous antibiotics, and cardiology consultation. Oligoarthritis associated with Lyme disease should be confirmed by either serologic or PCR analysis and treated with oral antibiotics for 28 days. Chronic polyneuropathy and chronic encephalopathy require neurologic consultation. It is recommended that all complicated cases of Lyme disease be referred to either a pediatric infectious disease or rheumatology specialist.

Children presenting with a deer tick attached to the skin should have it removed promptly. Ticks should be removed with either tweezers or fingers shielded with rubber gloves, grasping the tick as close to the skin as possible and pulling with steady, even pressure without squeezing or crushing the body of the tick. Prophylactic antibiotic treatment has not traditionally been recommended in the case of an attached tick since the transmission rate is low (<10%), but a recent prospective study found that 200 mg of doxycycline was effective in preventing EM in adults living in hyperendemic areas who had removed an attached deer tick within the prior 72 hours. However, this regimen is unproven in children and has the potential for significant side effects in those less than 8 years of age. Therefore, it cannot be routinely recommended.^{6,7}

Ehrlichiosis

Human ehrlichiosis is caused by the bite of an infected tick. In the United States, the lone star tick (*Amblyomma americanum*), the black-legged tick (*Ixodes scapularis*), and the western black-legged tick (*Ixodes pacificus*) are known vectors. The four species known to cause disease in humans are *Ehrlichia chaffeensis*, *phagocytophila*, *equi*, and, most recently, *ewingii*.⁸ Ehrlichiae are small, gram-negative bacteria that invade leukocytes, causing two clinically similar illnesses: human monocytic ehrlichiosis (reported from the southeastern and south-central United States) and human granulocytic ehrlichiosis (reported from Wisconsin and Minnesota).⁸⁻¹⁰

CLINICAL PRESENTATION

Disease caused by *Ehrlichia* species occurs more frequently in the spring and summer months, especially between April and September. Although rates of ehrlichiosis increase with age, there have been reported cases of severe and fatal infections in children and young adults. The incubation of *Ehrlichia* is 5 to 10 days after the initial tick bite. Infected humans may be asymptomatic, or may exhibit constitutional symptoms such as fever (>38°C), headache, malaise, myalgias, nausea, vomiting, diarrhea, cough, photophobia, arthralgias, confusion, and rash. The rash associated with ehrlichiosis occurs in 60% of infected children, and can be described as macular, maculopapular, or petechial, occurring on the face, trunk, and extremities, or rarely (<10%) on the palms or soles. If untreated, ehrlichiosis may progress

to more severe illness: meningoencephalitis, seizure, coma, cardiomyopathy, adult respiratory distress syndrome, respiratory failure, disseminated intravascular coagulation, and renal failure. The mortality rate is 2% to 3%.⁸⁻¹⁰

The diagnosis of human ehrlichiosis can be made on clinical suspicion, but is confirmed by blood smear (demonstrating the organisms by Giemsa staining or Diff-Quick methods), serologic testing (indirect immunofluorescence), PCR, or blood culture. Serologic testing may not be useful in the first week as IgM and IgG levels increase during the second week of illness. Laboratory findings associated with ehrlichiosis include leukopenia (60%), thrombocytopenia (70%), elevated liver enzymes (85%), and hyponatremia less than 130 mEq/L (40%). Differential diagnosis of ehrlichiosis includes Rocky Mountain Spotted Fever, meningococcal infection, subacute bacterial endocarditis, secondary syphilis, idiopathic thrombocytopenic purpura, gonococcemia, and neoplastic disease.⁸⁻¹⁰

MANAGEMENT

Antibiotics should not be withheld pending diagnostic studies in children with clinical suspicion for human ehrlichiosis. Doxycycline (4.4 mg/kg per day divided twice a day, maximum daily dose 200 mg) for children ages 8 years or older should be given by either the oral or the intravenous route and continued for at least 3 days after the defervescence of the fever, for a minimum of 5 to 10 days. The use of doxycycline may be considered in children less than 8 years of age in consultation with an infectious disease expert, recognizing the potential for significant side effects. Children who are toxic appearing, have severe constitutional symptoms, or have severe illness (adult respiratory distress syndrome, meningoencephalitis, renal failure, disseminated intravascular coagulation, coma, cardiomyopathy) should be admitted to the hospital for supportive care. Consultation with pediatric infectious disease and critical care specialists should be considered.

Food-borne Illness

“Food-borne illness” refers to an acute onset of symptoms caused by the ingestion of contaminated food. The etiology of contamination in food may be infectious agents such as bacteria, bacterial toxins, or viruses, or noninfectious causes, such as poisons or chemicals. Onset and duration of symptoms vary, depending on the specific cause.¹¹

CLINICAL PRESENTATION

The clinical manifestations of food-borne illness caused by infections depend on whether an enterotoxin or cytotoxin is released by the etiologic organism.¹² Enterotoxins, which can be formed prior to ingestion or while in the intestine, cause symptoms without penetrating the intestinal mucosa, leading to watery diarrhea, usually without leukocytes (Table 71-4). Cytotoxins cause destruction of the lining of the intestinal mucosa, resulting in bloody diarrhea with leukocytes, and may invade lymphatic tissue, causing systemic symptoms (Table 71-5). An infectious etiology not caused by either an enterotoxin or cytotoxin is *Clostridium botulinum*. Symptoms include descending weakness and paralysis within 4 days of the ingestion of contaminated canned foods, such as mushrooms, smoked fish, or vegetables. Symptoms result from the absorption of botulinum toxin by the intestine,

Table 71–4 Enterotoxins Causing Food-borne Illness

Agent	Source	Incubation (hr)	Clinical Manifestations*	Treatment
Staphylococci	Improperly stored meats, bakery, dairy	2–6	Intense vomiting and watery diarrhea, abdominal cramps, low-grade fever	Supportive
<i>Bacillus cereus</i>	Contaminated grains, meats, vegetables	1–6	Intense vomiting, abdominal cramps	Supportive; vancomycin or ciprofloxacin if invasive
<i>Clostridium perfringens</i>	Inadequately cooked meats and poultry	8–16	Diarrhea and abdominal cramps	Supportive
<i>Vibrio cholerae</i>	Contaminated water and food (shellfish)	8–20	Abdominal cramps and diarrhea; vomiting and fever are rare	Supportive
<i>Vibrio parahaemolyticus</i>	Raw or improperly cooked seafood	8–24	Profuse “rice” watery diarrhea for 3–5 days without abdominal cramps or fever	Tetracycline or doxycycline (shortens duration of symptoms)
Enterotoxigenic <i>Escherichia coli</i>	Contaminated meats, cheese, salads	8–24	Profuse watery diarrhea for 3–5 days	Tetracycline or doxycycline (shortens duration of symptoms)
<i>Giardia lamblia</i>	Contaminated water	2–3 days	Watery diarrhea ± vomiting or abdominal cramping	Supportive
			Mild bloody diarrhea ± abdominal cramping for possibly more than 1 wk, ± anorexia	Metronidazole

*Clinical manifestations for less than 2 days unless noted.

Table 71–5 Cytotoxins Causing Food-borne Illness

Agent	Source	Incubation (hr)	Clinical Manifestations	Treatment
Salmonella	Beef, poultry, dairy, eggs, fish, reptiles	12–30	Abrupt onset of moderate to large amount of diarrhea becoming bloody ± abdominal pain or vomiting or low-grade fever	Intravenous cephalosporin if bacteremic, <3 mo of age, or immunosuppressed
Shigella	Potato, egg salad; lettuce, raw vegetables	12–30	Abrupt onset of bloody diarrhea, tenesmus, abdominal cramps lasting 3–7 days	Bactrim or ampicillin if severe disease, dysentery, or immunosuppressed
<i>Campylobacter jejuni</i>	Undercooked chicken or cattle	3–5 days	Foul-smelling, watery then bloody diarrhea ± abdominal cramps for 5–8 days, ± fever	Azithromycin or erythromycin (shortens duration of symptoms)
<i>Yersinia enterocolitica</i>	Contaminated pork or milk	4–6 days	Acute abdominal pain, fever, diarrhea	Bactrim or gentamycin (decreases duration of fecal excretion)
<i>Escherichia coli</i> O157:H7	Food or water contaminated with cow feces	3–5 days	Severe bloody diarrhea with painful abdominal cramps and low-grade fever; hemolytic-uremic syndrome in 3%–5%	Supportive
<i>Entamoeba histolytica</i>	Contaminated food or water	12–24	Sudden onset of bloody diarrhea with vomiting or abdominal cramps possibly lasting for more than a week	Metronidazole

which blocks the release of acetylcholine at the neuromuscular junction. Treatment may require respiratory support in an intensive care setting.

Enterotoxins, which produce symptoms within 4 to 6 hours of ingestion, include *Staphylococcus aureus* and *Bacillus cereus*. Cytotoxin-induced illness requires ingestion of organisms that must then multiply and invade the mucosa of the gastrointestinal tract. For this reason, patients often develop symptoms more than 6 to 12 hours after the food is ingested. Cytotoxins are more likely to produce fever, bloody diarrhea, and severe systemic symptoms.

For the most part, diagnosis is made clinically. However, a majority of food-borne illness can be diagnosed by routine stool culture or specialized staining, microscopic analysis for ova and parasites, or detection of toxin in the stool. Prior to laboratory results, history, such as onset and duration of symptoms, frequency and consistency of vomiting and/or diarrhea, presence of abdominal cramping, or systemic symptoms, will provide some clues to the etiology of the illness in the emergency department. Also important is the type of food ingested prior to symptoms, recent travel history, and similar symptoms in close contacts.

Physical examination should focus on the state of hydration as well as other potential life-threatening complications, such as neurologic, respiratory, hepatic, and renal failure. Laboratory studies, such as complete blood count, blood culture, or serum electrolyte analysis, may be helpful to determine the extent of systemic involvement. Stool cultures should be reserved for cases of bloody diarrhea, severe abdominal pain, immunocompromised or very young hosts, or toxic-appearing infants and children. Stool analysis for ova and parasites should be considered in cases of prolonged incubation or duration of symptoms. Some infectious causes, such as *Yersinia*, may mimic appendicitis, and therefore radiologic studies may be required to rule out an acute abdomen. In pediatric patients, two potential complications that should be looked for are Guillain-Barré syndrome (associated with *Campylobacter* infection) and hemolytic-uremic syndrome (associated with *Escherichia coli* O157:H7) (see Chapter 47, Peripheral and Neuromuscular Disorders; and Chapter 88, Renal Disorders).¹³

MANAGEMENT

While a majority of cases of food-borne illness can be managed at home without any specific therapy, some children require hospitalization, intravenous hydration therapy, and antibiotics (see Tables 71–4 and 71–5; see also Chapter 72, Vomiting and Diarrhea, for additional information on food-borne illness).

Diseases Associated with Foreign Travel

Distinguishing between diseases associated with foreign travel can be difficult since many present with fever associated with constitutional symptoms such as headache, myalgias, malaise, anorexia, and vomiting/diarrhea. Therefore, history of recent travel to endemic areas should point to a possible diagnosis.

Typhoid fever, caused by ingestion of contaminated water or food with *Salmonella typhi*, is endemic to India and Africa. Malaria, caused by the bite of an infected mosquito transmitting a species of *Plasmodium*, is endemic to sub-Saharan

Africa, Southeast Asia, and India. Dengue fever, caused by the bite of an infected mosquito (*Aedes aegypti*), is endemic to the Caribbean and Central and South America.

The clinical features and complications associated with these selected diseases are varied and often overlap (Table 71–6). Management includes diagnosis by clinical suspicion, followed by supportive care and antibiotics if indicated. Intensive care hospitalization is necessary if complications are present. Consultation with a pediatric infectious disease specialist is also suggested.^{14–17}

Infectious Mononucleosis

Clinical Presentation

Infectious mononucleosis is caused by Epstein-Barr virus (EBV), a member of the herpesvirus family. Infection is transmitted via contact with oropharyngeal secretions. While commonly asymptomatic in young children, adolescents and young adults often present with low-grade fever, pharyngitis, lymphadenopathy, and splenomegaly after an incubation of 4 to 6 weeks. Other constitutional symptoms associated with EBV include malaise, rash, headache, anorexia, nausea, chills, and myalgias. Rare complications of EBV infections include pancreatitis, cholecystitis, myocarditis, myositis, glomerulonephritis, encephalitis, transverse myelitis, and cranial nerve palsies (Table 71–7). Spontaneous splenic rupture occurs in 1% to 2% of cases of infectious mononucleosis. The differential diagnosis of infectious mononucleosis includes rubella, *Toxoplasma gondii*, adenovirus, human immunodeficiency virus, cytomegalovirus, human herpesvirus-6, and Stevens-Johnson syndrome.

The diagnosis of infectious mononucleosis can be made either by clinical suspicion or serologic testing.¹⁸ Heterophile antibodies are typically present in 75% of older children and adolescents by the end of the first week of symptoms, and in 90% by the third week of symptoms. In children younger than 10 years, there is a 10% to 15% false-negative rate for detecting heterophile antibodies. EBV antigens can also be detected to determine stage of illness. Laboratory

Table 71–6 Selected Infections Associated with Foreign Travel

Disease	Initial Symptoms	Complications	Diagnosis	Treatment
Typhoid fever	Fever increase over 2–3 days, headache, malaise, cough, rose spots. After 1st week: coma, abdominal distention, “pea soup” diarrhea, respiratory distress	Intestinal hemorrhage, intestinal perforation, acute renal failure, myocarditis, DIC	Stool culture for <i>Salmonella</i> ; serologic tests (ELISA); elevated ESR, PT/PTT, LFTs; hyponatremia, hypokalemia, anemia	Ciprofloxacin, chloramphenicol, cefotaxime, ampicillin
Malaria	Paroxysms of fever, chills, sweats; flulike symptoms, vomiting and diarrhea, febrile seizures, meningitis, anemia, jaundice	Toxicity, high fever, dehydration, severe anemia, seizure/coma, pulmonary edema, renal failure, shock, bleeding diathesis	Blood smear (thick/thin); serologic tests (ELISA)	Chloroquine, quinine, quinidine, mefloquine, halofantrine
Dengue fever	Fever, headache (frontal/retro-orbital), generalized macular rash, bone pain, nausea/vomiting, anorexia, cutaneous hyperesthesias	Dehydration, bleeding diathesis, DIC, shock, myocarditis, encephalopathy, liver failure	Serologic tests (ELISA); leukopenia, thrombocytopenia; elevated BUN, LFTs	Supportive care

Abbreviations: BUN, blood urea nitrogen; DIC, disseminated intravascular coagulation; ELISA, enzyme-linked immunosorbent assay; ESR, erythrocyte sedimentation rate; LFTs, liver function tests; PT, prothrombin time; PTT, partial thromboplastin time.

Table 71–7 Clinical Manifestations of Infectious Mononucleosis**Early Findings**

Classic triad
 Fever
 Pharyngitis (exudative or nonexudative)
 Lymphadenopathy (bilateral posterior cervical)
 Rash (generalized maculopapular)

Late Findings

Hepatomegaly/splenomegaly
 Jaundice
 Palatal petechiae
 Chronic fatigue

Rare Findings

Pancreatitis
 Cholecystitis
 Myocarditis
 Myositis
 Glomerulonephritis
 Encephalitis
 Transverse myelitis
 Cranial nerve palsies

Unique to EBV

Bilateral upper lid edema
 Uvular edema

studies supportive of EBV include elevated transaminase levels, relative lymphocytosis (>60%) with greater than 10% atypical lymphocytes, mild to moderate leukocytosis (12,000 to 20,000 cells/ μ l), mild thrombocytopenia, and elevated erythrocyte sedimentation rate.

Management

Treatment of infectious mononucleosis is supportive. Several studies have demonstrated some effectiveness of corticosteroids in reducing the pain associated with pharyngitis.^{19,20} In children and young adults with splenomegaly, close follow-up (at least 3 weeks from the beginning of symptoms) is required with their primary care physician. Those who participate in contact sports or extreme activities should refrain over this time period.²¹

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS), caused by a member of the Coronaviridae virus family, produces a flulike illness that may progress to life-threatening complications, such as pneumonia, respiratory failure, or death.²² Thought to be originally from the Guangdong province in southern China when 305 cases of atypical pneumonia occurred there in February 2003, subsequent outbreaks have seen the illness spread to Asia, Canada, and the United States. The mortality rate has been estimated at 10%. A detailed clinical case definition of SARS may be found at www.cdc.gov/ncidod/sars/.

Clinical Presentation

After an incubation period of 2 to 10 days, patients present with constitutional symptoms such as fever (>100.4°F), headache, myalgias, fatigue, chills, anorexia, and diarrhea, followed in 2 to 7 days with nonproductive cough, dyspnea, and progressive hypoxemia. Mechanical ventilation may be nec-

essary in patients with respiratory failure. Chest radiographs demonstrate pneumonia (focal interstitial or generalized patchy infiltrates) after a week of symptoms. Lymphopenia develops in 70% to 90% of infected patients. Other laboratory findings associated with SARS include leukopenia, thrombocytopenia, mild hyponatremia and hypokalemia, elevated liver enzymes, and elevated creatine kinase.

The diagnosis of SARS can be made in patients with both (1) radiologic confirmation of pneumonia or acute respiratory distress syndrome of unknown etiology and (2) one of the following risk factors 10 days before onset of illness: travel to mainland China, Hong Kong, or Taiwan or close contact with an ill person with history of recent travel to those areas; health care or laboratory worker in close contact with patient with suspected SARS; or involvement in cluster of cases of atypical pneumonia. Other serologic testing is necessary, but should be at the recommendation of local and state health departments.

Management

Patients with a suspicion of SARS should be admitted to a critical care unit for supportive care. Respiratory droplet precautions should be instituted. Controversy exists regarding the efficacy of corticosteroids or ribavirin in the treatment of patients with SARS.²³

Vomiting and Diarrhea

Courtney H. Mann, MD

Key Points

The differential diagnosis and workup of the patient with *isolated* vomiting are different from those for a patient with vomiting *and* diarrhea.

The differential diagnosis for vomiting is age specific.

To be confident of the diagnosis of gastroenteritis, vomiting *and* diarrhea must be present.

Assessment for dehydration must incorporate historical, physical, and laboratory findings, as no one finding alone can sufficiently predict the degree of fluid deficit present.

Oral rehydration and new antiemetics are proving to have a role in treating pediatric vomiting and diarrhea.

Introduction and Background

Vomiting is an extremely common complaint in infants and children who present to the emergency department (ED). A large percentage of infants and children with vomiting have a viral etiology for their symptoms and have a self-limiting, vomiting disease process. However, vomiting may be the presenting symptom for several life-threatening conditions. The child who presents to the ED with vomiting may not require multiple laboratory analyses and extensive testing; however, a complete history and physical examination tailored to identify serious conditions is essential.

“Diarrhea” is defined as an increase in the quantity of stools. Children frequently have an occasional “loose” stool; however, an increase in stool volume separates children with true diarrhea from those with normal stool patterns. While vomiting may be caused by a viral illness, *gastroenteritis*, as a diagnosis, must include both vomiting and diarrhea. Gastroenteritis accounts for significant illness in young children; estimates suggest that the average child younger than 5 years old in the United States has between 1.3 and 2.3 episodes of gastroenteritis per year.¹ Gastroenteritis is a common cause of mortality for children in developing countries, accounting for over 2 million deaths annually, and also results in over

1.5 million outpatient visits, 200,000 hospitalizations, and 300 deaths per year in the United States.^{2,3}

Recognition and Approach

Generally, it is not difficult to recognize the child who presents with vomiting and diarrhea; however, the history is often as important as the physical examination in determining the underlying etiology and the potential for dehydration. Depending on the underlying etiology and severity of illness, clinical presentations vary widely.

The pathophysiology of nausea and vomiting is complex and not completely understood. There are multiple different input triggers to the brain for vomiting; however, the actual coordination of vomiting by the brain occurs in the same area of the medulla oblongata regardless of the type of input. Input areas include receptors in the gastrointestinal (GI) tract, chemoreceptors in the area postrema of the brainstem that monitor emetic agents in the blood and cerebrospinal fluid, and vestibular and visual afferents.⁴ Because there are many different neurotransmitters involved in vomiting, not all therapies will abolish all types of vomiting. In general, serotonin receptor antagonism has been the target of pharmacologic therapies for vomiting.

The pathophysiology of diarrhea is also multifactorial. The average adult intestinal epithelium must handle 6500 ml of fluids per day, and this volume is reduced to less than 250 ml/day of stool output. During diarrhea, fluid output overwhelms the capacity of the GI tract to reabsorb fluids.^{2,5} Diarrheal illness may result from a great number of causes. From an infectious standpoint, however, there are two types of pathogens that cause a diarrheal illness: inflammatory and noninflammatory. Inflammatory illness is usually caused by invasion of the intestinal border and cytotoxin production by certain types of bacteria. In contrast, the pathogens that cause noninflammatory diarrhea produce endotoxins and cause local destruction of the intestinal border.

Clinical Presentation

Clinical features of a child who presents to the ED with vomiting or diarrhea depend on the severity of the illness and the underlying etiology. Diagnostically, it is convenient to consider the child who presents with isolated vomiting separately from the child who presents with vomiting and diarrhea. The differential diagnosis of isolated vomiting is extraordinarily

broad and age specific. Possible etiologies include toxicologic, infectious, metabolic, neurologic, and pregnancy, as well as psychological and behavioral issues (Table 72–1).

Disorders Causing Vomiting or Diarrhea

Gastroesophageal Reflux

In the young infant, gastroesophageal reflux (GER) is often a cause of recurrent vomiting or “spitting up”; however, reflux is a diagnosis of exclusion in the ED. Physiologically, GER is distinct from vomiting. GER results from effortless regurgitation of gastric contents and is attributed to a motility disturbance affecting the esophagus and lower esophageal sphincter.⁶ GER is common during infancy, with as many as 50% of infants having recurrent regurgitation during the first 4 months of life⁷ (see Chapter 35, Vomiting, Spitting Up, and Feeding Disorders). Formula changes are largely unnecessary and can become expensive and frustrating for parents. Basic reflux precautions such as smaller, more frequent feeds and allowing the infant to remain upright for 30 minutes after feeds can be helpful. Reassuring the family that most children spontaneously outgrow GER by the age of 1 usually helps alleviate parental anxiety.

Once more life-threatening conditions are excluded, the healthy newborn with suspected reflux, who is well appearing and gaining weight, may be safely discharged with close follow-up by the primary physician. Pharmacologic intervention and specific diagnostic testing for GER are reserved for children with serious disease manifesting as respiratory symptoms or poor weight gain. There are no current data to suggest that pharmacologic therapy affects the natural history of uncomplicated GER.⁷ Symptomatic GER that persists past the first year of life should be further investigated on an outpatient basis with possible referral to a pediatric gastroenterologist.

Pyloric Stenosis and Malrotation with Volvulus

In contrast to GER, two causes of life-threatening vomiting in the newborn period are pyloric stenosis and malrotation with volvulus. It is important to consider the diagnosis of pyloric stenosis in the newborn child with progressively worsening vomiting (see Chapter 76, Pyloric Stenosis). The classically taught “projectile” vomiting may not be present; however, the progressively worsening nature of the emesis usually helps distinguish it from simple reflux. Although infants may appear quite well early in the illness, they often seem frustrated and hungry. Both an upper GI tract series and ultrasound are useful in establishing the definitive diagnosis. Surgical pyloromyotomy is curative.

Another life-threatening consideration in the newborn period is malrotation with volvulus (see Chapter 83, Malrotation and Midgut Volvulus). These infants have bowel that congenitally was not positioned or attached properly, allowing for the possibility of twisting of this bowel onto itself and the formation of a volvulus. These infants are often well appearing and present with bilious emesis and a distended abdomen. An upper GI series is the diagnostic test of choice, and surgical correction is the treatment.

Age-Specific Causes

Determining the presence of diarrhea in the young infant based on a parent’s history may be difficult given the broad

Table 72–1 Differential Diagnosis of Vomiting by Age

Newborn

- Reflux
- Pyloric stenosis
- Sepsis
- Meningitis
- Viral illness, gastroenteritis
- Urinary tract infection
- Inborn errors of metabolism
- Congenital adrenal hyperplasia
- Milk allergy
- Malrotation with/without volvulus
- Ileus
- Incarcerated hernia
- Hirschsprung’s disease
- Esophageal atresia/stenosis

- Ingestion/overdose
- Diabetes mellitus
- Pancreatitis
- Hepatitis
- Obstructive uropathy
- Migraines
- Pregnancy
- Psychological (bulimia/anorexia)

range of normal stool patterns. Infants who are breast-fed may normally have several loose stools a day. These stools tend to be poorly formed, with a yellow or green tint, and may be mistaken by parents as diarrhea. Stool frequency must be considered abnormal if there is a significant change from the child's normal pattern. Young infants may become infected with viral or bacterial gastroenteritis, and because they lack the fluid reserves of older children, are more likely to become significantly dehydrated.

Another age-specific cause of vomiting and diarrhea in the young infant is a food allergy. Although true food allergies in infants are not as common as the formula changes initiated to address them, the most common food hypersensitivity reactions in infants are to cow's milk or soy protein. The most prominent symptom is typically diarrhea, which may be Hemocult positive. A leukocytosis with eosinophilia may be present. Vomiting is common, although most vomiting in this age group is related to GER and not to a milk allergy. Children with a severe allergy also may develop anemia and hypoproteinemia. Treatment consists of removal of the offending agent from the diet; a trial of hypoallergenic formula is also reasonable.^{8,9} Resolution of symptoms usually occurs in the first few days after dietary change. Symptoms that do not resolve in the first 2 weeks may be related to GER or another etiology. Allergy to human milk is very rare; however, breast-fed infants may develop symptoms in response to foods in the mother's diet. Therefore, it is important to remove cow's milk from the mother's diet as well as from the infant's. Unlike allergies to peanuts, shellfish, and eggs, children usually outgrow their sensitivity to cow's milk before the age of 3 years.¹⁰

Bacteria, Viruses, and Parasites

Most older infants and young children who present with diarrhea and vomiting have an infectious etiology as the cause for their symptoms. Bacteria, viruses, and parasites all may cause acute gastroenteritis in children; however, viruses are the most common offending agent. The most frequent causes of viral gastroenteritis are rotaviruses, adenoviruses, *Astrovirus*, and *Calicivirus*. Rotaviruses account for a large majority of the cases and contribute to significant hospitalization of children annually, as well as 20 to 40 deaths per year in the United States. Attempts at developing a rotavirus vaccine continue despite difficulty with earlier trials, which showed an increased rate of intussusception in children who received the vaccine.¹¹⁻¹³

Bacterial causes of diarrhea include *Aeromonas*, *Campylobacter jejuni*, *Clostridium difficile*, and enteroinvasive, enterohemorrhagic, enteroaggregative, enteropathogenic, and enterotoxigenic strains of *Escherichia coli*, as well as *Salmonella*, *Shigella*, and *Vibrio cholerae*. Specific bacterial pathogens have important clinical manifestations and epidemiologic considerations that may impact treatment and the aggressiveness with which the specific bacterial species is investigated. *Shigella* species include over 40 serotypes of gram-negative bacilli that cause inflammatory colitis. In the United States, the majority of infections are caused by *Shigella sonnei* and typically result in a watery diarrhea without gross blood or severe systemic symptoms. However, complications from *Shigella* can include bacteremia, Reiter's syndrome, hemolytic-uremic syndrome (HUS), and encephalopathy. *Shigella* infections have been associated with

seizures and may represent an important cause of febrile seizures. The mode of transmission is the fecal-oral route, and risk factors include living in or travel to areas with poor sanitation, crowded living situations, and day care center attendance. The illness is typically self-limited, resolving within 72 hours of illness onset, and treatment is generally not indicated unless children are immunocompromised, develop severe dysentery, or manifest severe systemic symptoms (Table 72-2). Outbreaks in child care centers require treatment of all symptomatic persons to limit the duration of the carrier state and prevent further spread of the disease.

Clostridium difficile is a gram-positive bacillus that is commonly present in the environment. Infections typically cause a colitis termed *pseudomembranous colitis* with bloody or heme-positive diarrhea. Systemic symptoms are common, and the disease can be severe and even fatal in immunocompromised children. Acute infection is usually the result of recent prolonged antimicrobial therapy. Colonization of healthy newborns and children less than 2 years old is common and does not typically warrant treatment unless these children are symptomatic. However, discontinuation of antibiotics is reasonable in this age group. Diagnosis of the disease occurs by detection of the *C. difficile* toxin in the stool using laboratory enzyme assays.

Salmonella organisms are gram-negative bacilli with more than 2460 serotypes. The primary sources of *Salmonella* include direct contact with animals such as poultry, livestock, and reptiles as well as contact with or ingestion of contaminated food sources such as beef, poultry, fish, eggs, and dairy products. Other foods and objects may become cross contaminated after coming in contact with infected foods and serve as a vector for transmission. Infections with *Salmonella* generally causes a watery diarrhea with mild fever and abdominal cramping. The illness is typically self-limited, and antibiotic treatment is unnecessary in healthy patients. However, *Salmonella* can cause serious illness, such as meningitis and osteomyelitis, and can cause invasive infections that result in bacteremia. Mortality from invasive disease is higher in young infants, children with hemoglobinopathies such as sickle cell disease, and immunocompromised children. Antimicrobial therapy is generally indicated those children considered at increased risk for invasive disease (see Table 72-2).

In addition to perinatal and newborn sepsis, *Listeria* may also cause diarrhea and fever, and rarely meningitis and encephalitis, in otherwise healthy children and young adults. Exposure generally occurs from contact with contaminated foods such as unpasteurized milk and cheeses, hot dogs, deli meats, undercooked poultry, and raw vegetables. Antibiotics are indicated in neonates with sepsis and in infants and children with severe systemic symptoms and extraintestinal manifestations.

Giardia lamblia is a flagellate protozoan that typically causes an asymptomatic infection. Both humans and animals serve as reservoirs, and infection can occur from contact with contaminated water or food, or directly from hand-to-mouth transfer of cysts from an infected person. Infection generally results in diffuse, watery, foul smelling, mucoid diarrhea, as well as abdominal pain and flatulence. Because the illness may be protracted with diarrhea that is intermittent, diagnosis may be delayed. Weight loss, anemia, and

Table 72–2 Management of Organisms Causing Diarrhea

Organism	Indications for Treatment	Medications
<i>Aeromonas</i> <i>Campylobacter</i>	More than mild symptoms More than mild symptoms, those who have a relapse of illness, immunocompromised	Third-generation cephalosporins (e.g., cefixime) Erythromycin, azithromycin, doxycycline (if ≥8 yr old) for total of 5–7 days If bacteremia, administer aminoglycoside, meropenem, or imipenem
<i>Clostridium difficile</i> <i>Listeria</i>	More than mild symptoms or mild disease Infection identified during pregnancy, severe symptoms, meningitis, encephalitis	Discontinue causative antibiotics Oral metronidazole or vancomycin Ampicillin and aminoglycoside together
<i>Giardia lamblia</i>	Symptomatic patients, household contacts of high-risk patients such as those with hypogammaglobulinemia, cystic fibrosis, pregnant women with toddlers	Trimethoprim-sulfamethoxazole if penicillin allergic Metronidazole, albendazole, nitazoxanide In pregnant women use paromomycin
<i>Salmonella</i> *	Age <3 mo, chronic GI tract disease, malignancy, hemoglobinopathies, HIV, immunosuppressive therapy, severe colitis, bacteremia, or sepsis	Ampicillin, amoxicillin, trimethoprim-sulfamethaxazole, cefotaxime, ceftriaxone
<i>Shigella</i> *	Antibiotics are recommended for all patients except those with mild or resolving disease	Sulfamethoxazole-trimethoprim (resistance is rising) or cefixime or azithromycin for 5 days or ceftriaxone
<i>Yersinia</i>	Sepsis, non-GI infections, immunocompromised patients.	Trimethoprim-sulfamethoxazole, aminoglycosides, cefotaxime, doxycycline (if ≥8 yr old)
<i>Vibrio</i>	Patients with severe symptoms, immunocompromised, liver disease ? carriers	Doxycycline or tetracycline if ≥8 yr old Cefotaxime, gentamicin, chloramphenicol

*NOTE: There is currently high ampicillin, amoxicillin, and sulfa resistance in *Salmonella* and *Shigella* infections.
Abbreviations: GI, gastrointestinal; HIV, human immunodeficiency virus.

anorexia are common by the time of final diagnosis. Trophozoites may be identified by direct smear examination of diarrheal stools. Treatment is indicated for all symptomatic patients and for asymptomatic carriers exposed to high-risk people such as those with hypogammaglobulinemia and cystic fibrosis.

Campylobacter species are gram-negative bacilli that cause diarrhea, abdominal pain, and fever. Stool may contain blood, especially in neonates and young infants. Although most infections are self-limited, 20% of patients may have a relapse of symptoms of a prolonged illness. Immunoreactive complications, including arthritis, erythema nodosum, and polyneuritis (e.g., Guillain-Barré syndrome), may occur during the convalescent period. Infection generally occurs from contact with or ingestion of contaminated water, improperly cooked poultry, or unpasteurized milk. Pets such as dogs, cats, hamsters, and birds are also potential sources of infection. Treatment can prevent relapses if given early in the illness.

Yersinia is a gram-negative bacillus that can cause diarrhea, fever, and abdominal pains. The diarrhea is often bloody with mucus. Older children infected with *Yersinia* may develop a pseudoappendicitis syndrome with fever, right lower quadrant abdominal pain, and an elevated white blood cell count. *Yersinia* bacteremia occurs most frequently in the very young child and those who are immunosuppressed or have a condition with excessive iron storage, such as desferrioxamine use, sickle cell anemia, or thalassemias.

Routine stool culturing and testing is unnecessary in the healthy child who presents with an acute onset of illness and a short duration of symptoms. Antibiotic treatment of bacterial pathogens is only recommended in subsets of patients at risk for complications who also might benefit from treatment (see Table 72–2). Generally, supportive care and close follow

up are the most essential treatments. Diarrhea that appears bloody, suggesting acute dysentery, or that is chronic in nature requires additional testing. During outbreaks of specific bacterial pathogens, more aggressive surveillance testing may be warranted and will usually be coordinated by local health authorities.

Minor Head Injury

Another frequent presentation associated with vomiting is minor head injury. The toddler age group is highly mobile, and minor head injuries are common. Children frequently present with vomiting after a minor head injury and, although parents are often warned to watch for vomiting, there is no clear association between the severity of head injury and vomiting.¹⁴ There is evidence to suggest that vomiting after a minor head injury may be related to intrinsic patient factors rather than the severity of the injury. There appears to be a subset of children who are more likely to vomit and who have a higher incidence of motion sickness, migraines, family history of migraines, and prior unexplained vomiting episodes.¹⁵ Vomiting that is persistent or latent in onset may be more likely to signify head injury.

Diagnostic Considerations in the Adolescent Patient

There are some unique diagnostic considerations in the adolescent patient who presents to the emergency department with vomiting. Isolated vomiting in a postmenarche adolescent female should always raise the suspicion of pregnancy, and ED testing can ensure proper follow-up and counseling. In addition, psychological disorders such as bulimia and anorexia may also present as recurring episodes of vomiting and diarrhea. Adolescents are also more likely to take intentional overdoses or abuse recreational drugs and then have

vomiting as a symptom of toxicity or withdrawal. Migraines also become more common in older children and adolescents, and vomiting is typically a predominant feature of presentation.

Dehydration

Although the differential diagnosis for vomiting and diarrhea is exhaustive, fluid loss is a common consequence, regardless of etiology. The terms *volume depletion* and *dehydration* are used interchangeably daily on a clinical basis; however, it is important to remember that “dehydration” specifically refers to a state of hypertonicity and cannot be truly determined without laboratory analysis.¹⁶ Fortunately, most children in the United States have only mild to moderate hypovolemia from their illness. One of the most important clinical indicators in determining the degree of hypovolemia is a documented weight loss. Previous visits to the ED or a private physician during the same illness can provide a source of weights for comparison. A parental report of history and observations of clinical symptoms in their child is highly sensitive, although not very specific, for predicting dehydration. A parental report of normal fluid intake and urine output significantly reduces the likelihood of significant dehydration.¹⁷ Conventionally used clinical signs of dehydration are important and have fair interobserver reliability; however, individually they lack sufficient sensitivity in determining the degree of dehydration.^{18,19}

Diagnosis of clinically significant dehydration must be based on the presence of a constellation of clinical findings as well as historical features (Table 72–3). Conventional teaching of the clinical signs and their estimated degree of dehydration are included for consideration; however, the provider is cautioned to remember that there has not been any systematic validation of these signs. The presence or absence of these signs must be considered in the context of the child’s history, ongoing fluid losses, comorbid conditions, and severity of possible underlying etiology. Analyzing these classic parameters, one author found that all features were associated with dehydration, although there were only four independent predictors of dehydration: capillary refill greater than 2 seconds, absent tears, dry mucous membranes, and general ill appearance.¹⁹ The presence of two of these four features predicted 5% dehydration with 79% sensitivity and 87% specificity, while the presence of three of the four features predicted 10% dehydration with 82% sensitivity and

83% specificity.¹⁹ Severely dehydrated children with fluid deficits over 10% are much more likely to have a significant clinical finding; however, clinical findings tend to overestimate the degree of dehydration in patients with mild to moderate dehydration.

Diagnostic Testing

Diagnostic testing in the patient who presents with vomiting or diarrhea includes both laboratory and radiographic evaluation. Most patients who present with symptoms of vomiting and/or diarrhea will need only a thorough history and physical examination. As with physical findings, conventionally used serum electrolyte studies have poor predictive value in determining the degree of dehydration.^{20–23} Routine laboratory testing is not essential and, given the trend of oral rehydration in these children, venipuncture to obtain a specimen for laboratory analysis is not clinically necessary and often traumatic for the child. In addition, serum electrolyte testing has been shown to be the 12th most costly contributor to hospital costs.²⁴ Although laboratory analysis may not prove useful by itself in determining the degree of dehydration in a child, the question of whether or not laboratory testing identifies clinically significant abnormalities that alter management and change outcome is a separate one. In one study, investigators found that all children with a clinically significant electrolyte abnormality had at least one of the following features: age less than 6 months, vomiting, delayed capillary refill, dry mucous membranes, tachycardia, or the presence of diabetes mellitus.²⁴ Ultimately, the provider is left to use clinical judgment when deciding to obtain serum electrolytes. In general, it is probably prudent to check serum electrolytes in children who are ill appearing, have a history inconsistent with simple gastroenteritis or viral-induced illness, have a history to support new-onset diabetes, have underlying comorbid conditions, require intravenous (IV) hydration, or are not clinically improving as expected.

Further laboratory testing in the patient with gastroenteritis is generally not indicated. Most episodes of gastroenteritis are viral induced and self-limited, and routine stool studies are not indicated.²⁵ Available tests include fecal leukocytes, occult blood testing, bacterial cultures, and *C. difficile* toxin, *Giardia* antigen, and rotavirus antigen detection. Fecal leukocytes may be present when the infecting pathogen causes a diffuse, invasive colitis; however, it is important to remember that the lack of fecal leukocytes does not exclude the

Table 72–3 Clinical Signs and Estimated Degree of Dehydration

	<i>Signs of Dehydration</i>		
	Minimal or None	Moderate	Severe
General appearance	Well/alert	Fatigued/irritable	Lethargic
Eyes	Normal	Sunken	Very sunken
Tears	Present	Absent	Absent
Mucous membranes	Moist	Somewhat dry	Very dry
Thirst	Not thirsty	Drinks	Will not drink
Skin pinch	Retracts immediately	Slow	Very slow
Capillary refill	Normal	Prolonged	Prolonged
Pulses	Normal	Normal	Weak/thready
Heart rate	Normal	Increased	Increased
Urine output	Normal	Decreased	Minimal
Blood pressure	Normal	Normal	Normal/low

diagnosis of infectious diarrhea or the possibility of significant illness. For example, patients infected with the causative agent of HUS, enterohemorrhagic *E. coli*, generally have minimal to no white blood cells on stool smears.

Radiographic studies may be a valuable adjunct to the evaluation of the child who presents with isolated vomiting, especially when the diagnosis is in question and the history does not support the diagnosis of a straightforward viral illness. Radiographic testing should be tailored to answer a specific diagnostic question and refine the differential, and should never replace a complete history and physical examination. Indiscriminate use of higher radiation content studies such as computed tomography scans should be discouraged given recent concerns over radiation exposure in children with growing tissues and organs.²⁶ It is important to appreciate the limitations of certain frequently obtained studies, such as plain radiographs of the abdomen. Findings on plain films of the abdomen, for example, are extremely nonspecific and cannot exclude diagnoses such as intussusception, appendicitis, or malrotation.²⁷ Plain abdominal radiographs are most useful in detecting bowel obstructions, foreign bodies, and catastrophic events such as bowel perforation or volvulus. Investigators have shown that limiting radiographs to patients with prior abdominal surgery, suspected foreign body ingestions, abnormal bowel sounds, abdominal distention, or peritoneal signs can identify all patients with a radiographic diagnosis of a major disease and could have eliminated 48% of all studies ordered.²⁸ Plain films of the chest to rule out pneumonia as a cause for vomiting and referred abdominal pain may also be considered if clinically indicated.

Important Clinical Features and Considerations

Several important clinical signs should raise the suspicion for certain specific etiologies. Bilious emesis suggests obstruction or pathology distal to the ampulla of Vater and has classically been considered a herald sign for surgical disease. While this may certainly be the case in the neonate with bilious emesis, the importance of bilious emesis in older infants and children is less clear.²⁹ Studies have shown that between 20% and 50% of infants presenting with bilious emesis within the first week of life have a surgical condition.^{30,31} For example, it is the classic common presentation in infants who have malrotation with volvulus (see Chapter 83, Malrotation and Midgut Volvulus).

Bloody emesis is another clinical symptom that will frequently panic parents and lead them to seek medical care. Hematemesis may result from trauma to the nasopharynx or from the GI tract. Most upper GI bleeds due to vomiting in children are self-limited (see Chapter 75, Gastrointestinal Bleeding). Reports of endoscopy findings in children with hematemesis after vomiting suggest that Mallory-Weiss tears are rare and that another postemetic condition called prolapse gastropathy syndrome may be a more likely cause for the hematemesis.³² Prolapse gastropathy syndrome describes a small gastric mucosal hemorrhage occurring in the proximal stomach resulting in hematemesis. Whether the infrequent incidence of Mallory-Weiss tears is a result of pediatric physiology or is related to underdiagnosis, the management of hematemesis in children is largely supportive and endoscopy is rarely indicated.

Bloody diarrhea is another symptom that requires the consideration of specific etiologies. Bloody diarrhea may be due to dysentery from infections, while any concern for enterohemorrhagic *E. coli* O157:H7 requires additional work up given its potential for causing HUS. If a child has a history of diarrhea for several days that suddenly becomes bloody, the diagnosis of HUS should be considered (see Chapter 131, Hemolytic-Uremic Syndrome). HUS is characterized by bloody diarrhea, hemolysis, and renal insufficiency. Laboratory testing to evaluate for anemia, renal failure, and the presence of *E. coli* O157:H7 is indicated. Another important consideration in the child with bloody stools is intussusception. The history may be complicated by the presence of a recent gastroenteritis illness. Bowel edema and inflammation from a recent gastroenteritis can make bowel more likely to intussuscept. Recurrent episodes of abdominal pain may not be prominent, requiring the provider to maintain a high degree of clinical suspicion to avoid missing this clinical entity (see Chapter 74, Intussusception).

Abdominal pain is a frequent complaint in the patient with frequent vomiting. However, persistent, reproducible abdominal tenderness on clinical examination suggests a diagnosis beyond a simple viral illness (e.g., appendicitis). Pain associated with gastroenteritis frequently resolves with hydration therapy and is typically described as crampy in nature and ill-localized. In addition, abdominal distention is not frequently associated with a routine viral illness and is more likely to be present in the child who has additional pathology, such as intestinal obstruction, mass, or ascites.

The child with chronic medical conditions or special health care needs requires additional consideration of unique etiologies. Children with central nervous system ventricular shunts may present with vomiting as a sign of shunt malfunction (see Chapter 42, Conditions Causing Increased Intracranial Pressure). Although drowsiness has been shown to be the best clinical predictor of ventriculoperitoneal shunt malfunction, vomiting is also common, affecting as many as 73% of patients.³³ Children with a history of malignancy may present with vomiting related to chemotherapy or secondary to recurrent disease (see Chapter 45, Brain Tumor). Neurologically impaired children also have an oversensitive emetic reflex and are more likely to have frequent vomiting episodes. These children may also have subtle findings such as isolated vomiting with a volvulus. Vomiting may be a sign of bladder perforation in children who have received bladder augmentation for a small or neurogenic bladder. Rupture may occur even years after a repair, and symptoms may be subtle, particularly in children with spina bifida.^{34,35} Following fundoplication, children may still have activation of the emetic reflex, resulting in retching symptoms without frank emesis.⁶ Vomiting in children with metabolic disorders such as diabetes may signal underlying infections and diseases as well as contribute to significant morbidity in these children if it is not rapidly addressed.

Management

Management of presumed viral-induced isolated vomiting or gastroenteritis focuses on fluid therapy. Since its inception in the 1960s, the use of oral rehydration therapy (ORT) with oral glucose-electrolyte solutions has directly contributed to a decrease in mortality from acute gastroenteritis worldwide.²

Table 72–4 Sample Protocol for Oral Rehydration Therapy (ORT)

- Obtain current weight and estimate percentage dehydration
- Consider ondansetron 0.2 mg/kg per dose (max. 4 mg) orally 20 min prior to start of therapy
- Administer 20 ml/kg per hour of Rehydralyte/Pedialyte for 2–4 hr via syringe, or consider continuous nasogastric feeds through a 5-French feeding tube
- Add additional 10 ml/kg for each diarrheal stool
- If child tolerates 2 hr of ORT and is clinically improving, may continue ORT at home for next 2 hr of therapy
- Resume age-appropriate diet in 4–6 hr
- If more than 2 episodes of vomiting during ORT, may change to intravenous fluid therapy

Contraindications to ORT:

- Severe dehydration (oral rehydration may still proceed cautiously if no other contraindications exist)
- Shock
- Altered mental status
- Child < 3 mo of age
- Concerns for abdominal pathology
- Abdominal distention or ileus
- Significant comorbid conditions (congenital heart problems, prior abdominal surgeries, metabolic diseases, diabetes)

With ORT, pediatric mortality from diarrheal illness has declined from an estimated 5 million deaths per year in 1982 to 3 million in 1992 and 1.5 to 2.5 million per year currently.² Despite its worldwide success, the use of the technically more simple ORT has lagged behind in the United States. Research has shown that ORT leads to shorter length of stay in the ED, increased parental satisfaction with the visit, decreased hospital admission rates, and rapid improvement in symptoms.^{36–40} ORT not only encompasses the rehydration phase, as the term implies, but also refers to the replacement of ongoing losses and early enteral feeding.

In the patient with minimal or no evidence of dehydration who has symptoms of gastroenteritis, the treatment goal is to provide compensation for ongoing losses. Parents should continue normal feedings and supplement each diarrheal stool or emesis with an additional 10 ml/kg of a commercially available pediatric electrolyte replacement solution. In children with mild to moderate dehydration, the fluid deficit is replaced rapidly over 4 hours, with subsequent return to normal enteral feedings and continuing replacement for ongoing losses (Table 72–4). Children with signs of severe dehydration or shock require immediate resuscitation with rapid initiation of IV fluids. An initial IV fluid bolus of 20 ml/kg over 30 minutes using normal saline or lactated Ringer’s solution is appropriate and may be repeated in boluses of 20 ml/kg as needed, to a typical maximum of 60 ml/kg. Failure to respond to treatment with IV fluids must raise the suspicion of other illnesses such as cardiac, metabolic, or neurologic disorders.

Pharmacologic therapy for gastroenteritis includes medications marketed for vomiting and diarrhea. In general, antidiarrheal medications are not recommended. In particular, antimotility agents containing ingredients such as loperamide, diphenoxylate, and atropine are not intended for use in children, and there is no clinically significant evidence that they change outcomes.^{1,2} These medications have significant side effects, including ileus, sedation, respiratory depression, paradoxical agitation, and increased nausea. Deaths

have also been reported with loperamide use.⁴¹ Agents such as bismuth subsalicylate have shown limited efficacy in acute gastroenteritis, and toxicity from the salicylate component is a concern. Until recently, experience with antiemetic treatment was limited to phenothiazines, most frequently promethazine. Because children are particularly sensitive to the side effects of promethazine, the Food and Drug Administration (FDA) recently added warnings to its label stating that it should not be used in children less than 2 years of age and should be used with caution in children if used at all. Side effects include agitation and dystonic reactions; however, more commonly, phenothiazines cause significant sedation. This extreme sedation is problematic for two reasons. First, a profoundly sedated child will be unable to participate in aggressive ORT either at home or in the ED. Second, sedation caused by phenothiazines makes it difficult to assess a child and determine clinical improvement or deterioration.

Fortunately, newer antiemetic medications have emerged over the last several years. Studies have recently demonstrated benefit from the use of the serotonin antagonist ondansetron in the treatment of pediatric gastroenteritis.^{42–45} Ondansetron has been used extensively for the management of vomiting in the pediatric postoperative and oncology settings; however, its application to the patient with gastroenteritis is a relatively new development. A single dose of ondansetron administered either IV or orally in the ED can decrease the frequency of vomiting and hospital admission rates.^{42,43} Oral ondansetron also decreases the need for IV fluid therapy in the ED setting and can be a valuable adjunct in the management of gastroenteritis with ORT. The oral dose is typically 0.2 mg/kg per dose and the IV dose is typically 0.15 mg/kg per dose, with a maximum of 4 mg per dose. Use is generally limited to children over the age of 6 months. The routine practice of sending patients home with a prescription for ondansetron is generally unnecessary and not likely to be currently cost effective. In addition, although the diarrhea component of gastroenteritis may persist for days, the vomiting is typically self-limited and occurs early in the illness. Parents who receive a prescription for an antiemetic could theoretically be more likely to wait out a progressively worsening illness at home, when the actual etiology of persistent vomiting may be more severe than a viral acute gastroenteritis.

Zinc supplementation is associated with improved intestinal permeability and in developing countries has been shown to decrease number of stools per day and number of days of illness, and to be a cost-effective adjunct to ORT.^{2,46,47} Further research is needed before zinc supplements can be recommended as a standard adjunct to therapy in developed countries. The addition of probiotics, defined as live microorganisms in fermented foods that improve balance in intestinal microflora, has also been the topic of research in acute gastroenteritis. The *Lactobacillus* species has been shown to be effective as a treatment for children with acute gastroenteritis; however, specific supplements marketed for this use are not subject to regulation by the FDA and therefore are not routinely recommended.^{2,48}

Recommendations for the timing and composition of feeding during acute gastroenteritis have changed significantly in recent years. The “refeeding syndrome,” described as severe fluid and electrolyte shifts that occur when malnourished or starved patients begin enteral feeds, has not

been described in children with simple gastroenteritis who begin enteral feeds. The syndrome is an uncommon yet potential problem in the severely malnourished, and was classically described in adult survivors of concentration camps.⁴⁹ Children should be allowed to resume a normal diet as soon as the rehydration phase of ORT or IV fluid therapy is completed.

The availability of over-the-counter rehydration solutions may also lead parents to think they are superior to a normal diet for their child with diarrhea. Severe malnutrition and deprivation stools can result from the prolonged, inappropriate use of these solutions. Parents need to be reminded that they should never be used as a substitute for more nutritious foods. Breast-fed infants should be encouraged to breast-feed even during the rehydration phase, while formula-fed infants should resume their normal formula as soon as rehydration is completed. Early refeeding improves weight gain after rehydration and is not associated with a significant increase in diarrhea.⁴⁹ True lactose intolerance following acute viral gastroenteritis is uncommon, and changing an infant to a lactose-free formula is unnecessary. If diarrhea worsens after introduction of lactose-containing formulas, a temporary trial of a lactose-free formula is reasonable. There is evidence that soy formulas may provide additional bulk to the stools; however, overall stool output remains unchanged.⁵⁰ Soy formula is therefore not recommended, although it may provide some relief from the irritant diaper dermatitis that results from liquid stools. Formula is not superior to a normal mixed diet in children who are taking solid foods.⁵¹ These children should be encouraged to resume a nonrestricted diet with a focus on foods high in complex carbohydrates such as fruits, lean meats, vegetables, and yogurt. Foods high in simple sugars, such as juices and sodas, should be consumed sparingly. The classically recommended BRAT (bananas, rice, applesauce, and toast) diet is considered too restrictive and does not supply the nutrition needed for optimal recovery.²

Summary

The prognosis for an infant or child with vomiting and diarrhea depends on the specific etiology. Clinicians must diligently evaluate these children for serious abdominal and extra-abdominal disorders that can cause vomiting. Children with gastroenteritis typically recover with appropriate supportive care and treatment. Those with mild to moderate dehydration should begin to improve in the ED a couple of hours after the initiation of fluid therapy. They generally become more alert and interested in their surroundings, such as toys, and express the desire to drink or eat. Admission should be considered for any child who is not responding to appropriate fluid therapy, has abdominal pain that remains vague and requires serial examinations, or requires the services of a consultant such as a surgeon. Transfer to a pediatric hospital for evaluation by pediatric subspecialists may be required in areas where the local medical staff is uncomfortable caring for children or when the etiology requires subspecialists found only at a children's center.

Chapter 73

Appendicitis

Steven G. Rothrock, MD

Key Points

Infants and young children frequently present with atypical clinical features (e.g., vomiting that precedes pain, diarrhea, genitourinary features, and diffuse tenderness).

Clinicians should not rely exclusively on normal serum parameters (e.g., white blood cell count, C-reactive protein) to rule out appendicitis.

Computed tomography (CT) can be an accurate test if proper techniques are used (spiral CT, thin collimation, thin reconstructed images, rectal contrast with or without intravenous contrast).

Performance of a rectal examination to elicit tenderness does not add useful information to the clinical evaluation of children with possible appendicitis.

Introduction and Background

Appendicitis is the most common surgical abdominal disorder in children ages 2 and older.¹ While abdominal pain is a common symptom in children presenting to the emergency department, only 1% to 8% with this complaint will have appendicitis.²⁻⁴ As features of appendicitis (e.g., fever, vomiting) frequently overlap with those of more common diseases (e.g., gastroenteritis, viral syndromes), identifying this disorder can be difficult. This overlap of clinical features, in part, accounts for misdiagnosis rates of nearly 70% to 100% in infants, up to 57% for toddlers, 12% to 28% for school-age children, and nearly 15% for adolescents.¹

Recognition and Approach

To accurately diagnose appendicitis, clinicians must be aware of the age-specific variations in anatomy and development that affect presenting features (Table 73-1).

In neonates and infants, the appendix is funnel shaped and not easily obstructed. This accounts for an extremely low rate

of appendicitis in infancy. The thin-walled appendix is prone to perforation, and the cecum is less able to distend and decompress the appendix when it expands. As children age, lymphatic tissue increases within the gastrointestinal tract, increasing the propensity for appendiceal luminal obstruction and development of appendicitis. Lymphatic tissue proliferation peaks in the late teen years, the age at which appendicitis is most common.^{1,5}

Appendices of infants and young children have greater mobility and are less likely to be fixed to mesentery compared to older children. Moreover, an underdeveloped omentum often cannot contain purulent material following perforation. These features account for a lower rate of contained abscesses and a higher rate of diffuse peritonitis in infants and children ≤ 5 years old compared to older children.¹

Communication skills play an important role in describing onset, quality, and characteristics of pain. As infants less than 2 years old cannot describe pain, the median time from symptom onset to diagnosis is 3 to 4 days. Most cases are perforated at diagnosis, and most are evaluated by a physician and incorrectly diagnosed before appendicitis is detected.¹ Preschool-aged children usually cannot describe their symptoms well, and the classic sequence of abdominal pain followed by vomiting is often not appreciated. In fact, vomiting is often the first symptom noted by parents, while pain is often not noted until after the onset of vomiting.⁶ Moreover, diagnosis usually occurs after perforation, with symptoms of pain, fever, and vomiting predominating. In school-age children and adolescents, the history and physical examination are generally more reliable. Older children more accurately relay descriptors including onset of centrally located pain that later migrates to the right lower quadrant, quality of pain, and features that aggravate pain.

Advanced appendicitis (e.g., perforation, gangrenous appendix) is more common in younger age groups. This advanced disease state is reflected in radiologic examinations. Compared to adults, bowel obstruction and ileus are more common with perforation, while ultrasonography (US) may be less able to visualize an increased wall-to-wall diameter following appendiceal perforation. Diminished mesenteric and intra-abdominal fat have the potential to obscure typical computed tomography (CT) findings of inflammation in uncomplicated appendicitis, while intra-abdominal abscess formation is more common in younger children (especially those < 10 years old).⁷

Table 73–1 Frequency of Age Specific Presenting Features of Appendicitis

Presenting Feature	Age		
	<2 years	2 to 5 years	6 to 12 years
Pain	35% to 77%	89% to 100%	98% to 100%
Vomiting	85% to 90%	66% to 100%	68% to 95%
Fever	40% to 60%	80% to 87%	4% to 64%*
Diarrhea	18% to 46%	33%	9% to 16%
RLQ tenderness	<50%	58% to 85%	>80% to 95%
Diffuse tenderness	55% to 92%	19% to 28%	15% to 83% [†]

*The percentage of school-aged children with fever varies with the duration of symptoms. Only 4% are expected to have fever within the first 24 hours of symptoms.

[†]The percentage of school-aged children with diffuse abdominal tenderness varies with the presence of perforation. Without perforation, the rate is 15%. With perforation, the rate is 83%.

Abbreviation: RLQ, right lower quadrant.

Adapted from Rothrock SG, Pagane J: Acute appendicitis in children: emergency department diagnosis and management. *Ann Emerg Med* 36:39–51, 2000.

Clinical Presentation

Presenting Features

Presenting clinical features of appendicitis differ depending upon the child's age (see Table 73–1).

Neonates

Cases of neonatal appendicitis are rare, occur primarily in premature neonates, and are due to distal colonic obstruction (e.g., Hirschsprung's disease), cardiac emboli, incarcerated hernias, or a localized form of necrotizing enterocolitis and not appendiceal lumen obstruction.^{8–11} Due to difficulty with diagnosis and rarity of this disorder in neonates, mortality exceeds 80% and most cases are diagnosed at autopsy.^{9,10} Abdominal distention and vomiting are the most common symptoms present in the majority of cases. Other features include irritability or lethargy, a palpable mass, abdominal wall cellulites, hypotension, hypothermia, and respiratory distress.¹

Infants and Toddlers

Appendicitis is a rare disease in children younger than 2 years, with initial misdiagnosis rates of nearly 100%.^{12–15} Typical symptom duration prior to diagnosis is greater than 3 days, with perforation rates that approach 100%.¹² The most common symptoms are vomiting, abdominal pain, fever, and diarrhea^{5,12–16} (see Table 73–1). Other nonspecific presenting symptoms include irritability in one third of cases, difficulty breathing or grunting in 8% to 23%, upper respiratory infection symptoms in 40%, and right hip pain/stiffness in 3% to 23%.^{13–15,17,18} Diffuse abdominal tenderness is present in most cases, while localized right lower quadrant tenderness is noted in few cases.^{12–14,16,18} Other features include lethargy due to sepsis, abdominal rigidity or distention, and an abdominal or rectal mass due to abscess formation.^{5,13,14,18}

Preschoolers

Diagnosis of appendicitis in preschool-age children is difficult. Most preschool-age children have symptoms for 2 or more days before presenting, and nearly half are initially misdiagnosed.^{19,20} Abdominal pain, vomiting, and a complaint of fever are present in most cases.^{16,19–23} Parents often report that vomiting preceded the onset of pain.⁶ This atypical sequence of events may be due to the fact that parents may

only notice their child is ill after vomiting begins. Anorexia, a symptom common to older children and adults, may be difficult to elicit in younger children. Guarding, rebound tenderness, and a documented temperature above 37.5° C (99.5° F) are variably present.^{16,19–23} Unlike younger infants, right lower quadrant tenderness is more common than diffuse tenderness as a result of a more well-formed omentum with more localized peritonitis following perforation.^{22,24}

School-Age Children

The incidence of appendicitis increases and the clinical evaluation becomes more reliable in school-age children. Nearly one third of children at this age relay that their pain began centrally and later migrated to the right lower quadrant.^{1,25} In those without this sequence, pain usually begins and remains in the right lower quadrant or begins and remains diffuse.²⁵ Pain is described as steady and worse with movement in most cases, while it is described as colicky in 11% to 35%.^{25,26} Pain with jumping or with coughing is present in 93%.²⁷ Vomiting is present in 68% to 95% of cases and may precede or begin simultaneously with the pain in 18%.^{25,26} Anorexia occurs in 47% to 75%, diarrhea in 9% to 16%, constipation in 5% to 28%, and dysuria in 4% to 20% of school-age children with appendicitis.^{6,25} Prior episodes of similar pain are found in up to one third of cases.²⁵ Family history is often overlooked when considering the diagnosis of appendicitis. However, having a first-degree relative who has had appendicitis (especially under the age of 11) increases a child's risk for developing appendicitis 3- to 10-fold.^{28–31}

Physical examination findings differ depending upon the timing and stage of presentation. If symptoms have been present for less than 24 hours, 4% of patients will have a temperature $\geq 38^\circ\text{C}$ (100.4° F). If symptoms have been present for 24 to 48 hours, 64% of patients will have a temperature elevation, while even more are febrile if symptoms have been present for 48 hours or more.³² Right lower quadrant tenderness is present in almost all school-age children with appendicitis. However, tenderness may extend to the entire lower abdomen in 15% without perforation, and in up to 83% with perforation.²⁵ Bowel sounds are normal or hyperactive in 93% of children with appendicitis and may not be hypoactive or absent unless diffuse peritonitis or bowel obstruction is present.³³ Guarding is present in 51% of

cases, and rebound in 41% without perforation, while these features are present in 91% and 85% of cases with perforation, respectively.^{25,26} Importantly, assessing for peritoneal signs is more difficult in children than in adults. Rebound tenderness should not be elicited in children as many without appendicitis will have some degree of tenderness with this maneuver. Instead, percussion tenderness is considered to be a more reliable means of assessing for peritonitis.²⁷ Finally, performance of a rectal examination to elicit tenderness does not add useful information to the clinical evaluation of children with possible appendicitis.¹

Adolescents

The peak incidence of appendicitis is during adolescence and early adulthood. While the history and physical examination become more reliable, pelvic pathology becomes more common in females, potentially obscuring the diagnosis. Adnexal tenderness and cervical motion tenderness are often present in these cases. In fact, one third of females ages 15 and older with appendicitis are initially misdiagnosed as having pelvic disorders, gastroenteritis, or urinary infections.³⁴

Ancillary Studies

The only required test for children with possible appendicitis is a serum or urine β -human chorionic gonadotropin test (i.e., a pregnancy test) in adolescent girls (see Chapter 90, Ectopic Pregnancy). Other tests, including serum markers, urinalysis, and imaging adjuncts, have variable utility for either excluding or diagnosing appendicitis. Knowing the utility and limitations of each of these studies is useful for emergency physicians.

While many authors have recommended a serum white blood cell (WBC) count in children with suspected appendicitis, this test has only limited utility for diagnosing this disorder. Sensitivity of an elevated WBC count (>10 to 12×10^9 cells per liter) ranges from 51% to 91%.¹ Sensitivity falls even further (18% in one study) if symptoms have been present less than 24 hours.¹ In contrast, an elevated neutrophil percentage (i.e., a left shift) is present in the majority of cases in the first 24 hours after symptom onset.¹ Either the WBC count or neutrophil percentage is elevated in most children with appendicitis who have had symptoms for more than 24 hours.¹ These tests also are elevated in nearly half of all patients with gastroenteritis, mesenteric adenitis, pelvic inflammatory disease, and many other infectious disorders that must be differentiated from appendicitis. The WBC count cannot differentiate between cases of perforated and nonperforated appendicitis. Moreover, it is unclear if following serial WBC counts in suspected appendicitis is useful. Conflicting studies (primarily limited to adult patients) have found serial WBC counts will fall,³⁵⁻³⁷ rise,³⁸ or remain unchanged³⁹ in cases of appendicitis.

Another inflammatory mediator, C-reactive protein (CRP), has been used widely to stratify the risk of appendicitis. An elevated CRP is 43% to 92% sensitive and 33% to 95% specific for diagnosing appendicitis in children.¹ These wide ranges are due to the varied upper thresholds used for defining an abnormal CRP (0.9 to 5.0 mg/dl). CRP level has been shown to be superior to the WBC upper thresholds at detecting appendiceal perforation and abscess formation (disorders that are more common in pediatric appendicitis).¹

In a study that included adults, one author found sequential CRP levels useful at diagnosing appendicitis. Initial CRP was 60% sensitive, with sensitivity rising to 86% by 4 hours, 95% by 8 hours, and 100% by 12 hours after admission.³⁶

Seven percent to 14% of children with appendicitis have greater than 5 WBCs per high-power field or greater than 5 red blood cells per high-power field on microscopic urinalysis.⁶ These findings can lead to an erroneous diagnosis of a urinary tract infection or nephrolithiasis. In fact, 17% of children with appendicitis have bacteriuria, a finding that becomes even more common in advanced disease states (e.g., perforation, abscess formation).⁴⁰ Proposed mechanisms for these abnormalities include direct spread of bacteria from the inflamed appendix to the urinary tract and inflammatory changes due to a proximate inflamed appendix.⁴⁰

Scoring Systems

Numerical scoring systems that combine clinical features and serum markers can stratify the risk that a child has appendicitis. One of the simplest and most widely studied clinical appendicitis scores is the MANTRELS or Alvarado score. This score assigns points for clinical features and serum WBC count and neutrophil percentage (Table 73-2). The MANTRELS score, while originally derived in adults, has shown utility at stratifying appendicitis risk in adolescents, although reliance solely on this test to make the diagnosis of appendicitis has limitations.⁴¹ Studies have shown a score of ≥ 7 to be 86% to 90% sensitive and 72% to 86% specific for diagnosing appendicitis in children, while a score ≥ 5 is 93% to 100% sensitive.⁴¹⁻⁴³ Other authors have modified the MANTRELS score in children by dropping the neutrophil percentage and found a modified score ≥ 7 to be 76% to 90% sensitive for detecting appendicitis.¹ One prospective study modified the MANTRELS score further, by substituting rebound tender-

Table 73-2 Clinical Appendicitis Scores

Feature	MANTRELS Score	Pediatric Appendicitis Score (PAS)
Migration of pain from central to right lower quadrant area	1	1
Anorexia or acetoneuria	1	1
Nausea with vomiting	1	1
Tender right lower quadrant	2	2
Rebound tenderness	1	—
(Rebound equivalent—pain with hopping or coughing, or percussion tenderness)	—	2
Elevated temperature $\geq 38^\circ\text{C}$ (100.4°F)	1	1
Leukocytosis	2	1
Shifted white blood cell count ($>75\%$ neutrophils)	1	1
Total Score	Interpretation	
MANTRELS		
≤ 4	Low likelihood of appendicitis	
5–6	Possible appendicitis	
≥ 7	Probable appendicitis	
PAS		
≤ 6	Low likelihood of appendicitis	
≥ 6	Possible or probable appendicitis	

ness with an alternate test for peritonitis (pain with cough, pain with jumping, or percussion tenderness) and assigning 2 points to this feature while removing 1 point from the leukocyte count²⁷ (see Table 73–2). The authors found this modified Pediatric Appendicitis Score had 100% sensitivity and 92% specificity for diagnosing appendicitis if a cutoff of ≥ 6 was used to diagnose appendicitis.²⁷ However, the prevalence of appendicitis was high ($>60\%$ of cases), children may have been seen late in their disease course, and it is uncertain if the Pediatric Appendicitis Score's test characteristics will be as accurate if applied to a less ill emergency department population.

Imaging Studies

In general, plain abdominal radiographs are not helpful for diagnosing uncomplicated appendicitis in children. Commonly cited findings of rightward scoliosis, soft tissue changes, localized ileus, and “free peritoneal fluid” occur in children with and without appendicitis.⁴⁴ Radiographs in children with appendiceal perforation may show bowel obstruction, a right lower quadrant mass, or a calcified appendicolith.^{12,45} Of these radiographic findings, a calcified appendicolith is the most specific for appendicitis, present in 10% to 20% of young children with perforated appendicitis, in less than 10% with uncomplicated appendicitis, and in only 1% to 2% of children without appendicitis.^{45–47} However, plain radiographs are normal or nonspecific in over three quarters of children with appendicitis, and this modality, in general, should not be used to exclude or diagnose this disorder.^{46–48}

Ultrasonography has been studied extensively in children with suspected appendicitis. Experienced centers have found ultrasound to be nearly 90% sensitive and greater than 95% specific for diagnosing appendicitis, while others have reported a sensitivity as low as 44% to 48%.^{49–52} Ultrasonographic findings diagnostic of nonperforated appendicitis include an appendiceal diameter greater than 6 mm, a “target sign” with five concentric layers, distention or obstruction of the appendiceal lumen, and muscular wall thickness greater than 2 mm. Ultrasonographic accuracy is diminished in perforated cases as the appendix may no longer be enlarged, and nonspecific features of absent peristalsis or a pericecal or perivesical mass may be the only findings. The primary advantages of ultrasound are noninvasiveness, lack of radiation exposure, and high specificity. Retrospective studies have found its use to be associated with increased cost, increased time to surgery, and increased length of hospitalization without altering complication rates.⁵³ Due to limited experience and reported poor sensitivity, many centers do not perform ultrasound on children with suspected appendicitis. For those sites performing ultrasound, a negative examination should not be relied upon to exclude appendicitis due to its limited sensitivity.

CT is an accurate test for diagnosing appendicitis. CT has superior sensitivity to ultrasonography.^{51,52,54,55} Moreover, radiologists are more confident in their interpretation of CT for appendicitis compared to ultrasound.⁵⁶ The most accurate CT studies have employed a standardized, focused helical technique with narrow collimation (3 to 5 mm) and narrow reconstructed images (every 1 to 3 mm) starting at the top of L3 or the iliac crest and extending distally to the acetabular roof or pubic symphysis. Using these techniques,

sensitivities $\geq 95\%$ have been achieved in children.^{51,52,54,57–60} Some experts recommend rectal contrast for improved visualization of the cecum and pericecal structures, and to opacify the lumen of uninflamed, unobstructed appendices.^{7,51,58–60} Administration of rectal contrast requires a cooperative patient who can retain the material (e.g., age > 3 to 4 years, no mental disability, and absent diarrhea). Others recommend intravenous contrast to improve bowel wall visualization. A single study found unenhanced CT to be accurate in children.^{52,54,57} Sensitivity of CT is substantially lower (53% to 84%) when nonstandardized techniques are used, CT is not helical, or narrow collimation and narrow reconstructed images are not employed.^{55,61,62} False-negative CT scans also may be related to diminished pericecal fat at in children less than 10 years old, use of adult diagnostic criteria (e.g., 6-mm wall-to-wall appendiceal diameter), and lack of radiologic experience.^{7,63} The most common CT abnormalities, found in more than 90% of appendicitis cases, are an appendiceal wall-to-wall diameter greater than 6 mm and periappendiceal fat stranding.^{7,63,64} Other less common findings include focal cecal wall thickening adjacent to an inflamed appendix, an abscess, adenopathy, and right lower quadrant or pelvic fluid.^{7,63,64} An appendicolith is identified on CT in 65% of children with appendicitis and in 14% of nondiseased appendices.⁶⁵ Alternate diagnoses in children without appendicitis are found in 30% to 34% of cases (e.g., nephrolithiasis, pyelonephritis, ovarian cyst or mass, ovarian torsion, inflammatory bowel disease, Meckel's diverticulum).^{59,66} The main concern with CT scanning is radiation exposure.

Important Clinical Features and Considerations

An important reason that it is difficult to diagnose appendicitis at younger ages is the multitude of more common nonsurgical disorders that cause similar symptoms. In fact, gastroenteritis and upper respiratory tract infections are the most common misdiagnoses in infants and children ultimately diagnosed with appendicitis⁶ (Table 73–3).

Management

During evaluation, it is appropriate to control pain with short-acting intravenous analgesics. Providing analgesics to children with acute abdominal pain does not affect diagnostic accuracy or alter the clinical outcome of these children.^{67–69} Pediatric surgeons are significantly less likely to provide analgesia before definitive diagnosis compared to emergency physicians.⁷⁰ To address their concerns, it may be appropriate to devise a policy whereby the surgeons are given a short window of opportunity to evaluate the patient. After their evaluation or if they are unable to see the patient in an expeditious manner, analgesics are administered. A reasonable initial medication is 0.05 mg/kg of intravenous morphine sulfate.⁶⁸

Intravenous volume replacement should be administered to all children with suspected appendicitis and evidence of dehydration or sepsis. Maintenance fluids are indicated because children suspected of having appendicitis should be kept nil per os (NPO). Children with sepsis or evidence of perforation (e.g., temperature $> 100.4^\circ$ F, diffuse peritonitis,

Table 73–3 Most Common Misdiagnoses in Children with Appendicitis

Initial Misdiagnosis	Percentage of Cases
Gastroenteritis	42
Upper respiratory tract infection*	18

ill appearance, symptoms duration > 36 to 48 hours) require broad-spectrum intravenous antibiotics. A single study found that use of ticarcillin/clavulanate plus gentamicin was associated with quicker defervescence and fewer infectious complications compared to traditional therapy of ampicillin and gentamicin plus clindamycin.⁷¹ Small studies have shown that monotherapy with cefoxitin, piperacillin/tazobactam, imipenem/cilastin, or ampicillin/sulbactam is equivalent to traditional multiple-drug therapy in preventing infectious complications from ruptured appendicitis.⁷² A meta-analysis also suggests that antibiotics are effective in preventing postoperative complications in children with uncomplicated appendicitis.⁷³ However, antibiotics were effective whether they were given pre- or postoperatively in uncomplicated appendicitis.⁷³ For this reason, antibiotic decisions in uncomplicated appendicitis can be deferred to the admitting surgeon.

Definitive therapy of acute appendicitis is appendectomy prior to perforation. Unfortunately, a large number of children develop perforation prior to diagnosis. For these patients, immediate fluid resuscitation and antibiotic therapy are required. A subset of children with perforated appendicitis and an appendiceal abscess may undergo delayed (interval) appendectomy 4 to 8 weeks following an initial course of intravenous antibiotics, depending upon the clinical presentation and initial response to intravenous antibiotics.^{74,75}

Summary

Most children who receive appropriate treatment for appendicitis do well. While a retrospective audit of adult patients with appendicitis who underwent interhospital transfer concluded no harm came to low-risk patients, no such studies have been performed in children.⁷⁶ Children with appendicitis suffer more morbidity than adults, and transferring for economic reasons alone is inappropriate. Children with complicated appendicitis have a better outcome when cared for by pediatric surgeons.⁷⁷ With this in mind, it may be appropriate to transfer a subset of complicated cases that do not require immediate surgery in addition to cases in which the general surgeon is inexperienced with children and unable to provide appropriate care (see Chapter 150, Emergency Medical Treatment and Labor Act [EMTALA]).

Chapter 74

Intussusception

Jonathan I. Singer, MD

Key Points

The diagnosis of intussusception should be considered in any infant or child with severe, episodic abdominal pain.

The combination of rhythmic abdominal pain, vomiting, blood in the stool, and an abdominal mass is absent in most patients with intussusception.

An atypical clinical pattern (e.g., atypical age, absence of pain, nonbloody diarrhea, altered mental status) is common in intussusception.

Prolonged history, in the face of a normal examination, should not exclude the diagnosis of intussusception.

A normal plain abdominal radiograph cannot exclude the diagnosis of intussusception.

Introduction and Background

Intussusception is an invagination (or telescoping) of one segment of the intestinal tract into another. The invagination may be within the same portion of gastrointestinal (GI) tract (intra-gastric, jejunojejunal, colocolic), or a proximal portion of the intestine can invaginate into a distal adjacent part (duodenal-jejunal, ileocolic, sigmoid-rectal). More than 90% of cases of intussusception that occur in infants and children are ileocolic.¹ The telescoped bowel causes bowel wall ischemia and edema and leads to abdominal pain and other associated features of intussusception.²

Recognition and Approach

Intussusception may occur at any age (Fig. 74–1). Cases have been described in preterm infants, throughout childhood, and into adulthood.³ Neonates constitute less than 1% of all reported pediatric cases. In large series, most intussusceptions occur prior to age 2. A majority of this subgroup have occurred between the fifth and ninth month of life. Of late, more cases have been depicted in children beyond the fifth

year of age. Intussusception historically has been described in well-nourished children, but institutional reviews from the past decades have substantiated encounters in under-nourished children.⁴ Intussusception affects males two times more frequently than females. While most cases are sporadic, occasional familial associations have been reported.^{5,6}

The cause of intussusception is unknown in 90% of pediatric cases. There is no recognized etiology for an abnormal peristaltic wave that leads to the invagination. Venous and lymphatic flow from the intussuscepted segment is interrupted. Obstructed venous drainage produces edema of the bowel wall. Epithelium may be sloughed and mixed with stool, leading to bloody, mucus-filled stools. If the intussusception is undiagnosed, compromised arterial blood flow may lead to bowel necrosis with bowel perforation.

In 10% of cases an identifiable cause for intussusception is found.⁷ Intussusceptions that occur within the first month of life are more often associated with an abnormal congenital malformation.^{8,9} An abnormal “lead point” (pathologic lesion) for intussusception is common in children older than 4 years, and may be due to various infections, inflammatory disease states, posttraumatic events, and surgical procedures (Table 74–1). Beyond the 14th year of life, intussusception is uniformly associated with a lead point.⁷

The tempo of intussusception may be variable. Most children have an abrupt onset of symptoms, and parents seek medical attention within 24 hours of onset. This acute presentation results from complete intestinal obstruction or release of neuroactive GI tract hormones.¹⁰ Some children have symptoms that are prolonged from days to weeks (chronic intussusception).¹¹ A longer duration of symptoms is more characteristic of patients beyond 2 years of age and in those who have an incomplete (nonstrangulating, nonischemic) intussusception.

Clinical Presentation

The pain of intussusception can produce a sudden screaming fit in a child, with doubling of the thighs onto the abdomen. Pain may last several minutes. After an asymptomatic interval, repeated paroxysms will cause the child to cry out again. The child may be inconsolable or may seem comfortable in a knee-chest position in the arms of the caregiver. Vomiting tends to occur shortly after the initial painful episode. Children typically vomit only gastric contents. Occasionally, the emesis may be bilious, fecal, or bloody. Bowel movements

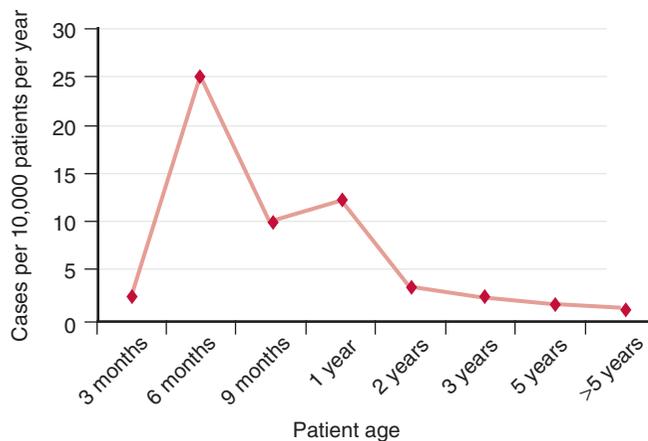

FIGURE 74-1. Annual incidence of intussusception at different ages.^{2,42-45}

Table 74-1 Risk Factors and Pathologic Lead Points for Intussusception

Cystic fibrosis
Foreign body ingestion
Gastrojejunal feeding tube
Hemangiomas
Hemophilia
Henoch-Schönlein purpura (intussusception develops in 3–5% with this disorder)
Intestinal duplications
Intestinal lymphoma
Intestinal polyps (e.g., juvenile polyps, Peutz-Jeghers syndrome)
Meckel's diverticulum
Neurofibromatosis
Peyer's patch hypertrophy (postviral or parasitic enteritis)
Rotavirus vaccine
Surgical procedures (especially retroperitoneal surgery, as in Wilms' tumor removal)
Trauma with bowel wall edema or hemorrhage

vary from formed to liquid. Within 3 to 24 hours, stool is passed that has a gelatinous, mucus-like consistency. The presence of blood in fecal material may be trace to copious.¹²

While the classic triad of intussusception is colicky, intermittent severe abdominal pain, vomiting, and rectal bleeding, this combination of features is found in less than one third of all patients.¹³ Between 85% and 92% of children manifest colicky abdominal pain, while 60% to 80% of patients experience vomiting.^{1,4} Gross blood is present in the stools of 40% to 50% of patients.^{12,14} “Current jelly” stools, which are mucoid, bloody, and maroon in color, account for a minority of bloody stools.¹² Of those children without gross blood in the stool, 75% have occult blood on rectal examination.¹⁴

The child with intussusception is often well perfused, hydrated, and alert despite apparent discomfort.¹³ The abdomen is flat, nondistended, and occasionally scaphoid. The abdomen is typically soft and nontender except in the region of the intussusception, where voluntary guarding may be seen. A sausage-shaped, sometimes ill-defined, and variably tender mass may be present on palpation of the right upper quadrant or right midabdomen. The combination of a right upper quadrant mass and a scaphoid right lower

abdomen is termed *Dance's sign* and is highly suggestive of an intussusception. In some cases, rectal examination may reveal a mass. Classic signs are often absent in infants and children with intussusception, and no single or combination of examination features can reliably exclude this disorder.^{13,15}

Atypical symptoms and signs may lead to misdiagnosis or a delay in diagnosis.¹⁶⁻¹⁸ Clinicians need to be aware of the broad range of atypical presentations that occur in intussusception (Table 74-2). When patients present with typical clinical features (e.g., intermittent severe pain, an abdominal mass, and bloody stool), the diagnosis is readily apparent. When the picture is less complete, and atypical manifestations dominate, other diagnoses may be entertained.¹⁹ The differential diagnosis is broad and based on the wide variety of pediatric disorders causing pain, vomiting, an abdominal mass, and rectal bleeding (Table 74-3).

Diagnostic Evaluation

Several laboratory tests should be undertaken when there is suspicion of intussusception. Following a rectal examination, the stool should be tested for occult blood. A negative guaiac test does not exclude the diagnosis, but decreases the likelihood that intussusception is present.¹⁴ When the duration of symptoms is brief, and the child is without dehydration, hyperthermia, or peritoneal irritation, blood chemistries and complete blood count are not useful diagnostically. However, these tests are of utility in the face of significant bleeding, shock, or dehydration. Cultures of blood, urine, and stool are appropriate for the septic-appearing child.²⁰ The child with altered mental status requires a bedside estimate of blood sugar.

One of several imaging procedures should be undertaken when there is a suspicion of intussusception. Diagnostic emergency imaging may take the form of plain abdominal radiography, ultrasonography (US), or computed tomography (CT).

Plain abdominal radiographs usually constitute the first imaging test when intussusception is suspected. A supine and upright or supine and left lateral decubitus film of the abdomen can be obtained. The most important role of plain abdominal radiography is to uncover contraindications to contrast enema. Patients with radiographic evidence of a high-grade bowel obstruction, intraperitoneal air, or pneumatosis intestinalis should not be subjected to contrast enema. The secondary function of plain radiographs is to see if intussusception is likely. The radiographic findings suggestive of intussusception include minimal intestinal gas, minimal fecal content in the colon, mass lesion, inability to visualize the liver tip, localized air-fluid levels, and dilated small bowel loops.²¹ In fact, intussusception may be the most common cause of bowel obstruction under the age of 2 years.²² The diagnosis can be confirmed only when plain film shows the head of the intussusception within the bowel lumen.²² It is important to recognize that films may be normal in up to 25% to 26% of cases, with another 53% of plain films having nonspecific or equivocal findings.^{23,24} Due to nonspecificity of plain films, radiologists agree on the radiographic findings in as few as 12% of cases.²⁴

Ultrasonography may also be useful in establishing the diagnosis of intussusception and, when it is discovered, may dictate the optimum mode of reduction. Ultrasonography tends to be of greater utility in patients with a nonspecific

Table 74–2 Atypical Clinical Features in Intussusception^{1,11,13,15,17,40,46–52}

Age	While the most common age range is 5–9 mo, cases of intussusception are reported in older children, adolescents, and even adults.
Absent pain	8–18% of infants and children have painless intussusception. Others may have a single paroxysm of pain without rhythmic, periodic pain.
Chronic and transitory pain	Individuals with subacute and chronic presentations may be overlooked. Many cases of intussusception are ultimately diagnosed in individuals who have had symptomology from weeks to months. Cases of transient (self-reducing) intussusception have been reported.
Vomiting	Vomiting is the chief complaint in 40% of children who present to the emergency department. Vomiting may be the first identified complaint, preceding pain by many hours. While vomiting is usually nonbilious, occasional infants have presented with bilious vomiting.
Diarrhea	Nonbloody diarrhea is a prominent complaint, occurring in up to 19% of cases.
Nonbloody stool	Only half of all patients have gross rectal bleeding. Of the remaining patients, 25% have heme-negative stool.
Altered mental status	Depressed consciousness with obtundation or coma state may be the primary manifestation or dominant concern of the caregiver.
Nonspecific prodrome	Respiratory manifestations, fever, and nonspecific complaints such as anorexia, nausea, and constipation may precede the readily diagnosed symptom complex.
Prior surgery	Previous abdominal surgery, particularly retroperitoneal dissection (e.g., Wilms' tumor removal), is a risk factor for intussusception. Intussusception of the appendiceal stump is a known complication of appendectomy. The interval from operation to onset of intussusception may be as long as 5 years. Gastrojejunal tubes predispose to intussusception.
Vital signs	Tachycardia, fever, hypertension, or apnea may be seen early in the course of intussusception. Hypotension, poor perfusion with pallor, and diaphoresis may be seen in the context of prolonged symptomology, excessive blood loss, and ischemic bowel with secondary sepsis.
Neurologic findings	Apathy, miosis, decreased motor tone, seizure, or opisthotonic posturing may occur as the initial indication of illness or well after gastrointestinal signs are present.
Abdominal mass	Between bouts of invagination, an abdominal mass may be absent. During invagination, the mass may pass into the hepatic flexure and may be difficult or impossible to feel.
Rectal examination	Despite only a brief history of illness, the intussusception may protrude through the anus.

Table 74–3 Differential Diagnosis of Intussusception

	<i>Physical Features</i>				
	<i>Prominent Symptoms</i>			<i>Abdominal Mass</i>	
Abdominal Pain	Vomiting or Diarrhea	Altered Mental Status	Congenital	Acquired	Rectal Bleeding
Appendicitis	Malrotation with midgut volvulus	Metabolic derangement	Teratoma	Wilms' tumor	Ischemic bowel due to shock
Epiploic appendicitis	Appendicitis	Endocrinopathy	Dysgerminoma	Pheochromocytoma	Rectal prolapse
Primary peritonitis	Bowel obstruction	Diabetic ketoacidosis	Yolk sac tumor	Lymphoma*	Meckel's diverticulum*
Torsion, ovary/testicle	Incarcerated hernia	Drug intoxication	Embryonal carcinoma		Juvenile polyp*
Mesenteric ischemia	Infectious enterocolitis Pseudomembranous colitis or invasive bacterial enteritis	Closed head injury		Adenocarcinoma	Fissure

*These disorders can also serve as a lead point and cause intussusception.

history, normal physical examination, or atypical clinical pattern. Sonographic findings of intussusception are a large sonolucent target, a bull's-eye or donut sign on the transverse (cross) section, and a sleeve or pseudo-kidney sign on the longitudinal section.²⁵ When either plain films or US exhibits positive findings that are nonspecific or highly suggestive, an air or barium contrast enema should be undertaken to reduce the intussusception if no contraindications exist.

A contrast enema with barium or air under fluoroscopic or sonographic guidance is the procedure of choice for diagnosing intussusception. Moreover, these techniques can successfully reduce the intussusception in 65% to 90% of cases.^{26–28} Success rates are highest for individuals who have had symptoms for less than 24 hours.¹³ Neonates and patients beyond age 4 are less likely to experience reduction and more likely to require surgical exploration. Rare complications of

air and barium contrast studies include bleeding and perforation.²⁹ Additional risks include the reduction of necrotic bowel or reduction without detecting a pathologic lead point.^{7,30}

Spiral CT has occasionally been employed to diagnose equivocal cases, although this technique is not routinely recommended. CT findings include a distended bowel loop with a thickened, edematous wall and an eccentric, crescentic or wedge-shaped, low-density intraluminal mass that represents the invaginated mesentery.¹¹

Important Clinical Features and Considerations

An unusual type of intussusception is a small bowel intussusception (SBI), accounting for less than 2% of all cases.³¹

Children with this variant are older than typical cases (mean age 4 to 4.5 years) and have a longer duration of symptoms prior to initial presentation (mean 76 hours).^{31,32} In contrast to typical ileocolic cases, an SBI can be located in the left side of the abdomen. Ultrasound may miss this disease in up to 24% of cases since the outer diameter of the intussusception is smaller than for ileocolic cases and the location is often atypical.^{31,32} Due to its proximal location, air contrast and barium enema are not useful for diagnosis or reduction of SBI.³² Diagnosis is often made by CT or during laparotomy when other surgical disorders are suspected.^{31,32}

Controversy exists as to the exact sequence of radiologic procedures needed in suspected intussusception. Some centers with extensive US experience rely on a normal scan to exclude the diagnosis in patients with a moderate to low clinical suspicion, only obtaining contrast studies if the US is positive or equivocal.³³ Since US misses up to 5% of ileocolic cases (and 24% of SBI cases), close observation is required for patients with a negative US. If a high clinical suspicion is present, contrast enema is still required.³³⁻³⁵ Use of US in this manner can decrease the radiation risk and exposure to an invasive procedure. Moreover, US can be used to direct the hydrostatic reduction and improve the reduction rates with contrast enemas.^{36,37} Ultrasound-guided hydrostatic reduction is less successful if the intussusception is left sided or contains entrapped fluid (edema). One study of US-guided reduction analyzed the thickness of the hypoechoic external layer of the intussusceptum to determine its association with successful reduction. The authors found that reduction was 100% successful if this layer was less than 7.2 mm thick, 68% successful if it was 7.5 to 12 mm thick, and never successful if the bowel wall was greater than 14 mm thick.³⁸

During evaluation or reduction of intussusception, clinicians may be tempted to administer sedatives. However, infants and children must be able to perform a Valsalva maneuver during contrast studies, and administration of these medications may reduce the successful reduction rates.³³

Management

The uncomplicated patient does not require airway intervention or either respiratory or circulatory support. Monitoring that is appropriate for the degree of patient instability should be initiated. Intravenous lines are inserted in all patients, and a fluid bolus is administered to all individuals with either excessive diarrhea or blood loss from ischemia or frank hemorrhage. A normal saline bolus is administered at a rate of 20 ml/kg over a brief time frame and repeated until the patient becomes hemodynamically stable. All patients should be placed on “nothing by mouth” status. Although not universally performed, pending surgical consultation and imaging procedures, a nasogastric tube is recommended.

Following resuscitation, a decision must be made concerning whether there are contraindications to nonoperative attempts at reduction of the intussusception. For patients without contraindications, the radiologist and surgical consultant can determine whether air insufflation or barium reduction is employed.²⁹ If pneumatic or hydrostatic pressure techniques fail to reduce the intussusception, a repeated effort at nonoperative reduction from 30 minutes to 24 hours

later is an option.^{26,39} With failure of reduction, operative therapy must be employed. About 60% of cases that could not be reduced nonoperatively are successfully reduced at surgery without resection.²⁶

Summary

Patients who require surgical reduction of intussusception generally have an uncomplicated postoperative course. Those who undergo surgical reduction experience a recurrence rate between 2% and 5%.²⁵ Individuals who have successful nonoperative reduction who had been stabilized before undergoing the contrast enema have prompt return of intestinal function. Their vital signs, if altered, return to normal within hours. Patients who have presented with altered mental status have abrupt return to alertness following reduction.⁴⁰ Patients who have had nonoperative reduction have a 2% to 20% rate of recurrence.³⁰ Recurrence may occur up to 1 year following the initial intussusception. However, most cases occur within 1 to 3 days following pneumatic or hydrostatic reduction. It is not possible to establish which patients are likely to have recurrent intussusception based on presenting signs and symptoms, age, or sex.⁴¹ Some facilities admit the child to the hospital for a 24-hour time frame. Other institutions observe the child in the emergency department for less than a 24-hour time frame prior to discharge home.²⁷ Otherwise healthy children who have a successful enema reduction suffer no adverse outcomes when discharged from the emergency department.³⁹ If observation within the emergency department is carried out, at discharge the emergency physician must ascertain if parents understand the indications that warrant a return for further medical attention (i.e., recurrent symptoms, vomiting, new or different pain, or GI bleeding).

Gastrointestinal Bleeding

Jeffrey S. Blake, MD and Stephen J. Teach, MD, MPH

Key Points

Most gastrointestinal bleeding in children is self-limited and not life threatening.

The presence of significant gastrointestinal bleeding usually can be identified clinically.

Emergency department evaluation should prioritize early recognition and management of active bleeding and hemorrhagic shock.

Severe gastrointestinal bleeding requires rapid volume resuscitation and consultation with a gastroenterologist or surgeon to identify and control the source of hemorrhage.

Establishing a definitive diagnosis in the emergency department is not always possible, but making a presumptive diagnosis may be acceptable once life-threatening disorders are excluded.

Introduction and Background

Many causes of gastrointestinal (GI) bleeding are unique to infants and children (e.g., necrotizing enterocolitis, formula intolerance, midgut volvulus). The frequency of specific causes depends on both the age of the patient and the location of bleeding¹ (Tables 75–1 and 75–2). Fortunately, mortality is low in infants and children with GI bleeding since most causes are benign and comorbid conditions (e.g., atherosclerosis, coronary artery disease) are rare.

Recognition and Approach

While GI bleeding in children occurs frequently in the intensive care setting,² this complaint is not commonly seen in infants and children presenting to an emergency department (ED). In fact, GI bleeding only accounts for 0.3% of children presenting to a pediatric ED.³ Moreover, only 4% of these cases have a serious cause for their disorder, and mortality is less than 1%.³

Bleeding from the GI tract is never normal and can signify serious disease or common benign disorders. At any age, swallowed blood may be misinterpreted as gastrointestinal bleeding. Neonates can ingest blood at the time of birth or may ingest blood while nursing from a nipple that has nearby maternal bleeding. Swallowed blood from a nosebleed or intraoral source can be mistaken for GI bleeding, especially if bleeding is heavy and triggers hematemesis that consists of swallowed blood. Food and drinks may contain red dye that turns the stool, red but the stool will be heme negative when tested for occult blood. Clinicians must be able to differentiate between disorders that mimic bleeding, benign causes of bleeding, serious causes of bleeding, and surgical disorders that require acute intervention.

Clinical Presentation

Initial evaluation is directed at assessing the hemodynamic stability of infants and children with GI bleeding. Assessment is also directed at determining whether or not there is ongoing bleeding (Table 75–3). This assessment is based on heart rate, palpation of central and peripheral pulses, blood pressure, mental status, respiratory rate and pattern, and signs of cutaneous perfusion. Although tachycardia is a sensitive indicator of acute, significant GI bleeding in children, children have an impressive ability to increase their systemic vascular resistance and to maintain a normal blood pressure in response to hypovolemia (compensated shock). Therefore, hypotension is considered a late finding in progression of shock (decompensated shock). Quantifying the amount of bleeding requires visual inspection or a historical description of the bleeding. Importantly, children may present with fatigue, syncope, weakness or other alteration in mental status without any bleeding noted from the GI tract.⁴

Confirming the presence of bleeding is an important evaluation step since true GI bleeding can easily be confused with hemoptysis, hematuria, vaginal bleeding, or swallowed blood from the nose, mouth, or oropharynx. Several “mimickers” of true GI bleeding include foods and medications that make vomitus appear red (food coloring, tomatoes, fruit juices), stools appear red (food coloring, beets, ampicillin), or stools appear black (licorice, spinach, iron supplements). Testing stool and emesis or gastric aspirates for occult blood is usually sufficient to confirm or rule out true GI bleeding in these cases. There are a large number of reasons for false positive and false negative stool testing⁵ (Tables 75–4 and 75–5).

Table 75–1 Causes of Acute Upper Intestinal Bleeding*

	Common	Uncommon
Newborn and Infant	Swallowed maternal blood Human milk During delivery Esophagitis	Gastric ulcer Bleeding diathesis
Older Child		
Esophagus	Esophagitis Acid reflux Pill induced Mallory-Weiss tear	Esophagitis Viral (herpes, cytomegalovirus) Allergic Fungal Caustic ingestion Varices Dieulafoy lesion Foreign body Duplication cyst
Stomach	Gastritis Prolapse gastropathy Aspirin Nonsteroidal anti-inflammatory drug Stress ulcer/gastritis	Gastritis Crohn's disease Portal hypertension <i>Helicobacter pylori</i> infection Ulcer Zollinger-Ellison syndrome Cushing's ulcer Leiomyoma Varices Vascular malformation Dieulafoy disease
Duodenum	Duodenitis Crohn disease	Ulcer <i>Helicobacter pylori</i> infection Curling's ulcer Vascular malformation Foreign body Lymphoid hyperplasia Varices Dieulafoy disease Duplication cyst Hemobilia
Other	Swallowed blood Oral/nasal pharynx	Swallowed blood Munchausen syndrome by proxy Pulmonary hemorrhage

*From Squires R Jr: Gastrointestinal bleeding. *Pediatr Rev* 20: 95–101, 1999. Copyright 1999.

Clues to help distinguish upper from lower GI tract bleeding sources include the appearance of the stools and emesis. Vomited blood, or hematemesis, typically comes from an upper GI source (proximal to the ligament of Treitz). Blood may appear bright red if it is fresh blood or resemble dark “coffee grounds” if it is older blood that has been exposed to gastric acid for a period of time. Melena is described as dark, black or maroon, tarlike stools that usually also come from an upper GI source unless the bleeding is abrupt. Lower GI bleeding with a slow transit time may occasionally present as melena as well. Hematochezia is bright red blood coming from the rectum and usually comes from the lower GI tract (distal to the ligament of Treitz). However, upper GI bleeding in large amounts or in the presence of a rapid intestinal transit time also can cause hematochezia. Streaks of blood

Table 75–2 Causes of Lower Intestinal Bleeding*

	Common	Uncommon
Newborn and Infant	Allergic colitis Anal fissure Milk protein intolerance Necrotizing enterocolitis (premature) Swallowed maternal blood Infectious diarrhea	Juvenile polyp Vascular lesions Hirschsprung's enterocolitis Meckel's diverticulum Intestinal duplication Intussusception Infectious enterocolitis
Older Child		
	Anal fissure Intussusception Infectious enterocolitis <i>Salmonella</i> <i>Shigella</i> <i>Campylobacter</i> <i>Escherichia coli</i> O157:H7 <i>Yersinia enterocolitica</i> <i>Clostridium difficile</i> Inflammatory bowel disease (>4 yr of age) Meckel's diverticulum Perianal streptococcal cellulites Juvenile/inflammatory polyp	Inflammatory bowel disease (<4 yr of age) Vascular malformations Intestinal duplication Henoch-Schönlein purpura Cecitis Infectious diarrhea Cytomegalovirus colitis Amebiasis Hemorrhoids Colonic or rectal varices Ulcer at surgical anastomosis Solitary ulcer of the rectum Nodular lymphoid hyperplasia Sexual abuse Rectal trauma

Table 75–3 Important Questions during Evaluation of Gastrointestinal (GI) Bleeding

- Does this patient have severe bleeding or signs of hemorrhagic shock?
- Does this patient have true bleeding or a mimicker?
- Is the blood coming from the GI tract, nasopharynx, or vagina?
- Is it an upper or lower GI tract source of bleeding?
- Does this patient have a potentially life-threatening condition associated with the GI bleeding?
- Is there an associated coagulopathy or platelet disorder?
- Does this patient need emergent endoscopy or emergent surgery?

on the outside of a stool, as opposed to being mixed together with the stool, point to an anorectal source of bleeding such as hemorrhoids or rectal fissures.

Although definitively identifying the source of GI bleeding may not be possible in the ED, clinical features can be used to discriminate between benign and life-threatening causes.

Historical Features

Age is an important determinant of likely causes of GI bleeding (see Tables 75–1 and 75–2). A description of the bleeding (color, quality, location, and quantity) can aid in distinguishing between an upper and a lower GI tract source. The presence of light-headedness or syncope suggest significant volume loss and the need for rapid assessment and management.

Abdominal pain associated with bilious emesis and abdominal distention should alert clinicians to the possibility of intestinal obstruction as seen with volvulus (see Chapter

83, Malrotation and Midgut Volvulus) or intussusception (see Chapter 74, Intussusception). Both volvulus and intussusception can cause intermittent, or “colicky,” abdominal pain and bloody, mucoid stools. An abdominal mass or tenderness is not always present with intussusception and stools are often not characterized as resembling “current jelly.” Stools may range from bright red blood to melena or they may be Hemocult negative.⁶ Another unique condition is necrotizing enterocolitis, which occurs most often in premature infants but can also be seen in full-term infants during the first few weeks of life. Patients often present with abdominal distention and feeding intolerance, and, in more severe cases, they develop septic shock or an acute abdomen from ischemia, peritonitis, or a perforated bowel.

Focal epigastric abdominal pain suggests esophagitis, gastritis, or peptic ulcer disease, all of which are common causes of GI bleeding in children.⁷ Mild, diffuse abdominal pain associated with bloody, mucus-containing diarrhea and fever suggests infectious enteritis (see Chapter 72, Vomiting and

Diarrhea). Hemolytic-uremic syndrome (see Chapter 131, Hemolytic-Uremic Syndrome) can cause bloody diarrhea, most often due to *Escherichia coli* O157:H7, and has a classic triad of hemolytic anemia, thrombocytopenia, and renal failure.

Painless rectal bleeding is often related to structural lesions, including juvenile polyps, Meckel’s diverticulum, and arteriovenous malformations. Juvenile polyps, also known as inflammatory polyps, are present in up to 3% of children, with most children remaining asymptomatic or presenting after the age of 1 to 2 years.⁸ Symptoms include bright red, painless, rectal bleeding during or immediately after defecation.⁸ Bleeding usually stops on its own, and severe bleeding or hemorrhage is rare. Up to 30% of children have iron deficiency anemia. Rarely, polyps can act as an intussusception, causing abdominal pain or prolapse through the rectum, resulting in pruritis and a bloody discharge. A Meckel’s diverticulum is a remnant of the embryonic yolk sac found in 2% of the population.⁹ Two thirds of the time it is lined with gastric mucosa, which can lead to painless intermittent rectal bleeding due to ulceration of the adjacent bowel. The mean age at presentation is 8 to 10 years, although symptoms can develop at any age.⁹ Arteriovenous malformations of the GI tract are rare lesions that lead to painless bleeding. The cecum and proximal small intestine are the most common bleeding sites.¹⁰ Diagnosis can be difficult, and many of these lesions are detected during evaluation for other disorders (e.g., Meckel’s diverticulum).

A known history of constipation or new description of infrequent, hard stools or pain with passage of stools (tenesmus) suggests anal fissures, one of the most common cause of lower GI bleeding in children.³ Severe constipation in a toxic-appearing infant could represent Hirschsprung’s enterocolitis and is a surgical emergency (see Chapter 77, Constipation).

Infants and children may have recurrent bleeding from inflammatory bowel disease, peptic ulcers, severe gastroesophageal reflux disease (GERD), and, less commonly, bleeding esophageal varices from portal hypertension caused by cirrhosis or extrinsic etiologies.⁷ Chronic use of steroids and nonsteroidal anti-inflammatory agents can cause peptic ulcer bleeding.¹¹ While gastritis and peptic ulcers may be due to stress from trauma, burns, surgery, systemic illness, or mechanical trauma from a gastrostomy tube,¹² they are often associated with *Helicobacter pylori* infection in children.¹³ *Helicobacter pylori* can cause chronic, intermittent epigastric pain with emesis, hematemesis, and occult bloody stools.¹³ Other uncommon, but important, causes of GI bleeding include caustic ingestions and foreign body ingestions.

A history of cutaneous vascular malformation or problems with easy bruising or bleeding from other sites suggest a bleeding diathesis. Other inherited causes of bleeding include familial polyposis, coagulopathies, and inflammatory bowel disease.

A dietary history may indicate ingestion of specific foods that mimic true GI bleeding. Formula-fed infants may develop allergies to milk or soy proteins, which are found in most standard infant formulas.¹⁴ Breast-fed infants occasionally have allergic colitis since food antigens can be passed through breast milk¹⁴ (see Chapter 35, Vomiting, Spitting Up, and Feeding Disorders). Besides bleeding, infants may present with irritability, vomiting, diarrhea, poor feeding, or failure to thrive.¹⁴ Infants commonly have “physiologic” gastroesophageal reflux, which is usually asymptomatic.

Occasionally, however, reflux can be complicated by esophagitis and may be difficult to distinguish clinically from allergic colitis, although infants with reflux esophagitis are more likely to have a prominent vomiting history without diarrhea.⁷

Finally, acute-onset vomiting or retching from any etiology followed by brisk hematemesis may be due to a Mallory-Weiss tear, a mechanical injury of the esophagus.¹⁵

Physical Examination

An immediate first step is to check the vital signs for the presence of fever or evidence of hypovolemia. Then, the nose should be inspected for epistaxis, the oropharynx for signs of trauma, and the maternal nipples (of breast-fed infants) for lacerations since all of those situations can lead to swallowed blood that may then be perceived as intestinal bleeding. Mucosal pigmentation of the lips and gums may point to Peutz-Jeghers syndrome, a rare condition associated with hamartomas of the stomach and intestines that are predisposed to bleeding.

An abdominal examination is performed to elicit tenderness, signs of an acute abdomen or bowel obstruction, masses, or features of liver disease such as hepatomegaly, splenomegaly, ascites, or caput medusa. If a gastrostomy tube is present, aspiration of the contents may reveal gross or occult blood.

Visual inspection of the anus may reveal anal fissures, surrounding erythema suggesting a perianal group A β -hemolytic streptococcal infection, perianal fistulas, or hemorrhoids. A digital rectal examination is required after visual inspection to look for hard, impacted stool in the rectal vault, a mass or polyps, or an empty rectal vault (Hirschsprung's disease) and to test stool for gross or occult blood. An examination of the external genitalia is performed to identify vaginal bleeding or a prolapsed urethra in females. Finally, skin breakdown from contact or infectious diaper dermatitis also can be a source of bleeding.

Inspection of the dermis may reveal pale, mottled, cool skin, with weak or absent peripheral pulses and delayed capillary refill, which would indicate hypovolemia. Bruising or petechiae suggests a coagulopathy, thrombocytopenia, or Hensch-Schönlein purpura, a vasculitis characterized by diffuse abdominal pain, arthralgias, and palpable purpura of the lower extremities and buttocks.

Important Clinical Features and Considerations

Gastric Aspiration and Lavage

Aspiration of blood from a nasogastric (NG) tube indicates a high risk that a serious upper GI bleed is present. However, in adults, this technique does not reveal blood in 21% to 31% of patients with endoscopically proven upper GI bleeding.^{16,17} Furthermore, blood is obtained from NG aspiration in a significant number of patients without a GI bleeding source; in these cases the blood is possibly due to trauma associated with NG tube placement.^{16,17} Therefore, clinicians should not rely solely on this test to diagnose or exclude upper GI bleeding.

In the past, gastric lavage with iced saline was recommended for treating upper GI bleeding. It was thought that the saline caused vasoconstriction at the bleeding site and

diminished bleeding. However, studies have failed to demonstrate diminished bleeding or improved outcome with this technique, and it can no longer be recommended.^{18–20}

Laboratory Testing

In general, routine laboratory testing is of limited utility in the evaluation of GI bleeding, and the need for testing can be guided by findings on the history or physical examination. A complete blood cell count and a type and crossmatch are indicated in suspected anemia due to acute or chronic blood loss. However, the hematocrit may be normal in acute bleeding since sufficient time may not have passed for extravascular fluid reaccumulation, which lowers the hematocrit. Thrombocytopenia may be present in leukemia, platelet disorders (e.g., idiopathic thrombocytopenic purpura), or disseminated intravascular coagulopathy. Although eosinophilia in peripheral blood or stool is associated with allergic colitis, the diagnosis of this disorder is largely clinical. Coagulation studies (prothrombin time, partial thromboplastin time) are used to indirectly assess hepatic function and confirm a coagulopathy that may be causing or contributing to GI bleeding. A blood urea nitrogen–creatinine ratio greater than 30 is 98% to 100% specific for an upper GI bleeding source, although this cutoff is only 68% sensitive.^{21,22}

Other optional tests include a serum bilirubin level to further assess liver function, serum transaminase levels to look for hepatocellular injury, serum *H. pylori* titer to guide treatment in suspected peptic ulcer disease, serum creatinine level to assess renal function, and stool cultures in patients with possible bacterial enteritis.

An Apt test may be useful in breast-feeding infants suspected of swallowing maternal blood when the mother has dry, cracked, bleeding nipples. This test uses sodium hydroxide solution to distinguish maternal from fetal blood since fetal blood remains stable in an alkaline environment and retains its pink color, whereas maternal blood reduces and takes on a yellow color. The Apt test is designed for bright red blood, not that which has already been denatured such as coffee grounds–colored emesis or melena.

Imaging

Radiologic imaging may be helpful in specific clinical scenarios. For example, plain abdominal radiographs can confirm intestinal obstruction (volvulus, intussusception), mass effect, perforated bowel (peptic ulcer disease), enterocolitis (necrotizing or Hirschsprung's) or a foreign body. Plain radiographic findings in necrotizing enterocolitis include pneumatosis intestinalis and thickened bowel walls containing multiple small air collections. Plain radiographic findings in intussusception include a small bowel obstruction, sparse large bowel gas, a soft tissue mass, or a crescent sign (soft tissue mass projecting into the transverse colon), or the plain film may be completely normal.^{23,24} Ultrasonography is used to diagnose intussusception, while a barium or air enema is used to diagnose and reduce intussuscepted segments of bowel.^{23,24} An upper GI series can confirm cases of intestinal malrotation with intermittent volvulus. Abdominal computed tomography may be helpful if mass lesions or vascular malformations are suspected or in the evaluation of the acute abdomen. Technetium-labeled nuclear medicine scans may be helpful in diagnosing a bleeding Meckel's diverticulum ("Meckel's scan") or in identifying a bleeding source

where diffuse bleeding does not permit endoscopy. Angiography may also be useful in localizing a site of bleeding when a focal source is suspected.

Endoscopy

Endoscopy is often the most reliable and definitive method of diagnosing certain conditions in patients with significant or chronic upper or lower GI bleeding. It is most useful in cases of active bleeding with focal lesions such as esophagitis, Mallory-Weiss tears, gastritis, gastric and duodenal ulcers, polyps, and vascular malformations.⁷ Endoscopy can be performed electively or emergently depending on the severity and cause of the GI bleeding.

Management

Immediate Management of Severe GI Bleeding

Initial management includes rapid establishment of intravenous (IV) access (two large-bore IV lines, of at least 20 g in a child and 22 g in infants), administration of supplemental oxygen, and assessment of the patient's hemodynamic status. For patients with signs of hypovolemic shock, rapid bolus infusion of crystalloid solution (20 ml/kg of either normal saline or lactated Ringer's solution) is indicated, followed by an immediate reassessment of intravascular volume status. For persistent signs of hypovolemia, the child should receive repeated fluid boluses and an infusion of packed red blood cells. Existing coagulopathies are treated with fresh frozen plasma or specific factor products, and platelet disorders with platelet transfusions. If bleeding appears to come from an upper GI source, a histamine₂ (H₂)-receptor antagonist or proton pump inhibitor can be administered to help decrease gastric acidity. Octreotide, vasopressin, or somatostatin is administered IV in patients with variceal bleeding.⁷ Desmopressin (DDAVP) 0.3 mcg/kg IV will reverse bleeding diatheses associated with renal failure.²⁵

Patients with significant ongoing upper GI bleeding (e.g., shock, hypotension, anemia) require emergent endoscopy to identify the source and control the bleeding. Gastroenterologists can employ several techniques to control bleeding: electrocoagulation, laser photocoagulation, injection of sclerosing agents or epinephrine, and application of elastic bands or mechanical clips to bleeding vessels.⁷ Surgery consultation is indicated for patients with suspected surgical disorders (Hirschsprung's enterocolitis, intussusception, volvulus, perforation), persistent bleeding despite attempted endoscopic intervention, complicated esophageal varices, or bleeding from large vascular anomalies.

Patients with a suspected serious cause for their bleeding (e.g., surgical disorder, varices, ulcer) or with hypotension, persistent tachycardia, or signs of hypovolemia require admission. If the cause of bleeding is unknown, vital signs are normal, the amount of blood loss is minimal, and no serious disorder is suspected, closely coordinated follow-up in 1 to 2 days with a primary care physician or gastroenterologist may be appropriate.

Disease-Specific Treatments

Allergic Colitis

Treatment of allergic colitis consists of eliminating the offending antigen from the diet. Many patients who are aller-

gic to cow's milk protein will also have an allergy to soy milk protein.²⁶ If allergic colitis seems very likely, then a trial of protein hydrolysate formula could be helpful since these formulas have smaller peptides with fewer antigens. In persistent cases, amino acid-based formulas may be necessary. Breast-fed infants may also have allergic colitis from antigens transmitted through breast milk; therefore, the mother may also need to eliminate soy and milk, or even other typical allergenic foods (peanuts, seafood, etc.), from her diet. Symptoms of allergic colitis usually resolve within several days of removing the offending antigen.

Anal Fissures

Since anal fissures are most often a consequence of constipation, treatment focuses on treatment of constipation which, in uncomplicated cases, includes increased fluid intake, increased dietary fiber, decreased dietary fat, and the use of stool softeners.

Esophagitis, Gastritis, and Peptic Ulcer Disease

Empirical use of acid-suppressive medications (H₂-receptor blockers or proton pump inhibitors) may be all that is needed for managing esophagitis secondary to GERD. In infants, GERD is a common and mostly benign condition. For this reason, medications are usually reserved for infants with complications such as GI bleeding, respiratory complaints (stridor, aspiration), or failure to thrive. If severe or complicated GERD is suspected, acid-suppressive medications should be administered. For patients with insignificant GI bleeding, outpatient referral to a gastroenterologist is acceptable for confirmation of diagnosis and further management, such as testing and treatment for *H. pylori*. Eradication of *H. pylori* with antibiotics can dramatically reduce relapse rates of duodenal ulcers. Severe bleeding from a peptic ulcer requires immediate consultation with a gastroenterologist since endoscopic control of bleeding may be needed.

Esophageal Varices

Endoscopic band ligation and sclerotherapy as well as vasoactive therapies (vasopressin, octreotide) have successfully been used in children to treat bleeding esophageal varices.²⁷ If time permits, a gastroenterologist should be consulted when using these agents. In rare cases in which endoscopic and medical management fail, surgical control of bleeding may be required.

Summary

GI bleeding in children is usually benign and self-limited. However, the list of potential causes is extensive. The clinical examination can exclude most life-threatening causes. Early recognition and management of hypovolemic shock and prompt identification of disorders requiring surgical intervention are required to ensure a good outcome for patients with serious causes of bleeding.

Pyloric Stenosis

David D. Cassidy, MD

Key Points

Pyloric stenosis is most commonly seen in previously healthy white male infants, 2 to 8 weeks of age, who present with progressively worsening vomiting that eventually becomes projectile.

The classic presentation of pyloric stenosis is of a dehydrated-appearing infant, 2 to 8 weeks old, who presents with nonbilious projectile vomiting. On physical examination, the infant may have visible peristaltic waves in the left upper abdomen and a palpable olive-shaped mass in the epigastrium, which is the hypertrophied pylorus.

If the hypertrophied pylorus is palpated in the appropriate clinical setting, no further workup is necessary.

If the presentation is atypical and the physical examination is not conclusive, either ultrasound or upper gastrointestinal imaging contrast studies are needed to confirm or exclude the diagnosis.

Introduction and Background

Pyloric stenosis, also known as infantile hypertrophic pyloric stenosis (IHPS), is the most common cause of gastric outlet obstruction in infancy and the most common abdominal condition requiring surgery in the first few months of life. Pyloric stenosis occurs because of hypertrophy and hyperplasia of the circular musculature surrounding the pylorus and antrum of the stomach. This results in constriction and obstruction of the antral region of the stomach and pyloric channel by compression of the longitudinal folds of the mucosa with subsequent gastric outlet obstruction and hyperperistalsis of the stomach. As a result of the obstruction and hyperperistalsis, gastric musculature hypertrophy and dilation occurs. Gastritis with hematemesis may result from prolonged stasis.

Recognition and Approach

Pyloric stenosis occurs in approximately 2 to 5 cases per 1000 live births and is most common in white males.^{1,2} The male : female incidence ratio ranges from 2.5 : 1 to 5.5 : 1, with the highest incidence occurring in first-born males. There appears to be a genetic predisposition, with a greater than fivefold increased risk in first-degree relatives.³ Recent data suggest that the incidence of IHPS is increasing in the United States and abroad.⁴

It is now thought that pyloric stenosis is not a result of a developmental defect of the pylorus present at birth.^{5,6} Biochemical, hormonal, and environmental theories have been proposed as to why pyloric stenosis develops in some infants.⁷⁻¹³ Numerous reports have suggested the association between early postnatal exposure to macrolide antibiotics (erythromycin) and pyloric stenosis in infants.¹⁴⁻¹⁸ Experts have proposed that early exposure (between 3 and 13 days of life) is associated with an eightfold increased risk of pyloric stenosis.¹⁸

Clinical Presentation

Pyloric stenosis typically occurs in infants 2 to 8 weeks old, with a peak incidence at 3 to 5 weeks, but has been seen in infants as early as 1 day of age^{19,20} and as old as 5 months.²¹ Initially, the infant's vomiting may be unpredictable and infrequent, but later it occurs with almost every feeding. Misdiagnosis of pyloric stenosis is usually due to early presentations of the disease in which the infant appears well and the vomiting history seems more consistent with gastroesophageal reflux or a viral syndrome. As the disease progresses, the intensity of the vomiting increases until projectile vomiting ensues. Observation of the child after oral fluid challenges and serial examinations in the emergency department may reveal persistent or projectile vomiting that will help lead to the diagnosis. Emesis is nonbilious with stomach contents but may contain old or new blood if gastritis is also present. Constipation may be present because the infant is dehydrated. Some infants may have diarrhea, referred to as "starvation stools," which further confuses the clinical picture.

On physical examination, the infant will appear hungry and readily accept a bottle but will subsequently vomit, usually within 5 to 10 minutes of feeding. Early in the disease the infant may appear healthy, but prolonged vomiting leads

to dehydration, metabolic alterations, lethargy, and malnutrition. Obtaining a birth weight and comparing it to the current weight is crucial. Infants with pyloric stenosis should have no weight gain or even a weight loss, whereas an infant with reflux regurgitation typically continues to gain weight. One interesting physical finding that has been described in the literature is a hypoplastic or absent mandibular frenulum found in 92% of infants with pyloric stenosis compared to only 1.6% of controls.²²

In the past, experts have stated that a definitive diagnosis can be made in up to 87% of infants with IHPS by performing a careful physical examination of the upper abdomen and palpating the enlarged pylorus.^{23,24} However, more recent prospective studies have shown that physical examination reveals a pyloric olive in only 23% to 55% of cases.²⁵⁻²⁷ Palpation of an enlarged pylorus, commonly referred to as an “olive” because of its shape, is an important skill for emergency practitioners. In many cases, palpation of a pyloric olive is all that is needed to confirm the diagnosis of IHPS and no further studies are indicated. The combination of the classic history of vomiting in the appropriate age group with the identification of the pyloric olive has a positive predictive value of nearly 100%.²⁸⁻³⁰ In order to facilitate the palpation of the pylorus, the infant must be calm and cooperative. This can be accomplished using a blanket for warmth and a pacifier or gauze soaked with a small amount of dextrose water for sucking. If the stomach is distended, it will hamper the examination unless aspirated by nasogastric tube. Most experts recommend that the infant be in the supine position during examination, but others have found better success at identifying the olive by placing the infant in the left lateral decubitus position³¹ or in the prone position.³² Bringing the infant’s knees up to the abdomen helps relax the abdominal musculature, which aids in palpation of the olive. Once positioned, the examiner identifies the edge of the liver with his or her fingertips just to the right of the xiphoid process. Gentle pressure deep to the liver and progressing downward or caudally should reveal a palpable 2-cm pyloric olive just on or to the right of the midline (Fig. 76–1). To confirm the diagnosis, the pylorus should be rolled under the examiner’s fingertips. In the later stages of the disease, visible peristalsis of the stomach from left to right in the upper quadrant of the abdomen is sometimes seen just prior to vomiting. This peristalsis occurs in response to vigorous contractions of the stomach against the obstruction in the pylorus but may not be present if the stomach is empty.

The differential diagnosis for the vomiting infant is extremely broad (see Chapter 35, Vomiting, Spitting Up, and Feeding Disorders; and Chapter 72, Vomiting and Diarrhea). The most common conditions that are confused with pyloric stenosis include gastroesophageal reflux, improper feeding techniques, gastroenteritis, and pylorospasm. Helpful information in determining the etiology of the vomiting includes the age of the child and the timing, frequency, consistency, and volume of emesis. Infants with gastroesophageal reflux typically present shortly after birth with nonprojectile, low-volume regurgitation that occurs after most feedings and remains fairly constant. In pyloric stenosis, the vomiting does not begin until 2 to 3 weeks of age and becomes progressively worse and later projectile. Obstructive causes usually present with an abrupt presentation of vomiting that can be bilious in certain cases. Bilious vomiting in the neonate

FIGURE 76–1. Examination of an infant for an enlarged pylorus.

should always prompt an aggressive workup to rule out malrotation and midgut volvulus (see Chapter 83, Malrotation and Midgut Volvulus). Nongastrointestinal causes of vomiting should also be considered, including sepsis, urinary tract infections, increased intracranial pressure, inborn errors of metabolism, pain, toxins, and medications (see Chapter 35, Vomiting).

Infants with severe and prolonged vomiting may become profoundly dehydrated with associated metabolic derangements. Persistent vomiting results in loss of hydrogen and chloride ions as well as compensatory renal sodium conservation and potassium wasting in response to volume loss. Laboratory analysis in patients who have been ill for a prolonged period may reveal varying degrees of a hypochloremic, hypokalemic metabolic alkalosis. Despite only being seen in delayed presentations, the presence of hypochloremic metabolic alkalosis significantly increases the likelihood that the cause of the infant’s symptoms is pyloric stenosis.^{33,34} If the infant remains dehydrated for a prolonged period of time, a metabolic acidosis may ensue, indicating the need for aggressive resuscitation.

If a pyloric mass is not palpated, further diagnostic imaging studies are warranted. Plain abdominal radiographs may reveal gastric dilation, which is suggestive of but not pathognomic for pyloric stenosis. The two main diagnostic studies that are used for pyloric stenosis are ultrasound and an upper gastrointestinal tract (UGI) series. Both studies have a similar accuracy with sensitivity of 90% to 100%.^{28,35} Despite this, ultrasound is more commonly recommended over UGI studies as the initial imaging modality of choice, mainly due to its rapid noninvasive nature, its lack of radiation, and the elimination of the risk of contrast aspiration that may be associated with UGI studies. Ultrasound allows for direct visualization and measurement of the hypertrophied pyloric muscle, whereas a UGI series does not see the muscle, although hypertrophy is inferred by the demonstration of thinning and elongation of barium in the region of the

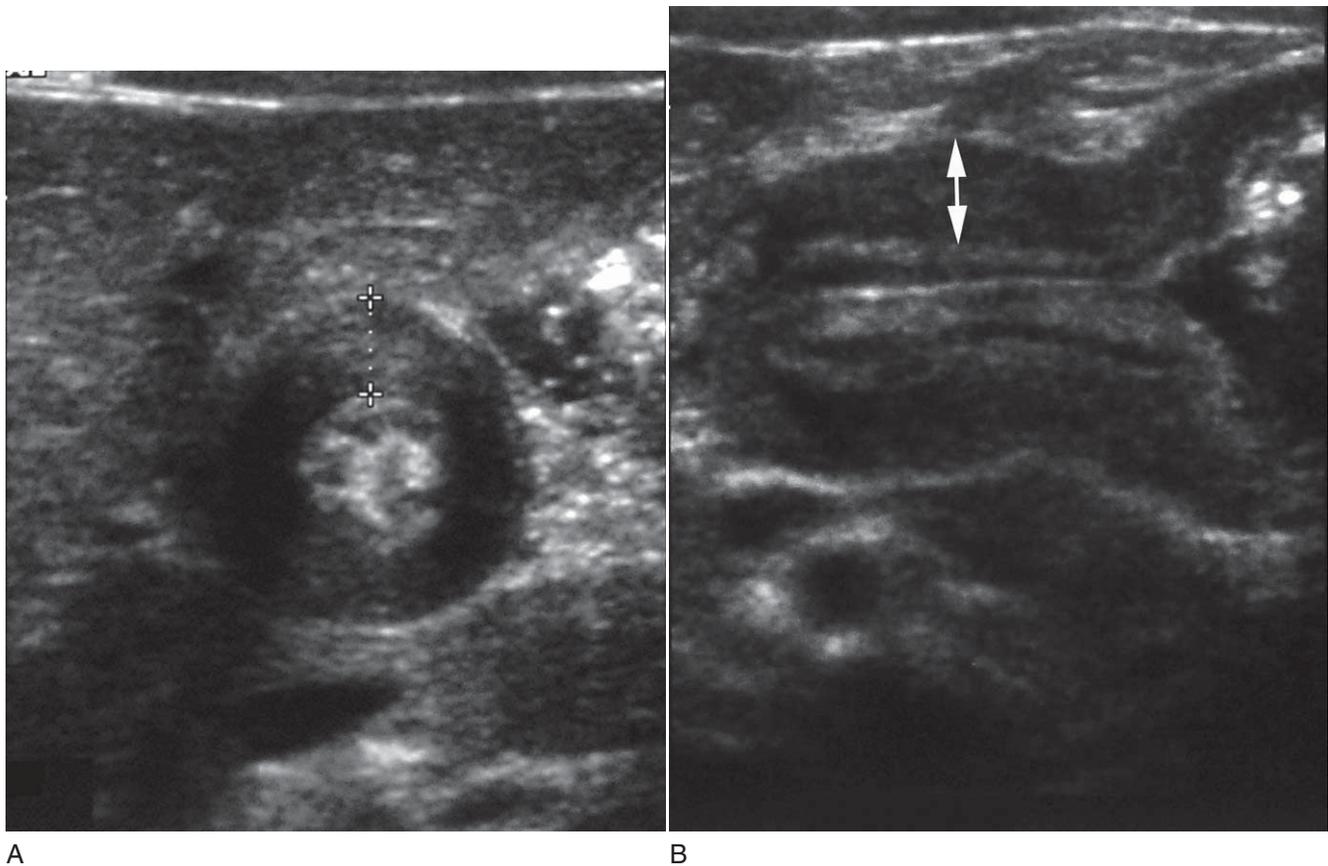

FIGURE 76-2. **A**, Cross-sectional or transverse sonogram of an infant revealing the classic “target sign” as well as an abnormally thickened hypoechoic muscle (cursor marks) measuring 4.4 mm (>3.0 mm is diagnostic for pyloric stenosis). **B**, Longitudinal sonogram of an infant revealing an abnormally thickened hypoechoic muscle (arrows).

pylorus. The accuracy of ultrasound for pyloric stenosis is operator dependent and therefore ultrasound should only be performed by experienced sonographers. Ultrasound diagnostic criteria for pyloric stenosis vary and include a pyloric muscular thickness (serosa to mucosa) greater than 3 to 4 mm, a pyloric canal length of more than 14 to 16 mm, and pyloric thickness or diameter (serosa to serosa) of 11 mm or greater (Fig. 76-2). Using these criteria, sensitivities of 91% to 100% and specificities of 99% to 100% have been reported.³⁶⁻³⁸ Pyloric muscular thickness greater than 3 mm is the most widely accepted diagnostic criterion for pyloric stenosis (see Fig. 76-2). Ultrasound is more accurate than UGI in differentiating pylorospasm from pyloric stenosis. Both cause canal narrowing and delayed gastric emptying, but on ultrasound the entire pyloric muscle can be seen and the thickness of the muscle measured. To avoid a false-positive result, the thickened pylorus should be observed by ultrasound for at least 5 minutes to differentiate pyloric stenosis from the transient thickening of the pylorus seen with pylorospasm. False-negative studies are usually a result of improper technique and measurement errors. Pyloric muscle thickness correlates with the size of the infant and increases as the disease progresses; therefore, false-negative studies may also be seen with premature or extremely small infants as well as early presentations of pyloric stenosis.³⁹

In most cases, a UGI imaging study is indicated if ultrasonography is unavailable or if the ultrasound examination is inconclusive. It is the preferred and most cost-effective study

in atypical presentations or if an alternative diagnosis such as gastroesophageal reflux or malrotation is more likely.^{28,29} In a study in which a UGI series was used as the first imaging study over ultrasound, only 6% of infants required an ultrasound as second study to complete their evaluation. In contrast, 25% of infants required a UGI series to complete their workup when ultrasound was the initial test.²⁸ The UGI contrast study will reveal an elongated pyloric channel (the “string sign”) and a bulge of the pyloric muscle into the gastric antrum (the shoulder or nipple sign) best seen on oblique views. The classic “railroad” or “double track” sign of two thin parallel streams of barium traversing the pylorus, caused by redundant mucosa in a narrowed pyloric lumen, is pathognomonic. The barium should be evacuated from the infant’s stomach after the procedure is completed.

One proposed algorithm to determine which study to order in atypical cases is based on gastric aspirate volume. After at least a 1-hour fast, gastric contents are removed from the infant and quantified. If the aspirate is ≥ 5 ml, gastric outlet obstruction is suspected and an ultrasound should be the initial test, followed by a UGI series if necessary. If the aspirate is less than 5 ml, a medical cause for the emesis is suggested and a UGI series should be ordered first. Using this approach saves time and cost and has a sensitivity of 91%, a specificity of 88%, and an accuracy of 89%. The accuracy is greatly increased if the infant has fasted at least 3 to 4 hours.²⁷ Others have used volumes of 10 ml and the 3- to 4-hour fast with similar accuracy.⁴⁰ Another less common yet very

accurate diagnostic tool that has been used in pyloric stenosis is endoscopy. It is sometimes used if other diagnostic modalities have failed to confirm or exclude the diagnosis of pyloric stenosis.^{41,42}

Important Clinical Features and Considerations

It is important to realize that a significant number of infants with pyloric stenosis will present early in their course and therefore have less of these typical features. Infants may only have postprandial vomiting as their chief complaint and lack a palpable pyloric olive. Although the presence of hypochloremic, hypokalemic metabolic alkalosis significantly increases the likelihood of pyloric stenosis, these metabolic derangements are becoming rarer because of earlier recognition of the disease. Recent studies have revealed that only 10% to 22% of patients presenting with pyloric stenosis have electrolyte abnormalities.^{43,44} Premature infants commonly present atypically. They present later than term infants, have less vomiting that is usually not projectile, and are less likely to have the diagnostic physical examination finding of a palpable hypertrophied pylorus.^{39,45}

Management

Before surgery is performed, the infant must be adequately hydrated and electrolyte disturbances corrected. The metabolic alkalosis is chloride sensitive and will not correct unless excess chloride in the form of sodium chloride is given. After initial fluid resuscitation of normal saline with 20 ml/kg is complete, 5% dextrose with one-half normal saline at a rate of 1.5 times maintenance is used.^{46,47} Potassium is replaced as needed after urine output has been established. Because correction of pyloric stenosis is not a surgical emergency, correction of dehydration and metabolic derangements may be performed over a 12- to 48-hour period prior to surgery. Ramstedt pyloromyotomy is the most common procedure used to correct pyloric stenosis. Some surgeons prefer laparoscopic pyloromyotomy repair because of its shorter recovery time, but open pyloromyotomy appears to have fewer complications and a higher efficacy.⁴⁸ Two small patient series with 33 total cases studied the effect of atropine administered intravenously initially and then orally for several weeks. Over 90% percent of infants had successful normalization of pyloric muscle hypertrophy with resolution of symptoms, thus avoiding operative management.^{49,50}

Summary

With early recognition, preoperative management, and operative management, morbidity and mortality from pyloric stenosis is extremely low. Knowing the classic features of the disease, early and atypical presentations, and laboratory and radiologic features will assure prompt diagnosis and appropriate surgical referral.

Chapter 77

Constipation

David D. Cassidy, MD and Aaron Wohl, MD

Key Points

Ninety-five percent of children with constipation have no serious underlying pathology.

Emergency physicians and families of children with chronic functional constipation must initiate treatment with the understanding that success requires 6 to 24 months for most children.

Treatment consists of child and family education, evacuation of stool impaction, and a maintenance stage that needs to be closely followed in the primary care setting.

Introduction and Background

Constipation, though rarely an emergent condition, is a very common complaint in children presenting to the emergency department. In one study, it was found to be the third most common medical etiology for abdominal pain in children presenting to a pediatric emergency department.¹ Constipation accounts for up to 3% of all general pediatric outpatient visits and 25% of pediatric gastroenterology consultations.^{2,3} This condition is extremely unpleasant for both the patient and the parents and, if chronic, can completely disrupt the family's normal lifestyle. It is therefore extremely important for the emergency physician to be well versed in the evaluation and treatment options for this very common condition.

In children, constipation can be defined by many different diagnostic criteria but can be broadly labeled as infrequent bowel movements with one or more associated symptoms. These associated symptoms include a change in a usual non-problematic bowel pattern, painful defecation, hard stools that cause abdominal pain, purposeful withholding of stool, fecal retention, rectal prolapse, fecal soiling, and encopresis. *Soiling* is used to describe fecal material leakage around a buildup of stool impaction. *Encopresis* is defined as the involuntary, or voluntary, passage of formed, semi-formed, or liquid stool into a place other than a toilet after 4 years of age for at least once a month for 6 months.⁴ Many use the two

terms interchangeably. Some base the definition of constipation on the history of fewer than two to three bowel movements per week.^{2,5} Confirming the diagnosis of constipation based on bowel patterns is a very difficult task. There is a large variation in the frequency of bowel movements in individual children depending on their age as well as their diet.⁶

Recognition and Approach

Functional or idiopathic constipation is the most common cause and is responsible for 90% to 95% of all defecation difficulties in children.⁷ The peak incidence occurs between 2 and 4 years of age, which corresponds with the typical time of toilet training.² Constipation is equally distributed by gender in the toddler-age child but becomes more prevalent in males by school age, with an approximate ratio of 3 : 1. Many factors have been proposed as precipitants of constipation during early childhood, including the initiation of toilet training, dietary transitions from breast milk to formula, starting school or day care, and lack of fiber intake. In adults, an increase in fiber intake can be an appropriate treatment for constipation. For children, though, the role of dietary fiber is controversial, as evidence from controlled studies indicating that dietary modification is beneficial does not exist.⁸

The most common cause of constipation is an acquired behavior brought on by a painful or unpleasant episode of defecation that leads to stool withholding by the child in order to avoid further painful bowel movements. In one study, 63% of children with constipation and soiling had painful defecation that began before 3 years of age.⁹ This withholding of stool then leads to incomplete rectal emptying, which leads to stool impaction. The impacted stool becomes more firm as the reabsorption of fluids continues. The retention of stool in the rectum leads to an increased volume of the colon and distention of the rectum. Distention causes the sensory threshold to increase, and the signal for the need to defecate now arises only with significantly more stool in the rectum than normal. Experts suggest that increased distention leads to rectal and sphincter muscle weakening, leading to more chances of incomplete evacuation and soiling accidents in between stool attempts.⁶ When the child finally defecates, it is even more unpleasant, which results in further withholding, thus perpetuating the problem. Leakage of loose stool around the fecal impaction in the rectum is the mechanism for soiling and encopresis.

These factors underscore the importance of early recognition and treatment of constipation in order to prevent this worsening cascade of events. Early, effective treatment of painful defecation in infancy and early childhood might reduce the incidence of chronic fecal impaction and fecal soiling in school-age children.

Clinical Presentation

Parents may bring in their infants with the complaint of grunting, screaming, and straining prior to what appears to be normal bowel movements and a normal bowel pattern. This is usually not a sign of constipation but is a result of immature coordination between the contraction of the infant's abdominal muscles and the relaxation of the pelvic floor muscles and is termed *infant dyschezia*. Parents should be reassured that, with time and practice, this process becomes coordinated and the symptoms resolve.¹⁰ Infants usually do not have formed stools, and if formula fed may only have one to two stools per week. If the infant is passing hard, pellet-like stools, this will result in inappropriate contraction of the anal sphincter while straining to defecate. This leads to the pain and withholding cycle described previously and constipation in infants.

The older child will typically present with abdominal pain, abdominal distention, nausea and vomiting, anorexia, and irritability.¹⁰ There may not be a history of decreased frequency of stools because neither the parent nor the child pays close attention to bowel patterns once the child is toilet trained. There may be a history of previous episodes of transient colicky abdominal pain relieved with passage of a large bowel movement. Occasionally, the chief complaint is constipation. The parent may describe the child squirming, performing rhythmic movements, standing on the toes, or assuming the fetal position, all of which are attempts to withhold stool by tightening of the gluteal muscles and anal sphincter. Children with a long-standing problem will also have symptoms of painful defecation, very hard and large stools, stool withholding, soiling, and encopresis. A recent study found that some children with unrecognized constipation may present with upper gastrointestinal symptoms, including recurrent vomiting and gastroesophageal reflux.¹¹

There is a clear link between constipation and optimal functioning of the urinary system. Constipated children may present with a history of urinary incontinence, urinary frequency, poorly emptying bladder, and recurrent urinary tract infections.^{12,13} The frequently full, dilated rectum pushes on the bladder, causing frequent urination and improper emptying of the bladder, which may lead to stasis and infection. Soiling, especially in girls, leads to increased incidence of urinary tract infections from fecal flora.

The differential diagnosis for functional constipation is extensive and varies with age (Table 77–1). It is imperative that the emergency physician conduct a thorough history and physical examination to aid in ruling out an organic cause of constipation. Delay of passage of meconium stool or constipation in the newborn should always be considered organic in nature. Hirschsprung's disease, anal anatomic abnormalities, and intestinal obstruction should be considered as possible causes.

Hirschsprung's disease is a rare condition resulting from the lack of ganglion cells in the rectosigmoid colon, which

Table 77–1

Differential Diagnosis of Constipation

Functional Causes of Constipation

- Fecal retention
- Depression
- Harsh toilet training, toilet phobia
- Avoidance of public/school bathrooms
- Anorexia nervosa
- Sexual abuse
- Developmental and behavior disorders

Organic Causes of Constipation

Anatomic/Obstructive

- Anal fissure, anal stricture, anal stenosis
- Imperforate anus, anteriorly displaced anus
- Pelvic masses
- Rectal abscess, rectal polyps
- Acquired strictures from inflammatory bowel disease or necrotizing enterocolitis

Foreign body

Metabolic/Endocrine

- Dehydration
- Malnutrition
- Hypomagnesemia, hypokalemia, hypercalcemia, hypophosphatemia
- Cystic fibrosis
- Meconium ileus
- Celiac disease
- Hypothyroidism, hyperparathyroidism
- Diabetes mellitus and insipidus
- Renal tubular acidosis
- Multiple endocrine neoplasia type IIb
- Acute illness
- Cow's milk intolerance

Neurologic

- Hirschsprung's disease
- Cerebral palsy
- Spina bifida
- Myelomeningocele
- Neurofibromatosis
- Intestinal neuronal dysplasia
- Spinal cord lesions
- Werdnig-Hoffmann disease and hypotonia
- Botulism

Connective Tissue Disorders

- Scleroderma
- Systemic lupus erythematosus
- Ehlers-Danlos syndrome

Drugs

- Anticholinergics
- Opiates
- Phenobarbital
- Antidepressants
- Sympathomimetics
- Antihypertensives
- Sucralfate
- Antacids
- Iron, lead
- Vitamin D intoxication

leads to a nonfunctioning, dilated rectum. Less than 10% of neonates with Hirschsprung's disease pass meconium in the first 48 hours; therefore, a delay of defecation in a full-term infant should raise the suspicion for this diagnosis.¹⁴ Most infants with Hirschsprung's disease are symptomatic during the first month of life and may present with signs and symptoms of an intestinal obstruction. Bilious vomiting, abdominal distention, decreased bowel movements, and reluctance to feed are the most common symptoms. Other presentations

include failure to thrive, malnutrition, or intermittent vomiting with abdominal distension. A fecal mass may be palpated in the left lower abdomen. Rectal examination reveals an empty, nondilated vault. Life-threatening complications of Hirschsprung's disease include toxic megacolon and enterocolitis. Abdominal distention (83%), explosive diarrhea (69%), vomiting (51%), fever (34%), lethargy (27%), rectal bleeding (5%), and colonic perforation (2.5%) are seen with Hirschsprung's enterocolitis, with the mortality rate being as high as 20%.¹⁵ Plain film findings may reveal colonic distention with a 90% sensitivity but only 24% specificity. The identification of the intestinal "cutoff sign" (gaseous intestinal distention with an abrupt cutoff air-fluid level at the pelvic brim) has a sensitivity of 74% and a specificity of 86% for Hirschsprung's enterocolitis.¹⁵ After the first year of life, Hirschsprung's disease is found in less than 1% of children with constipation.¹⁴

After a few weeks of life, the most common causes of constipation are dietary factors and anal fissures. Organic causes can be divided into metabolic, endocrine, neurologic, anatomic (obstructive), connective tissue disorders, and medication/drug-induced constipation (see Table 77-1). Beyond infancy, the most common cause is functional.⁵

Historical factors that aid in the diagnosis of functional constipation are meconium passage within 48 hours of birth, decrease in the usual frequency of bowel movements, pain or discomfort with stool passage, hiding with defecation during toilet training, a small amount of blood on stools associated with anal fissures, and abdominal pain that appears to be relieved with stool passage. Families may also report a low-fiber, high-dairy diet.

Historical factors that suggest an organic cause for constipation are first meconium passage greater than 48 hours after birth, constipation since birth, the passage of pencil-thin stools, bloody diarrhea, significant abdominal distention, fatigue, fever, bilious vomiting, weight loss, abnormal child development, development of constipation prior to initiation of toilet training, and absence of encopresis. Specific medications and supplements can lead to constipation (see Table 77-1).

Important features of the physical examination include a thorough abdominal examination looking for tenderness and a fecal mass in the suprapubic or left lower quadrant of the abdomen. A digital rectal examination is recommended, as well as an external examination of the perineum and perianal area. This allows for assessment of anal location and permits the examiner to evaluate for the presence or absence of anal fissures and hemorrhoids, to test for occult blood in the stool, to evaluate for the presence of an anal wink and a cremasteric reflex, to assess anal sphincter tone, and to assess the size and contents of the rectal vault.¹⁶ Organic disorders are associated with absent of anal wink, clinical dehydration and muscle wasting, pilonidal dimples and hair tufts, a flat buttocks, an anteriorly displaced anus, an empty rectal vault, and diminished or absent deep tendon reflexes, an absent cremasteric reflex, and decreased lower extremity strength and tone. A rectal examination is an important part of the clinical examination that is often overlooked. One study found that only 77% of children who were referred to pediatric gastroenterologists had a prior rectal examination.¹⁷ Firm, packed stool is found in the rectum in most children who have functional constipation and correlates highly

with the objective findings of constipation on abdominal radiographs.^{18,19}

No specific laboratory assessments are recommended in the evaluation for constipation in children unless particular organic causes are suspected. There is also no strong evidence to support the routine use of abdominal radiographs to aid in the diagnosis of constipation. However, fecal impaction of the rectum and colon can be accurately assessed objectively from a plain abdominal radiograph.¹⁸⁻²¹ In order to limit exposure to ionizing radiation, plain abdominal radiographs should be reserved for ruling out more serious underlying pathology, when the history and physical do not strongly support the diagnosis of simple functional constipation, and in cases of severe intractable constipation.

Important Clinical Features and Considerations

Misdiagnosis of this condition is common in children because of difficulty in properly assessing the frightened child and a frequent lack of a good history of infrequent bowel movements. Parents are usually not knowledgeable about the bowel habits of their toilet-trained children, and the child is usually too young to reliably describe his or her habits. Encopresis or soiling might be misinterpreted by some parents as diarrhea, leading to confusion as to the real problem of constipation. The key to diagnosing functional constipation is a suggestive history and examination that excludes serious pathology in a child who has undergone or is currently undergoing toilet training. It is essential that the emergency physician carefully evaluate young infants with the complaint of constipation to exclude organic causes and to initiate appropriate treatment for functional constipation. Organic causes of constipation are more common in infants and, if not recognized, can result in significant morbidity and mortality.

Management

Management options for constipation vary with the age of the child, the underlying cause of the problem, and the degree of constipation. In infants, treatment should be limited to mild osmotic agents such as malt soup extract, corn syrup, or the addition of a small amount of sugar to the infant's formula. Providing one of these options in cases of anal fissures will result in soft stools while the fissure heals. In toddlers and older children with mild constipation, addressing psychosocial issues surrounding toilet training and dietary advice may be all that is needed to remedy the problem. Treatment of moderate to severe constipation involves a three-step process: disimpaction, maintenance therapy, and monitoring (Fig. 77-1).²²

Disimpaction options include oral agents, rectal agents, or both, and disimpaction should be performed over 3 to 5 days depending on the severity of the problem. Recommended oral agents for disimpaction include mineral oil, magnesium citrate, lactulose, senna, and polyethylene glycol solutions either alone or in combination⁶ (see Fig. 77-1). Caution is necessary when selecting magnesium citrate as an oral agent in the very young because of the possibility of magnesium toxicity and electrolyte disturbances.²² Rectal disimpaction using phosphate and mineral oil enemas is very effective and

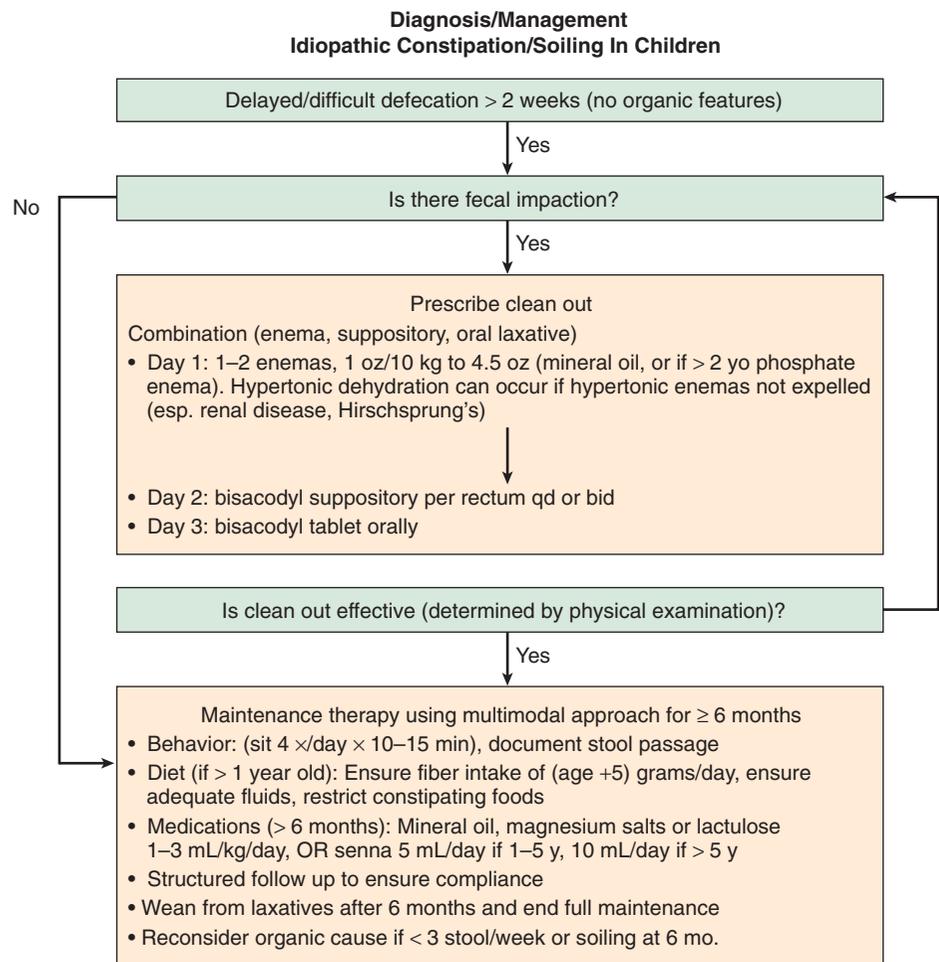

FIGURE 77-1. Diagnosis and management of idiopathic constipation in children.

provides results more rapidly but is invasive and can be unpleasant for the child and family. Enemas should be avoided in children less than 3 years old and in young children with severe neurologic disabilities. These children are at a higher risk of prolonged retention of the enema, leading to absorption of the solution and subsequent toxicity due to magnesium and phosphate content in the most widely used enemas.²³ Soap suds enemas have also been reported to cause bowel necrosis with perforation, and tap water enemas may cause water intoxication, hypervolemia, and dilution of electrolytes, thus leading to seizures.²⁵ Choosing between the oral route, the rectal route, or both is based on the degree of constipation and a discussion with the parents and child.

Once disimpaction is accomplished, the goal of treatment is to prevent recurrence of constipation. Education on the mechanism of constipation as well as fecal soiling helps with the overall treatment plan. Dietary modification, pharmacologic interventions, and behavior modifications are crucial in the maintenance stage. Increasing fiber in the diet and the increasing the child's fluid intake are helpful in maintaining normal bowel patterns (see Fig. 77-1). A short course of stimulant laxative followed by a long-term lubricant is needed in most cases. Mineral oil is an excellent maintenance agent but should not be used if there is an apparent aspiration risk due to young age or severe disability.²⁴ Follow-up with the patient's primary care physician is essential to assist with long-term care.

Summary

Constipation is commonly seen in the emergency department and a frequent cause of abdominal pain in young children. A careful history and physical examination are usually all that is needed to make the diagnosis. Initiating proper therapy as well as educating the child and parents is essential for long-term success in this sometimes chronic and complex condition.

Gastrointestinal Foreign Bodies

Craig A. Kizewic, DO and Madeline Matar Joseph, MD

Key Points

Consider the diagnosis of an esophageal foreign body in any child with a history of choking with or without vomiting, excessive salivation, dysphagia, or odynophagia.

Eighty percent to 90% of all objects, sharp or smooth, reaching the stomach will pass spontaneously over a 4- to 10-day period.

Esophageal button batteries can produce injury in as little as 2 hours and perforation in as little 6 hours. Therefore, immediate removal is advised.

Asymptomatic patients with esophageal coins can be observed for up to 24 hours with little risk of esophageal injury or aspiration.

Introduction and Background

Foreign body ingestion is a common, emergent problem in infants and children. Small children have a natural tendency to put objects in their mouths due to their oral orientation. The majority of ingestions occur between 6 months and 6 years of age, with 65% to 85% occurring in children less than 3 years of age.¹⁻⁶

Historically, esophageal foreign bodies have been considered less serious than bronchial foreign bodies. However, the prognosis of an untreated or unsuspected esophageal foreign body can be devastating. Unrecognized esophageal foreign bodies can cause a myriad of complications such as esophageal perforation, abscess formation, mediastinitis, or fistula formation, some cases of which have been fatal. Annually, 1500 children die from complications of esophageal foreign bodies. Recognition becomes even more challenging when dealing with developmentally delayed, emotionally disturbed, or very young children as they communicate less effectively and can ingest a wide variety of objects. Fortunately, the majority of foreign bodies reaching the stomach will pass through the gastrointestinal system without any

major complications. For the 10% to 20% of foreign bodies that do not pass, endoscopic removal is advised.^{1,4,6-8}

Many types of foreign bodies are ingested, such as nails, pins, thumbtacks, keys, jewels, toys, bones, various metal objects, and clothes holders. Of interest, variations with ethnicity occur. In Western cultures, up to 89% of gastrointestinal foreign body ingestions are coins and up to one third become impacted in the esophagus. In Asia, up to 90% of gastrointestinal foreign body ingestions are fish bones. Fish bones, however, represent up to 90% of sharp foreign bodies ingested in either culture. If the bone impacts in the esophagus, immediate removal is necessary to prevent esophageal perforation, mediastinitis, and abscess formation. Safety pins lodged in the esophagus pose this same risk.⁸⁻¹⁰

Button battery ingestion is becoming more frequent in the pediatric population as our technology advances and smaller batteries are used in cameras, hearing aids, flashlights, and games. The concern with button batteries is their tendency to cause esophageal erosion and perforation. All types of batteries can cause gastrointestinal trauma.

Magnets are found less frequently in the gastrointestinal tract, but pose a significant problem if more than one magnet is ingested. Multiple magnets are especially hazardous after separating from each other as they pass from the stomach to the duodenum through the pylorus. The individual magnets can then attract each other through the bowel wall and cause pressure necrosis, fistula formation, and/or bowel perforation.^{1,3,4,10-18}

Food impactions are rare in infants and children unless there is an anatomic or acquired stricture or a gastrointestinal motility disorder. When seen, they occur primarily in males and appear related to immature behavior or eating too quickly without adequately chewing the food. Even though this is rare, erythema and bleeding of the esophagus can be seen after removal of the food bolus. Bleeding is secondary to the actual food impaction or trauma to the esophageal wall during removal.¹⁹

Bezoars are concretions of incompletely digested particles such as hair, vegetable fiber, or milk products. Patients with gastrointestinal bezoars may present with a myriad of complaints ranging from subtle presentations such as epigastric pain, nausea, and vomiting to serious complications such as weight loss, gastric outlet obstruction, gastric ulceration, peritonitis, gastrointestinal bleeding, intussusception, obstruction, or perforation. Bezoars may appear as a

food-filled stomach or fecal matter in the colon and are easily missed on plain radiography. They can cause chronic abdominal pain in children as well as adults.^{20,21} The two most common types seen in the pediatric population are trichobezoars (hair) and lactobezoars (milk curds). In adults, phytobezoars (vegetable matter) predominate and most commonly affect adults with prior gastric surgery, gastroparesis, or decreased gastric acidity.²¹

Trichobezoars most commonly occur in young females 10 to 19 years of age with psychiatric disorders such as trichotillomania, mental retardation, or pica. Caregivers report trichophagia (eating or chewing on hair) in up to half of all cases. The trichobezoar starts from the intake of small quantities of hair that eventually do not pass the pylorus. The hair then mixes with other food particles to become a semisolid mass. Air trapped within the trichobezoar may be evident on plain films. A rare condition termed *Rapunzel syndrome* may occur if strands of swallowed hair extend from the trichobezoar past the pylorus into the intestine. This condition may lead to bowel obstruction.²⁰⁻²³

Lactobezoars are concretions of undigested milk products that occur in infants and toddlers and do not appear to affect children past 3 years of age. They can affect any child but are found mostly in premature infants, full-term breast-fed infants, and infants receiving concentrated formulas. Almost all types of milk products, including breast milk and soy-based formulas, can lead to the formation of lactobezoars. Similar to the presentation of other bezoars, lactobezoars may mimic a variety of medical and surgical conditions related to gastric outlet obstruction.^{20,24}

In children, the majority of foreign bodies lodge at the usual sites of anatomic narrowing. This includes locations such as the level of the cervical esophagus just inferior to the cricopharyngeus muscle, the aortic arch, the esophagogastric junction, the curvature of the duodenum, and the ileocecal valve. Up to 95% of fish bone ingestions lodge in the palatine tonsils, base of the tongue, vallecula, or pyriform sinus.^{1,2,8,10,25,26}

Recognition and Approach

Obtaining a history of foreign body ingestion in infants and small children can be difficult. Children less than 5 years of age cannot provide a reliable history, convey their degree of discomfort or distress, or indicate the presence of a foreign body. As such, their histories are often vague. The foreign body ingestion may not have been witnessed or may have occurred long before the patient presents to the physician. Children may have a history of choking, but symptoms are usually transient and not witnessed. These symptoms may not arouse concern in the caregiver and may have resolved before arrival at the emergency department.^{1,10}

Signs and symptoms such as refusal to eat, blood-tinged saliva, drooling, or crying can represent a myriad of other diagnoses; nevertheless, the two most sensitive indicators of an impacted foreign body are refusal to eat and blood-tinged saliva.^{10,14} The diagnosis of gastrointestinal foreign bodies is even more challenging in children who are developmentally delayed. They may have excess drooling and lack the ability to communicate any swallowing difficulty. Symptoms can persist for weeks before the discovery of an ingested foreign body.^{1,25}

A history of esophageal instrumentation or surgery should be elicited. Five clinical symptoms that should raise suspicion that acute foreign body ingestion has occurred are vomiting, dysphagia, odynophagia, choking, and excessive salivation.

Clinical Presentation

Patients with foreign body ingestion often present within the first 24 to 36 hours of ingestion, while the vast majority present within the first 6 hours of ingestion. Children less than 5 years of age may present with vague symptoms of refusal to eat, blood-tinged sputum, drooling, or vomiting. They are usually uncomfortable and crying. Children older than 5 years of age are usually able to provide a more detailed history of the ingestion and are able to communicate some degree of discomfort associated with a foreign body. If there is a history of ingestion coupled with vomiting, a foreign body sensation, and odynophagia, an esophageal foreign body is likely.^{1,17} A majority of patients will present with more than one symptom. However, 50% of children who swallow a coin are asymptomatic and present because the caregiver witnessed the ingestion.^{7,10,19,25}

Up to 76% of patients with chronic esophageal foreign bodies (1 week or greater after ingestion) present with respiratory distress, a cough, wheezing, or respiratory tract infection. Symptoms result from extension of esophageal wall edema to the highly compliant soft tissue separating the esophagus from the trachea. This can lead to partial tracheal or bronchial compression. The population most affected by chronic esophageal bodies includes children who are less than 5 years old or who are developmentally delayed.^{1,6}

Although rare, children with psychiatric disorders who present with the following symptoms should be evaluated for a bezoar: chronic abdominal pain, early satiety, weight loss, alteration in normal stool patterns, or passage of hair fragments in vomitus or stool. The symptoms have an insidious onset, and the diagnosis is often delayed. If undiagnosed, bezoars may lead to gastrointestinal bleeding, obstruction, or perforation. Although not reported in children, the mortality rates in adults are as high as 30%.²⁰

Patients can also present with complications from their esophageal foreign body, including fever, dysphagia, odynophagia, cough, dyspnea, pneumonia, or bilious vomiting. The presence of nonspecific or vague symptoms tends to obscure the diagnosis over hours to weeks in some instances. Rare complications, including vascular hemorrhage or mediastinitis, can occur. Rarely, children may develop hemoptysis or hematemesis due to vascular injury from migration or erosion of the esophageal foreign body through the aorta or another major blood vessel and require aggressive management. Mediastinitis has occurred up to 12 weeks or later from the initial ingestion. Patients present with fever, tachycardia, respiratory distress, stridor, retractions, and hypoxia.^{13,16,18,27}

Body packing is a recently reported phenomenon as smugglers are now using children as couriers. Both heroin and cocaine are the typical drugs that are smuggled in this fashion. The packets of drugs are wrapped and sealed in waterproof vehicles such as condoms or examination gloves. They are then swallowed or packed in the rectum or vagina. A single individual may transport as many as 200 individual packets internally. Patients may present with drug toxicity

due to complications from ruptured or leaking packets, intestinal obstruction, or perforation, or with rectal or vaginal bleeding due to retrograde packing, or they may be asymptomatic.²⁸

Important Clinical Features and Considerations

Several risk factors predict complications of ingested esophageal foreign bodies. Objects impacted for 2 or more days prior to presentation, foreign bodies lodged in the upper esophagus at the level of the cricopharyngeus muscle, or those visualized on a lateral cervical radiograph have higher complication rates. Sharp objects are the most dangerous and difficult to remove. As time passes, perforation rates increase to as high as 15% to 30%. Since the likelihood of hemorrhage and mucosal damage is higher, removal should occur within 4 to 6 hours.^{7,14,29} Some authors also state that rigid, irregular, wide (>2 cm), or long (>3 to 6 cm) objects should be removed since they are more likely to become impacted.^{7,23}

Delayed presentation of an ingested disk battery frequently occurs in children. Their symptoms consist of dysphagia, retrosternal chest pain, choking, odynophagia, and pneumonia. Complications resulting in burns to the trachea or esophagus have led to fatal tracheoesophageal fistulas. Batteries may cause damage in several ways. Leakage of caustic material causes liquefaction necrosis. Pressure from the battery itself causes necrosis of the esophageal wall, and completion of an electrical circuit leads to current injury. One study proved batteries immersed in saline release their toxic contents almost immediately. Another study showed leakage of potentially toxic materials after 4 hours of gastric acid exposure. Almost 50% of batteries recovered in stool show dissolution or fragmentation. Minor histologic changes occur as early as 2 hours postingestion, esophageal erosion from the epithelium to the muscle layer within 4 hours, and frank perforation in as little as 6 hours. Consequently, esophageal button batteries require expeditious removal. Mercuric oxide batteries can contain lethal doses of toxins; however, most of the toxin converts to a nontoxic substance after ingestion. For those batteries containing more than the lethal dose, elevated mercury levels and symptoms of toxicity can occur. Other batteries using heavy metals such as lithium and magnesium do not cause toxicity. All types of button batteries can cause a similar amount of esophageal damage. In general, larger batteries cause more damage. Batteries greater than 15 mm are more likely to become impacted and cause damage to the esophagus.^{13,18,30}

Ingestion of multiple magnets can cause severe damage. If multiple magnets are discovered in the stomach, they should be removed immediately. If allowed to pass through the pylorus, they can separate into groups and be attracted to each other through the bowel wall. This can lead to bowel wall necrosis with subsequent perforation or enteric-enteric fistula formation. If multiple magnets have already passed through the pylorus, the child must be monitored for signs and symptoms of intestinal obstruction or perforation. Should the child show any signs or symptoms of perforation or obstruction, emergent exploratory laparoscopy or laparotomy is mandated.^{3,4}

Patients with open safety pins or fish bones impacted in the upper esophagus usually are more symptomatic than

those with lower esophageal foreign bodies. Symptoms of sharp esophageal foreign body ingestion include coughing, dysphagia, odynophagia, drooling, and blood-tinged sputum. Complications resulting from safety pins and fish bones lodged lower in the esophagus include perforation, paraesophageal or retroesophageal abscess, mediastinitis, or, rarely, esophagocarotid or esophagoaortic fistula.^{2,8,26}

Other pitfalls include failure to recognize a sharp foreign body or a second foreign body, or foreign body impaction in an asymptomatic patient (which occurs in 35% to 50% of patients), and relying on plain radiographic studies to exclude a foreign body. A negative plain film study does not rule out the presence of a foreign body.^{1,14}

Management

Imaging Studies

Multiple diagnostic tests exist to help aid in the detection of gastrointestinal foreign bodies (Fig. 78–1). Plain radiographs have been the gold standard and are almost 100% sensitive in detecting safety pins, batteries, coins, and other metallic objects. Depending upon the site of the foreign body, anterior-posterior cervical, lateral cervical, posterior-anterior chest, and abdominal films may be required in patients with button battery, coin, or multiple magnet ingestions. A lateral cervical radiograph is one of the most important radiographs for identifying all objects. Button batteries show a step-off on lateral view and double density on the posterior-anterior view. While subcutaneous glass is visible on 100% of plain radiographs, ingested glass may not be visible on plain films. Moreover, nearly three quarters of fish bones and chicken bones cannot be seen on plain films. Thus, routine radiographs cannot be recommended for many foreign bodies.^{9,18,25,26,31}

Metal detectors are another viable option to localize metallic foreign bodies. They have a 98% sensitivity in determining whether coin ingestion has occurred and whether the coin is impacted in the esophagus. Even in the hands of inexperienced operators, metal detectors are an accurate screening test.³¹

Since Gastrografin is relatively contraindicated due to the risk of aspiration and chemical pneumonitis, a barium swallow study can be used to detect radiolucent foreign bodies lodged in the esophagus. This study not only provides useful information on the anatomy of the gastrointestinal system, such as anomalies and presence or absence of strictures, diverticulae, or congenital abnormalities, but also can identify bezoars, which appear as freely mobile, intraluminal masses.^{1,11,20} However, barium should be avoided if a perforation is suspected.

Computed tomography (CT) is underutilized for the detection of foreign bodies. CT is easy to perform and interpret and can clearly visualize multiple foreign bodies, bezoars, points of obstruction, radiolucent foreign bodies, and abscesses as well as associated inflammatory changes. CT scans using 2- to 5-mm thick cuts have 100% sensitivity and 94% specificity in detecting esophageal fish bones not visualized on plain radiographs.^{9,26,27,32}

Magnetic resonance imaging (MRI), like CT, is able to detect radiolucent gastrointestinal foreign bodies. However, the exact role for using MRI for managing patients with suspected foreign body ingestions is not defined.¹

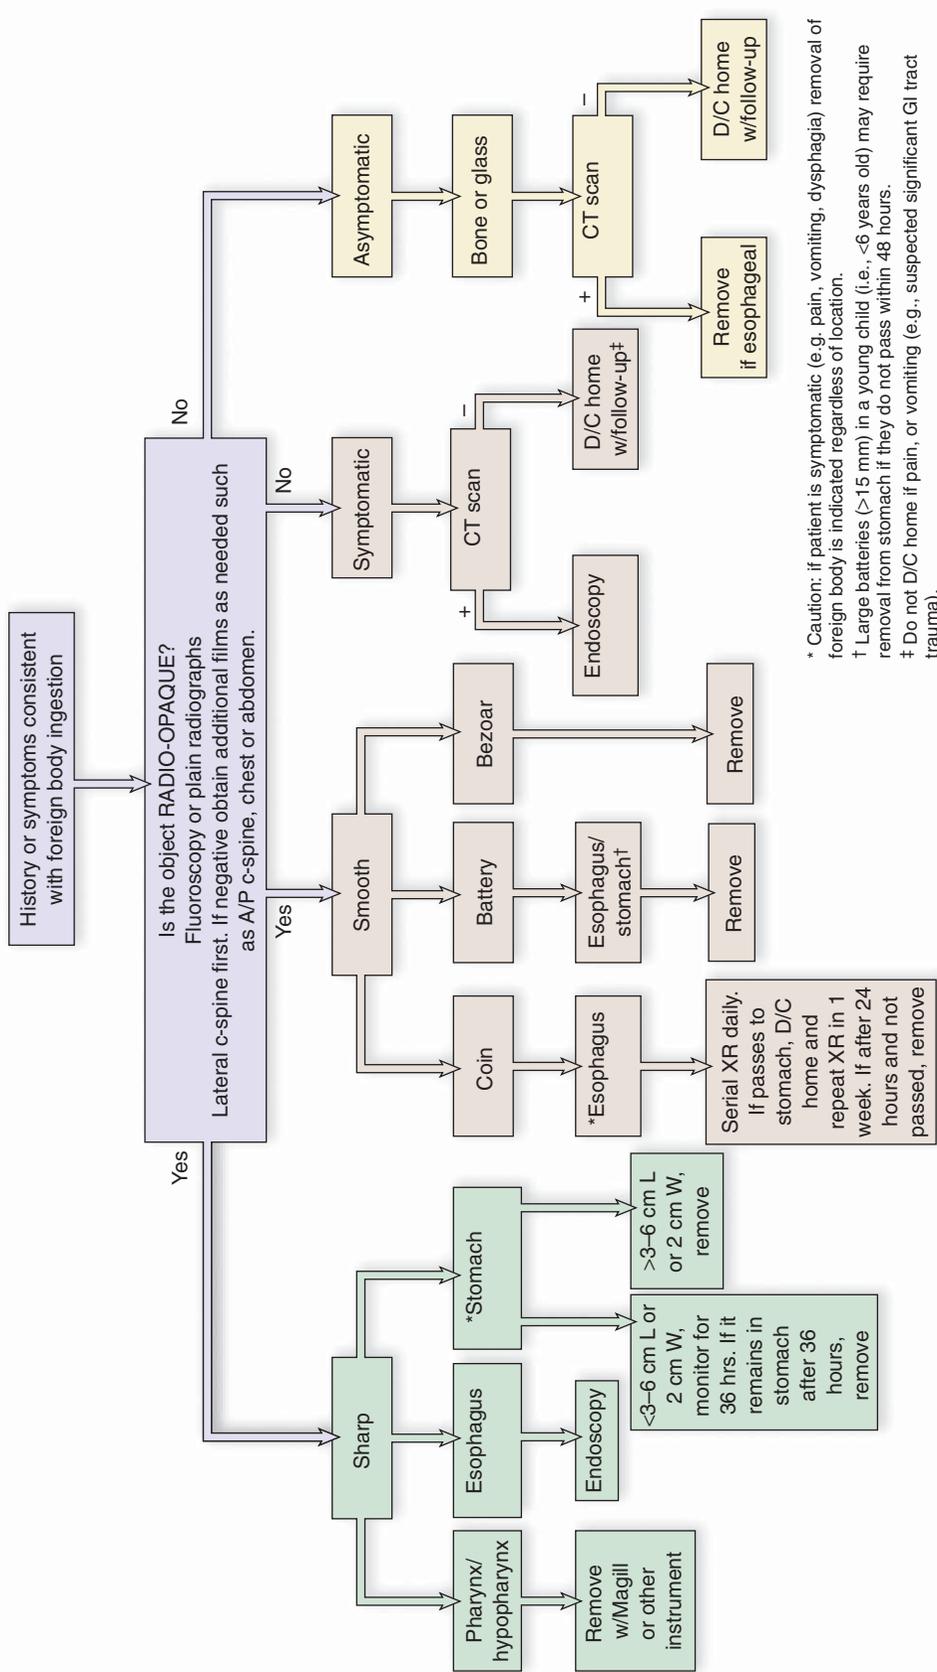

FIGURE 78-1. General approach to foreign body ingestion. (*Caution: If patient is symptomatic (e.g., pain, vomiting, dysphagia), removal of foreign body is indicated regardless of location.) Abbreviations: A/P, anterior-posterior; CT, computed tomography; D/C, discharge; L, long; W, wide; XR, radiograph.

Foreign Body Removal

The most acceptable technique to remove a gastrointestinal foreign body remains controversial. If the patient is symptomatic because of the ingestion, regardless of where the foreign body is, it should be removed as soon as possible.¹

Rigid endoscopy offers the major advantage of visualizing the esophageal lumen and determining the degree of esophageal injury. Multiple foreign bodies can be detected, and the mortality and perforation rate are almost nonexistent. This technique is indicated for patients whose symptoms have persisted for 12 hours, not improved, or deteriorated, or if there are positive radiographic findings and retrosternal symptoms.^{1,2,10,14}

Flexible endoscopy has an overall success rate of 99% for removing foreign bodies in the esophagus and stomach and is useful for sharp or smooth objects. It is safe, it offers the advantage of visualizing the patient's nasopharynx, pharynx, and larynx, and it is effective at removing foreign bodies that have failed to pass out of the stomach.^{11,12,25}

In the emergency department, Magill forceps can be used to remove occasional foreign bodies lodged in the oropharynx, hypopharynx, and upper esophagus. The greatest success rates with this technique are when fish bones, safety pins, or coins are visualized. If visualization of the foreign body fails, direct laryngoscopy under general anesthesia may be required.^{5,10,14}

One study looked at upper esophageal coin removal by emergency physicians using Magill forceps following rapid sequence intubation. Of 13 patients, 10 had coins successfully removed in this manner. The other 3 patients' coins were not visualized using laryngoscope and were successfully removed by using a Foley catheter. All patients were successfully treated in the emergency department, extubated, and discharged home within 5 hours.³³

In asymptomatic patients, Foley catheters or magnet probes with fluoroscopic guidance can be used to remove coins or magnetic objects such as batteries, needles, and pins. The success rate is as high as 94%. Depending upon the type of object, location, associated symptoms, and duration of ingestion, endoscopy to evaluate for esophageal trauma may be required following this technique.^{14,18,25,31}

Glucagon, a rapid, short-acting enteric smooth muscle relaxant, is successful in 75% of adults with impacted food in the esophagus. However, it has the potential to induce vomiting and possibly cause aspiration if given too rapidly. Moreover, in infants and children, attempts at coin removal with glucagon have proven unsuccessful and cannot be recommended.^{19,34}

Watchful waiting for coins or a single magnet impacted in the esophagus for less than 24 hours in the asymptomatic patient is successful if there is no history of esophageal disease or esophageal surgery. The majority of objects will pass into the stomach. Once in the stomach, the majority of objects will pass spontaneously within a week to 10 days.¹⁶ If the object fails to pass into the stomach after 24 hours or if symptoms (e.g., pain, vomiting, dysphagia) develop, endoscopic removal will be necessary.^{16,31,33,35} Safety pin management depends on where the safety pin is located in the gastrointestinal tract and whether the safety pin is open or closed. An open safety pin in the esophagus must be removed immediately due to the risk of perforation. If it has passed

into the stomach, daily radiographs may be obtained to monitor its movement as long as the patient remains asymptomatic. If the patient becomes symptomatic, immediate removal is necessary. If an open safety pin is lodged anywhere in the gastrointestinal tract for 2 days, surgical intervention is required.

Closed safety pins located in the esophagus may be treated as a smooth foreign body. Daily radiographs should be obtained to monitor the safety pin progress. If the patient becomes symptomatic or if it remains in the esophagus after 24 hours, it must be removed. For closed safety pins that pass into the stomach, serial radiographs may be taken on a daily basis to monitor the progress. If the safety pin has not passed after 7 days or the patient becomes symptomatic at any time, immediate surgical intervention is required. Once past the ligament of Treitz, the safety pin has a high likelihood of being eliminated without difficulty.^{2,5,8,25}

Summary

Gastrointestinal foreign body ingestion is a common problem in children presenting to the emergency department. Although esophageal foreign bodies have been historically viewed as less serious than bronchial foreign bodies, deaths from impacted esophageal foreign bodies do occur. An untreated or unsuspected foreign body can result in devastating complications such as esophageal perforation, abscess formation, mediastinitis, and fistula formation. While coins and smooth objects are relatively benign ingestions, some objects are more dangerous, including button batteries, fish bones, small chicken bones, and sharp objects.

Although signs of esophageal foreign body ingestion include coughing, dysphagia, odynophagia, drooling, and blood-tinged sputum, eliciting the history from a developmentally delayed child or a child younger than 5 years of age is challenging. Refusal to eat and blood-tinged sputum in the child younger than 5 and a history of ingestion coupled with vomiting, vague sensation of foreign body, and odynophagia in the child older than 5 indicates an ingested foreign body until proven otherwise.

Some pitfalls to avoid are failure to recognize a sharp foreign body, the presence of a second foreign body, or a foreign body impaction in the asymptomatic patient, and relying on negative plain films, which do not rule out the possibility of a foreign body. If a plain film is positive and the object is in the stomach, such as a single magnet, an open or closed safety pin, a coin, or an object less than 2 cm wide and less than 3 to 6 cm long, a short watch-and-wait approach has been used successfully with a good outcome.

Hepatitis

Evan J. Weiner, MD and Madeline Matar Joseph, MD

Key Points

Mild hepatitis is common, self-limited, and usually due to a generalized viral syndrome.

Vaccination has dramatically reduced the incidence of hepatitis B.

Hepatitis C remains underrecognized in children.

Half of acute liver failure cases are of unknown etiology. Liver transplantation teams should be involved early in the management of these cases.

New treatments are improving the outcomes of chronic hepatitis in children.

Introduction and Background

Hepatitis, defined as inflammation of the liver, encompasses a wide array of acute and chronic liver diseases from many etiologies. In the pediatric population, most hepatitis is related to a viral infection.

The overall incidence of hepatitis in children has changed dramatically over the past few decades due to many factors. Widespread hepatitis B vaccination has substantially decreased the incidence of hepatitis B in children.¹ In 1990, there were 3.0 cases of hepatitis B per 100,000 population among children ages birth to 19. By 2002, that rate decreased to 0.3 per 100,000.¹ Perinatal surveillance has decreased transmission of hepatitis B from mother to baby.² The prevalence of hepatitis C in children has been reported as 0.2% (ages 6 to 11 years) and 0.4% (ages 12 to 19 years).^{3,4} The identification of the hepatitis C virus has led to increased recognition of its role in chronic disease in children.³ Blood product screening for viral hepatitis has markedly decreased its iatrogenic transmission.³ New medical treatments for chronic hepatitis, specifically hepatitis C, offer hope for preventing end-stage liver disease.³ In addition, the success of pediatric liver transplantation programs has significantly improved outcomes in liver failure.⁵

Hepatitis A is widespread, with one third of the general U.S. population showing evidence of prior infection. Children ages 5 to 14 years have the highest reported incidence of hepatitis A; however, it is postulated that children under 5 have the actual highest incidence but they remain either undetected or asymptomatic.⁶ The overall incidence of hepatitis A has steadily been decreasing in the United States.⁷ Besides A, B, and C, other hepatitis viruses exist such as D (delta), E, and G. Hepatitis D can cause fulminant hepatitis in children with hepatitis B; however, it is rare in the United States.² Hepatitis E is also rare in the United States, but causes epidemics in the developing world.² Hepatitis G virus has been detected in U.S. children, especially those who have received blood products, but studies suggest it is not virulent.²

Recognition and Approach

The different hepatitis viruses are each distinct in their virology, transmission, and complications (Table 79–1). Hepatitis A virus infects the gastrointestinal tract and the liver, replicates in the liver, and sheds virus in bile and stool. A patient is most contagious 2 weeks prior to and 1 week after the onset of symptoms.⁷ Children are at risk of contracting hepatitis A if they ingest infected stool. Inadequate hygiene at home, child-care centers, and places of food preparation can contribute to infection. Foreign travel, contact with foreign travelers, or contact with those at occupational risk (e.g., food handlers) also can place a child at risk.⁷ Hepatitis A vaccination plays an important role in the prevention of hepatitis A, although routine vaccination is not yet recommended in nonendemic areas.^{6,8}

Hepatitis B virus infects the liver and causes a brisk viremia. It is readily found in all body fluids, such as saliva, semen, vaginal fluid, and breast milk. Chronic infection rates vary by age, with neonates and younger children having a higher risk. Complications of chronic hepatitis B include cirrhosis and hepatocellular carcinoma. Hepatitis C virus initially infects the liver, leading to a mild systemic illness. However, unlike hepatitis B, chronic infection rates are very high. This is primarily due to the rapid mutation rate of the virus, and its success in evading host defenses. Perinatal transmission occurs in 5% of babies born to an infected mother; however, this is increased if the mother is co-infected with human immunodeficiency virus (HIV).³ Injection drug use accounts for most cases of hepatitis C, now that there is universal screening of transfused blood products.

Table 79-1 Comparison of Clinical Features of Hepatitis A, B, and C

Virus	Family	Transmission	Incubation	Risk factors	Complications
Hepatitis A	Picornavirus	Fecal-oral	28 days	Poor hygiene Travel Endemic areas Occupational Male homosexual sex	Self-limited Fulminant hepatic failure (rare)
Hepatitis B	Hepadnavirus (DNA virus)	Percutaneous— blood exposure Perinatal Sexual	45–160 days	Baby of infected mother Unimmunized Sexual contacts Injection drugs Needle sticks	Chronic infection Hepatocellular carcinoma Fulminant hepatic failure Papular acrodermatitis Glomerulonephritis
Hepatitis C	Flavivirus (RNA virus)	Percutaneous— blood exposure Perinatal Sexual	2 wk–6 mo	Blood product recipient Baby of infected mother HIV Injection drugs Tattoos Sexual contacts	Chronic infection Cirrhosis Hepatocellular carcinoma

Abbreviation: HIV, human immunodeficiency virus.
Data from References 2, 3, and 7.

Clinical Presentation

Children with acute hepatitis often present with many nonspecific symptoms such as fever, nausea, vomiting, and malaise. More specific signs and symptoms include jaundice, icterus, right upper quadrant pain, and hepatosplenomegaly.^{3,6} More severe hepatic and extrahepatic complications may also be seen. Gastrointestinal bleeding can occur with cirrhosis. Encephalopathy and coagulopathy can occur in cases of hepatic failure. Chronic liver disease can also manifest as angiomias, anasarca, ascites, and growth retardation.⁹

Viral infections account for the majority of hepatitis cases in children. In addition to hepatitis A through E and non-A-E hepatitis, other viral syndromes such as Epstein-Barr virus, cytomegalovirus (CMV), adenovirus, enteroviruses, parvovirus B19, varicella-zoster virus, and herpes simplex virus can cause a degree of liver injury and inflammation.¹⁰⁻¹³ There have also been reports of cat-scratch disease causing granulomatous hepatitis.¹⁴ Genetic diseases such as Wilson's disease, α_1 -antitrypsin deficiency, and hemochromatosis may also be considered.¹⁵ Autoimmune diseases such as autoimmune hepatitis and systemic lupus erythematosus are other noninfectious causes of hepatic inflammation.¹⁶ Toxins and drugs such as acetaminophen, isoniazid, minocycline, nitrofurantoin, propylthiouracil, alcohol, and inhalants can cause significant liver injury.^{17,18} Although rare, Reye's syndrome may also be considered in cases of hepatitis and encephalopathy.¹⁹ Pregnancy, specifically HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), can be associated with elevated transaminases. In neonates, considerations include sepsis, inborn errors of metabolism, structural liver disease, and maternally acquired infections (syphilis, CMV, and HIV).⁵

An appropriate laboratory evaluation is very helpful and typically includes a complete blood count with platelets and reticulocytes, electrolytes, blood urea nitrogen, creatinine, transaminases, γ -glutamyl transpeptidase, total and direct bilirubin, alkaline phosphatase, albumin, prothrombin time, and activated partial thromboplastin time to rule out

coagulopathy. If viral hepatitis is likely, a hepatitis antibody/antigen panel may be assessed. This includes hepatitis A antibody immunoglobulin M (IgM) and immunoglobulin G (IgG) (anti-HA), hepatitis B surface antigen (HBsAg) and antibody (anti-HBs), hepatitis B core antibody IgM and IgG (anti-HBc), hepatitis C antibody (anti-HC), and hepatitis B e antigen (HBeAg) and antibody (anti-HBe) (Table 79-2). Hepatitis B and C virus polymerase chain reaction can quantify viremia in chronic patients and also diagnose patients in very early stages of acute disease before the appearance of antibodies.³ Other antibody tests include titers for Epstein-Barr virus, CMV, and parvovirus B19.¹⁰ Rapid viral testing (e.g., adenovirus) may provide a quick diagnostic tool in mild viral hepatitis.¹³ As clinically indicated, other tests may include an ammonia level, erythrocyte sedimentation rate, immunoglobulins, direct Coombs' test, tests for sexually transmitted diseases (gonorrhea/chlamydia, syphilis, HIV) (see Chapter 70, Sexually Transmitted Diseases), acetaminophen/drug levels (see Chapter 133, Classic Pediatric Ingestions), ceruloplasmin, copper, and α_1 -antitrypsin. In neonates, sepsis evaluation, titers for maternally acquired infection, and tests for inborn errors of metabolism may be considered¹⁵⁻¹⁷ (see Chapter 29, Inborn Errors of Metabolism).

Diagnostic imaging is usually not necessary in most cases of acute viral hepatitis. In cases of cholestatic or suspected structural liver disease, imaging options include ultrasonography, magnetic resonance imaging, and cholescintigraphy. Liver biopsy is indicated in acute liver failure, unclear diagnoses, cholestasis, neoplasm, chronic disease, and infiltrative disorders.

Important Clinical Features and Considerations

Viral hepatitis can be associated with many serious complications, ranging from chronic disease to hepatocellular carcinoma to fulminant liver failure and death. Chronic disease is caused by chronic hepatitis B and C infection, with hepatitis C causing the majority of cases in recent years. Chronic

Table 79–2 Interpretation of Hepatitis B Testing Results

Tests	Results	Interpretation
HBsAg anti-HBc anti-HBs	Negative Negative Negative	Susceptible
HBsAg anti-HBc anti-HBs	Negative Positive Positive	Immune due to natural infection
HBsAg anti-HBc anti-HBs	Negative Negative Positive	Immune due to hepatitis B vaccination
HBsAg anti-HBc IgM anti-HBc anti-HBs	Positive Positive Positive Negative	Acutely infected
HBsAg anti-HBc IgM anti-HBc anti-HBs	Positive Positive Negative Negative	Chronically infected
HBsAg anti-HBc anti-HBs	Negative Positive Negative	Four interpretations possible*

*1. Might be recovering from acute HBV infection.
 2. Might be distantly immune and test not sensitive enough to detect very low level of anti-HBs in serum.
 3. Might be susceptible with a false-positive anti-HBc.
 4. Might be undetectable level of HBsAg present in the serum and the person is actually chronically infected.
 Abbreviations: anti-HBc, hepatitis B core antibody; anti-HBs, hepatitis B surface antibody; HBsAg, hepatitis B surface antigen; IgM anti-HBc, hepatitis B core antigen immunoglobulin M.
 Adapted from Centers for Disease Control and Prevention: Guidelines for Viral Hepatitis Surveillance and Case Management. Atlanta: Centers for Disease Control and Prevention, 2004.

liver inflammation from these viruses can cause progressive fibrosis and cirrhosis. Fortunately, unlike adults, most children with hepatitis C demonstrate only mild fibrosis, and many even clear the virus.³ Patients with hepatitis C are frequently co-infected with HIV. The additional presence of HIV may increase the chances of progression of chronic liver disease from hepatitis C. However hepatitis C may or may not cause the progression of HIV disease.²⁰

Hepatocellular carcinoma is a recognized long-term complication of chronic hepatitis B infection. Unfortunately, survival with pediatric hepatocellular carcinoma is poor. Any child with evidence of chronic hepatitis B infection requires close surveillance with α -fetoprotein levels and ultrasonography.²¹ In adults, chronic hepatitis C infection has also been linked to hepatocellular carcinoma; however, this relationship has not been established in children.²

Fulminant liver failure is defined as the onset of hepatic encephalopathy and failure of vital liver function within 8 weeks of new-onset acute liver disease. Of interest, most cases of fulminant liver failure are caused by an unidentified (seronegative) hepatitis. Of the identified cases, most are due to hepatitis A and B, and rare cases are caused by hepatitis C.²² It is postulated that a yet-to-be-identified virus is the etiology for the remainder of cases.⁹ Aplastic anemia develops in a significant portion of these cases, some of which show evi-

dence of parvovirus B19 infection.²³ A large proportion of patients with fulminant liver failure will require liver transplantation.⁹

Management

Since most cases of acute viral hepatitis are self-limited, supportive care is the mainstay of treatment. For patients with chronic hepatitis, medical therapy improves outcome. The antiviral drug lamivudine has been shown to produce a significant virologic response in patients with chronic hepatitis B.²⁴ In patients with hepatitis C, courses of injected interferon alfa combined with oral ribavirin have been effective in viral clearance.²⁵ Interferon alfa and ribavirin therapy are cost effective and reduce the incidence of cirrhosis, hepatocellular carcinoma, and the need for liver transplantation in patients with hepatitis C.²⁶ Interferon alfa has also been used successfully to treat chronic hepatitis B, and interferon beta can be an effective option in patients unresponsive to interferon alfa.²⁷ Side effects of interferon alfa therapy include influenza-like syndrome, neutropenia, and behavioral changes.²⁸

There is a wide range of diagnoses that may cause hepatitis. Each diagnosis carries with it specific principles of management. Examples include chelation therapy in Wilson's disease and *N*-acetylcysteine in acetaminophen toxicity. In autoimmune hepatitis, anti-inflammatory drugs (e.g., prednisone) are the primary treatment. Other drugs such as cyclosporine, tacrolimus, mycophenolate mofetil, methotrexate, and cyclophosphamide remain options for treatment failures.¹⁶

The breakthrough of pediatric orthotopic liver transplantation has significantly improved outcomes in acute liver failure. Without transplantation, acute liver failure carries a greater than 70% mortality rate. One-year survival rates for acute liver failure patients following liver transplantation range from 65% to 92%. Unfortunately, in the neonate and infant, survival rates are much lower. To maximize outcome, orthotopic liver transplantation should be considered early in cases of fulminant liver failure.⁵

Summary

Most children with mild acute viral hepatitis can be followed as outpatients. Depending on their degree of illness severity, patients may need hospital admission for supportive care. Evidence of acute liver failure or impending liver failure requires admission to an intensive care unit. A pediatric gastroenterologist typically manages cases of acute and chronic hepatitis B and C, autoimmune hepatitis, and fulminant liver failure. Early involvement of a pediatric liver transplantation team is vital in the management of acute liver failure (see Chapter 81, Post-Liver Transplantation Complications). All cases of acute hepatitis A through G and unspecified hepatitis (including fulminant liver failure) should be reported to public health officials.²⁹

All patients with hepatitis should have appropriate follow-up with their primary care physician and consultant specialists. Measures to prevent the spread of hepatitis should be implemented, such as inpatient precautions, public health measures, and patient education. All susceptible children should be referred to their primary care physician for vaccination against hepatitis B. Susceptible children living in or

traveling to endemic areas, patients with chronic liver disease, men who have sex with men, patients with clotting factor disorders, users of illegal drugs (injection and noninjection), and people at occupational risk should be vaccinated against hepatitis A. Postexposure immunoprophylaxis should be administered to healthy patients exposed to hepatitis A or B. All pregnant women require hepatitis B surface antigen surveillance³⁰ (see Chapter 156, Postexposure Prophylaxis).

Pancreatitis

Mardi Steere, MBBS and Madeline Matar Joseph, MD

Key Points

Clinical signs of pancreatitis may be less distinct in children than in adults, with the absence of abdominal pain occurring in up to 13% of children.

A significant number of children with pancreatitis have an underlying etiology that may predispose them to recurrence or complications of pancreatitis.

Management in the acute setting is usually nonoperative, with a focus on bowel rest and narcotic analgesia.

Amylase and lipase can be normal in patients with pancreatitis (especially due to trauma).

Introduction and Background

Acute pancreatitis, while uncommon in children, is an important disease due to the potential complications and the frequent presence of a serious underlying etiology. Inappropriately activated and circulating pancreatic enzymes and antigens result in an inflammatory response and cause local pancreatic injury due to direct enzyme damage. This causes microvascular ischemia and pancreatic acinar obstruction,¹ which can result in peritoneal inflammation and a systemic inflammatory response. Other complications, such as pseudocyst and, rarely, exocrine insufficiency, also may occur.

While pancreatitis occurs less frequently in children than in adults, this disorder can occur as early as infancy and can be more difficult to recognize.¹ In this age group, complications are rare, although acute recurrent pancreatitis and chronic pancreatitis can occur. Recurrent and chronic inflammation lead to progressive destruction of the pancreatic parenchyma and ultimately to pancreatic insufficiency.

Recognition and Approach

Many etiologies of acute pancreatitis in children exist²⁻⁴ (Table 80-1). The most common cause is multisystem disease. This includes malignancies (such as acute lymphoblastic and

myeloblastic leukemias), systemic lupus erythematosus (SLE), hemolytic-uremic syndrome, and Crohn's disease.³ Blunt trauma is an important cause of acute pancreatitis, most commonly from bicycle handlebar injuries, although the diagnosis may be delayed due to associated injuries and hemodynamic instability.⁵ Specific drugs are strongly associated with the development of pancreatitis, including valproic acid (which may account for 60% of drug-related occurrences), azathioprine, L-asparaginase, acetaminophen, metronidazole, and multiple other medications. Although idiopathic disease occurs in 8% to 23% of cases, it is rare in children less than 3 years of age. An underlying etiology can be found in nearly 100% of children with pancreatitis who are younger than 3 years old.⁴

Recurrent pancreatitis occurs in some children, and chronic pancreatitis may occur in up to 10% of those with acute pancreatitis.^{2,3} Most cases of recurrent or chronic pancreatitis are due to an underlying disorder or anomaly of the pancreas. Recurrent or chronic pancreatitis may be due to hereditary illnesses that predispose children to pancreatic dysfunction, with the most common being cystic fibrosis.⁶ Hereditary pancreatitis, while rare, is an autosomal dominant mutation in the cationic trypsinogen gene, which results in progressive pancreatic inflammation and destruction, usually beginning in childhood or adolescence.⁷ This is a debilitating condition with a high risk of pancreatic insufficiency and a 40% lifetime risk of pancreatic cancer. Recurrent pancreatitis can also be due to congenital and acquired abnormalities of the pancreas such as traumatic stricture, pancreas divisum (in which the ventral and dorsal ducts fail to fuse embryonically), congenital sphincter of Oddi abnormality, choledochal cyst, duodenal duplication, and annular pancreas.⁶

Clinical Presentation

The most common symptoms and signs of pancreatitis in children are similar to those in adults, and include abdominal pain, vomiting, and abdominal tenderness and distention. Abdominal pain, however, may have a different pattern than in adults, occurring more commonly in the epigastrium, right upper quadrant, or left upper quadrant. Pain that radiates to the back is less common in children compared to adults.^{3,4} Of note, abdominal pain may be completely absent in up to 13% of children. Less common signs and symptoms include fever, tachycardia, hypotension,

jaundice, and signs of acute abdomen such as guarding, rebound tenderness, and decreased bowel sounds (Table 80–2).

Laboratory investigations most often reveal an elevated serum amylase and lipase. These parameters are elevated up to three times normal in 63% to 83% of children with pancreatitis.^{2,3} Unfortunately, an elevated amylase is not specific for pancreatitis and can be found in many abdominal and nonabdominal disorders (Table 80–3). An elevated lipase is more specific than hyperamylasemia for pancreatitis, although elevated levels can be found in renal failure, biliary tract disease, hypertriglyceridemia, and alcohol abuse. Less reliable diagnostic tests include trypsin and amylase to creatinine clearance, which have not been studied well in children.

In pancreatitis, imaging can help determine the etiology of the disease. Ultrasonography (US) is 62% to 95% sensitive in detecting acute pancreatitis, while the sensitivity of computed tomography (CT) is 80% to 95%.⁸ Pancreatic size and pancreatic duct diameter measured by US are increased in pancreatitis⁹ (Table 80–4). These measurements can help identify biliary obstruction in jaundiced patients and other anatomic abnormalities with acute pancreatitis.⁹ Ultrasonog-

raphy is also able to identify gallstones with near-100% sensitivity.⁸ Abdominal CT may be more sensitive than US in diagnosing pancreatitis, with sensitivities greater than 94% for diagnosing severe disease. On CT, most patients with acute pancreatitis have an enlarged pancreas, surrounding inflammation, and peripancreatic fluid collections.^{10,11} CT can identify abscesses, pancreatic necrosis, and pseudocysts.^{10,11} Moreover, CT can be used to grade disease severity and establish prognosis.¹⁰

Endoscopic retrograde cholangiopancreatography (ERCP) enables the measurement of biliary and pancreatic sphincter manometry and may help to identify morphologic changes of the pancreatic duct and branches. It is most helpful in children with acute recurrent or chronic pancreatitis, in whom the pancreatic duct may be abnormal in up to 56% of cases.¹² It may also be useful in cases of acute pancreatitis when ultrasound is nondiagnostic. Therapeutic ERCP at the time of imaging is also possible, and includes biliary or pancreatic sphincterotomy, stone extraction, and balloon dilation or stenting of the duct.^{12,13}

Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive test that can visualize the pancreatic duct, bile duct, and stones. MRCP does not cause pancreatitis and has the advantage over ERCP of visualization of pseudocysts and of the dorsal pancreatic duct in the case of pancreas divisum.^{14,15} It does, however, have lower resolution than ERCP and lacks the option of therapeutic intervention at the time of imaging.

The differential diagnosis of pancreatitis can be extensive depending on the presentation. Abdominal pain and vomiting may be due to myriad causes, both intra-abdominal and extra-abdominal.¹ Fever and jaundice should prompt the clinician to investigate hepatic and biliary etiologies in addition to pancreatic causes. A family history of peptic ulcer disease or chronic abdominal pain may be misleading, as cases of hereditary pancreatitis may have been undiagnosed, or misdiagnosed, in other family members.

Table 80–1 Etiologies of Pancreatitis in Children

Etiology	Percentage
Multisystem	25–53
Idiopathic	8–23

Important Clinical Features and Considerations

The absence of abdominal pain does not preclude the diagnosis of acute pancreatitis in children. In patients with vomiting, abdominal distention, or fever, a history of risk factors for pancreatic disease should be obtained. Important historical features include recent medications or drugs, recent infections, symptoms of systemic disease, and family history of pancreatic disorders or inflammatory disorders such as Crohn's disease, SLE, or diabetes mellitus. A family history of nonspecific recurrent abdominal pain should raise suspicion of a hereditary cause.

Complications of acute pancreatitis, while uncommon, have important and sometimes debilitating sequelae. Pancreatic pseudocysts are the most common complication, especially in the setting of trauma or chronic pancreatitis.² Conservative management and bowel rest results in spontaneous resolution of pseudocysts more frequently in children than in adults. Up to 25% completely resolve, although endoscopic, percutaneous, or surgical drainage may be required if a pseudocyst is persistent or causes symptoms.¹⁶ Complications of pseudocysts, while rare in children, include pseudocyst rupture, abscess formation, hemorrhage, and fistula formation. Pancreatic necrosis is very rare but is associated with infection of pancreatic tissue with gram-positive or gram-negative bacteria or with fungal organisms in up to 30% to 70%. Such infection of necrotic pancreatic tissue is the major risk factor for multiorgan failure and has a mortality of 2% to 24%. Treatment of pancreatic necrosis includes

intravenous antibiotics, with surgical intervention often indicated.¹ Pancreatic failure with exocrine insufficiency is an exceptionally rare complication of chronic pancreatitis in children, but results in malabsorption and diabetes mellitus.¹⁷ Death is rare in children and is usually due to multi-system failure resulting from underlying systemic disease.³

Potential pitfalls exist in the diagnosis of acute pancreatitis. Importantly, abdominal pain may be absent. Serum amylase and lipase may be normal in over 10% to 30% of affected children; conversely, they may be elevated in nonpancreatic disease (see Table 80–3). Plain radiographs of the abdomen usually appear normal in pancreatitis, as plain radiography is a poor imaging modality for this diagnosis. Ultrasonography has a high specificity and sensitivity for diagnosing pancreatitis, but if the pancreatic duct is not well visualized, the clinician may be falsely reassured that pancreatitis is absent.² CT may also be normal in early and mild pancreatitis.

Amylase and lipase elevations are common in patients with blunt abdominal trauma with no evidence of pancreatic trauma. Amylase and lipase also have poor sensitivity, with elevations reported in only 13% to 77% of CT-proven or laparoscopically proven cases of traumatic pancreatitis.^{18–24} Repeat values over time may increase the sensitivity of these tests in detecting significant pancreatic injury.²² Amylase and lipase levels cannot discriminate between pancreatic and nonpancreatic trauma. One study found that only 2% of patients with an elevated amylase or lipase actually had pancreatic injury.²¹ Moreover, as few as 13% with pancreatic trauma have elevated pancreatic enzymes.²⁴ For this reason, serum amylase and lipase should not be relied upon to diagnose or exclude pancreatic injury. Unfortunately, CT is also inaccurate for diagnosing pancreatic trauma, with normal scans in 33% to 53% of patients with laparoscopically proven pancreatic trauma.^{20,22,23,25} However, since there are no good studies for identifying pancreatic trauma (including CT), patients with a suspicious mechanism (e.g., significant handlebar trauma to the abdomen) may require admission, repeated pancreatic enzyme measurements, and observation (Fig. 80–1).

Management

Initial treatment of pancreatitis is primarily supportive. This includes complete bowel rest and intravenous fluids as ileus and third spacing of fluids can be significant. Placement of a nasogastric (NG) tube has been traditionally recommended; however, its use has not been shown to alter outcome of patients with mild to moderate pancreatitis. Patients with peritonitis, intractable vomiting, or severe systemic illness may require an NG tube.²⁶ Narcotic analgesia is often required for pain management and should be instituted early.^{2,3} In the past, meperidine was recommended for treating the pain of pancreatitis based on animal studies. However, all narcotics increase sphincter of Oddi contractions and interfere with peristalsis, and studies have never directly compared the effects of meperidine and morphine on sphincter of Oddi pressures. No outcome-based studies comparing these drugs have been performed in patients with acute pancreatitis. Morphine may be of more benefit than meperidine by offering longer pain relief with less risk of seizures. Experts now recommend morphine and other narcotics rather than meperidine for treating pain due to pancreatitis.²⁷

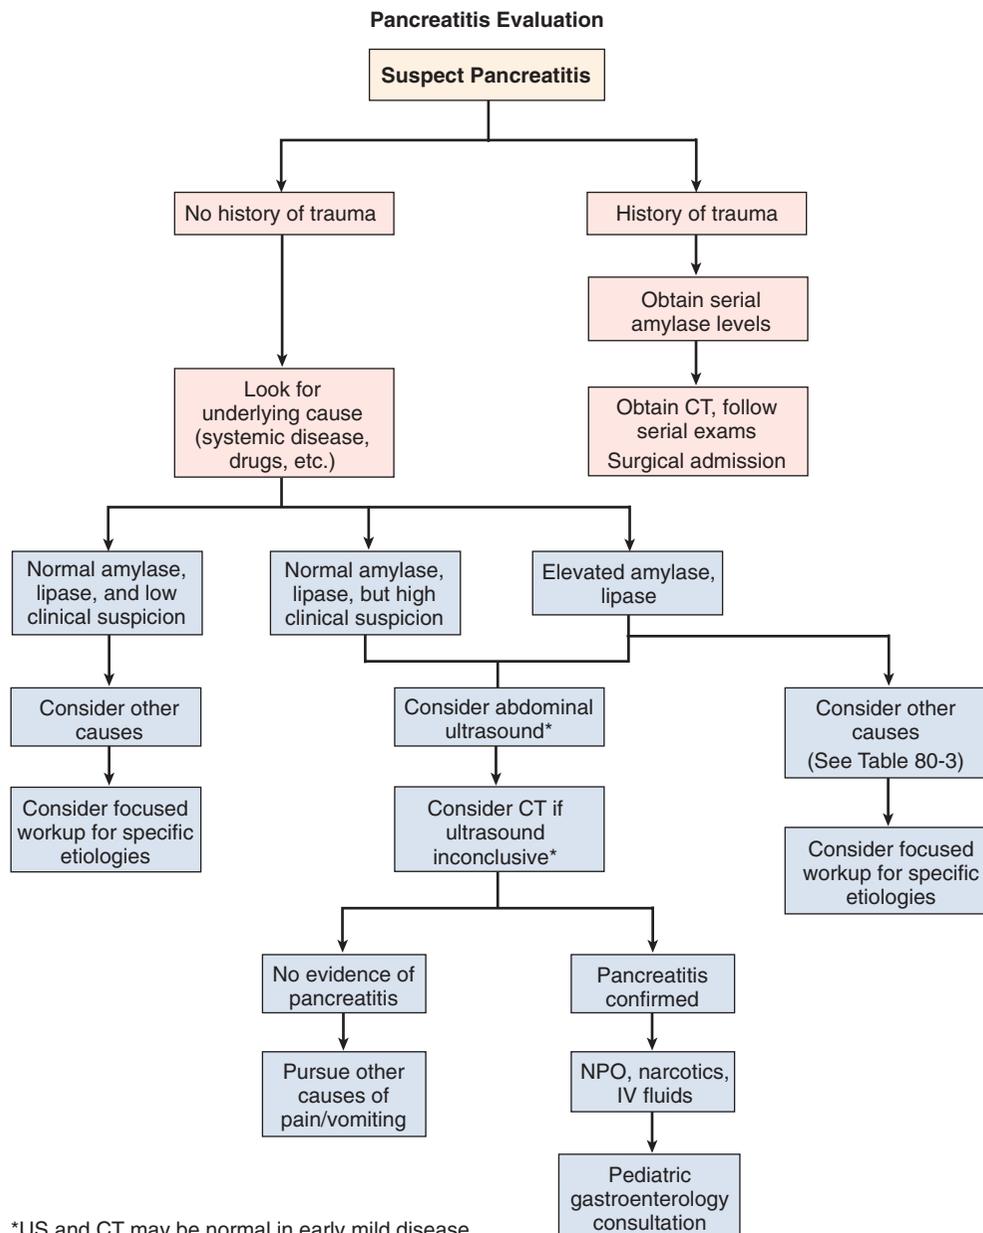

FIGURE 80-1. Pancreatitis evaluation. (*Ultrasound and CT may be normal in early mild disease.) Abbreviations: CT, computed tomography; IV, intravenous; NPO, nothing by mouth.

Antibiotic prophylaxis is only indicated if there are signs of concurrent infection or if a phlegmon, abscess, or necrosis develops. Total parenteral nutrition may be required if the illness is severe or prolonged, as the length of an acute episode of pancreatitis can last from 8 to 24 days, with a mean hospital stay of 13 days.²

Therapeutic ERCP with biliary sphincterotomy may be helpful in acute, recurrent, and chronic pancreatitis in children if manometry reveals abnormalities. This modality may have beneficial long-term effects, reducing frequency and severity of painful episodes.¹³

The indications for surgical intervention remain controversial. Laparotomy may be indicated in blunt trauma, during which acute pancreatitis may be discovered and treated surgically with external drainage.¹³ In severe acute pancreatitis with pancreatic necrosis, surgery may be indicated especially if infection of necrotic pancreatic tissue is suspected or

confirmed by needle biopsy.¹ Pseudocyst formation may necessitate surgical drainage, marsupialization, or complete resection, although observation for spontaneous resorption, followed by percutaneous drainage if the cyst persists, may be reasonable first-line options.²⁸

Due to the high potential for complications, consultation with a gastroenterologist should be initiated following admission. Surgical consultation is required in cases that are unresponsive to nonoperative management or for patients with phlegmon, hemorrhagic pancreatitis (to provide hemostasis), abscess formation, large pseudocysts, or necrosis. Patients with biliary tract disease also may require cholecystectomy or removal of biliary duct stones.

Complex surgical intervention may be indicated for chronic pancreatitis, particularly if the pancreatic duct is abnormal and therapeutic ERCP is unsuccessful.^{29,30} If patients experience persistent pain despite fat restriction, enzyme replace-

Table 80–5 Ranson Criteria in Pancreatitis*

On Admission	Within 48 Hr
Age > 55 yr	Hematocrit decrease > 10%
WBC > 16,000/mm ³	BUN rise > 5 mg/dl
Glucose > 200 mg/dl	Calcium < 8 mg/dl
LDH > 350 IU/L	Arterial PO ₂ < 60 mm Hg
AST > 250 IU/L	Base deficit > 4 mEq/L
	Fluid deficit > 6 L

*Three or more criteria predict a complicated clinical course; mortality rises when 4 or more criteria are met.

Table 80–6 Pediatric Criteria for Severe Pancreatitis*

On Admission	Within 48 Hr
Age < 7 yr	48-hr trough Ca ²⁺ (<8.3 mg/dl)
Weight < 23 kg	48-hr trough albumin (<2.6 g/dl)
WBC > 18,500/mm ³	48-hr fluid sequestration (>75 ml/kg in 48 hr)
LDH > 2000 IU/L	Rise in BUN (>5 mg/dl)

*Three criteria predict a severe outcome.

Abbreviations: BUN, blood urea nitrogen; LDH, lactate dehydrogenase; WBC, white blood cell count.

Adapted from DeBanto JR, Goday PS, Pedrosa MR, et al; Midwest Multicenter Pancreatic Study Group: Acute pancreatitis in children. *Am J Gastroenterol* 97:1726–1731, 2002.

ment, and non-narcotic analgesia, or a complication of chronic pancreatitis has occurred, the goal of surgery is to open the pancreatic duct, enabling its direct drainage into a loop of bowel.^{31,32}

Complications of therapy include acute pancreatitis, which may occur after therapeutic ERCP.²⁸ Surgical intervention may result in pancreatic insufficiency, peptic ulcer, or anastomotic ulcer.³³ For this reason, a trial of conservative treatment is usually recommended prior to any surgical intervention.

Severity of illness in adults can be predicted using scoring systems such as the Glasgow score or Ranson score, which identifies 11 criteria³⁴ (Table 80–5). These systems have not been widely validated in children, although one study has shown them to have 30% to 35% sensitivity and a specificity of 94% for diagnosing pancreatitis.²⁹ A pediatric scoring system developed by De Banto found that the presence of any 3 of 8 criteria predicted severe pancreatitis in children with a sensitivity of 70% and specificity of 79%²⁹ (Table 80–6). Evaluation for complications of pancreatitis should be ongoing, with monitoring of renal and respiratory function as well as close observation for signs of infection, necrosis, or hemorrhage.

Summary

Pancreatitis is an uncommon disease that is difficult to diagnose in children. Serum lipase and amylase may be normal

while US and CT may not reveal abnormalities in uncomplicated or early disease. Prognosis and likelihood of recurrence depend upon the etiology of the disease and vary depending on the underlying pancreatic abnormality. Diagnostic and therapeutic options continue to remain under investigation, with the roles of ERCP and MRCP still being refined in this population. To accurately diagnose this disease, clinicians must be aware of the myriad of risk factors and accuracy of the clinical examination and diagnostic adjuncts. Early diagnosis, close observation, appropriate resuscitation, and selective intervention may improve outcome for this serious disease.

Post–Liver Transplantation Complications

Samir S. Shah, MD

Key Points

Infection and organ failure are the most common reasons for emergency department evaluation of the liver transplant recipient.

The risk of infection and the likely causative organisms depend on the time interval since transplantation.

Patients receiving corticosteroids and other immunosuppressive medications may have blunted or atypical presentations of severe disease.

Early involvement of the transplant team and infectious disease specialists can facilitate management of these very complex patients.

Introduction and Background

Given the rarity of pediatric solid organ transplantations, most emergency physicians had little chance of seeing any of these children during their careers in the past. However, advances in the care of these children has led to greater longevity and therefore greater prevalence of these children in many communities¹ (see Chapter 66, Postsurgical Cardiac Conditions and Transplantation). One institution has reported that nearly two thirds of their pediatric liver transplant recipients live for 15 years or more after undergoing transplantation.² With more children undergoing liver transplantation and with their greater longevity, the likelihood that an emergency physician will see one of these children in the emergency department for a problem related or unrelated to their transplant increases. Given this fact, it is prudent to have some familiarity with the problems these children encounter posttransplantation.

Recognition and Approach

Identifying children who have undergone liver transplantation is typically straightforward. There are multiple indica-

tions for liver transplantation, and occasionally the indication is relevant to the presenting complaint. This is particularly true if the indication involves a systemic disease not cured by liver transplantation. Common indications for liver transplantation include cholestatic liver disease (e.g., biliary atresia, sclerosing cholangitis), acute fulminant liver failure (e.g., viral- or toxin-mediated destruction), chronic active hepatitis (e.g., autoimmune, chronic hepatitis B or C), metabolic disorders (e.g., Wilson's disease, urea cycle defects, disorders of bile acid metabolism), neoplasia (e.g., hepatoblastoma), and other conditions causing severe liver impairment (e.g., cystic fibrosis, chronic parenteral nutrition).

There are three basic types of liver transplantations based on how the liver was procured.³⁻⁵ One type is reduced-size transplantation. For these cases, a cadaveric liver is reduced in size until it is appropriate to fit the recipient. A second type is split-liver transplantation. In these cases, a cadaveric liver is divided into two separate functioning allografts. The third type is living-related donor transplantation. In these cases, a relative of the child donates part of his or her liver to be used for transplantation.

Clinical Presentation

Although children who have undergone liver transplantation can present to the emergency department with unrelated problems, there are well described complications related to transplantation and maintenance therapy. These complications most commonly arise from infections, the ongoing use of immunosuppressive agents, and graft rejection.

Infections

Post–liver transplantation infections can be related to donor-associated infections, seasonal variations, and posttransplantation-related immune suppression. Donor-associated infections are transmitted from the donor to the new host via the graft or accompanying blood cells, or from blood product transfusions. Infectious agents that can be transmitted from an asymptomatic donor to the new host include viruses, parasites, and endemic fungi (Table 81–1). Respiratory viruses might be seasonal (e.g., respiratory syncytial virus, influenza, human metapneumovirus) or endemic (e.g., parainfluenza virus type 3, adenovirus) and either community or

Table 81–1 Differential Diagnosis of Post-Liver Transplantation Infections by Site and Relative Frequency

Infection Site	Potential Causes (in Order of Frequency)
Central Nervous System	Herpes simplex virus Enteroviruses <i>Streptococcus pneumoniae</i> <i>Cryptococcus neoformans</i> Cytomegalovirus JC virus Human herpesvirus 6 Varicella-zoster virus Epstein-Barr virus Endemic mycoses*
Gastrointestinal Tract	Cytomegalovirus <i>Clostridium difficile</i> <i>Giardia lamblia</i> Cryptosporidium species Rotavirus Adenoviruses
Hepatobiliary Tract	Cytomegalovirus Herpes simplex virus Enteric gram-negative bacilli Varicella-zoster virus Epstein-Barr virus Human herpesviruses 6, 7, and 8 Adenovirus Hepatitis B virus Hepatitis C virus Candida species Aspergillus species <i>Cryptococcus neoformans</i> Endemic mycoses* <i>Toxoplasma gondii</i> Cryptosporidium species <i>Bartonella henselae</i> Candida species
Lower Respiratory Tract	Respiratory viruses† <i>Staphylococcus aureus</i> <i>Klebsiella pneumoniae</i> <i>Streptococcus pneumoniae</i> <i>Pseudomonas aeruginosa</i> <i>Legionella pneumophila</i> Cytomegalovirus Candida species Aspergillus species <i>Pneumocystis jiroveci</i> <i>Cryptococcus neoformans</i> <i>Coccidioides immitis</i> Epstein-Barr virus <i>Mycobacterium tuberculosis</i> Atypical mycobacteria
Central Venous Catheter	Coagulase-negative staphylococci <i>Enterococcus faecalis</i> <i>Escherichia coli</i> <i>Klebsiella</i> species <i>Pseudomonas aeruginosa</i> Candida species <i>Staphylococcus aureus</i> Other gram-negative bacilli

*Endemic mycoses include *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis*.

†Respiratory viruses include respiratory syncytial virus, influenza viruses, parainfluenza viruses, adenovirus, and human meta-Pneumovirus.

nosocomially acquired. Respiratory viral infections are most severe if acquired early after transplantation. Opportunistic infections arise due to immunosuppression, especially with agents that affect T-cell function. The causative organisms vary by site of infection (see Table 81–1).

The posttransplantation period is often categorized as “early,” “middle,” and “late,” which is useful for risk-stratifying children for specific infections.^{6,7} The early period is defined as the first month posttransplantation. The middle period is from 1 to 6 months posttransplantation. The late period is defined as greater than 6 months posttransplantation. Early-period infections commonly include surgical site infections, invasive device-related infections (e.g., central venous and urinary catheter-related infections), and nosocomially transmitted infections.⁸ The offending organisms are usually enteric and skin flora, including *Enterococcus* species, *Escherichia coli*, *Klebsiella* species, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida* species.⁹ Risk factors for invasive candidiasis include antibiotic prophylaxis for spontaneous bacterial peritonitis, posttransplantation dialysis, and repeat transplantation.¹⁰ Herpes simplex virus (HSV) infections occur 2 to 3 weeks following transplantation in those recipients not receiving antiviral prophylaxis with acyclovir.^{11–13} HSV mainly occurs through viral reactivation in seropositive individuals, though primary infection may also cause fulminant disease. Common manifestations of HSV infection include orolabial or mucocutaneous infections, esophagitis, and hepatitis. Middle-period infections include donor-associated and opportunistic infections such as cytomegalovirus (CMV), Epstein-Barr virus (EBV), *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia, *Nocardia* species, and *Toxoplasma gondii*. Late-period infections include community-acquired respiratory and skin infections as well as infections associated with immunosuppression. Fungal infections, including those caused by *Aspergillus* species, and infections with EBV cause late infections that occur as a consequence of prolonged immunosuppression. The late period is also a time during which posttransplantation lymphoproliferative disorder (PTLD) is seen.¹⁴ It is thought that infections with organisms such as EBV contribute to this form of lymphoma. Unlike other lymphomas, PTLD frequently fails to respond to chemotherapy.

Immunosuppressive Agents

Agents used for immunosuppression after transplantation can be divided into the following categories: corticosteroids, cytotoxic agents, calcineurin inhibitors, antilymphocytic agents, and monoclonal antibodies. Though the risk and types of infection vary with drug category, most patients receive immunosuppressive agents from more than one category.¹⁵ Besides placing the child at risk for severe and unusual infections, these medications also have significant side effects that may lead to an emergency department visit (Table 81–2). Side effects often occur as a consequence of drug interactions rather than as adverse effects of single agents in isolation.⁶ Three common types of drug interactions may occur in transplant recipients. First, up-regulation of cyclosporine or tacrolimus metabolism due to rifampin, isoniazid, phenytoin, and nafcillin may lead to lower blood levels for a given dose of immunosuppressive agent. Second, down-regulation of cyclosporine, tacrolimus, and rapamycin metabolism due to macrolide antibiotics and azole antifungal agents results in higher blood

Table 81–2 Immunosuppressive Agents, Mechanism of Action, and Potential Side Effects

Agent Category	Examples	Mechanism of action	Important adverse effects
Corticosteroids	Prednisone, methylprednisolone	Inhibit T-cell activation, proliferation, and function	Hyperglycemia, hypertension, gastritis, central nervous system changes (euphoria, depression, and rarely psychosis)
Cytotoxic agents	Azathioprine, cyclophosphamide, mycophenylate mofetil	Decrease number of functional T and B cells	Bone marrow suppression, diarrhea, emesis, hepatotoxicity (azathioprine)
Calcineurin inhibitors	Cyclosporine, tacrolimus, rapamycin, sirolimus	Inhibit T-cell activation, proliferation, and function	Hyperglycemia, nephrotoxicity, hepatotoxicity, hypertension, seizures
Antilymphocyte agents	OKT3	Monoclonal lymphocyte-depleting antibody	Aseptic meningitis, seizures, bone marrow suppression, diarrhea, pulmonary edema
Monoclonal antibodies*	Daclizumab, basiliximab	Anti-interleukin-2 receptor-specific antibody prevents T-cell proliferation and activation of the effector arms of the immune system	Nephrotoxicity, diarrhea, hyperglycemia

*All reported events for this class of drugs were similar in treatment and placebo recipients.

levels for a given dose of an immunosuppressive agent.¹⁶ Third, cyclosporine- and tacrolimus-associated nephrotoxicity can be exacerbated with high, but not low, doses of fluoroquinolones and trimethoprim-sulfamethoxazole. Patients receiving agents that may interact with their immunosuppressive medications require frequent monitoring of medication blood levels and tests of liver and renal function.

Graft Rejection

Acute graft rejection occurs in 60% of liver transplant recipients, and most episodes of rejection occur within the first 3 months following transplantation.¹⁷ Initial symptoms include fever, lethargy, jaundice, dark urine, light stools, pruritus, and occasionally anorexia. Ascites may be noted on physical examination. Chronic rejection occurs in 5% to 10% of patients undergoing transplantation. The primary clinical manifestations of chronic rejection include progressive jaundice and pruritus.

Important Clinical Features and Considerations

Phone Consultation

For physicians unfamiliar with pediatric liver transplant recipients, phone consultation with the transplant physician, a pediatric gastroenterologist, or a pediatric infectious disease specialist is usually indicated. At large pediatric tertiary care centers, there may be an on-call pediatric transplant coordinator who can be very helpful in connecting the emergency physician with the proper consultant. This arrangement can minimize frustration and expedite obtaining the information needed to appropriately care for the child in the emergency department. Once reached by phone, the consultant may request information that is not a typical part of an emergency department history. This is particularly true if the on-call specialist is unfamiliar with this particular child or if the consultation hospital is different from the hospital in which the child underwent transplantation. If possible, it is helpful to have the following information in hand while on the phone with the consultant. Consultants often find it helpful to know:

- Type of transplant: reduced-size, split-liver, or living-related transplant
- The time after transplant: to stratify the patient's risk for early, middle or late period infectious pathogens
- Candidate status at transplantation for varicella, HSV, measles, and mumps
- Candidate *and* donor status at transplantation for CMV, EBV, and hepatitis C virus
- Current antimicrobial prophylaxis, which reduces the risk of certain pathogens as follows: gancyclovir (CMV), acyclovir (HSV), nystatin or fluconazole (*Candida* species), and trimethoprim-sulfamethoxazole (*P. jiroveci*, *T. gondii*)
- Date of catheter placement and prior infections in the existing catheter

Obviously, not all of this information will be readily available to the emergency physician. However, it is helpful for the emergency physician to have some insight into what information the consultant will likely use to guide his or her decision making.

Blunted Presenting Signs and Symptoms

Fever is the most common reason for the emergency department evaluation of a liver transplant recipient. Fever can be the initial manifestation of a spectrum of illnesses that range from systemic viral or bacterial infection to acute organ rejection or hepatic artery thrombosis. However, fever does not accompany 40% of infections among liver transplant recipients; fever is less likely to accompany fungal infections than either viral or bacterial infections.¹⁸ Immunosuppressive medications also blunt other manifestations of severe disease (see Chapter 69, Human Immunodeficiency Virus Infection and Other Immunosuppressive Conditions; and Chapter 107, The Steroid-Dependent Child). Therefore, transplant recipients with subtle signs and symptoms typically warrant a more extensive evaluation than other children. Abdominal pain may represent a surgical emergency, even when relatively mild. Steroid therapy may dull the inflammatory response in a transplantation patient such that typical peritoneal signs may not accompany visceral perforation, bile leak, or infectious peritonitis. Central nervous

system complaints also warrant aggressive evaluation. For example, mild persistent headache or intermittent photophobia may be the only complaint in an immunosuppressed patient with cryptococcal or tuberculous meningitis.

Management

Initial Approach

The initial approach to the child who has undergone liver transplantation follows the same general principles used to evaluate any child presenting to the emergency department (see Chapter 1, Approach to Resuscitation and Advanced Life Support for Infants and Children; Chapter 5, Monitoring in Critically Ill Children; and Chapter 13, Sepsis). Because these children may have subtle presentations of serious conditions, they must be given a higher triage category than warranted by their chief complaint alone (see Chapter 155, Triage).

Laboratory Evaluation

The specific laboratory evaluation differs based on the presenting complaint. The following laboratory studies may be useful: hepatic function panel, electrolytes, creatinine, and prothrombin time. Elevated transaminases are usually seen with acute rejection, systemic viral syndromes (e.g., HSV, varicella), and viral hepatitis, and occasionally with chronic rejection and ascending cholangitis. Elevated conjugated bilirubin and alkaline phosphatase levels are usually seen with acute and chronic rejection and ascending cholangitis. The prothrombin time may be elevated with acute rejection, fat malabsorption (vitamin K deficiency), disseminated intravascular coagulation, and severe liver disease. In patients in the middle period posttransplantation, serum viral studies should be performed to detect CMV and EBV (Table 81–3).^{19,20} In patients with fever or with suspected infection, cultures of blood (including from a central venous catheter, if present) and urine should be performed. Patients with altered mental status may have elevated ammonia levels that suggest hepatic encephalopathy. In patients undergoing lumbar puncture, routine testing should include bacterial and fungal cultures of the cerebrospinal fluid (CSF), Gram stain, and protein and glucose levels. When possible, HSV polymerase chain reaction (PCR) and cryptococcal antigen testing should be performed on CSF specimens since early treatment of these conditions improves outcome. It is prudent to send additional CSF to the laboratory in case additional testing is required. Specific laboratory evaluation depends on the presenting symptoms (see Table 81–3).

Radiologic Evaluation

Children presenting with fever, respiratory complaints, or hypoxia require chest radiography. Pneumonia develops in up to 20% of liver transplant recipients within the early and middle periods posttransplantation.²¹ Diffuse alveolar or interstitial infiltrates suggest viral (e.g., CMV) and atypical bacterial pathogens. In these children, *Mycoplasma pneumoniae* infection may also manifest with lobar involvement. Perihilar infiltrates are often seen with *P. jiroveci* pneumonia. The bilateral alveolar infiltrates first appear in the perihilar areas and then progress peripherally. These patients often present with significant hypoxia despite minimal auscultatory abnormalities. Nodular infiltrates (defined as one or

more focal defects at least 1 cm in diameter with well-defined borders, surrounded by aerated lung) more commonly suggest *Legionella pneumophila*, *Candida* species, and *Nocardia asteroides* and occasionally represent *Aspergillus* species, *Mycobacterium tuberculosis*, and *P. jiroveci*. Micronodular infiltrates are seen with CMV and varicella pneumonitis.²² Segmental or lobar consolidation or pleural effusions (frequently bilateral) might be seen with bacterial causes, including gram-negative bacilli and *L. pneumophila*. Specific diagnostic testing is usually indicated (see Table 81–3) since detection of a specific pathogen may alter therapy. Definitive diagnosis of *P. jiroveci* pneumonia requires detection of the organism by silver stain in a properly obtained induced sputum or bronchoscopy sample. Those children with respiratory complaints or fever without a source and normal or nonspecific findings on radiography, as well as those with mediastinal or hilar lymphadenopathy, should undergo computed tomography (CT) of the chest for a more detailed evaluation.

Abdominal radiographs and CT is usually indicated for patients with fever or with gastrointestinal complaints. Fever without a source in liver transplant recipients may indicate the presence of an occult intra-abdominal abscess. Other potential intra-abdominal complications include intestinal perforation, intussusception, or luminal obstruction as a result of enlarged abdominal lymph nodes caused by PTLD. CMV colitis has also been associated with bowel perforation. Doppler ultrasound of the abdomen is useful for evaluating patients with suspected hepatobiliary complications. Potential hepatobiliary complications include stenosis, leaks, infectious cholangitis, and vascular complications (i.e., hepatic artery thrombosis, portal vein thrombosis, and venous outflow tract obstruction). Vascular complications are most common within the first 3 months following transplantation.²³ Hepatic artery thrombosis may present insidiously with impaired hepatobiliary perfusion leading to gradual biliary necrosis with strictures and, ultimately, allograft failure.

Empirical therapy for suspected bacteremia or cholangitis includes piperacillin-tazobactam, ticarcillin-clavulanate, imipenem, or a combination of ampicillin-sulbactam and gentamicin or ceftriaxone and metronidazole. Vancomycin should be added in patients with cardiovascular instability or a central access port. Patients with lobar consolidation should receive therapy with cefotaxime or ampicillin-sulbactam. Azithromycin should be added if atypical bacterial disease is suspected. Patients with suspected central nervous system infections should receive a combination of vancomycin and cefotaxime. The empirical initiation of antiviral and antifungal agents depends on the patient's presenting symptoms and initial laboratory studies. Patients with meningoencephalitis or lymphocytic CSF pleocytosis should empirically receive intravenous acyclovir. The HSV genome can be detected by CSF PCR for up to 7 days after the initiation of acyclovir.²⁴ Decisions to begin other empirical antiviral therapy or antifungal therapy should be made in consultation with infectious disease or liver transplantation experts. Agents for suspected viral infections include acyclovir for HSV, gancyclovir for EBV and CMV,²⁵ and oseltamivir for influenza. Potential antifungal agents include amphotericin B, fluconazole, caspofungin, and voriconazole.

Conditions that impair the patient's ability to ingest or absorb medications (e.g., vomiting, diarrhea) necessitate

hospital admission for parenteral administration of immunosuppressive medications and careful monitoring of immunosuppressive medication levels. Inadequate immunosuppression levels place the patient at high risk for acute rejection and graft loss.²⁶

Summary

Liver transplant recipients are at high risk for infectious and graft-related complications. The infecting organisms can be predicted to some extent by the time period following transplantation; however, any organism can cause disease during any given period posttransplantation. The clinical manifestations of illness can be subtle due to the anti-inflammatory and immunosuppressive effects of transplant-related medications. The transplant center and infectious disease specialists can assist in the management of these complex patients.

Inflammatory Bowel Disease

Barbara M. Garcia Peña, MD, MPH

Key Points

The use of steroids and other immunosuppressants can mask complications (e.g., perforation) in patients with inflammatory bowel disease.

Stress-dose steroids should be considered in ill-appearing patients who are already taking prednisone.

Clinicians should not rely on plain films to exclude most serious intra-abdominal complications such as bowel perforation, abscess formation, and biliary and pancreatic disorders.

Introduction and Background

Inflammatory bowel disease (IBD) is a chronic, remitting condition characterized by inflammation of the gastrointestinal (GI) tract. The two most common types of IBD are Crohn's disease and ulcerative colitis (UC). Crohn's disease is characterized by transmural segmental inflammation and granulomas affecting any segment of the GI tract. UC manifests as inflammation of the mucosal lining of the colon and rectum. Both diagnoses are relatively common in the pediatric population since up to 40% of patients who have Crohn's disease and 20% of patients who have UC come to medical attention before 20 years of age.^{1,2} The majority of children with IBD can be managed as outpatients on chronic pharmacotherapy. Despite their chronicity, these disorders can present to the emergency department as acute and potentially life-threatening GI emergencies.

Recognition and Approach

The cause of IBD is believed to be inappropriate activation of the mucosal immune system driven by normal GI flora. This abnormal response is facilitated by defects in the barrier function of the GI epithelium and the mucosal immune system.³ Although the cause of IBD continues to be unknown, genetic factors, environmental precipitants, and disease cofactors are thought to be the major etiologic agents. The aggregate effect of genetic, environmental, and a myriad of other processes is the continual activation of mucosal

immune responses with the resultant clinical manifestation of IBD.³⁻⁵

The inflammation in UC is typically limited to the colon and rectum and is seen primarily in the mucosal layer. It consists of continuous involvement along the bowel length with areas of inflammation, ulceration, hemorrhage, and edema. In severe cases, the inflammation may extend into the submucosa. Intervening areas of granulation tissue and regenerating epithelium may form islands of tissue called "pseudopolyps." Unlike Crohn's disease, there are no granulomas and little fibrosis is present.⁶

The incidence of UC in children has been gradually increasing, with the prevalence currently 41.1 to 80 cases per 100,000 population. The disease is more prevalent with white ethnicity and occurs more commonly in Northern Europe and North America. Females outnumber males by 50%. The age of onset is typically bimodal, with the major peak in the second and third decades and a second peak in the fifth and sixth decades.^{7,8}

Crohn's disease is a transmural inflammatory disorder that may affect any segment of the GI tract from mouth to anus and most often is discontinuous. Anal involvement, composed of skin tags, anal fissures, abscesses, and fistulas, occurs in approximately 25% of patients. Approximately 40% of patients with Crohn's disease have involvement of the terminal ileum. The inflammation is commonly transmural and manifests as mesenteric inflammation, fibrotic stiffening of the small bowel loops, adhesions, stricture formation, and fistulas to bowel, bladder, skin, or vagina. Histology reveals noncaseating granulomas in as many as 50% of patients.⁶

The incidence of Crohn's disease is approximately 3.5 per 100,000 population per year, making Crohn's disease more common than UC in pediatric patients. The epidemiology is similar to that of UC, with an increased prevalence among whites and a bimodal age of onset. There is approximately equal female:male representation.^{8,9}

Clinical Presentation

Patients with Crohn's disease and UC may present to the emergency department with similar symptoms. Fluctuating symptoms of diarrhea, crampy abdominal pain, and variable amounts of GI bleeding may be seen. In addition, systemic symptoms such as fever, weight loss, and fatigue, seen with any chronic inflammatory process, are commonly manifested in patients with IBD. A variety of extraintestinal signs

and symptoms, such as arthritis, uveitis, aphthous stomatitis, and pyoderma gangrenosum, are also often seen in these patients and may even be the sole presenting symptoms.⁶

Fortunately, true abdominal catastrophes occur only rarely. However, the emergency physician should be aware of these grave complications.

Ulcerative Colitis Complications

Fulminant Colitis

Fulminant colitis is a severe form of UC that affects approximately 5% to 15% of patients and has been shown to represent the initial presentation of the disease in up to one third of patients. Recent mortality rates have been described to be 10% or less.⁶ A several-week history of worsening GI symptoms accompanied by weight loss often precedes the presentation. These signs may be subtle or even absent in patients taking immunosuppressant medications or high-dose steroids.

Physical examination findings usually include a child who is pale, tachycardic, and febrile with postural changes in pulse and blood pressure. Clinical features of fulminant colitis include diffuse abdominal tenderness with signs of peritoneal irritation, fever, distention, and absent bowel sounds. Laboratory findings may include leukocytosis with a shift to the left, anemia, hypoalbuminemia, hypokalemia, and azotemia.¹⁰ Abdominal radiographs, including left lateral decubitus views, should be obtained to look for free air in the peritoneum. The radiograph may also show loss of colonic haustra, classic “thumbprinting,” which represents bowel wall edema and inflammation or dilation, seen most prominently in the transverse colon¹⁰ (Fig. 82-1).

Toxic Megacolon

Toxic megacolon is the persistent dilation of the colon in the setting of fulminant colitis, which occurs in 1.6% to 18% of patients with UC.¹¹⁻¹³ Possible triggering events include recent colonoscopy, barium enema, hypokalemia, and the use of opiates or anticholinergic drugs. Reported mortality rates vary between zero and 50%, with the higher numbers resulting from colonic perforation and sepsis.^{12,14}

Clinical features include an ill-appearing patient who may have changes in mentation with fever, toxicity, and dehydration. Tachycardia and hypotension are often present. Patients with toxic megacolon may actually show a decline in the frequency of bowel movements, reflecting increased colonic dilation instead of improvement. On abdominal examination, there is distention and tympany particularly in the region of the left and transverse colon. If peritoneal signs are present, they often signal perforation.⁶ Plain films usually show a nonobstructed, dilated large bowel with loss of haustra or thumbprinting. Computed tomography (CT) scans may be more accurate than plain films and also aid in excluding other disorders causing abdominal pain.

Bowel Perforation

Bowel perforation is a serious and lethal complication of UC that occurs in up to one third of patients with toxic megacolon.^{12,13} Clinical features include a patient with signs of sepsis with high fever, leukocytosis with left shift, and increasing abdominal pain with guarding. However, these signs and symptoms may be diminished or absent in patients taking

FIGURE 82-1. Barium study demonstrating fulminant ulcerative colitis. Note the pipelike colon on the left with no haustral markings identified.

high-dose steroids, those on immunosuppressants, and those who are malnourished. While abdominal radiographs may be helpful to demonstrate free air in the peritoneal cavity, CT may be required to make the diagnosis.¹⁰

Gastrointestinal Bleeding

Although *bloody diarrhea* is the hallmark of ulcerative colitis and occurs in over 95% of patients, *severe gastrointestinal bleeding*, although uncommon, also may be seen in these patients. Hemorrhage accounts for only 6% to 10% of all urgent colectomies in ulcerative colitis.^{14,15} Patients with pancolitis as well as those with toxic megacolon are more prone to hemorrhage.¹⁶

Crohn's Disease Complications

Bowel Obstruction

Patients with Crohn's disease involving the gastroduodenum can mimic the presentation of peptic ulcer disease with epigastric pain, postprandial vomiting, and hematemesis and melena. These patients may also present acutely with *gastric outlet obstruction* with a several-week history of epigastric pain, worsening postprandial vomiting, and progressive weight loss. Physical examination may reveal a dehydrated, tachycardic patient with hypoactive bowel sounds.^{10,17}

Patients with Crohn's disease involving the small bowel most often have right lower quadrant pain and diarrhea. As the fibrosing process progresses, *small bowel obstruction* may occur. Patients usually present with a history of low-grade symptoms prior to the onset of the acute episode, which is usually a partial obstruction. Rarely, a patient may present more urgently with a high-grade obstruction without prior

premonitory symptoms. Small bowel adhesions should also be considered in the patient with prior abdominal surgical history, and present in an abrupt fashion. This type of obstruction can rapidly progress to strangulation and bowel necrosis.¹⁰ The diagnosis of bowel obstruction can usually be made by plain abdominal radiograph. If plain films are normal and bowel obstruction still suspected, CT is indicated.

Patients with disease involving the large bowel rarely manifest complications of obstruction. When it occurs, it is usually secondary to a stricture, giant pseudopolyposis, or an underlying malignancy.^{10,18}

Abscesses and Fistulas

Abscesses and fistula formation are common complications due to the invasive nature of Crohn's disease. Abscesses can be seen in the peritoneum, retroperitoneum, pelvis, and liver. Abscesses occur in 12% to 25% of patients with Crohn's disease and occur most often in those with ileocolitis.^{10,19,20} Patients commonly present with fever and a right lower quadrant mass. The mass may be a phlegmon with inflamed loops of bowel and mesentery or a frank abscess, in which case the patient appears toxic with high fever and leukocytosis with left shift. A history of fistulas predisposes to abscess formation.¹⁰ The diagnosis of intra-abdominal abscess can usually be made by abdominal ultrasonography or CT (Fig. 82–2).

An abscess in the psoas muscle is a rare complication of Crohn's disease and is caused by a fistula into the retroperitoneum. The patient commonly presents with fever in association with groin or hip pain. It may be the first presentation of IBD. On examination, a palpable flank mass or a flexion contracture of the hip may be seen.¹⁰

Another urgent presentation is perianal fistula complicated by abscess in patients with Crohn's disease. Perianal disease is more commonly associated with disease of the large bowel than the small bowel.¹⁰

Liver abscesses occur with greater frequency in patients with Crohn's disease than in the general population. The pathogenesis seems to be direct extension from an intra-abdominal abscess and portal bacteremia. *Streptococcus milleri* is the organism frequently is found on culture. Patients

FIGURE 82–2. Intra-abdominal abscess diagnosed in a patient with Crohn's disease.

present with fever, right upper quadrant pain and tenderness, jaundice, and weight loss.^{19,21}

Perforation

Patients with Crohn's disease, like those with UC, can present urgently with peritonitis secondary to perforation, which is usually microperforation. This often occurs in the right lower quadrant, and features may mimic appendicitis. Free perforation with peritonitis is rare in patients with Crohn's disease. It may occur spontaneously or be due to a ruptured abscess. Patients appear toxic and often have a high fever, worsening abdominal pain, tenderness, and peritoneal signs. These signs may be muted in those patients who are immunosuppressed, malnourished, or taking steroids.¹⁰

Other Presentations

Significant *hemorrhage*, although uncommon (published prevalence of 1.3%), can also be seen in patients with Crohn's disease. Those patients with ileocolitis have the greatest frequency of severe hemorrhage (see Chapter 75, Gastrointestinal Bleeding).²²

Fulminant colitis and *toxic megacolon* can also be seen in patients with Crohn's disease, but are much less common than in ulcerative colitis.¹⁰ Patients' presenting features are similar to those with ulcerative colitis.

Extraintestinal Complications

Pancreatitis is a common cause of abdominal pain in patients with IBD. The diagnosis must be considered in any patient with abdominal pain and the underlying diagnosis of IBD. Many of the drugs used to treat IBD, such as azathioprine,²³ 6-mercaptopurine,²⁴ sulfasalazine,²⁵ mesalamine,²⁶ and metronidazole,²⁷ can cause acute pancreatitis. Elevated serum amylase and lipase and abdominal ultrasonography or CT scan confirm the diagnosis (see Chapter 80, Pancreatitis).

Biliary tract disease is common in Crohn's disease due to an increased risk of gallstone formation. Extensive disease of the ileum or ileal resection causes a decreased bile acid pool, which makes bile lithogenic. Patients may present with biliary colic, acute cholecystitis, or cholangitis (see Chapter 85, Gallbladder Disorders).¹⁰

Patients with IBD are at an increased risk for *thromboemboli* due to their intrinsic hypercoagulable state. IBD patients have increased factor V and VIII levels, thrombocytosis, abnormal platelet activity, and decreased antithrombin III levels.^{28–30} They may present with deep venous thrombosis or pulmonary emboli. Rarely, patients with IBD may even present with cerebrovascular accidents caused by arterial thrombosis (see Chapter 130, Disorders of Coagulation).

IBD is associated with both central and peripheral *arthritis*. Sacroiliitis and spondylitis are the most common types of central arthropathy and are independent of IBD intestinal exacerbations. The peripheral arthritis is often oligoarticular and migratory, usually involving the wrists, fingers, knees, and ankles. Peripheral arthritis usually follows exacerbations of intestinal disease. Treatment is directed at controlling the IBD either with steroids or sulfasalazine. Nonsteroidal anti-inflammatory drugs should be used with caution since they have been shown to exacerbate the symptoms of IBD.¹⁰

Ocular emergencies consist of episcleritis and anterior uveitis. The episcleritis parallels the course of the intestinal disease, while the anterior uveitis typically does not. Anterior

uveitis presents rapidly with photophobia, blurred vision, and pain. On examination, one can distinguish anterior uveitis from conjunctivitis by the involvement of the perilimbal area. Treatment is with topical steroids and closely coordinated ophthalmology follow-up (see Chapter 48, Eye Disorders).¹⁰

IBD patients have an increased frequency of *uroolithiasis*. Chronic dehydration, metabolic acidosis induced by diarrhea, and a hypercatabolic state associated with IBD cause uric acid stones. In addition, patients with Crohn's disease who have extensive ileal disease and steatorrhea are at greater risk for calcium oxalate stones (see Chapter 88, Renal Disorders).¹⁰

Urosepsis is a second urologic condition complicating patients with Crohn's disease. Infection may result from an enterovesical fistula that subsequently leads to cystitis and pyelonephritis. Pyelonephritis can also be caused by an obstructive nephropathy. Patients with Crohn's disease may form fistulas posteriorly that involve the ureter, most often on the right. This leads to hydroureter and hydronephrosis with resulting urosepsis (see Chapter 86, Urinary Tract Infections in Children and Adolescents).¹⁰

Important Clinical Features and Considerations

Infants and children with IBD are often prescribed strong immunosuppressant agents, including steroids, aminosalicylates (e.g., sulfasalazine, mesalamine), infliximab (tumor necrosis factor monoclonal antibody), methotrexate, cyclosporine, and azathioprine. These agents can mask serious underlying infections and GI complications such as bowel perforation, while making treatment of these complications difficult. Importantly, steroids can suppress endogenous production of adrenocorticoid hormones, making treatment of infections and sepsis difficult (see Chapter 107, The Steroid-Dependent Child).

Management

For patients with IBD who present with abdominal pain or vomiting, clinicians must initiate resuscitation while performing an expedited evaluation to determine if specific GI complications are present. Patients should be resuscitated with normal saline and administered intravenous (IV) antibiotics if bowel perforation is suspected. For patients on chronic steroids, a stress dose of hydrocortisone may be required. While plain films may reveal complications of obstruction or perforation, CT scan may be required to make these diagnoses. Surgical consultation for immediate surgery (e.g., perforation) or close monitoring (toxic megacolon, significant bleeding, intra-abdominal abscess) will be required in many cases.

Management of fulminant colitis necessitates aggressive therapy due to the possibility of impending perforation. Deaths occur because the severity of the colitis is not diagnosed early enough and appropriate therapy is begun too late.³¹ The clinician should immediately administer IV fluids with concomitant correction of any electrolyte abnormalities. Abdominal radiographs should be taken and stool cultures performed to exclude bacterial pathogens, ova and parasites, and *Clostridium difficile*. Early gastroenterology or

surgical consultation with a limited flexible sigmoidoscopy will help confirm the diagnosis and evaluate for pseudomembranous colitis. More extensive endoscopic evaluation and barium studies are contraindicated since they could potentially precipitate toxic megacolon or perforation.³² All patients should be placed on bowel rest. Narcotic analgesics, anti-diarrheal medications, and nonsteroidal anti-inflammatory medications are contraindicated due to the risk of precipitating toxic megacolon.^{10,32-36} The mainstay of therapy for fulminant colitis is systemic steroids. Hydrocortisone (1 to 5 mg/kg per 24 hours divided every 8 to 12 hours, to a maximum of 250 mg), prednisone (2 mg/kg IV every 8 hours, to a maximum of 80 mg/day), or methylprednisolone (0.5 to 1.7 mg/kg per 24 hours divided every 6 to 12 hours) should be started as soon as possible. Antibiotics are not indicated in fulminant colitis unless the patient appears toxic and exhibits fever, leukocytosis with left shift, and abdominal tenderness. If there is not a significant improvement within 2 weeks, surgical intervention is indicated.^{10,32}

Treatment for toxic megacolon requires close monitoring. In addition to the therapy for fulminant colitis mentioned previously, broad-spectrum antibiotics such as metronidazole, in addition to a third-generation cephalosporin (or ampicillin and gentamicin), should be initiated.^{10,37} A nasogastric tube is placed to decompress the bowel. If there is no evidence for perforation, an initial trial of aggressive medical therapy should be initiated.³¹ If there is no improvement within 48 to 72 hours, surgery is indicated.^{10,37}

Due to the high morbidity and mortality seen with bowel perforation, the slightest evidence suggesting perforation in patients with IBD mandates immediate surgical consultation. Immediate IV antibiotics effective against enteric organisms are indicated.

Severe GI bleeding is uncommon in patients with IBD. However, in those who are hemodynamically unstable and present with GI hemorrhage, aggressive IV fluids and early transfusion of blood are indicated. Surgery is the definitive, and often life-saving, treatment (see Chapter 75, Gastrointestinal Bleeding).¹⁰

Treatment for bowel obstruction is initially conservative and includes bowel rest, nasogastric suction, intravenous fluid and electrolyte replacement, intravenous corticosteroids, and parenteral nutrition. If patients do not respond to medical therapy, surgery is indicated.¹⁰

Management of intra-abdominal abscesses initially includes bowel rest, parenteral nutrition, and antibiotics providing both aerobic and anaerobic coverage. Single-drug regimens, including imipenem or cefepime, or multiple-drug regimens, such as metronidazole plus a third- or fourth-generation cephalosporin or aztreonam plus metronidazole, can be used.³⁸ Definitive therapy involves a percutaneous or surgical drainage procedure and resection of the diseased bowel that harbors the fistulous tract.³⁹

Summary

UC and Crohn's disease are usually characterized by a chronic, relapsing course. Despite the protracted nature of these diseases, patients can also present acutely with GI emergencies. Urgent manifestations may include intestinal and extraintestinal disease. Intestinal emergencies, such as obstruction, perforation, abscess formation, and hemor-

rhage, are often more severe and can be life-threatening. Extraintestinal emergencies include rheumatologic, ocular, urologic, and hematologic complications. Successful management of the complications associated with IBD depends on early diagnosis and expedient treatment involving both medical and surgical options.

Malrotation and Midgut Volvulus

James D'Agostino, MD

Key Points

Infants and children with malrotation may be asymptomatic or present with duodenal obstruction, internal hernias, or an acute volvulus.

Bilious emesis in a young infant is a midgut volvulus until proven otherwise.

Infants with midgut volvulus are usually well appearing and often have few abnormal physical findings.

An upper gastrointestinal tract series is the diagnostic study of choice in patients suspected of having midgut volvulus.

Introduction and Background

During embryologic development, the intestinal tract is a linear tube that extends from the stomach to the anus. The proximal (duodenojejunal) midgut is initially situated above and the distal (cecocolic) midgut is situated below the superior mesenteric artery (SMA). During the 4th and 5th week of gestation, the midgut grows rapidly and normally herniates out of the peritoneal cavity into the umbilical cord.¹ Each section returns to the abdominal cavity and rotates 270 degrees counterclockwise, leaving the duodenojejunal section to the anatomic right of the SMA and the cecocolic loop to the anatomic left of the SMA. Following rotation, the intestines fix to the posterior abdominal wall, with the cecum attaching to the right iliac fossa and the duodenojejunal junction fixating in the left upper quadrant at the ligament of Treitz, and the connecting midgut mesentery extending between these two points and adhering to the posterior abdominal wall.

Malrotation results from either absent (nonrotation) or incomplete rotation about the SMA. Incomplete fixation of the mesentery is often associated with malrotation. When nonrotation occurs, the bowel lengthens at the site of the SMA. The mesentery does not enlarge and forms a narrow base that can easily twist about the SMA. When nonrotation or malrotation occurs, the bowel can twist upon itself, causing

a volvulus with bowel obstruction and vascular compromise^{2,3} (Fig. 83–1). Other complications can occur when obstructing fibrous bands (Ladd's bands) directly cause proximal intestinal obstruction (especially at the duodenum) or when incomplete fixation of the mesentery leads to an internal hernia. A small percentage of patients with malrotation may be asymptomatic, with anatomic abnormalities only noted during surgery for other disorders.¹

Recognition and Approach

In the first week of life, up to one half of all neonates with bilious vomiting have a surgical cause for their symptoms. Intestinal obstruction due to malrotation and midgut volvulus, followed by intestinal atresia and meconium ileus, are the most common disorders found at this age.^{4,5} Importantly, most neonates with these surgical lesions have normal or nonspecific findings on abdominal radiographs, and few have abnormal physical examination findings.⁶ Beyond the first 1 to 2 months of life, midgut volvulus is a rare cause of bilious vomiting. In infants and children older than 2 months, gastroenteritis is the most common cause of bilious vomiting,⁷ while intussusception is the most common pathologic cause in children 3 months to 2 years old.⁸

The incidence of malrotation is 1 in 500 births.⁸ Nearly half of all patients present in the first week of life, two thirds present in the first month of life, and more than three quarters present by 1 year.^{8,9} A small number of patients with complications from malrotation present beyond 1 year of age, with occasional cases documented in adults.^{3,10,11}

Nearly half of all patients with malrotation have associated congenital anomalies. Common associations include intestinal atresia, duodenal webs, imperforate anus, cardiac anomalies, Meckel's diverticulum, and trisomy 21. Gastroschisis, omphaloceles, congenital diaphragmatic hernias, Hirschsprung's disease, gastroesophageal reflux, intussusception, and extrahepatic anomalies are also associated with malrotation.^{1,12}

Clinical Presentation

Infants and children born with malrotation may present with symptoms related to an acute or chronic midgut volvulus, duodenal obstruction, or complications of an internal hernia, or they may be completely asymptomatic, with anatomic abnormalities found during evaluation for unrelated disorders.

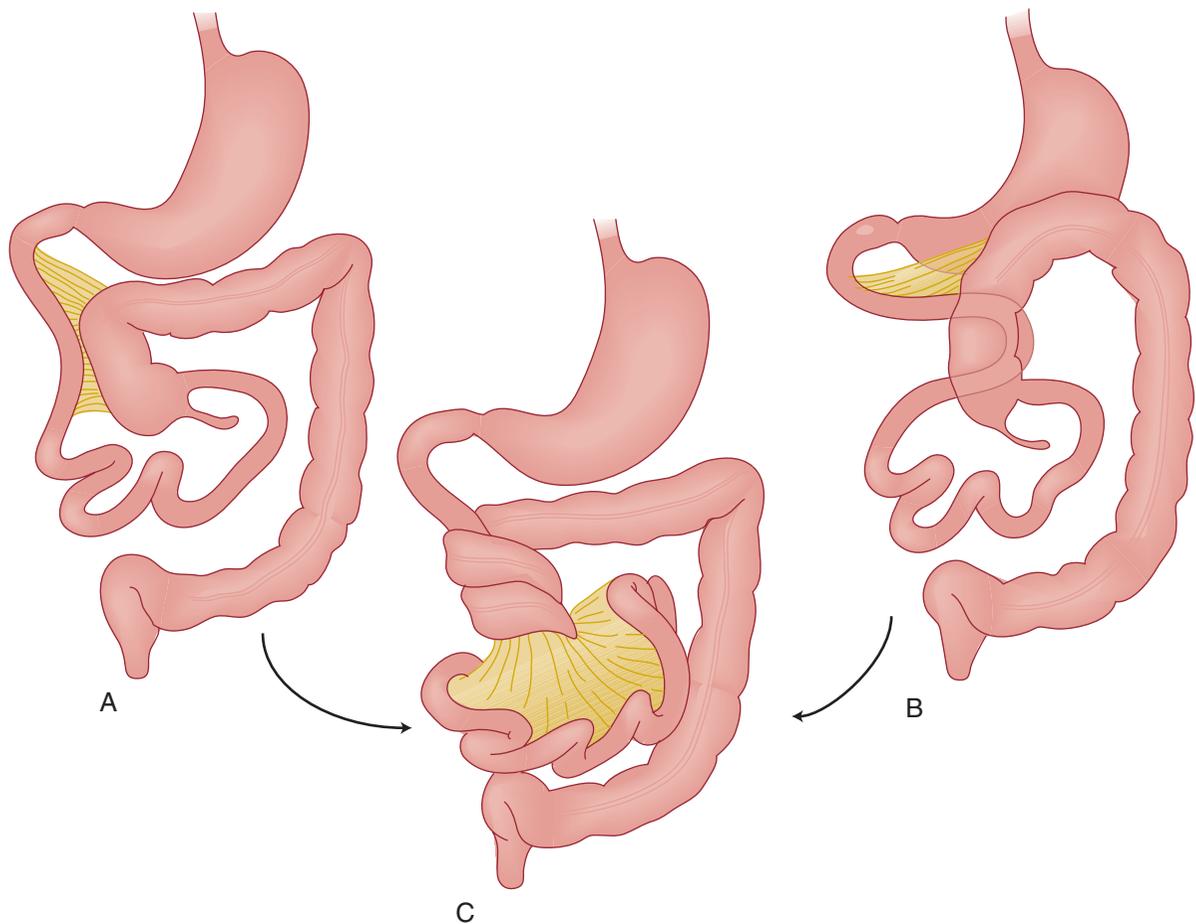

FIGURE 83-1. Incomplete mesenteric attachment in nonrotation (A) and in incomplete rotation (B) below can lead to volvulus (C).

Midgut Volvulus

Infants with an acute midgut volvulus typically have an onset of bilious vomiting and abdominal distention with eventual dehydration and shock due to bowel obstruction and intestinal ischemia. In infants less than 2 months old, bilious vomiting is present in 71% to 97% of cases.^{3,13,14} Constipation is variably present, and rectal bleeding is noted in a minority of patients.^{13,14} Physical examination abnormalities are uncommon in midgut volvulus. Most young infants are well appearing, while nearly three quarters have a normal abdominal examination. Abdominal distention, a palpable mass, and tenderness are occasionally present.¹⁵

Infants older than 2 months and children with an acute midgut volvulus often present with less classic features than younger infants. In one series, bilious emesis was present in only half of all cases.¹⁴ Older children may have symptoms of chronic intermittent vomiting, crampy abdominal pain, failure to thrive, constipation, bloody diarrhea, and hematemesis.^{15,16} Chronic diarrhea and failure to thrive due to malabsorption have been documented in children with malrotation and chronic midgut volvulus.¹⁷

With acute midgut volvulus, intestinal ischemia progresses to gangrene, and virtually all patients will develop abdominal pain and peritoneal signs. At this stage, tachycardia and hypovolemia are present. After bowel infarction, peritonitis, abdominal distension, profound dehydration, and shock

occur.⁸ When the diagnosis is delayed, the patient may be pale and grunting.¹⁸

Duodenal Obstruction

Obstructing Ladd's bands may compress the duodenum, causing obstruction in infants with malrotation. Vomiting may or may not be bilious depending upon the location of the obstruction. Infants may have progressively forceful vomiting similar to patients with pyloric stenosis (see Chapter 76, Pyloric Stenosis). Unlike with midgut volvulus, abdominal distention does not occur due to the proximal nature of the obstruction. Many infants with malrotation and duodenal obstruction have failure to thrive and chronic vomiting, with the obstruction only noted after patients have been evaluated for presumptive gastroesophageal reflux.¹²

Internal Hernias

Infants and children with malrotation-associated internal hernias have chronic recurrent abdominal pain. Intermittent vomiting and constipation are present. Due to the chronicity of symptoms, older children are often diagnosed with psychosocial behavioral abnormalities prior to being correctly diagnosed.

Diagnostic Studies in Malrotation

A complete blood cell count, electrolytes, blood urea nitrogen, creatinine, and type and crossmatch are usually obtained

FIGURE 83–2. Double bubble sign due to duodenal obstruction by Ladd’s bands. Note the gas-filled stomach and proximal duodenum. (From Warner BW: Pediatric surgery. In Townsend CM Jr, Beauchamp RD, Evers BM, Mattox KL (eds): *Sabiston’s Textbook of Surgery*, 17th ed. Philadelphia: WB Saunders, 2004, p 2108.)

in these patients and may reveal dehydration, acidosis, or an elevated white blood cell count. However, these tests are not useful in diagnosing malrotation and midgut volvulus.

Radiographic findings in patients with midgut volvulus are variable. Plain radiography of the abdomen may demonstrate a small bowel obstruction or a paucity of gas.¹¹ A duodenal obstruction may cause a “double bubble” sign, with a gas-filled stomach and proximal duodenum with a paucity of gas distal to the duodenal obstruction (Fig. 83–2). At times, a normal bowel gas pattern can be seen because the obstruction is usually in the proximal bowel.⁹

In patients suspected of having malrotation with midgut volvulus or duodenal obstruction, the diagnostic study of choice is an upper gastrointestinal tract (UGI) series.^{8,9} Malrotation with midgut volvulus is suspected when the duodenojejunal junction is in an abnormal location (i.e., not to the left of the vertebral column) and the contrast material either ends abruptly or tapers in a corkscrew fashion, indicating abdominal proximal intestinal obstruction.^{8,19} Alternately, a UGI series may reveal the site of blockage with duodenal obstruction.

Ultrasonography is an alternate study that may reveal an abnormal anatomic relationship between the superior mesenteric artery and vein in malrotation.⁹ Ultrasonographic examination below the head of the pancreas may reveal a circle of vascularity representing the superior mesenteric vein twisting around the SMA, forming the “whirlpool” sign.^{19,20} This sign may be absent in one tenth to one third of malrotation cases.^{21,22}

Important Clinical Features and Considerations

Infants and children with malrotation and even early volvulus have few, if any, abnormal physical findings.^{13,23} The majority of infants and children with this disorder have

normal abdominal examinations, and a minority of patients have abdominal distention without abdominal tenderness.³ Moreover, one study found that 95% of the patients appeared well during their initial examination.¹³ The obstruction in midgut volvulus is usually high and proximal, and abdominal distention may not be present. Because the obstruction is proximal, plain radiographs may be normal or show a gasless abdomen in a significant number of cases.¹²

Lethargy as an initial sign of intra-abdominal disorders with impaired intestinal blood flow has been documented in infants with intussusception^{24–26} and with volvulus.^{14,27} The mechanism for altered level of consciousness with impaired intestinal blood flow is unknown.^{24,28} Apathy, lethargy, listlessness, hypotonia, and decreased reaction to intravenous line insertion are found in patients with impaired intestinal blood flow. Infants and children with this clinical picture may be mistakenly diagnosed as having sepsis.^{26,28} For this reason, clinicians must consider the diagnosis of midgut volvulus in infants with an altered mental status with vomiting (bilious or nonbilious) or abdominal distention.

Duodenal webs, duodenal stenosis, and duodenal atresia can result in a clinical picture similar to midgut volvulus. In the immediate neonatal period, intestinal atresia and meconium ileus can cause bilious emesis. Lower intestinal tract obstruction usually causes abdominal distention. Adynamic ileus, duodenal reflux of bile into the stomach from benign causes of vomiting, and intussusception can result in bilious vomiting. However, bilious vomiting in a young infant is malrotation and midgut volvulus until proven otherwise.

Management

When midgut volvulus is suspected, surgical consultation for immediate laparotomy is required. Intravenous fluids are begun and, if vascular collapse is present, rapid normal saline boluses are given until adequate perfusion is attained. A nasogastric tube is inserted into the stomach. Intravenous antibiotics effective against enteric organisms are administered to all septic-appearing infants, and all infants with peritonitis. While plain film findings can be suggestive, normal films should not dissuade clinicians from considering the diagnosis. A UGI series should be coordinated with the consulting surgeon to ensure that prompt surgical repair takes place if volvulus is proven.

Summary

Malrotation represents absent or incomplete rotation of the intestine during fetal development. The most serious consequence of malrotation is the development of a midgut volvulus. Infants with this disorder usually present in the first few months of life with bilious vomiting. However, most infants are well appearing and physical examination findings are often absent. Suspicion for this disorder requires simultaneous initiation of resuscitation, radiologic confirmation, and surgical consultation. Clinicians must be aware of the utility and limitations of plain radiography, ultrasonography, and a UGI series in diagnosing this disorder.

Chapter 84

Abdominal Hernias

Michael Witt, MD, MPH and John C. Brancato, MD

Key Points

Strangulated hernias require emergent surgical repair.

Incarcerated hernias are an impending surgical emergency that require surgical consultation and repair if they are not easily reduced in the emergency department.

Infants and children with abdominal wall hernias can present in a classic manner with a painful abdominal wall mass, or atypically with acute abdominal or scrotal pain, or fussiness and irritability.

Umbilical hernias are usually benign and self-resolving. They rarely become incarcerated or strangulated.

Introduction and Background

A hernia is an abnormal protrusion from one anatomic space into another. Each type of abdominal hernia has its own underlying cause, frequency, diagnosis, and indications for acute and elective repair; however, the management is similar for each. The hernia sac is usually lined with parietal peritoneum, although the bowel wall can occasionally comprise one wall. Contents of the sac can include intestines, omentum, appendix (including acute appendicitis), ovaries, fallopian tubes, Meckel's diverticuli, or even ventriculoperitoneal shunt catheters.^{1,2}

Recognition and Approach

Inguinal Hernia

Inguinal hernias are the most frequent type of abdominal hernia in children. They are six times more frequent in males than females. At least 5% of all males develop a hernia in their lifetime. Inguinal hernias are most frequent in the first year of life, manifesting in up to 30% of premature infants.^{3,4} They occur equally among ethnicities. They are located on the right side in 60% of cases and on the left side in 30% of cases, and are bilateral in 10%.

In males, the processus vaginalis is a portion of the peritoneum that follows the path of the descending testicle and becomes a component of the inguinal canal together with connective tissue and muscle. In females, the processus vaginalis follows the round ligament as it travels through the inguinal ring into the labia. Typically the layers of the processus vaginalis fuse. However, in some infants the structure remains patent and the possibility exists for abdominal contents to enter. The processus vaginalis is patent in 60% of infants less than 12 months old, 40% of infants less than 24 months old, and up to 20% of adults.⁵

“Direct” hernias are defined as an inguinal canal defect medial to the inferior epigastric vessels. This hernia sac travels through the internal inguinal ring, within the cremasteric fascia, and down the spermatic cord. “Indirect” hernias are present when the inguinal canal defect is lateral to the inferior epigastric vessels, and the hernia sac travels through the posterior wall of the canal into the scrotum. Indirect hernias are far more common in children, because in infancy the canal is short and the external ring lies almost directly over the internal ring.⁴

Risk factors for hernias include prematurity, low birth weight, urologic conditions (exstrophy of the bladder, cryptorchidism, hypospadias and epispadias), abdominal wall defects (prune-belly syndrome, patent processus vaginalis), and a family history. Other risk factors include ventriculoperitoneal shunts and peritoneal dialysis catheters, severe ascites, connective tissue disorders (Ehlers-Danlos or Marfan syndrome), cystic fibrosis, meconium peritonitis, intersex syndromes (testicular feminization, hermaphroditism), mucopolysaccharidoses (Hunter's or Hurler's syndromes), hepatosplenomegaly, abdominal masses such as Wilms' tumor, and congenital dislocation of the hips.⁶

Umbilical Hernia

Umbilical hernias are also extremely common, occurring in 1 in 6 Americans. Unlike other types of hernias, they are 6 to 10 times more common in African Americans. Because they frequently resolve on their own, their frequency drops rapidly beyond toddlerhood.

Closure of the umbilical ring usually occurs around the end of the first trimester of gestation. If the ring does not close, this may lead to an umbilical hernia varying in size from undetectable to “giant” (>2.5 cm). These hernias generally contain omentum and not intestine. Specific risk factors include Beckwith-Wiedemann and Down

syndromes, ascites, peritoneal dialysis, or a history of abdominal laparoscopy.⁷

Less Common Pediatric Hernias

Femoral hernias are uncommon, with less than 500 cases reported in all age groups. They are especially rare under the age of 15 years.⁸ They are equally common in males and females across all pediatric ages. They are thought to be due to enlarged femoral rings. The contents of the hernia sac may include intestine, appendix, ovary, fallopian tube, or ectopic testis.⁸ Because these hernias are rare and difficult to diagnose, they are often diagnosed as lymphadenopathy or inguinal hernias. In fact, many patients have inguinal herniorrhaphies prior to the final diagnosis. Difficulty with diagnosis leads to prolonged incarceration periods and a high risk of strangulation.^{4,9}

Spigelian hernias are even less common in children (<30 reports in the pediatric literature), although they closely resemble traumatic anterior abdominal wall hernias.^{10,11} They occur along the lateral border of the rectus muscle at the junction of the semilunar line and the semicircular line of Douglas. The defect is generally 1 to 3 cm and usually contains fat or bowel. These hernias may sit under the external oblique muscle, making them difficult to diagnose.^{10,11} Children with spigelian hernias present with pain, abdominal tenderness, or signs of incarceration. To further complicate the diagnosis, these hernias may coexist with inguinal hernias, or they may even contain an acutely inflamed appendix.¹²

Sliding hernias occur when one wall of the hernia sac is formed by the wall of the intestine. *Richter's hernias* occur when only the antimesenteric surface of the bowel, nearly always the lower ileum, protrudes through an abdominal wall defect and obstruction or strangulation occurs.¹³ Richter's hernias can occur in children as young as 8 years old, although the average presenting age is 70 years. The location of the hernia is most frequently femoral, followed by ventral abdominal wall defects. Symptoms generally include nausea and vomiting, abdominal distention, and occasionally a palpable mass. Because only part of the bowel circumference is involved, these hernias may not cause an obstruction as they progress to incarceration. This may delay correct diagnosis and result in poor outcomes. In contrast, hernias with complete obstruction manifest with signs and symptoms such as vomiting and distention, leading to earlier exploration and diagnosis.¹⁴

Obturator hernias are most common in elderly debilitated women, but occur rarely in children. Patients tend to present with symptoms similar to those with other types of hernias. The hernia mass is generally hidden beneath the thigh adductor muscles and is generally not diagnosed until surgery for a bowel obstruction.¹⁵

Epigastric hernias occur midline just superior to the umbilicus, and the defect arises where the blood vessels penetrate the linea alba. The hernia sac generally contains incarcerated but not strangulated epigastric fat. Patients with these hernias usually can wait for elective surgical intervention, but occasionally strangulation occurs.^{3,4}

Lumbar hernias are also quite uncommon. These are often associated with the lumbocostovertebral syndrome, which consists of a lumbar hernia and associated skeletal abnormalities such as hypoplastic or absent ribs, scoliosis, and hemivertebrae. They are most frequently noted in infancy,

and patients generally present with prominent lumbar swelling. These hernias require early operation to avoid complications, and large defects often need prosthetic graft material.¹⁶

Incarceration and Strangulation

At any given time, the majority of infants and children with hernias are asymptomatic. Many children are undiagnosed until signs or symptoms of incarceration or strangulation occur. A *reducible hernia* is one in which the hernia sac and contents can be replaced into the abdominal cavity, either spontaneously or with methods described later (see Chapter 169, Hernia Reduction). *Incarceration* occurs when the abdominal contents are trapped through the wall defect and are unable to spontaneously reduce. This results in edema and subsequent blockage of the regional lymphatics and venous blood flow. Further increasing edema compromises the arterial blood supply to the herniating tissue, resulting in ischemia, necrosis, and gangrene. This complication is termed *strangulation*.

Clinical Presentation

In the emergency department, patients often present with the first occurrence of a hernia after noting a bulge at the inguinal rings, within the scrotum or labia, or within the abdominal wall (Fig. 84–1). While this is often concerning to the parents, it is usually not painful. The mass can appear intermittently and often evades detection, making diagnosis difficult. The swelling may protrude with straining or crying, and resolve with relaxation and the supine position. This often results in a history of crying associated with the lump and the subsequent erroneous conclusion that the hernia is causing pain. By increasing intra-abdominal pressure, clinicians may be able to identify a hernia that has reduced. Techniques for identifying the hernia include having the patient cough, growl, blow bubbles, or lean posteriorly. For inguinal hernias, the mass may be identified by direct visualization or by palpating the superficial inguinal ring and feeling the mass protrude during one of the previously noted maneuvers. The “silk glove sign” describes a physical examination technique used to identify the presence of a hernia sac within the inguinal canal. It is elicited by laying a finger over the inguinal structures and lightly rubbing perpendicularly along the superior-inferior axis at the level of the pubic tubercle. A feeling similar to rubbing two pieces of silk together may represent thicker cord structures in the canal, such as a hernia sac.³

Patients with new or previously identified hernias may present to the emergency department with an abrupt change in symptoms due to incarceration or strangulation. These symptoms can be nonspecific, and include pain, irritability, crying, decreased feeding, nausea and vomiting, or abdominal distention.^{17,18} The swelling may be discolored, irreducible (incarcerated), erythematous, or tender.

If herniation is allowed to continue, progression to incarceration and strangulation can occur. This change can occur in as little as 2 hours.³ Patients who present during late incarceration or strangulation may display increasing pain and irritability and signs of systemic toxicity. Specifically, dehydration, peritonitis, abdominal distention, bilious vomiting, and hemodynamic compromise may be present.

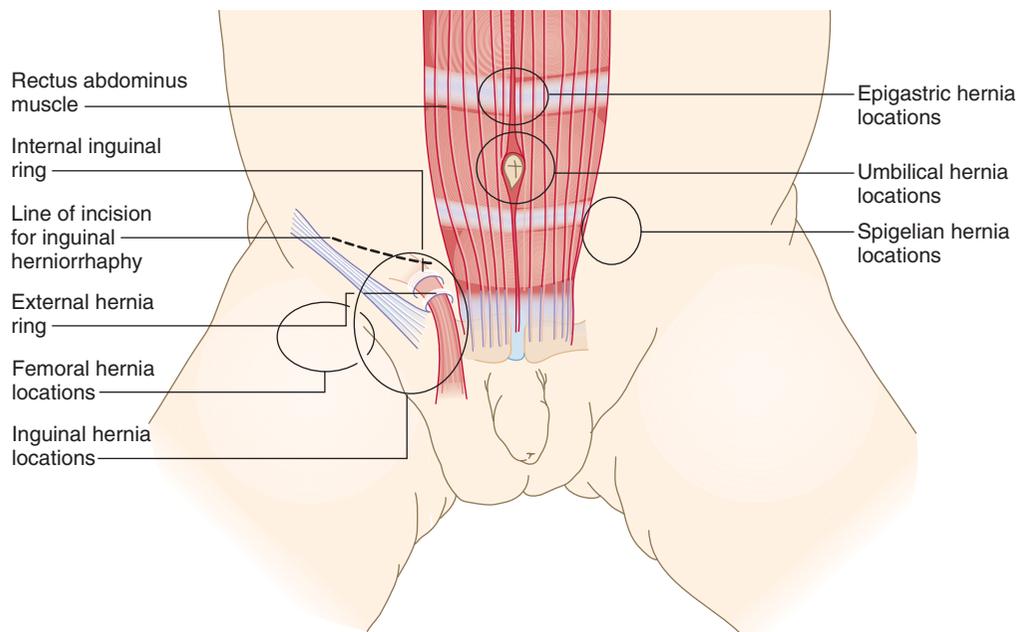

FIGURE 84–1. Anatomic location of various abdominal hernias.

Clinicians need to be aware of unusual presentations of abdominal hernias as these are easily misdiagnosed and can result in significant morbidity. Irritability may be the only indication that there is a problem. An acute abdomen may misdirect the physician toward other intra-abdominal pathology before a hernia is recognized. Importantly, all infants and children with irritability or any gastrointestinal-related complaints require a genitourinary examination to exclude a hernia or associated scrotal pathology. The presence of an acute scrotum may indicate acute testicular pathology or an incarcerated or strangulated hernia.¹⁹ Furthermore, it is possible to have an inguinal hernia with a concomitant testicular strangulation.

Infants who are unable to communicate may present with increasing fussiness, crying, decreased oral intake, or fever. Younger children can also be a diagnostic challenge because they may not disclose concerns about their genitalia, such as a lump or pain.

Children with special health care needs are a population with a greater incidence of hernias due to their frequent prematurity, low birth weight, and coexisting disease (e.g., ventriculoperitoneal shunts, mucopolysaccharidoses, connective tissue diseases).

While the diagnosis is often obvious, an abdominal wall hernia may be difficult to diagnose (Table 84–1).^{2,3,17,20} Most cases can be diagnosed clinically, and adjunctive diagnostic studies are primarily reserved for questionable cases. Plain films of the abdomen are not useful unless intestinal obstruction is suspected. Transillumination of the scrotum is a simple diagnostic method that may help to differentiate hydrocele from hernia. While an otoscope may be effective for transillumination, the head can become prohibitively warm; a true transilluminator used for intravenous line placement provides better illumination. Transillumination can identify the homogeneous bright-light transmission of a hydrocele versus a more varied appearance or even peristalsis seen with intestinal contents of a hernia sac.

Table 84–1 Differential Diagnosis of Abdominal Wall Hernias

Inguinal lymphadenopathy
Hydroceles
Undescended or retracted testicles
Testicular torsion
Torsion of the appendix testis
Testicular neoplasm (seminoma, cystic lymphangioma, gonadoblastoma)
Diastasis recti abdominus
Other abdominal wall hernias (especially femoral)
Traumatic abdominal wall defect

Ultrasound can help identify the contents of a hernia sac. An ultrasound scan also can identify the size of the abdominal wall defect and can be used in cases of acute scrotum to differentiate and diagnose testicular versus scrotal pathology.^{1,21} In many centers, ultrasonography is used to identify contralateral wall defects opposite to the known hernia rather than exploring the opposite side during surgery.²²

Important Clinical Features and Considerations

While many hernias are obvious, some patients require several physician visits to confirm a spontaneously reducing hernia, with much frustration and concern on the part of both parents and clinicians. Simultaneously, the physician should be aware of the other possible diagnoses, particularly testicular disorders (see Chapter 87, Testicular Torsion and Chapter 89, Penile and Testicular Disorders). The most frequent alternate diagnoses in patients initially suspected of having an inguinal hernia are hydroceles, retracted or undescended testicles, and lymphadenopathy. Separation of testis and epididymis also can result in both an inguinal mass and

a full scrotum.²³ Patients may have multiple simultaneous hernias, potentially confusing the clinical picture.

The vast majority of patients with hernias do not present with acute complications. However, intestinal obstruction or infarction can occur rapidly with few initial symptoms. If allowed to continue, infarction of bowel or omentum, testicular or ovarian necrosis, or sepsis can follow and result in significant morbidity or even death.

Management

Immediate therapeutic management is based on the clinical condition of the child. Ill-appearing or septic children require fluid hydration, antibiotics with gastrointestinal flora coverage, gastric decompression, prompt surgical evaluation, and possible operative intervention.¹⁷ Well-appearing children with a hernia require evaluation for incarceration and strangulation. In the non-toxic-appearing child, reduction of the hernia should be attempted to identify incarceration. If the hernia is easily reducible and not incarcerated, further efforts are directed toward surgical evaluation and elective repair as an outpatient.

Hernias that cannot be reduced (e.g., incarcerated hernias) will eventually become strangulated if not promptly treated. Approximately 70% of inguinal hernias resulting in incarceration occur in infants less than 12 months old. The question of whether to reduce a hernia in the emergency department in a relatively well-appearing child is an important one, as there is a possibility of reducing infarcted and gangrenous hernia contents into the abdominal cavity. A hernia should not be reduced if there is suspicion of peritonitis or if the hernia has been incarcerated for a prolonged period, the length of which is not established but at maximum is likely 4 to 6 hours.²⁴ If an incarcerated hernia is reduced in the emergency department, surgical consultation, serial examinations, or admission for close observation may be warranted. For discharged children, parents should be instructed to return if an irreducible mass returns, or if pain, swelling, or gastrointestinal symptoms (e.g., vomiting) occur.

Reduction is most likely to be successful by using a combination of methods. Calming the child with parents and distraction will help decrease the intra-abdominal pressure during crying or screaming. Placing the child in the Trendelenburg position may allow gravity to pull the hernia contents back into the abdominal cavity. Local application of ice may decrease localized edema.¹⁷ Detailed directions for manual reduction techniques are described in Chapter 169 (Hernia Reduction).

Frequently, a hernia is difficult to reduce due to pain or guarding, which increases intra-abdominal pressure. This obstacle can be overcome by administering intravenous pain medication or sedation to relax the abdominal muscles. Urgent surgical reduction is mandated if manual reduction of the hernia is not successful, as incarceration will progress to strangulation, potentially with bowel necrosis, sepsis, or death.

Prompt repair of abdominal wall hernias is indicated (except umbilical hernias) to avoid the majority of surgical complications, preferably within 1 to 4 weeks of diagnosis due to the common occurrence of incarceration (~10%).²⁵ Admission for early repair of other hernias may be mandated

in some situations, such as prematurity, difficulty with reduction, or coexisting medical conditions. In one study, over 15% of children scheduled for elective repair after reduction of an incarceration had an incarceration recurrence prior to surgery.²⁶ Exploration of the contralateral inguinal region during surgical repair, a previously common practice, may not be necessary except in known bilateral hernias or in children at higher risk for bilaterality, such as those with a left-sided hernia, boys less than 1 year of age, and all females (who have a higher incarceration rate).²⁷ Furthermore, ultrasound is increasingly being used to identify the presence of an inguinal defect on the opposite side, negating the need for contralateral exploration.²⁸⁻³⁰

Complications from surgical hernia repair are as high as 7% to 8%. This risk rises dramatically when the repair is performed emergently.^{7,31} The most common complications of surgery are hernia recurrence, bladder injury, infection, injury to several pelvic nerves (ilioinguinal, iliohypogastric, genitofemoral), fallopian tube injury, testicular atrophy, and vas deferens injury that can lead to serum antisperm antibodies.^{7,32} Up to 6% of repaired hernias may recur, although these hernias may actually be direct inguinal or femoral hernias that were not repaired initially.⁷ The greatest risk of complications is in the most extremely premature infants. In this population, impaired healing, spermatic cord injury, hernia recurrence, and postoperative respiratory failure may occur.^{2,6}

Most umbilical hernias close spontaneously by 3 to 5 years of age, and those that require surgical intervention are not generally repaired until after 4 years of age. Complications rarely occur and include incarceration (1 in 1500 cases) and strangulation.^{2,33} The primary pediatrician can follow these defects until closer to the age of repair. Simple closure is used for defects 1.5 to 2 cm, and for those greater than 2.5 cm, an umbilicoplasty is performed.^{4,34} Wound infection, seroma, and hematoma are the most frequent complications of repair.

Summary

Abdominal wall hernias are a frequent surgical problem seen in the emergency department. Although they rarely result in serious complications, accurate and prompt identification of incarceration or strangulation is mandatory. Abdominal wall hernias should be considered in the differential diagnosis of all children with abdominal or scrotal pain, vomiting, fussiness or inconsolability, fever, or decreased oral intake. A thorough examination is mandated, with prompt attention required to hernias that are not easily reducible. Because many subtypes of abdominal wall hernias are uncommon in children, knowledge of their incidence and unique presentation may result in earlier diagnosis and successful treatment.

Prompt surgical consultation is required in suspected cases of incarceration or strangulation. Early intervention is necessary to improve outcomes and decrease the risk of complications.

Gallbladder Disorders

Marc Y. R. Linares, MD and Nestor Martinez, MD

Key Points

The approach to gallbladder disorders in children does not significantly differ from that in adults.

Recognition of gallbladder disease in children can be challenging due to low incidence in this age group.

Children with hemolytic disease or sickle cell anemia who have upper abdominal pain have cholelithiasis until proven otherwise.

Acute cholangitis needs to be promptly identified and aggressively treated.

Introduction and Background

Gallbladder disorders are uncommon during childhood and often associated with predisposing conditions. During infancy, gallstones predominantly appear as a result of sepsis or the use of parenteral nutrition. Hemolytic diseases and diseases with rapid red blood cell turnover (e.g., sickle cell disease, hereditary spherocytosis, thalassemia, pernicious anemia) are the most commonly associated factors during early childhood and remain so during adolescence. Obesity and pregnancy during adolescence increase the risk of gallstone formation. There has been a recent increase in the recognition of pediatric cholelithiasis. Whether this represents a true increase in the incidence of cholelithiasis or simply better use of diagnostic tools in abdominal illnesses is impossible to determine at the present time. The prevalence of gallstones in the pediatric population varies according to age and geographic location and can only be estimated. Prevalence rates ranging as high as 0.2% have been reported.^{1,2}

Recognition and Approach

Infants and children with gallbladder disorders can present with (1) stones in the gallbladder (cholelithiasis), cystic duct, or common bile duct (choledocholithiasis); (2) inflammation of the gallbladder with (calculous cholecystitis); or (3) bacterial infection of the biliary tree (cholangitis). Gallstones are

absent in acalculous cholecystitis, biliary dyskinesia, and some cases of cholangitis.

The two main types of gallstones are cholesterol and bile-pigmented stones. Gallstone composition in children differs from that in the adult population. Cholesterol stones account for 10% of all gallstones in children compared to 70% to 90% in the adult population.³ The majority of gallstones in children are black pigmented stones (50%), while the prevalence of this type of gallstone varies from 4% to 40% in adults.³ These stones are associated with hemolytic diseases and parenteral nutrition. Diseases associated with hemolysis (e.g., sickle cell anemia, thalassemia, hereditary spherocytosis, pernicious anemia) constitute the most common predisposing factor in pediatrics and are seen in almost 60% of children younger than 12, but rarely before 5 years old.⁴⁻⁶ Diagnosis of gallstones follows a bimodal distribution; a small peak in infancy is followed by a steady increase until adolescence. The mean age at presentation is 12.2 years. Female predominance becomes noticeable after 14 years of age.^{4,7}

Clinical Presentation

Cholelithiasis

Pediatric cholelithiasis can occur at any age, from the neonatal period to adolescence. Fetal gallstones have been reported.⁸ Neonatal gallstones have a male preponderance, tend to resolve spontaneously within a few months, and are not associated with any known predisposing factors.⁹ Neonates are frequently asymptomatic. In the neonatal period, cholelithiasis is discovered incidentally or during evaluation of a risk factor such as parenteral nutrition or sepsis, or following surgery. Of note, parenteral nutrition is more often associated with sludge of the gallbladder than cholelithiasis.⁴ When cholelithiasis is uncomplicated, the physical examination is usually unremarkable and laboratory tests are normal. Ultrasound of the gallbladder is diagnostic in 96% to 100% of cases. Typical findings on ultrasound are a calculus with an acoustic shadow.

Gallbladder pseudolithiasis can mimic cholelithiasis. It has been associated with the prolonged use of ceftriaxone, a third-generation cephalosporin. In a prospective study, 11 of 44 children treated with ceftriaxone developed gallbladder pseudolithiasis.¹⁰ Only 2 of the 11 patients complained of right upper quadrant pain. Ultrasonography of pseudolithiasis was indistinguishable from that of cholelithiasis. All

pseudolithiasis cases resolved within 7 to 23 days after cessation of the drug.

Calculous Cholecystitis

Older children with calculous cholecystitis may have biliary symptoms (e.g., dyspepsia, nausea, fatty food intolerance), acute abdominal pain and fever, or nonspecific abdominal pain, or they may be relatively asymptomatic.⁴ Pain is often located in the right upper quadrant, is colicky in nature, and is associated with nausea and vomiting. Jaundice is present in 7% to 94% of cases depending upon the underlying etiology.^{4,11,12} Patients with cholecystitis due to hemolytic disease are more likely to have jaundice, while older patients with no underlying disease are less likely to have associated jaundice.^{4,11,12} The physical examination may reveal right upper quadrant abdominal tenderness with guarding, and an elevated temperature. Epigastric tenderness is reported in one third of patients. Patients less than 6 years old tend to present with nonspecific symptoms, such as poorly localized abdominal pain, nausea, and chest pain.⁷ Fatty food intolerance is usually seen in children 6 years and older.^{4,7} Laboratory tests often reveal an elevated white blood cell count. Elevation of alkaline phosphatase and γ -glutamyl transpeptidase (GGT) may indicate common bile duct lithiasis.¹³ Since this disorder is associated with pancreatitis, clinicians should obtain a serum amylase or lipase level when evaluating patients for possible cholecystitis. Ultrasound will reveal stones within the gallbladder or cystic duct in nearly 100% of cases, while a thickened gallbladder wall or pericholecystic fluid is present in 85% to 100% of children with calculous cholecystitis.

Acalculous Cholecystitis

Acalculous cholecystitis is rarely seen in children, and is usually associated with infectious or systemic illness. Coagulase-negative *Staphylococcus* species, *Brucella* species, *Escherichia coli*, and *Salmonella typhi* are some of the pathogens recovered from gallbladder bile cultures.¹⁴ It is more often seen in males, in the immediate postoperative period, and following abdominal trauma, systemic illness, or infection.^{15,16} The classic presentation includes acute onset of fever, right upper quadrant abdominal pain, and vomiting.¹⁶ Jaundice is present in about 40% of cases.^{15,16} The physical examination reveals right upper quadrant tenderness with guarding. In 25% of cases, the gallbladder is palpable and tender.¹⁵ Laboratory evaluation often shows an elevated white blood cell count and abnormal liver function tests. The diagnosis is confirmed by ultrasound of the gallbladder. Ultrasonographic criteria for diagnosis of acalculous cholecystitis include the following: gallbladder distention (diameter ≥ 1.5 to 2 cm longitudinally or ≥ 4 to 6 cm transversely), gallbladder thickening (wall thickness ≥ 3.5 mm), nonshadowing echogenic material or sludge in the gallbladder, and pericholecystic fluid collection.¹⁵ A combination of at least two of these criteria establishes the diagnosis.

Biliary Dyskinesia

Biliary dyskinesia is a disorder that involves motility abnormality of the biliary tract; it includes sphincter of Oddi dysfunction, cystic duct syndrome, and gallbladder hypokinesia. This disorder has been recognized as a cause of chronic abdominal pain, nausea, and vomiting in children and adolescents. Gallbladder hypokinesia is associated with obesity

(39%) and a family history of cholelithiasis (43%).¹⁷ The pain is reported as right upper quadrant in 48% and epigastric in 29% of cases. Nausea, vomiting, and fatty food intolerance are other predominant complaints. The diagnosis can be ascertained by measurement of ultrasonographic contractility of the gallbladder before and after injection of cholecystokinin (CCK). Ultrasonographic gallbladder contractility of less than 50% is present in all patients with this disorder. Gallbladder hypokinesia can also be diagnosed by determining a gallbladder ejection fraction of less than 35% using hepatobiliary ^{99m}technetium-labeled iminodiacetic acid (HIDA) scanning prior to and after CCK stimulation.

Hydrops

Hydrops of the gallbladder occurs when there is acute distention of the gallbladder without cholelithiasis or inflammation. Hydrops of the gallbladder has been associated with several infections, including ascariasis, staphylococcus, streptococcus, and Epstein-Barr virus infections.¹⁸ It has also been reported in conjunction with sepsis, trauma, Henoch-Schönlein purpura, and Kawasaki disease.¹⁹ Affected children typically present to the emergency department with acute onset of crampy abdominal pain, nausea, and vomiting associated with fever and jaundice. A right upper quadrant mass can be palpated in more than 75% of patients. Ultrasonography of the gallbladder confirms the diagnosis by showing an enlarged, acalculous gallbladder.

Acute Cholangitis

Acute cholangitis is rarely seen in children and is almost always associated with biliary tract surgery. The child usually presents with right upper quadrant pain associated with jaundice, high fever ($\geq 39^\circ$ C), and shaking chills (Charcot's triad). Overwhelming gram-negative sepsis and shock can complicate the presentation.

Other Complications

Other complications of gallbladder disease include common bile duct stones, emphysematous cholecystitis, and gallbladder perforation. Common bile duct stones are rare in infants and children, while gallbladder perforation and emphysematous cholecystitis are primarily complications found in elderly, diabetic adults with vascular disease.

Differential Diagnosis

The differential diagnosis of cholelithiasis, acalculous cholecystitis, and hydrops of the gallbladder includes hepatitis, Fitz-Hugh-Curtis syndrome, gastritis, peptic ulcer disease, pancreatitis, renal lithiasis, pyelonephritis, atypical appendicitis, and right lower lobe pneumonia. Physical examination and ancillary data will help guide the diagnostic evaluation.

Important Clinical Features and Considerations

Laboratory tests are rarely helpful in diagnosing gallbladder disease. A pregnancy test is mandatory in females of child-bearing age. Since pancreatitis occurs in up to 8% of patients with symptomatic cholelithiasis, a serum amylase or lipase level should be obtained in cases of suspected symptomatic

disease⁷ (see Chapter 80, Pancreatitis). Serum electrolytes, blood urea nitrogen, and creatinine levels should be obtained in patients with vomiting and dehydration. Liver function tests are unreliable for diagnosing biliary tract disease. If the alkaline phosphatase or GGT level is elevated, a common bile duct stone should be considered. Jaundice is associated with the development of cholangitis, the most serious pediatric complication of gallbladder disease.

Some controversy exists regarding the most appropriate diagnostic test for symptomatic biliary tract disease. While ultrasonography is nearly 100% sensitive at detecting cholelithiasis, this test is only 60% to 85% sensitive at diagnosing cholecystitis (e.g., thickened wall, pericholecystic fluid, stone obstructing cystic duct).¹³ A HIDA scan has greater sensitivity for the diagnosis of acute cholecystitis than ultrasound and has been recommended by some experts as the initial diagnostic test in suspected cholecystitis.²⁰ However, ultrasound is the preferred diagnostic test for most types of biliary disease in the emergency department setting since it is easier to perform, is less invasive, and can be performed rapidly.

Management

A surgical consultation should be obtained early in the course of the management of symptomatic gallbladder disease in children. Patients with symptomatic biliary disease should be admitted to the hospital and placed on “nothing by mouth” status. Patients with protracted vomiting require placement of a nasogastric tube connected to suction or gravity drainage. The clinician should administer intravenous fluids and correct electrolyte imbalances. Narcotics should be used for pain relief. It is a widely held misconception that meperidine should be used instead of morphine to avoid sphincter of Oddi constriction and pressure elevation, since meperidine has anticholinergic properties. Meperidine raises the common bile duct pressure 14% more than morphine, and anticholinergics have little to no effect on pain due to biliary tract disease.^{21,22} Moreover, pain is related to inflammation and not biliary pressures in most patients with symptomatic cholelithiasis.²² The duration of analgesic action of morphine is almost twice as long as meperidine, and its use in acute cholecystitis is appropriate. Nonsteroidal analgesics also have proven effective in adults, although their use for symptomatic biliary disease is limited in children.^{23,24} Antibiotics are indicated in cases of cholecystitis and cholangitis, and in febrile or ill-appearing patients. A blood specimen for culture should be obtained prior to their use. Therapeutic regimens vary, but are usually geared toward broad-spectrum coverage. Enteric organisms tend to predominate in gallbladder infections, and antibiotics are selected accordingly²⁵⁻²⁸ (Table 85-1).

Asymptomatic cholelithiasis and hydrops of the gallbladder may be managed by observation coupled with dietary restriction of fatty foods.²⁹ In patients with sickle cell or hemolytic disease, prophylactic cholecystectomy may be indicated if the patient is undergoing abdominal surgery for another reason.³⁰ In asymptomatic neonates and infants with gallstones, observation is the most appropriate management since the gallstones tend to spontaneously resolve.³¹ If an infant becomes symptomatic, placement of a cholecystotomy tube with biliary irrigation is the next approach. If this treatment is unsuccessful, cholecystectomy is performed.³²

Table 85-1

Antibiotic Choices in Childhood Cholecystitis

Single Drug Regimens

Ampicillin/sulbactam* or ticarcillin/clavulanate* or Cefepime[†] or Imepenem/cilastatin[†] or meropenem[†]

Multiple Drug Regimens

Mezlocillin plus gentamicin^{†,‡} or (Cefazolin or cefuroxime) plus metronidazole* or (Third-/fourth-generation cephalosporin) plus metronidazole[†] or Aztreonam plus metronidazole[†]

*Mild to moderate infection choices.

†Severe infection choices.

‡Mezlocillin is available in Europe but not in the United States.

Data from references 25-28.

Symptomatic cholelithiasis, acute cholecystitis, and acute cholangitis will require a combination of medical and surgical management. For calculous cholecystitis, early surgical therapy, within 7 days of diagnosis, is associated with a lower perioperative complication rate and avoids the risks of recurrent and complicated disease (e.g., cholangitis, pancreatitis, choledocholithiasis).³³ Laparoscopic cholecystectomy has become the treatment of choice, replacing open cholecystectomy. The laparoscopic procedure results in less postoperative discomfort for the patient and decreased length of hospitalization.³⁴⁻³⁶ However, laparoscopic surgery is associated with an increased risk of bile duct trauma and retained common duct stones, which may prompt patients to return to the ED with increasing pain, jaundice, or fever. In the presence of acute cholangitis, surgery may need to be delayed until the infection is under control. Broad-spectrum antibiotics are used to provide coverage for enteric organisms, most commonly *Enterococcus* or *E. coli*³⁷ (see Table 85-1). Once the patient has responded to antibiotic treatment, endoscopic drainage of the biliary system is performed.³⁸ Open surgical drainage can also be used, although it carries a higher rate of mortality and morbidity.³⁹ Initial nonoperative treatment is the best approach for acalculous cholecystitis.¹⁵ Close follow-up with serial gallbladder ultrasonographic examination is safe and effective in most cases. If the condition persists or worsens, cholecystectomy is performed. For patients with biliary dyskinesia, cholecystectomy will lead to complete relief of symptoms in up to 90% of cases, although 10% will have continued gastrointestinal complaints on follow-up.

Summary

With few exceptions, the approach to gallbladder disease in children does not differ from that in adults. The tendency for gallstones to resolve spontaneously in infancy should be kept in mind. Symptomatic patients should be admitted to a pediatric surgical service. If the hospital lacks one, the patient should be transferred to a tertiary pediatric hospital if possible. Ideally, all infants and children with biliary tract disease should be managed by a pediatric surgeon. However, logistics, local expertise, pediatric surgical availability, and patient characteristics (age, stability, and disease state) dictate when children should be transferred to a hospital with pediatric surgical expertise. If acute cholangitis is suspected, aggressive

treatment should be performed. This includes immediate fluid resuscitation, blood cultures, and antibiotic therapy. Pain control is an integral part of the initial treatment. If the patient is asymptomatic, referral to a pediatric surgical service and, in most cases, discharge home with surgical follow-up is appropriate.

Urinary Tract Infections in Children and Adolescents

Francis Mencl, MD and Daan Biesbroeck, MD

Key Points

Throughout childhood and adolescence, girls are more likely than boys to experience urinary tract infections.

The signs and symptoms of urinary tract infections are age dependent.

Escherichia coli causes the vast majority of pediatric urinary tract infections.

Most children with pyelonephritis can be treated as outpatients.

Introduction and Background

The urinary tract is a common site of infection for toddlers, school-age children, and adolescents (see Chapter 33, Urinary Tract Infection). Urinary tract infections can occur in any location within the urinary system from the kidney to the distal urethra. It is useful to discuss the urinary system as consisting of an upper tract (i.e., the kidneys and ureters) and a lower tract (i.e., the bladder and urethra). The clinical presentation, evaluation, and management of upper and lower tract infections differ somewhat.

When discussing urinary tract infections, one term that may cause confusion is *pyelonephritis*. The basic definition is rather straightforward. Pyelonephritis is simply inflammation of the kidney and renal pelvis from a bacterial infection.¹ In clinical practice, however, emergency physicians do not typically perform scintigraphy or other tests that can confirm kidney inflammation.²⁻⁵ In older children and adolescents, we assume pyelonephritis is present in the setting of fever, unilateral flank pain, and urinalysis findings consistent with infection. In younger children, flank pain is seldom recognized. It seems that this has led to the use of terms such as *febrile urinary tract infection* for younger children.⁶⁻⁹ When scintigraphy is performed, renal lesions are seen in 70% to 80% of children with febrile urinary tract infections.³ From

studies like this, it would appear that most children with concurrent fever and a urinalysis consistent with infection have renal involvement and could properly be categorized as having pyelonephritis. The inconsistent application of the term *pyelonephritis* to young children with febrile urinary tract infections makes reading the relevant literature confusing at times.

Recognition and Approach

Clinical experience suggests that urinary tract infections are common. Remarkably few studies address the epidemiology of these common infections. This is probably because urinary tract infections are not reportable diseases, and most children have uneventful clinical courses. From the available data, it seems quite clear that, outside early infancy, urinary tract infections are substantially more common in girls than boys.^{6,7,10-16} From Swedish population-based studies, the cumulative incidence of urinary tract infections during the first 6 to 10 years of life is 3% to 8% for girls and 1% to 2% for boys.¹⁷⁻¹⁹ Although immunocompromised children are more likely than other children to have unusual organisms such as fungi as the etiologic agents for clinically important urinary tract infections,²⁰⁻²³ *Escherichia coli* is the most common cause of urinary tract infections in all groups of children.^{6,10,12-14,24-28} The most common ages to see urinary tract infections in girls are during the toddler years, around the time of toilet training, and adolescence, when sexual activity begins.²⁵ Recurrent urinary tract infections also appear to be relatively common.^{7,25,26}

The anatomic features of the urinary tract make this a site likely to develop relatively frequent infections. The urinary tract is lined with transitional cells that usually form an impermeable lining and create a sterile space. Infection occurs when bacteria enter this space, adhere to the lining, and cause an inflammatory response. The virulence of the bacteria is directly related to their ability to attach and adhere to this lining. It is assumed that host susceptibility plays a role in the development of clinically important infections as well. In particular, girls are thought to be prone to urinary tract infections due to the presence of a relatively short urethra that resides in close proximity to the anus. Although bacteria may frequently enter the bladder, normal

voiding is thought to clear these potential pathogens out of the bladder with each episode of voiding. Underlying conditions that disrupt the normal flow of urine out of the bladder place the child at increased risk for a urinary tract infection.

Besides gender, risk factors for urinary tract infections include urinary stasis, diabetes, and race. Conditions that cause urinary stasis include vesicoureteral reflux, posterior ureteral valves, pelvic tumors, bladder diverticuli, urethral strictures or stenosis, phimosis, congenital megaureter and other anatomic abnormalities of the ureter, urethral foreign bodies, renal calculi, renal scarring, and various voiding disorders that require frequent bladder catheterization (e.g., spina bifida).^{29,30} Diabetes mellitus increases the risk of urinary tract infections in all age groups, and this may be increasingly important as the prevalence of pediatric diabetes is rising.³¹ It would appear that white children are at a higher risk for urinary tract infections than black children.^{8,32,33} The reasons for this are unclear.

Clinical Presentation

Signs and Symptoms

Signs and symptoms of urinary tract infections in children can be variable and nonspecific. This is especially true in children who are difficult to assess, including preverbal, developmentally delayed, and technology-dependent children. For all age groups, the exact frequency of various symptoms is unknown. This is most likely because these signs and symptoms are inconsistently reported in studies, have inconsistent definitions, or are used to define inclusion criteria for studies. Malodorous urine may prompt an emergency department visit. Although it is prudent to evaluate these children for urinary tract infections, malodorous urine poorly correlates with urinary tract infections.^{24,34}

The overall clinical presentation is age dependent. A nonspecific or sepsis-like presentation is a common manifestation of urinary tract infections in infants (see Chapter 33, Urinary Tract Infection in Infants). Fever appears to be commonly associated with urinary tract infections, particularly in infants and toddlers.^{6,7,10,15-17,26,28,35} Toddlers commonly exhibit a “gastrointestinal” presentation that may or may not include fever. Vomiting, diarrhea, or both are often the stated reason for the emergency department visit.³⁶ Lower abdominal pain with or without vomiting and diarrhea may also be the dominant complaint associated with urinary tract infections in toddlers. In children who have already been successfully toilet trained, enuresis might be the dominant manifestation of a urinary tract infection. School-age children and adolescents most often present with typical “adult” symptoms, including dysuria, hematuria, urinary frequency, and urinary urgency.

Physical Examination

In general, children and adolescents with urinary tract infections have normal physical examinations. At times, however, the physical examination may reveal clinically important findings. For example, palpation of the abdomen might reveal a mass that is partially obstructing normal urinary flow. One such “mass” that might be revealed in this manner is fecal impaction. Visual inspection of the genitalia is useful. In girls, the presence of labial adhesions, clinically appreciable

vulvovaginitis, or visible foreign bodies might reveal secondary causes of urinary tract infections.^{37,38}

Urine Testing

Growth of a single urinary pathogen from a culture of an appropriately obtained urine specimen is the criterion standard for making the diagnosis of a urinary tract infection. However, the results of a urine culture are not available during a routine emergency department visit. Therefore, the emergency physician must use alternative, suboptimal, available information to diagnose children with urinary tract infections. This process is imperfect. At best, emergency physicians can identify children highly likely to have clinically important urinary tract infections. Although the history and physical examination may suggest a urinary tract infection, testing of the urine is the primary tool used by emergency physicians to make the diagnosis of urinary tract infections in children. There are two main aspects of urine testing that greatly impact the results. The first is specimen collection. The second is the interpretation of the findings on urine testing.

There are several ways in which a urine specimen can be collected. For children and adolescents, these include using a perineal bag, clean-catch technique, or a urinary catheter. Suprapubic aspiration is another technique used to obtain urine, but is typically only used in young infants^{39,40} (see Chapter 33, Urinary Tract Infection in Infants). Commercially available perineal bags are conceptually simple, noninvasive, and inexpensive. A perineal bag is simply a relatively small plastic bag with a circumferential area of adhesive at the top around the opening. The bag can be placed with the opening around the genitalia of a child who is not yet toilet trained. Then, when the child spontaneously voids, the urine is collected in the bag and retrieved at the clinician’s convenience. The greatest problem with using urinary bags is that the specimen cannot be used for culture due to perineal contamination.^{9,41,42} Some clinicians consider a urinary bag specimen appropriate as a screening tool. It is probably true that, if the urine from a bag specimen shows no evidence of infection on the initial testing available in the emergency department, then a child is very unlikely to have a urinary tract infection. However, if the bag specimen shows any evidence of a urinary tract infection or is inconclusive, then another urine specimen must be obtained for a confirmatory urine culture. This can lead to very inefficient emergency department care and a frustrating experience as it may take quite a long time for a young child to have enough urine accumulate in the bladder for additional testing. Clean-catch urine specimens involve the simple collection of voided urine after appropriate cleaning of the distal urethral opening. Contamination is likely if proper cleaning is not performed. This is the most common technique used for collecting urine from toilet-trained children, adolescent boys, and adolescent girls who are not menstruating. Catheterized urine specimens are most appropriate for infants and toddlers who are not toilet trained, medically complicated children who cannot spontaneously void on command, and menstruating adolescent girls.

Several urinary tests can return useful results during the emergency department visit. These include leukocyte esterase and nitrate tests on the urinary dipstick, the white blood cell count from a microscopic urinalysis of centrifuged sediment, and a Gram stain on a centrifuged specimen. These tests have been studied for predicting a positive urine culture.

The leukocyte esterase test has a sensitivity and specificity of about 80% each.⁹ The sensitivity in the emergency department may be somewhat lower.⁴³⁻⁴⁷ The nitrate test is less sensitive (about 50%) but has excellent specificity (about 98%).⁹ The presence of white blood cells on microscopic urinalysis has a sensitivity of about 75% and a specificity of about 80%.⁹ Detection of bacteria on microscopic urinalysis has a sensitivity and specificity of about 80% each.⁹ When leukocyte esterase, nitrate, white blood cells, and bacteria tests are combined such that the overall urinary testing is considered positive for infection if any of them are positive, the sensitivity is nearly 100% and the specificity is about 70%.⁹ The tests that provide results during the emergency department visit are imperfect surrogates for a properly collected urine culture.

Blood Tests

Blood testing has a very limited role in the emergency department evaluation of children for urinary tract infections. In particular, blood cultures are frequently negative and, when positive, simply reflect the organism that can be easily identified from the urine culture.^{6,35,48-50} The indications for testing renal function and electrolytes are not entirely clear, but clinical dehydration or concerns over impaired renal function are probably reasonable (see Chapter 88, Renal Disorders; and Chapter 110, Dehydration and Disorders of Sodium Balance). One test that recently received substantial attention is a serum procalcitonin level to detect renal parenchymal involvement in children who have urinary tract infections.⁵¹⁻⁵⁵ There is no current role for serum procalcitonin levels in children with urinary tract infections in the emergency department.

Pregnancy Testing

For adolescent females, pregnancy testing plays an important role in the evaluation of urinary tract infections. In general, the treatment is more aggressive for the pregnant girl than it would be otherwise. As examples, asymptomatic bacteriuria is often treated with antibiotics and pyelonephritis usually is treated with parenteral antibiotics and admission to the hospital (see Chapter 91, Pregnancy-Related Complications).

Imaging

Imaging studies are rarely indicated in the emergency department. Guidelines published by the American Academy of Pediatrics suggest that a radiographic evaluation is indicated in young children with recurrent or persistent urinary tract infections, to rule out structural anomalies and find sources of infections.⁹ However, the timing and type of imaging are controversial. There are no controlled studies properly evaluating or comparing different management strategies, nor do any studies properly address the different age groups. Most studies are descriptive in design and the majority sample children through referral or hospitalization, or with recurrent urinary tract infections. Very few use prospective recruitment.²

Important Clinical Features and Considerations

Bubble Bath Urethritis

Despite numerous references to bubble bath urethritis, cystitis, or vaginitis in review articles, textbooks, and the lay

press and on the Internet, we found no epidemiologic information in the peer-reviewed literature. This condition appears to be uncommon, with one study of 54 premenarcheal girls with vulvovaginitis reporting a single case attributed to bubble bath use.⁵⁶ More cases were attributed to poor hygiene, and one girl had pinworms.⁵⁶ It is not clear if bubble baths actually cause dysuria. It is conceivable that this diagnosis is just a convenient term for transient dysuria that would have resolved on its own regardless of whether or not these girls stopped taking bubble baths.

Labial Adhesions

On occasion, an infant girl will have labial adhesions that impede the passage of a urinary catheter to obtain a specimen for testing. Clinical experience suggests that gentle lateral traction can often atraumatically separate these adhesions. If this is unsuccessful, the risks and benefits of obtaining a urine specimen through suprapubic aspiration or interpreting a bag urine specimen during the current emergency department visit will need to be weighed (see Chapter 33, Urinary Tract Infection in Infants). Treatment of the labial adhesions with topical estrogen appears to be effective.⁵⁷ The use of topical estrogen will take several days or weeks to release the adhesions.

Sexually Transmitted Diseases

In sexually active adolescents, acute uncomplicated urinary tract infection needs to be differentiated from urethritis, cervicitis, and vaginitis (see Chapter 70, Sexually Transmitted Diseases). Urethritis symptoms are generally milder than those seen with urinary tract infections, demonstrate a more gradual onset, and test positive for *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, or herpes simplex virus. Patients with vaginitis generally complain of vaginal discharge, dyspareunia, and pruritus. *Candida* or *Trichomonas vaginalis* are frequently responsible. These findings in a young child or in an adolescent who has not yet initiated sexual activity should raise suspicion of sexual abuse (see Chapter 118, Sexual Abuse).⁵⁸

Missed Appendicitis

A low-grade pyuria may be seen in cases of appendicitis. Children who have abdominal tenderness and a few white cells in their urine on microscopic urinalysis may have appendicitis. Familiarity with identifying these children is very helpful in avoiding mistakenly diagnosing a child who has appendicitis with a urinary tract infection (see Chapter 73, Appendicitis).^{59,60}

Management

The management of acute pediatric urinary tract infections is generally straightforward. The primary decisions that have to be made are determining if the child should be admitted to the hospital and selecting an appropriate empirical antibiotic. Based on clinical experience, the most common reason to admit a previously healthy child with an acute urinary tract infection to the hospital is concurrent, intractable vomiting (Table 86-1). Pyelonephritis is not an indication for admission in most children.

Antibiotic selection is primarily based on the local resistance patterns and cost. Antibiotic resistance is a continuing

Table 86–1 Admission Criteria for Children with Proven or Suspected Urinary Tract Infections

Associated kidney stone with ureteral obstruction
 Concurrent illness requiring admission
 Diabetes mellitus
 Documented severe reflux
 Family challenges precluding successful outpatient therapy
 Immunocompromised state
 Intractable vomiting
 Outpatient treatment failure
 Pregnancy and fever (with or without flank pain)
 Renal failure
 Severe and frequent recurrent infections
 Shock
 Solitary kidney or single functioning kidney
 Transplant recipient

concern.^{11,13,61,62} Since urine culture results are not available during the first emergency department visit, antibiotics will have to be selected empirically. Commonly selected antibiotics include cephalexin (25 mg/kg per dose given 3 or 4 times per day), nitrofurantoin (5 mg/kg per dose given twice a day), and trimethoprim-sulfamethoxazole (5 mg/kg per dose given twice daily with dosing based on the trimethoprim component). For children selected for outpatient treatment, the addition of a dose of parenteral antibiotics in the emergency department prior to discharge does not improve the clinical outcome.^{6,15,26,63,64} The duration of outpatient therapy for acute urinary tract infections in children is controversial.^{63–65} The traditional approach is to have a young child with a urinary tract infection be prescribed at least 7 days of oral antibiotics. During this week, the child is to follow up with the primary care physician, who will arrange for imaging studies of the urinary tract. If the child has abnormal anatomy, he or she is typically placed on prophylactic antibiotics until a pediatric urologist evaluates him or her for surgical repair of the abnormal anatomy. There have been no new practice guidelines to suggest an alternative course of action, but the utility of this approach for first urinary tract infections has been questioned.⁵ Older school-age girls and adolescents are often treated with short, 3- to 5-day courses of oral antibiotics in a manner similar to adult women.

Summary

Pediatric urinary tract infections can be difficult to diagnose. The symptoms in the very young, developmentally delayed, medically complicated, immunocompromised, or technology-dependent child might be vague or suggestive of alternative, incorrect diagnoses. The tools available to diagnose urinary tract infections in the emergency department are imperfect. Although multiple antibiotics are effective for treating acute urinary tract infections, antibiotic resistance is a continuing concern.^{11,13,61,62} Most patients can be treated as outpatients with appropriate follow-up with their primary care physician. Recurrent infections are common, but the clinical significance and long-term sequelae of untreated or recurrent urinary tract infections are unknown. The prognosis for children with urinary tract infections is usually excellent.

Chapter 87

Testicular Torsion

Martin I. Herman, MD

Key Points

Early recognition of testicular torsion is important to a successful outcome as testicular viability may be lost within hours of the onset of torsion.

Manual or surgical detorsion is required to relieve testicular torsion.

Testicular torsion is one of several causes of the “acute scrotum,” and ultrasound is currently the preferred imaging modality for making a definitive diagnosis.

Although most boys with testicular torsion presenting to the emergency department are adolescents, torsion may occur at any age.

Introduction and Background

Testicular torsion (i.e., twisting of the spermatic cord) is one of the three most common causes of the “acute scrotum.”¹ In prior decades, testicular torsion commonly led to testicular necrosis. Orchiectomy rates as high as 90% were common prior to the 1960s. By the 1980s, testicular loss due to torsion dropped to 33% of identified cases.² Unfortunately, as of the late 1990s, the rate of orchiectomy following testicular torsion has remained at approximately 33%.³ A key role for emergency physicians is to expeditiously recognize boys with testicular torsion so that prompt treatment may be rendered. As in other conditions involving ischemia, “time is tissue.”

Recognition and Approach

The epidemiology of testicular torsion can be somewhat confusing. This is especially true when cases of testicular torsion involving an undescended testis and cases in very young infants are included. Testicular torsion is not a reportable diagnosis and does not lead to a publicly visible problem, debilitating morbidity, or mortality if untreated. Because of this, there may be cases of testicular torsion that go unrecognized. Reported rates range from 1 in 4000 males younger than 25 years² to 1 in more than 22,000 males between 1 and

25 years of age.³ The age distribution of cases of testicular torsion is bimodal, with peaks in early infancy and in adolescence. More than half of all cases of testicular torsion occur in adolescents.²

During embryonic development, the testes descend from the abdomen and enter the scrotum through the inguinal canal. The peritoneum invaginates into the scrotum and forms a sac, the tunica vaginalis. The tunica vaginalis envelops the testicle and epididymis partially or completely. Normally, the tunica surrounds only part of the testicle and epididymis, leaving the posterior aspect of the epididymis and the superior pole of the testis able to attach to the posterior wall of the scrotum. If the tunica surrounds the entire complex and attaches higher up on the cord structures, the testicle does not become fixed to the posterior scrotal wall and is left free to twist upon its vertical axis. This twisting disrupts the blood supply to the testis.

Several risk factors have been identified for testicular torsion. These include spasm of the cremaster muscle and increased gonad size due to a surge in testosterone level, cold weather,⁴ scrotal trauma,⁵ or bicycling.⁶ In a recent study, age was the sole identifiable risk factor for orchiectomy in cases of testicular torsion.³

Clinical Presentation

Infants with torsion usually present with a painless, swollen scrotum that does not transilluminate. Typically, the testicle has already necrosed and orchiectomy is indicated. Adolescent boys typically present with a history of sudden, severe scrotal and lower abdominal pain. A history of heavy exercise or seemingly minor blunt trauma is often elicited. In the setting of an acute scrotum, nausea and vomiting have been reported to have a high positive predictive value for testicular torsion, but only modest sensitivity.⁷ Fever is uncommon. Many adolescent boys diagnosed with testicular torsion will admit to having had prior similar pain episodes that resolved without treatment.⁸

In addition to testicular tenderness, emergency physicians may find an elevated testicle with a palpable twist, an abnormal axis of the testicle, an abnormal scrotal position of the epididymis, or an abnormal testicular axis when compared to the contralateral testis. The presence of any of these findings is highly suggestive of testicular torsion.⁸ Absence of the cremasteric reflex is also suggestive of testicular torsion, but it is normal for this reflex to be absent in boys younger than

30 months.⁹⁻¹¹ Unfortunately, physical examination findings may be unreliable as the position of the epididymis may seem normal if the torsion involves 360 or 720 degrees of rotation. The epididymis-testis interface can be obscured by pain or swelling. Relief of pain by elevating the scrotum (i.e., Prehn's sign), indicative of epididymitis, is unreliable. Pyuria, also suggestive of epididymitis, may be present in 30% of males with testicular torsion. Clinical experience suggests the only reliable sign ruling out testicular torsion is the presence of a cremaster reflex.

When the diagnosis cannot confidently be made on the basis of history and physical examination, urgent scintigraphy, ultrasound, or magnetic resonance imaging (MRI) of the scrotum is typically indicated. In fact, in one study, up to 50% of patients with an acute scrotum were misdiagnosed when the examiners relied solely on the physical examination to make their diagnosis.¹² Since it was first advocated in 1973, scintigraphy has been the preferred imaging procedure for the acute scrotum. Scintigraphy provides high sensitivity and specificity in detecting testicular torsion.¹³ However, exposure to radionuclides, poor after-hours availability, equipment complexity, and length of examination times has limited the usefulness of this technique for emergency department patients with suspected testicular torsion. In contrast, ultrasound poses no exposure to ionizing radiation, is more widely available, allows the sonographer to obtain fairly detailed images of scrotal anatomy, and also has high sensitivity and specificity.¹⁴⁻¹⁷ Color Doppler ultrasound is used to detect blood flow to the testes. Unfortunately, color Doppler ultrasound is quite user dependent. In one study of asymptomatic boys, bilateral blood flow, although almost certainly present in all of them, was detected in only 58%.¹⁸ Color Doppler ultrasound is now more commonly used than scintigraphy.^{16,19} The factors most likely to determine the selection of imaging study are the time frame in which the study can be performed and the experience of the examiner in interpreting the results.¹⁶ Emergency physicians are increasingly performing bedside ultrasound in the emergency department (see Chapter 179, Ultrasonography). Although described in the literature,^{20,21} the performance of bedside ultrasound by emergency physicians to evaluate patients for testicular torsion is not a standard procedure. MRI can be used to quantify testicular perfusion and evaluate the scrotal contents.^{22,23} The use of MRI to evaluate children with an acute scrotum is uncommon. This is most likely due to limited availability, the common need for sedation, and prolonged scanning times.²⁴

Important Clinical Features and Considerations

Pitfalls to the diagnosis occur because not all patients have the typical history or findings on examination. Testicular torsion may be painless in as many as 10% of cases, particularly in young infants. Intermittent torsion may occur, resulting in intermittent episodes of pain and a normal ultrasound and physical examination at the time of presentation to the emergency department. Location of the pain may be abdominal rather than scrotal. This is particularly true in cases of undescended testes.²⁵ A history of sexual activity or significant pyuria, more typically seen with epididymitis, may be seen in cases of testicular torsion. Any or all of these may mislead the examiner, leading to a delayed or missed diagnosis.²⁶

Delaying a diagnosis or missing the diagnosis of testicular torsion can result in decreased spermatogenesis and testicular atrophy with complete resorption of the testis later in life.^{2,27-31} Spermatogenesis can be impaired after as little as an hour of ischemia.³¹ Semen and endocrine function may be preserved if blood flow is returned to the testis within about 12 hours.²⁷ Although not intuitively obvious, testicular torsion may affect the contralateral testis. The etiology of this deleterious effect is unknown but is currently being pursued through animal studies.³² One theory is that antispermatozoa antibodies are developed and affect spermatogenesis in the contralateral testis.^{30,33} This can limit future fertility. Medical malpractice issues also arise in the setting of a delayed or missed diagnosis of testicular torsion. An analysis of medical liability insurance data from New Jersey revealed a mean indemnity payment of \$60,191 in cases of missed testicular torsion.³⁴ Unfortunately, many adolescent boys present too late for gonadal salvage.^{28,35}

Management

Detorsion (i.e., physical untwisting of the spermatic cord) is the only way to return blood flow to a testis involved in testicular torsion. Most other causes of an acute scrotum are readily treatable with analgesics or antibiotics (see Chapter 89, Penile and Testicular Disorders). The main diagnosis to identify or exclude is testicular torsion. Once torsion is identified, testis survival is dependent on two primary factors, the duration of the torsion and the tightness of the twist.^{30,36}

Manual detorsion is an important intervention for emergency physicians to be able to perform. If a twist in the cord can be felt on examination or the testicular axis is clearly abnormal and the boy has had pain for fewer than 12 hours, manual detorsion by the emergency physician is indicated.^{2,28,30,36,37} Manual detorsion can provide immediate relief of pain, increase the chance for testicular survival, and minimize the risk of immunologic injury to the contralateral testis.³⁸⁻⁴⁰ Torsions typically twist medially. Hence, rotating the testicle laterally will untwist the cord and bring pain relief. If the clinician is standing at the foot of the bed, facing the boy, the right testis would undergo detorsion by twisting it counterclockwise. The left testis would undergo detorsion by twisting it clockwise. It may be necessary to repeat the derotation procedure as spermatic cords twist as many as three times around. Detorsion should be repeated until pain is relieved and the testis returns to a normal anatomic position. On occasion, a testicular torsion will twist laterally. In these instances, the usual detorsion technique will result in increased resistance and pain. Obviously, attempts at detorsion in the opposite direction are indicated.⁴¹ If available at the bedside, ultrasound can be used to monitor detorsion efforts, documenting the return of blood flow to the testis.^{38,42} Surgical confirmation should follow immediately as testicular infarctions have been noted after manual detorsion was performed.⁴³ For patients with pain for more than 12 hours, observation and symptomatic treatment may be all that is needed, but this decision must be made after surgical consultation since intermittent torsion is always a possibility.^{37,44} Color Doppler ultrasound may be prudent in these cases to investigate alternative diagnoses.

Adjunctive therapy to minimize reperfusion injury or immunologic damage to the salvaged testicle and

contralateral testicle has been studied. When allopurinol, dexamethasone, or free radical scavengers have been given prior to detorsion, each has demonstrated some protective effect.⁴⁵⁻⁴⁸ However, more study is needed before incorporating pharmaceutical adjuncts into the emergency department management of testicular torsion.

Summary

Emergent urologic consultation to assess the need for scrotal exploration is indicated when the history and physical examination strongly suggest testicular torsion. Manual detorsion may provide immediate relief of pain and restore blood flow at least temporarily. Imaging studies should be reserved for cases for which there is diagnostic uncertainty. Delaying the surgeon's evaluation or impeding the patient's transport to the operating room by waiting for results of imaging studies in cases with a high probability of the child having testicular torsion should be avoided. Testicular salvage and potential future fertility depend on a timely restoration of blood flow to the involved testis.

Renal Disorders

Suzanne M. Beno, MD

Key Points

Kidney stones are uncommon in children and do not typically present with dramatic renal colic.

Glomerulonephritis leads to hypertension, while nephrotic syndrome leads to hypotension.

Renal tubular acidosis is a rare but well-described cause of a non-anion gap acidosis in children.

Selected Diagnoses

- Acute renal failure
- Chronic renal failure
- Poststreptococcal glomerulonephritis
- Nephrotic syndrome
- Kidney stones
- Human immunodeficiency virus–associated nephropathy
- Renal tubular acidosis
- Hypertension
- Renal transplantation

Discussion of Individual Diagnoses

Acute Renal Failure

Acute renal failure is an acute reduction in renal function characterized by an increase in creatinine and nitrogenous waste products, as well as a reduced ability to appropriately regulate fluid and electrolyte homeostasis. Acute renal failure can appear *de novo* or can arise in the setting of preexisting renal dysfunction. Advances in technology and improvement of care have shifted the epidemiology of acute renal failure. Previously, the most common etiologies of acute renal failure were hemolytic-uremic syndrome, intrinsic renal disease, burns, and sepsis.¹ More recently, acute renal failure is most commonly a comorbidity of underlying or systemic disease¹ (Table 88–1). The incidence of acute renal failure is highest in critically ill neonates, infants with congenital heart disease, and recipients of bone marrow or solid organ transplants.² Oncologic complications are now a more frequent cause of acute renal failure than sepsis.

Clinical Presentation

The clinical presentation of acute renal failure is variable, somewhat age dependent, and strongly influenced by the underlying comorbid disorder. The variable presentation can typically be intuited from the general pathophysiologic processes the child is experiencing. When a hypertensive emergency develops, the dominant presentation may be that of congestive heart failure or encephalopathy with altered mental status or seizures (see Chapter 65, Hypertensive Emergencies). Due to fluid and electrolyte disturbances, cardiac dysrhythmias from hyperkalemia or seizures from hyponatremia may be prominent components of the clinical presentation. Children with acute renal failure are at increased risk of serious infections, and the presentation may be dominated by a comorbid infection. Anemia may lead to weakness and pallor. In addition, the likelihood of various specific diagnoses is somewhat age dependent. Urinary obstruction from posterior urethral valves is seen in neonates. Cortical necrosis and renal vein thrombosis occur more commonly in neonates. Hemolytic-uremic syndrome is most often seen in young children. Rapidly progressive glomerulonephritis generally occurs in older children and adolescents. Compared to adults, children frequently develop severe multiorgan system failure early in their course of illness.³

Various diagnostic tests are used in the diagnosis and management of acute renal failure. If the child still produces urine, a urinalysis provides useful information regarding urinary casts, can identify coexisting urinary tract infection or hematuria, and provides a specimen for additional testing (e.g., urinary electrolytes). Obviously, blood tests such as a serum blood urea nitrogen (BUN) and creatinine are useful in assessing overall renal function. Serum electrolytes can identify hyperkalemia and hyponatremia, which are commonly seen in acute renal failure. A complete blood count can determine the degree to which the child is anemic. A chest radiograph is useful for identifying pulmonary edema and assessing the size of the cardiac silhouette. An electrocardiogram may be useful for definitively characterizing cardiac dysrhythmias. Although infrequently obtained in the emergency department, an echocardiogram is useful for identifying pericardial effusions and assessing overall cardiac pump function. A renal ultrasound is a quick, noninvasive study that can assess kidney size and identify hydronephrosis. Other imaging studies, including a dimercaptosuccinic acid scan, voiding cystourethrogram, technetium-99m–labeled mercaptoacetyl triglycine scan, and intravenous

Table 88–1 Etiologies of Acute Renal Failure in Infants and Children

Acute tubular necrosis

Sepsis
Nephrotoxin ingestion
Transplantation complication
Urinary obstruction

pyelogram, are seldom indicated as part of the emergency department evaluation of children with acute renal failure.

Management

The basic principles of emergency department management include identification of life-threatening complications, restoration of fluid and electrolyte balance, the initiation of prompt dialysis when indicated, and restoration of renal function when possible. Identifying the exact cause of acute renal failure may require renal biopsy and therefore is seldom done in the emergency department. Fortunately, the emergency department management of these children does not require knowing the exact diagnosis.

Prerenal acute renal failure is defined by clinically important fluid deficits and should be managed with bolus infusions of isotonic crystalloid, and is confirmed with restoration of normal urine flow and a decrease in solute retention with establishment of euolemia. Failure to establish urine flow can mean that volume losses have been underestimated, urinary obstruction exists, or irreversible parenchymal or tubular injury has already occurred. If cardiac pump function is compromised, overly aggressive fluid administration can lead to worsening fluid overload and respiratory compromise from pulmonary edema. The combination of intravenous normal saline and medication to increase urine output may be needed. Mannitol, furosemide, dopamine, and fenoldopam have all been used to treat children with prerenal acute renal failure and maximize their urine flow. Hyperkalemia is an urgent concern and is managed with resins such as sodium polystyrene sulfonate (i.e., Kayexalate), calcium gluconate for cardiac stabilization, a combination of intravenous insulin and glucose, and sodium bicarbonate to drive potassium into the intracellular compartment, which can be a life-saving, temporizing measure (see Chapter 114, Hyperkalemia). Gross fluid overload and life-threatening hyperkalemia are indications for emergent hemodialysis.² Other electrolyte and metabolic derangements may require specific treatment (see Chapter 111, Metabolic Acidosis; and Chapter 115, Hypocalcemia).

Mortality from acute renal failure is related to the etiology, the need for renal replacement therapy, and the degree of multiorgan system failure.³ The highest mortality remains in children who develop acute renal failure following cardiopulmonary bypass surgery.³ Critically ill children have a survival rate of about 50%.² Infants with acute renal failure have a somewhat better survival rate of about one third.² Survival rates for children undergoing hemodialysis are higher than those receiving peritoneal dialysis or continuous

renal replacement therapy. Vasopressor use and hypoalbuminemia have emerged as markers for poor outcome.³ Patients with severe electrolyte or hemodynamic instability require hospitalization in a pediatric intensive care setting. Stable patients can be managed on the floor with pediatric nephrology consultation. Early identification and management of children developing multisystem organ failure currently holds the most promise for improving pediatric outcomes.³

Chronic Renal Failure

Chronic renal failure is the progressive decline in renal function that can ultimately lead to end-stage renal disease, a condition currently affecting 5 to 10 children per million each year in the United States.³ Various etiologies account for chronic renal failure in children, including hereditary diseases, glomerulopathies, obstructive uropathy, reflux nephropathy, renal dysplasias, and complications of multisystem diseases.⁴

Clinical Presentation

Signs and symptoms of renal failure do not appear until the glomerular filtration rate falls below 20% of normal.⁵ The signs and symptoms of chronic renal failure are typically nonspecific. Children experiencing chronic renal failure may present with excessive fatigue, anorexia, vomiting, short stature, skeletal pain, polyuria, and polydipsia.⁴ Signs of anemia, including congestive heart failure, fetid breath, chronic sequelae of hypertension, asterixis, peripheral neuropathies, growth retardation, abnormal neurocognitive development, pubertal delay, and disordered psychosocial maturation, may also be present.⁴ Infants may simply present with failure to thrive (see Chapter 36, Failure to Thrive).

The diagnostic evaluation of children with chronic renal failure depends on whether the condition is previously known or not. For those children not known to harbor chronic renal failure, the emergency physician will typically focus the evaluation on identifying the child's overall diagnosis. For example, an infant with poor weight gain may undergo an evaluation including tests specifically directed at assessing renal function in addition to others that address alternative diagnoses in the differential diagnosis of failure to thrive. For children with known chronic renal failure, the workup is typically focused on assessing current renal function, identifying a decline in renal function, identifying concurrent illnesses, and assessing the child for relatively common complications of chronic renal failure. Frequently indicated tests include a serum BUN and creatinine to assess the degree of azotemia in children not yet dialysis dependent. Electrolytes (specifically looking for clinically significant hyponatremia, hyperkalemia, hypocalcemia, and hypophosphatemia) and a complete blood count to assess for anemia are also useful. If obtained, a renal ultrasound typically reveals small kidneys. Radiographs usually demonstrate diffuse osteomalacia. Children undergoing peritoneal dialysis may require testing of the dialysate for peritonitis.

Management

Immediate therapeutic interventions are directed at correcting electrolyte, fluid, and acid-base balance in addition to supporting cardiovascular function. Congestive heart failure can be managed with diuresis (typically with intravenous

furosemide) and judicious transfusion with packed red blood cells to increase the oxygen-carrying capacity of the blood. Immediate hemodialysis is not often indicated in children with chronic renal failure, but is indicated if life-threatening fluid overload or clinically significant hyperkalemia are present.⁶

Disposition and follow-up depend upon the degree of azotemia, the severity of uremic symptoms, the severity of fluid and electrolyte imbalances, and the presence of concurrent illnesses or complications. Coordinating care with a child's nephrologist is prudent.

Poststreptococcal Glomerulonephritis

The term *glomerulonephritis* refers to kidney inflammation accompanied by inflammation of the capillary loops in the renal glomeruli.⁷ Given this definition, renal biopsy is required to definitively identify glomerulonephritis. Thus this diagnosis is not formally made in the emergency department. Instead, a constellation of clinical and laboratory findings is used to support a presumptive diagnosis. Of the myriad causes of the acute forms of disease, the most common is poststreptococcal glomerulonephritis. Since the exact cause of acute glomerulonephritis is not identified in the emergency department, understanding the paradigm of poststreptococcal glomerulonephritis offers insight into this and other causes of acute glomerulonephritis.

Clinical Presentation

Poststreptococcal glomerulonephritis is caused by immune complexes becoming lodged in the glomeruli of the kidneys.⁸ These immune complexes are typically composed of streptococcal antigens (from group A β -hemolytic *Streptococcus pyogenes*), antibodies, and complement.⁸ The presence of these immune complexes leads to glomerular inflammation, which in turn results in the loss of blood and protein in the urine, azotemia (i.e., a rise in serum BUN and creatinine), fluid retention, and systemic hypertension. The clinical presentation can be predicted from this pathophysiologic process. The typical presentation is of a child between 3 and 15 years of age with edema, hypertension, hematuria, and proteinuria.⁸ The urine may be the color of tea or cola due to the presence of blood. These children will often have a history of untreated pharyngitis 1 to 2 weeks prior or an untreated skin infection 2 to 4 weeks prior to the onset of symptoms.⁸ Nonspecific symptoms such as malaise, lethargy, anorexia, abdominal pain, headache and low-grade fever can also be present.⁸

The evaluation of these children typically involves testing blood and urine. Useful blood tests include a BUN and creatinine to assess for azotemia, a set of electrolytes to assess for gross disturbances, and a complete blood count to assess for anemia or thrombocytopenia. Serum tests useful in identifying a prior streptococcal infection include the anti-streptolysin O titer, the anti-deoxyribonuclease B titer, and the streptozyme test.⁸ Urinalysis typically reveals hematuria, proteinuria, a degree of pyuria, and cellular casts. Other tests such as complement levels are usually ordered in coordination with a pediatric nephrologist.

Management

Immediate therapeutic interventions include restriction of fluid intake, correction of electrolyte abnormalities, and

management of hypertension. Traditional treatment of poststreptococcal glomerulonephritis is directed toward eradication of the infectious source with penicillin, amoxicillin, or erythromycin and symptomatic relief. The utility of antibiotics has recently been questioned.⁹ Children with postinfectious glomerulonephritis have more than a 95% chance of complete recovery resulting in normal renal function and normal blood pressure, denoted by return of blood pressure and renal function to baseline.⁸

The disposition of a child with suspected poststreptococcal glomerulonephritis is controversial. Universal hospitalization is advocated by some, while selective hospitalization is advocated by others. Coordinating care with the pediatric nephrologist who will be caring for the child after the emergency department visit is prudent and can provide guidance as to local practice styles and expectations.

Nephrotic Syndrome

The term *nephrotic syndrome* refers to a group of diseases involving defective glomeruli whereby marked proteinuria and lipiduria occur.¹⁰ More than 85% of cases of nephrotic syndrome in children are idiopathic. When these children undergo renal biopsy, the biopsies are normal or near normal and these children are referred to as having "minimal change disease." Nephrotic syndrome is relatively rare. Emergency physicians are more likely to encounter children experiencing complications from a known diagnosis of nephrotic syndrome than to identify a new case. Although children of any age can develop nephrotic syndrome, toddlers are the most commonly affected group.¹¹

Clinical Presentation

The initial clinical presentation of nephrotic syndrome usually includes edema that can be most easily appreciated in the hands and face but may be present elsewhere, such as in the scrotum or vulva.¹¹ For children with known nephrotic syndrome, complications may include recurrent edema, ascites with or without spontaneous bacterial peritonitis, and pleural effusions.¹² Children with nephrotic syndrome are thought to be in a hypercoagulable state and are at an increased risk for thromboembolic events such as deep venous thromboses and stroke.¹³ Because children with nephrotic syndrome are treated with relatively long-term corticosteroids, they are at increased risk for serious or life-threatening infections (see Chapter 107, The Steroid-Dependent Child). If relatively severe disease occurs, these children may present with edema and dehydration or hypotension.

Urine and blood tests are useful in assessing children with known or suspected nephrotic syndrome. The presence of abundant protein in the urine can be the first clue to diagnosing children who manifest subtle clinical symptoms. A simple dipstick urine test is usually sufficient in the emergency department. A low serum albumin supports the diagnosis of nephrotic syndrome and can be used, to some extent, to assess the severity of disease. Serum albumin may be as low as 5 g/L (0.5 g/dl). Electrolyte abnormalities are seldom clinically significant, but minor abnormalities are expected given the dehydration and fluid shifts occurring in cases of nephrotic syndrome. Other tests are not typically indicated for the emergency department management of children with nephrotic syndrome unless they are part of working through

a differential diagnosis or evaluating complications such as infections.

Management

The emergency department management of children with nephrotic syndrome is relatively straightforward. For stable toddlers with edema, proteinuria, and hypoalbuminemia, specific treatment can await phone consultation with a pediatric nephrologist to coordinate the next phase in the diagnostic and management plan. For unstable children who are markedly dehydrated and intravascularly depleted, the administration of intravenous albumin is indicated.¹¹ These children are at risk for fluid overload, and intravenous furosemide may be needed to avoid or treat pulmonary edema during fluid resuscitation. Central venous pressure monitoring in these children is likely indicated. The mainstay of subacute management in children with nephrotic syndrome is the administration of oral corticosteroids. The initiation of steroids is seldom emergent. One exception to this is in children who are on chronic steroids to treat their nephrotic syndrome who become acutely ill or traumatized. These children are adrenally suppressed and require supplemental steroids during these acute physiologic challenges. In the emergency department, a single dose of intravenous hydrocortisone is indicated in these acutely ill or injured steroid-dependent children (see Chapter 107, The Steroid-Dependent Child).

The disposition of children with nephrotic syndrome depends on whether the diagnosis is previously known, disease severity, and the likelihood of a concurrent illness. Known cases with mild symptoms and an adequate serum albumin may be treated as outpatients with care coordinated with the child's pediatric nephrologist. An increase in the dose of oral steroids or reinitiating a course of oral steroids may be the primary intervention in these cases. Newly diagnosed toddlers, children outside toddlerhood (i.e., infants, school-aged children, and adolescents), children with known nephrotic syndrome suspected of having a complication or infection, and otherwise medically complicated children typically require admission to a hospital with a pediatric nephrologist. Children in shock or experiencing hemodynamic compromise and those experiencing serious neurologic sequelae typically require admission or transfer to a pediatric intensive care unit.

Fortunately, the prognosis for toddlers with nephrotic syndrome is good. About 90% of these children will achieve remission with standard treatment. However, many will relapse several times throughout childhood prior to becoming persistently symptom free. Steroid-resistant forms (e.g., focal segmental glomerulosclerosis) have a much worse prognosis; one third of these children will progress to end-stage renal disease and require dialysis within 5 years of their diagnosis.¹³

Kidney Stones

Kidney stones are uncommon in children. Incidence is equal among boys and girls. The cause of pediatric kidney stones is usually a metabolic abnormality, a structural abnormality, or a chronic urinary tract infection. When analyzed, the majority of pediatric kidney stones are either calcium oxalate (about 50%) or calcium phosphate (about 25%). Struvite, cystine, uric acid, and other types of stones are individually

uncommon. Children on ketogenic diets and those with metabolic conditions such as cystic fibrosis are at increased risk for developing kidney stones.¹⁴

Clinical Presentation

Children rarely have the classic adult presentation of dramatic flank pain with stone passage.¹⁴ The younger the child, the lower the likelihood the child will have adult-like symptoms. Abdominal, flank, or pelvic pain occurs in about half of children, while infants may present with acute crying episodes.¹⁴ Like many other pediatric conditions, kidney stones may present with nonspecific signs and symptoms, including abdominal pain with vomiting. Identifying the rare case of a kidney stone in the context of many children with gastroenteritis, acute cystitis or pyelonephritis, intussusception, and appendicitis is challenging.

The emergency department evaluation of a child with a suspected kidney stone includes laboratory tests and imaging. Serum tests assessing the BUN and creatinine will identify children with renal insufficiency and renal failure. Examining urine may reveal gross hematuria, and a urinalysis may reveal microscopic hematuria and a few white blood cells per high-powered field. The presence of many white blood cells per high-powered field suggests pyelonephritis or an infected kidney stone. A kidney-ureter-bladder plain radiograph may reveal a kidney stone in the renal pelvis or ureter. In cases of a suspected kidney stone, renal ultrasound is indicated; the expected finding is unilateral hydronephrosis. The utility of a noncontrast computed tomography scan of the abdomen looking specifically for hydronephrosis and the stone is limited by concerns over radiation exposure and the sensitivity of the scan for detecting kidney stones in children.¹⁵ Half of children younger than 10 years of age with kidney stones have an identifiable metabolic disorder.¹⁶ Therefore, unlike most adults, children diagnosed with kidney stones warrant a metabolic workup at some point. Although this practice has been de-emphasized in the care of adults with kidney stones, straining the urine (from a bagged specimen or a spontaneous void) through cheesecloth may yield a stone that can be sent to the laboratory for analysis. This may assist the follow-up physician in making a specific diagnosis.

Management

The emergency department management of children diagnosed with kidney stones is much more straightforward than making the diagnosis. Analgesia is clearly indicated in those children experiencing pain. The administration of intravenous fluids is usually indicated, particularly if the child is dehydrated from vomiting or able to maintain adequate oral intake. Children with fever, hydronephrosis, and pyuria may harbor an infected kidney stone. These children require prompt pediatric nephrology and urology consultations. Prompt percutaneous drainage of the involved ureter may be indicated.

The disposition of a child with a newly diagnosed kidney stone depends on several factors. Admission is clearly indicated when persistent vomiting is present, the child is suspected of having an infected kidney stone, the child has uncontrollable pain, the diagnosis is unclear, or adequate follow-up is unlikely to occur, or for medically complicated children with kidney stones. Selected older children with

known stones and an episode of renal colic who have their pain controlled may be appropriate for discharge home provided that ongoing care can be coordinated with their pediatric nephrologist.

Human Immunodeficiency Virus–Associated Nephropathy

The term *HIV-associated nephropathy* is used for a fulminant form of focal sclerosing glomerulosclerosis seen in children (and adults) infected with the human immunodeficiency virus (HIV).¹⁷⁻¹⁹ As of 2001, there were only 60 cases of HIV-associated nephropathy identified in children younger than 21 years of age in the United States.¹⁷ These children develop severe proteinuria without edema. Advanced renal disease is usually present at the time of diagnosis, and rapid progression to end-stage renal disease is expected. The earliest sign or symptom of HIV-associated nephropathy is usually proteinuria. Providing highly active antiretroviral therapy (HAART) seems to be the most effective treatment approach in these children. Given that these children are typically immunocompromised, an overall assessment for comorbid illnesses is prudent (see Chapter 69, Human Immunodeficiency Virus and Other Immunosuppressive Conditions). Coordinated care with a pediatric nephrologist and a pediatric infectious disease specialist are indicated.

Renal Tubular Acidosis

Renal tubular acidosis is a rare condition characterized by a hyperchloremic, non-anion gap metabolic acidosis in which bicarbonate handling by the kidney is deranged. Confusingly, there are three types of renal tubular acidosis designated types 1, 2, and 4. What was previously called “type 3 renal tubular acidosis” is now thought to be a mixed form of types 1 and 2, thus the term is no longer used.²⁰ The classic presentation is of an infant who is failing to thrive.²¹ The most common cause of a hyperchloremic, non-anion gap metabolic acidosis is diarrheal disease. This may obscure the diagnosis in children who have both renal tubular acidosis and diarrhea. However, one presentation of renal tubular acidosis is the very slow resolution of a hyperchloremic, non-anion gap metabolic acidosis following a diarrheal illness.²⁰

Diagnostic tests specifically useful in identifying and classifying children with renal tubular acidosis include a venous blood gas to assess the bicarbonate level and blood pH, serum electrolytes to determine if hyperkalemia is present and calculate the anion gap, a urinalysis to assess the urinary pH, and urinary electrolytes to calculate the urinary anion gap.^{20,21} In general, these diagnostic studies are undertaken as part of a workup for failure to thrive, and renal tubular acidosis is identified secondarily. If a normal urinary anion gap is present, the diagnosis of type 2 renal tubular acidosis is supported.²⁰ If the urinary anion gap is elevated and the patient is hypokalemic, the diagnosis of type 1 renal tubular acidosis is supported.²⁰ If the urinary anion gap is elevated and the patient is hyperkalemic, the diagnosis of type 4 renal tubular acidosis is supported.²⁰

Emergency department management is directed at treating the metabolic acidosis. For seriously ill children, treatment with intravenous sodium bicarbonate is reasonable. For stable children, coordinated care with a pediatric nephrologist is prudent. Oral treatment with citrate is a reasonable

option for stable children.²⁰ Severe abnormalities in the serum potassium may require specific treatment (see Chapter 113, Hypokalemia; and Chapter 114, Hyperkalemia). Disposition is usually determined by the overall presentation of the child. Children who require a more extensive workup for failure to thrive often benefit from inpatient evaluation and treatment.²¹

Hypertension

In the emergency department, elevated blood pressure readings range from clinically insignificant numbers to life-threatening emergencies (see Chapter 65, Hypertensive Emergencies). Besides life-threatening emergencies, there are a few key issues regarding pediatric hypertension in the emergency department. These include defining hypertension, the appropriateness of screening for pediatric hypertension, and the evaluation and management of a child thought to have hypertension.

In order to diagnose a child with hypertension, an agreed-upon standard against which to compare blood pressure readings needs to exist. The most widely recognized standard has been written by the National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, organized by the National Heart, Lung, and Blood Institute.²² This group has developed tables of both systolic and diastolic blood pressure measurements based on age, gender, and height. Based on these tables, a blood pressure measurement can be compared with the 50th, 90th, 95th, and 99th percentiles. With this data set as a standard, the working group defined hypertension as “average systolic blood pressure and/or diastolic blood pressure that is ≥ 95 th percentile on ≥ 3 occasions.” In addition, children were defined as having “prehypertension” or “high normal” blood pressure if “average systolic blood pressure or diastolic blood pressure levels are ≥ 90 th percentile but less than < 95 th percentile.” Adolescents with blood pressure levels are $\geq 120/80$ mm Hg should be considered “prehypertensive.” Although these definitions seem rather straightforward, the tables used for these determinations contain over 1900 individual blood pressure values. The complexity of these tables limits their utility. The working group also states, “Elevated blood pressure must be confirmed on repeated visits before characterizing a child as having hypertension.”²² Since three visits are required to define hypertension, it would seem unlikely that hypertension, particularly in otherwise asymptomatic children, could be identified in the emergency department.

Screening children for hypertension is an area of interest for those focusing on the public health of children. The working group even suggests “children > 3 years old who are seen in a medical setting should have their blood pressure measured.”²² As laudable as this seems, it is unlikely that the working group considered emergency department visits included in this “medical setting.” It is not intuitive that a child who is highly febrile or has just had a seizure or has sustained a fracture after falling off a bicycle should have his or her blood pressure measurements used as part of universal screening for pediatric hypertension.²³ In one study of those children who had their blood pressure measured, more than half had blood pressures greater than the 90th percentile.²⁴ It is unlikely this represents the prevalence of prehypertension in children. It is likely these children had elevated blood

pressures due to fear, pain, fever, or some other confounding factors.

If a child in the emergency department is thought to have clinically significant hypertension, an evaluation is indicated. Compared with adults, who predominantly have essential hypertension, children are more likely to have secondary hypertension.²⁵ Of these secondary causes, renal causes predominate. Therefore, if consultation is needed for a child with hypertension, a pediatric nephrologist (instead of a cardiologist) is preferred. A first approach is to obtain blood pressures in all four extremities; if coarctation of the aorta is present, the blood pressure in the legs may be higher than that in the arms.²² In obese adolescents, essential hypertension is probably the most likely diagnosis, and primary care follow-up may be all that is required. For younger children with markedly elevated blood pressures on repeated measurements during the emergency department visit and in those children with known renal disease, serum BUN and creatinine, a microscopic urinalysis looking for hematuria and casts, a chest radiograph looking for an abnormal cardiac silhouette or pulmonary edema, and an electrocardiogram evaluating age-adjusted voltage as a marker for left ventricular hypertrophy are indicated.²⁶ In certain circumstances, other studies may be useful, including a renal ultrasound, an echocardiogram, thyroid studies, or a urinary drug screen. Initiating pharmacologic treatment for children with asymptomatic hypertension cannot be advocated because multiple blood pressure measurements in a setting other than the emergency department are needed to appropriately make the diagnosis. Close follow-up with a primary care provider is the most prudent course of action in the vast majority of these cases.

Renal Transplantation

Renal transplantation is considered the treatment of choice for end-stage renal disease in children.²⁷ Better psychomotor development, psychosocial outcome, rehabilitation, and quality of life are expected when renal transplantation is compared to long-term dialysis. The general care of children following solid organ transplantation is a balance between optimizing patient growth rates and maintaining allograft function with adequate immunosuppression and minimal drug complications. Transplant recipients are at risk for rejection of the allograft, complications from their immunosuppressive therapy, and specific transplant-related conditions such as posttransplantation lymphoproliferative disease. Transplant recipients may present to the emergency department with a variety of surgical issues, including wound complications and problems involving urine leak and ureteral stenosis or obstruction. They will often present with decreased urine output, increased serum creatinine, and lower abdominal or suprapubic discomfort. A renal ultrasound might identify hydronephrosis. Lymphoceles can develop and cause compression of the iliac vessels resulting in leg swelling and discomfort. After transplantation, these children are at risk for hypertension, hyperlipidemia, metabolic bone disease, and chronic allograft nephropathy.

Surveillance for signs and symptoms of renal allograft dysfunction is a priority for these children. The most sensitive indicator of renal dysfunction is an elevated serum creatinine.²⁷ Urine output may not be a useful clinical indicator because of decreased concentrating ability. Volume depletion

should be treated aggressively as it both hinders graft survival and increases immunosuppressive-related nephrotoxicity. Fever in these children must be investigated as it can be a manifestation of many different infections, rejection, or sepsis. Renal imaging studies and further workup should be performed in consultation with a pediatric nephrologist, the child's transplant surgeon, or both. The prognosis for these children continues to improve, and future directives involve increasing numbers of renal transplantations while new induction therapies and augmentation of tolerance in immunosuppression are advanced.

Chapter 89

Penile and Testicular Disorders

Roger A. Band, MD

Key Points

Epididymitis is being recognized with increasing frequency in prepubertal boys.

Paraphimosis is a time-sensitive emergency requiring prompt reduction.

Ultrasonography is a noninvasive, accurate, and readily available modality for the evaluation of the acute scrotum.

Selected Diagnoses

- Epididymitis and epididymo-orchitis
- Balanitis and balanoposthitis
- Torsion of the appendix testis
- Hydroceles, inguinal hernias, and varicoceles
- Testicular masses
- Priapism
- Hemospermia
- Paraphimosis
- Minor genital injuries

Discussion of Individual Diagnoses

Epididymitis and Epididymo-orchitis

Epididymitis is inflammation of the epididymis and is commonly thought to be due to an infection. *Epididymo-orchitis* is inflammation of the epididymis and testis and is along the same continuum of disease as epididymitis. These conditions are being recognized with increasing frequency in prepubescent boys. Previously, epididymitis was thought to be a condition limited to sexually active adolescents and adults. Urinary pathogens have traditionally been thought to be the cause of epididymitis in prepubertal boys. Some recent evidence suggests that epididymitis either is a post-infectious phenomenon or is due to the combination of a minor anatomic abnormality and chemical irritation by urine.¹⁻³ In sexually active adolescents, epididymitis is usually caused by pathogenic, sexually transmitted bacteria. The

most common are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.^{3,4}

The classic manifestations of epididymitis are testicular pain, scrotal swelling, an intact cremasteric reflex, and a normal testicular orientation within the scrotum.³ With the exception of an intact cremasteric reflex, testicular torsion may share many of these features. Testicular torsion and torsion of the appendix testis are thought to occur with greater frequency than epididymitis in the prepubertal age group.⁵ The currently accepted diagnostic approach in these boys typically involves obtaining a color Doppler ultrasound to rule out testicular torsion⁶ (see Chapter 87, Testicular Torsion). The expected ultrasonographic finding in cases of epididymitis and epididymo-orchitis is unilateral increased blood flow to the involved testis.⁶ The utility of a urinalysis is unclear. Serum studies are nonspecific and of no utility in differentiating causes of the acute scrotum.

The generally accepted management of epididymitis and epididymo-orchitis is supportive care and antibiotics. Supportive care includes analgesics (e.g., acetaminophen with codeine), anti-inflammatory agents (e.g., ibuprofen), and bed rest with scrotal elevation. Appropriate antibiotics are determined by the boy's age. The American Urologic Association has suggested that most cases of epididymitis and epididymo-orchitis can be treated on an outpatient basis with oral antibiotics.⁷ Appropriate antibiotics for prepubertal children include azithromycin and trimethoprim-sulfamethoxazole.⁷ Sexually active adolescents should be treated for presumptive *C. trachomatis* and *N. gonorrhoeae*. Appropriate antibiotic selections for adolescent boys with epididymitis or epididymo-orchitis include the combination of a single oral dose of cefixime 400 mg plus a single oral dose of azithromycin 1 g. The American Urologic Association suggests inpatient admission and parenteral antibiotics if the boy has intractable pain, vomiting, very high fever, or overall severe illness.⁷ As new data emerge in support of noninfectious causes, the recommendation that all patients receive antibiotics has been challenged. In one study of 44 boys ages 2 to 14 years, 38 (86%) had immunologic studies suggesting recent infections with viruses or *Mycoplasma pneumoniae*.¹ Only 3 of the boys received antibiotics, and all 44 were without testicular abnormalities or symptom recurrence on follow-up. Current practice suggests against withholding antibiotics from boys with epididymitis. However, larger studies, if performed, may lead to a change in the management of epididymitis and epididymo-orchitis in the future.

Balanitis and Balanoposthitis

Balanitis is inflammation of the glans penis. *Balanoposthitis* is inflammation of the glans penis and the foreskin. Balanitis and balanoposthitis can have irritant, infectious, or traumatic etiologies and represent a continuum of the same disease process.^{8,9} Although balanoposthitis may occur in sexually active adolescents and young men, the most common presentation in the pediatric emergency department is of an uncircumcised preschool-age boy who presents with a red, swollen foreskin and a complaint of localized pain. Discharge, if present, is scant. Clinical experience suggests difficulty with urination is rare in these cases.

Little has been written about this clinical condition in prepubertal children. In a single study of 100 boys with balanitis or balanoposthitis, 3 boys were younger than 2 years, 76 were 2 to 5 years, 15 were 6 or 7 years, and 6 were 8 or 9 years of age.¹⁰ Only 5% of the boys in this study were not yet toilet trained. The most common signs and symptoms reported in this study were redness (100%), swelling (91%), and discharge (73%). Dysuria was seen in only 13%. Of these 100 boys, 32 presented acutely and had cultures of their penile discharge obtained. Of these, 15 (47%) showed no growth on culturing, 7 (22%) revealed mixed growth, 5 (16%) grew *Staphylococcus aureus*, 4 (13%) grew *Proteus vulgaris*, and one (3%) grew *Morganella morganii*. The authors of this small study concluded that balanitis and balanoposthitis are self-limited and can be managed expectantly (i.e., without antibiotics).¹⁰

The only published guidelines for the treatment of balanitis focus on sexually active adults.¹¹ There are no evidence-based treatment options. Oral analgesia and rest seem prudent. For intense inflammation, the use of topical 1% hydrocortisone cream may be beneficial. Based on the available microbiologic epidemiology, the reasonable options include expectant care without antibiotics, prescribing an oral antistaphylococcal antibiotic (e.g., cephalexin 25 mg/kg per dose administered four times per day) for 7 to 10 days, or prescribing an extended-coverage oral antibiotic that is antistaphylococcal and also is active against *P. vulgaris* and *M. morganii* (e.g., amoxicillin/clavulanic acid 10 mg/kg per dose based on the amoxicillin component, administered 3 times per day) for 7 to 10 days.

Torsion of the Appendix Testis

Torsion of the appendix testis is a common, benign, self-limited cause of acute scrotal pain and swelling in the prepubertal age group, accounting for approximately 25% to 50% of all acute scrotal complaints.² Caused by torsion of an embryologic remnant, torsion of the appendix testis typically involves a gradual onset of unilateral scrotal pain associated with an intact cremasteric reflex and a normal testicular orientation within the scrotum.¹² Focal tenderness can be elicited at the superior lateral testicular pole. Early in the process, a focal area of echymotic or blue discoloration, referred to as the “blue dot sign,” may be visible.^{2,3} Aside from the focal area of tenderness, the remainder of the testis examination is normal. Boys with torsion of the appendix testis generally have fewer associated systemic complaints, such as nausea and vomiting, than boys with testicular torsion.² In cases of presumed torsion of the appendix testis, it is difficult to definitively rule out testicular torsion (see Chapter 87, Tes-

ticular Torsion), and therefore an ultrasonographic evaluation is generally recommended.^{6,13} Once a definitive diagnosis of torsion of the appendix testis has been made, supportive care including oral analgesics, bed rest, and scrotal elevation are the mainstays of therapy.

Hydroceles, Inguinal Hernias, and Varicoceles

The broad rubric of painless scrotal masses includes hydroceles, indirect inguinal hernias, and varicoceles. A *hydrocele* is an accumulation of fluid within the tunica vaginalis that remains after closure of the processus vaginalis during infancy or occurs secondary to a patent processus vaginalis.¹⁴ This process can occur secondary to epididymitis, orchitis, torsion of the appendix testis, and testicular torsion.^{15,16} An *indirect inguinal hernia*, like a hydrocele, results from a patent processus vaginalis. This allows bowel to escape from the pelvis into the scrotum via the inguinal canal, which can sometimes be difficult to distinguish clinically from a hydrocele. An attempt should be made to reduce the herniated mass as soon as possible so long as the child appears well. If reducible in the emergency department, children with these hernias can be referred to a pediatric surgeon for an outpatient evaluation. However, the herniated contents may become entrapped or incarcerated distal to the inguinal rings. Consultation with a pediatric surgeon or transfer to a facility with a pediatric surgeon is indicated in these cases (see Chapter 84, Abdominal Hernias; and Chapter 169, Hernia Reduction).

Varicoceles are uncommon in young children. Varicoceles have been described as having a “bag of worms” feel within the scrotum on physical examination and are most prominent on standing, with near resolution of the “mass” upon lying down. Varicoceles involve dilation of the testicular vein and the associated pampiniform plexus of veins that are within the spermatic cord. Adolescent boys with varicoceles may experience stunted testicular growth and subsequent infertility. If a varicocele is diagnosed in the emergency department, referral to a urologist for an outpatient evaluation is prudent.^{13,16,17}

Testicular Masses

A painless scrotal mass is the most common presentation of testicular cancer.¹⁸ Although rare in children, testicular tumors occur in all age groups. Testicular tumors have a bimodal age distribution, with peak incidence between 2 and 4 years of age and in young adult men. Often, young boys give a history of minor groin trauma, which leads them to identify the unrelated painless testicular mass.¹⁹ Testicular tumors are generally firm, irregular, and inseparable from the testicle.^{2,3} Urgent urologic referral and ultrasonography are prudent in these cases.^{2,18} The anticipated tests needed to begin the workup of a testicular mass include a chest radiograph, a complete blood cell count, a serum β -human chorionic gonadotropin level, and a serum α -fetoprotein level.¹⁹ Obtaining these tests in coordination with the urologist who will follow up with the patient may expedite the diagnosis.

Priapism

Priapism refers to a sustained erection that is painful and occurs in the absence of sexual stimulation. This condition primarily involves engorgement of the corpora cavernosa and is relatively uncommon in children.²⁰ Priapism is seen in the

setting of poor venous outflow as occurs with the sludging associated with sickle cell disease, leukemic infiltration, and polycythemia of the newborn.^{5,20,21} For boys with sickle cell disease, as many as one third may experience priapism in their lifetime.²¹ Due to the marked pain and potential for ischemic changes, fibrosis, and impotence that are associated with priapism, this process should be addressed emergently. Management is directed at treating the underlying cause. In children, the most common cause of priapism is vaso-occlusive crisis associated with sickle cell disease (see Chapter 127, Sickle Cell Disease). If conservative measures (e.g., oxygen, hydration, analgesia) fail to relieve the priapism, transfusion and corporal irrigation with saline and vasoconstrictive agents, including phenylephrine, may be necessary.^{5,20} Invasive management of priapism in children is typically undertaken by pediatric urologists if available.

Hemospermia

Hemospermia is the presence of blood in the ejaculate. Although potentially morbid conditions may underlie this surprising and angst-provoking sign, hemospermia is most often a benign condition in adolescent boys. The most common history is that of an adolescent boy who notices blood-tinged semen either after masturbation or upon removing a condom after sexual intercourse.²²⁻²⁴ The differential diagnosis of hemospermia includes genitourinary infections, inflammatory disorders (primarily younger patients), genitourinary tuberculosis, blood dyscrasias, suprathereapeutic anticoagulant therapy, and malignancy.^{25,26} Nonetheless, hemospermia in otherwise healthy adolescent boys is overwhelmingly idiopathic, self-limited, and benign.²⁴⁻²⁶ Reassurance and primary care or urologic follow-up are typically all that is indicated.

Paraphimosis

Paraphimosis is a time-sensitive emergency seen after retraction of the foreskin without return of the foreskin over the glans. This constriction of the glans by the swollen, retracted foreskin leads to venous congestion and edema of the glans and the foreskin. As swelling increases, reduction of the foreskin becomes increasingly difficult and painful. This is a relatively uncommon condition that only occurs in uncircumcised boys.^{5,27} Manual reduction of the foreskin should be attempted after adequate regional anesthesia with a dorsal nerve ring block, topical anesthesia, oral analgesics, or pariental procedural sedation. Reduction can be accomplished by compressing the foreskin to mechanically reduce the swelling and then placing direct pressure on the glans to reduce it through the phimotic ring of tissue^{5,14,27} (see Chapter 177, Paraphimosis Reduction). Inability to manually reduce the foreskin will necessitate an urgent dorsal slit procedure or circumcision. These invasive procedures are typically performed by a urologist.

Minor Genital Injuries

Accidental injury to the scrotum is fairly common during childhood.⁵ These injuries generally result from straddle injuries or a direct blow to the groin. Testicular injuries exist along a continuum of severity from mild contusions to testicular rupture.²⁸ Scrotal hematomas arise from bleeding that occurs within the scrotal wall and are characterized by pain, swelling, and ecchymosis. Scrotal hematomas typically obscure

injuries to the scrotal contents, making ultrasonographic evaluation particularly valuable in this setting.²⁸ Penetrating injuries to the male genitalia are uncommon in children.^{28,29} Surgical exploration by a surgeon or urologist familiar with the pediatric scrotum is typically indicated. Testicular torsion can present with a history of pain that is temporally related to a coincident, apparently minor blunt scrotal injury (see Chapter 87, Testicular Torsion). The pain associated with testicular torsion can be mistakenly attributed to the trauma, leading to a delay in diagnosis that can result in loss of testicular viability, orchiectomy, and infertility.²⁸

Zipper injuries involving the penile foreskin are relatively common in boys between 2 and 6 years of age. A hurried attempt to zip the pants after urinating is a common history.^{5,30} The two most commonly accepted modalities for freeing the entrapped skin include soaking the penis in mineral oil before trying to loosen the zipper, and cutting the median bar of the zipper with wire cutters. This allows the zipper mechanism to fall apart, in turn freeing the foreskin. Clinical experience suggests that procedural sedation is very helpful in facilitating the release of the boy's foreskin from the zipper. Warm soaks and oral analgesia are usually the only care necessary after releasing the zipper.^{5,30}

Ectopic Pregnancy

Daniel F. Brennan, MD

Key Points

Ectopic pregnancy should be considered in any menstruating female with abdominal pain or vaginal bleeding.

β -Human chorionic gonadotropin (β hCG) testing (qualitative urine or serum) is a reliable starting point in diagnosis.

Transvaginal sonography can “rule in” intrauterine pregnancy at 4 to 5 weeks, when β hCG levels are 1000 to 1400 IU/L, essentially “ruling out” ectopic pregnancy.

Sonography often reveals signs diagnostic of or suspicious for an ectopic pregnancy. Even an indeterminate sonogram is highly suggestive of ectopic pregnancy when the quantitative β hCG exceeds the discriminatory zone.

Therapy with laparoscopy or methotrexate is not 100% effective in eliminating ectopic pregnancy.

Introduction and Background

Ectopic pregnancy is the extrauterine implantation of an ovum, most commonly (95%) within the fallopian tube, and usually in the ampulla (73%).¹ Over the past 35 years, ectopic pregnancy has become increasingly common, exceeding 100,000 cases per year in the United States.²⁻⁴ Much of this increase occurred in the 1970s and 1980s, mirroring a similar increase in risk factors (notably pelvic inflammatory disease [PID]), but the relatively larger increase in absolute numbers also reflects improved detection. Adolescents have increased behavioral and perhaps physiologic susceptibility to sexually transmitted infections (STIs),⁵ especially *Chlamydia*, which predisposes them to an increased risk of ectopic pregnancy. Although ectopic pregnancy rates seem to have stabilized over the past 10 to 15 years, tubal pregnancy still carries significant morbidity. Delay in presentation or diagnosis

can result in tubal rupture, hemoperitoneum, and maternal death.

Enhanced patient and physician awareness of this disease will allow existing and developing diagnostic tools to be used to detect ectopic pregnancy earlier, improving maternal health and future fertility. The use of sensitive β -human chorionic gonadotropin (β hCG) assays in combination with ultrasonography has become the mainstay of diagnosis, reducing the need for invasive testing. Additionally, earlier diagnosis allows noninvasive treatment options to be used more commonly.

Recognition and Approach

Since 1970, the frequency of ectopic pregnancy has increased to now represent about 2% of all pregnancies.²⁻⁴ Given the likelihood of acquiring risk factors (prior ectopic pregnancy, PID, intrauterine device, tubal surgery, infertility) with increased sexual maturity, it is not surprising younger women are at lower risk. Indeed, women ages 15 to 24 years have a 0.66% ectopic pregnancy rate, while women ages 25 to 34 years and 35 to 44 years have two- (1.54%) and threefold (2.15%) this risk.² With more recent trends toward outpatient therapy of ectopic pregnancy in the 1990s, reliable data on incidence has been more difficult to obtain.^{3,5} Encouragingly, a significant reduction in PID has occurred over this later time period, with possible stabilization of the ectopic pregnancy rate.⁶ Although rates of *Gonorrhea* and *Chlamydia* infections in women less than 19 years old have fallen by nearly 50% since the 1980s, prevalence remains highest in this age group.⁷ Increased cervical ectopy makes adolescent women particularly susceptible to *Chlamydia* infection,⁷ now the most frequent STI in the United States, with adolescent women leading all groups (see Chapter 70, Sexually Transmitted Infections).⁸ With an often indolent course and predisposition for ascending infection and tubal damage, it is a major cause of ectopic pregnancy.⁸ Frequent unprotected sex and high fertility rates make ectopic pregnancy an important diagnostic consideration in any young woman with abdominal pain or vaginal bleeding.

During the same era, case fatality rates have declined 90% due to improved and earlier diagnosis.² Improved pregnancy testing (β hCG), sonography, and laparoscopy permit diagnosis of ectopic pregnancy before tubal rupture in 60% to 90% of cases.⁹ Despite enhanced diagnostic techniques, misdiagnosis is still problematic. Ectopic pregnancy continues to be

the most common cause of pregnancy-related first trimester maternal death, nearly always due to hemorrhage.¹⁰ Mortality rates are highest in young women less than 19 years old, markedly in nonwhites.²

Clinical Presentation

Clinically, ectopic pregnancy is primarily a disease of the first trimester, with most cases presenting in the first 8 weeks of gestation with abdominal pain or abnormal vaginal bleeding.^{11,12} Given the physiologic similarity of adolescent and older but generally healthy menstruating women, one would expect the clinical presentation to be very similar. An abrupt, life-threatening illness with tubal rupture and hemoperitoneum was more common in the past, manifesting as signs of peritoneal or diaphragmatic irritation, orthostasis, syncope, tachycardia, or shock. A more benign and insidious presentation is more common currently, although adolescents lacking access to care may present later with a greater degree of illness.

The early manifestations of pregnancy are primarily related to the evolving hormonal milieu, regardless of site of implantation. Later, as the conceptus outstrips the limited decidual reaction afforded it by the fallopian tube, declining hormonal levels may mimic those of failing intrauterine pregnancies (IUPs). Endometrial decline with vaginal bleeding is common. Consequently, early ectopic pregnancies may be difficult to distinguish clinically from normal or abnormal IUPs. Invasion into submucosal vessels can produce pain from a tubal hematoma, and bleeding with or without frank rupture. Common clinical findings are summarized in Table 90–1.^{11–19} The differential diagnosis is broad, including a host of abdominal and pelvic conditions (Table 90–2).²⁰ Commonly the diagnostic challenge is to differentiate ectopic pregnancy from viable or nonviable IUP.

Standard history and physical examination are insufficiently sensitive to detect unruptured ectopic pregnancies, since there are no significant differences in symptoms between ectopic and intrauterine pregnancy patients.¹⁴ Clinical diagnosis is only 55.3% sensitive and 49% accurate for detecting ectopic pregnancy on initial visit.^{14,21} Common pitfalls in diagnosis include overlooking risk factors (25%) or subtle signs of blood loss (36%).²² Delays in diagnosis have often occurred when pain was “atypical” and examination benign.²² Tubal rupture is likewise poorly predicted by clinical features,¹⁷ although shock index may have some predictive value.²³

Thus, history and physical examination value lies primarily in identifying risk factors and physical findings to heighten suspicion.^{24,25} As a consequence, the clinician should pursue the diagnosis in all women of reproductive age who present with abdominal or pelvic pain, or abnormal vaginal bleeding. Given the unreliability of menstrual and sexual history in establishing pregnancy status,²⁶ liberal β hCG pregnancy testing is warranted.

Diagnosis

Diagnosis of ectopic pregnancy initially relies upon β hCG testing to confirm pregnancy status, and ultrasonography to attempt to determine location. Early detection reduces maternal morbidity and mortality and allows more conservative treatment options, including medical therapy.

Table 90–1 Clinical Manifestations of Ectopic Pregnancy^{11–19}

History

Risk factors (past history of infertility, PID, IUD, tubal surgery, prior ectopic): 51–56%
 “Classic” history (amenorrhea followed by abdominal pain, vaginal bleeding): 69% (but this more often represents threatened abortion)
 Abdominal pain: >90–100%
 Variable character, intensity, location
 Absence of pain does predict absence of tubal rupture
 Menstrual history
 Normal menstrual history: 15–30% or more
 Amenorrhea < 4 wk: 15%
 Amenorrhea > 12 wk: 15%
 Rupture before missed menses: 15%
 Abnormal vaginal bleeding: 50–80%
 Usually scant, dark; heavier favors miscarriage
 Symptoms of pregnancy (breast tenderness, morning sickness, “feeling pregnant”)
 Shoulder pain (infrequent)

Physical Examination

“Classic”: shock & adnexal mass (“rarity”)
 Hemodynamic status
 Shock: <5%
 Parasympathetic response to hemoperitoneum (paradoxically low pulse)
 Abdominal examination
 Tenderness: 50%
 Peritoneal signs (less common)
 Pelvic examination
 Adnexal mass: 25–33%
 Adnexal tenderness/cervical motion tenderness: 50%
 Uterine size
 Normal: 71%
 6–8 wk size: 26%
 9–12 wk size: 3%
 Normal pelvic examination: 10%

Abbreviations: IUD, intrauterine device; PID, pelvic inflammatory disease.

Table 90–2 Differential Diagnosis of Ectopic Pregnancy²⁰

Normal intrauterine pregnancy
 Spontaneous abortion
 Corpus luteum cyst, hemorrhage
 Ovarian cysts/torsion
 Appendicitis
 Pelvic inflammatory disease
 Renal colic/pyelonephritis
 Endometriosis
 Diverticulitis
 Ileitis

Laboratory Diagnosis: Pregnancy Testing

The detection of human chorionic gonadotropin (hCG) produced by trophoblasts in early pregnancy is the key to pregnancy diagnosis. Furthermore, the predictable rise of this hormone with normal IUP growth can help identify abnormal gestations—both by serial measurement of quantitative β hCG levels over time and by correlation of ultrasound findings with β hCG levels.^{27,28}

QUALITATIVE URINE OR SERUM β HCG TESTING

Although the time of implantation has been found to be variable with respect to the expected menses,²⁹ by the time of missed menses (13 to 14 days after conception), the smaller than 1-mm zygote produces serum β hCG levels of 50 to 300 IU/L. A variable but similar range of β hCG concentrations in urine and serum has been noted in early pregnancy: in the fourth week, serum concentrations range from 11 to 3476 IU/L (median 254 IU/L) and urine concentrations from 12 to 2548 IU/L (median 210 IU/L).³⁰ Butler et al. found even a variety of home urine pregnancy tests, with manufacturers' reported sensitivities of 25 to 100 IU/L, to reliably detect hCG at 50 IU/L concentration (15 of 15 kits tested).³¹ Also, although many office or emergency department (ED) point-of-care urine tests are sensitive to 25 IU/L, significant variability has been reported in the ability of home, point-of-care, and laboratory β hCG tests to detect hyperglycosylated hCG, which may be the predominant form of hCG initially.^{29,30} Despite variation in assay performance, hCG secretion, and urine concentration, all qualitative tests reliably detect pregnancy, although the time at which they do so varies.³⁰ Clinically, qualitative urine tests have performed well when compared to qualitative serum tests, with 100% sensitivity and 99% specificity.³² Similarly, as compared to serum quantitative tests (sensitivity 5 IU/L), urine assays with sensitivity of 20 IU/L had a 1% false-negative rate.³³ Urine "false-positives" may actually represent detection of β hCG in early pregnancy losses.³² Serum false-positive hCG up to 900 IU/L can occur in 1 in 3300 women due to the presence of heterophilic antibodies, a problem not encountered with urine testing.³⁰ Various investigators have found urine β hCG tests to be 95% to 100% sensitive and specific for pregnancy when compared to serum assays.^{32,34} In the detection of ectopic pregnancies, qualitative assays with a threshold β hCG of 10 IU/L would have a sensitivity of 99.5% and tests with a threshold β hCG of 25 to 50 IU/L would detect 91% to 96%.^{35,36} The convenience of obtaining urine samples and comparable performance makes urine β hCG testing the preferred method in many EDs. In the event that clinical suspicion of pregnancy persists despite a negative qualitative test, quantitative serum immunoassays are sensitive to 5 IU/L or less and can rule out pregnancy in virtually 100% of cases.³⁶⁻³⁸

QUANTITATIVE SERUM β HCG TESTING

Although ectopic pregnancies tend to produce less β hCG than IUPs of comparable gestational age,^{39,40} the range and variation of β hCG produced by both (0 to 100,000 IU/L)³⁵ makes a single level nondiagnostic.^{40,41} Quantitative β hCG may be low or high in both ectopic pregnancy and IUP. Similarly, quantitative β hCG is not diagnostic in predicting tubal status. Both ruptured and unruptured ectopic pregnancies are seen in the β hCG less than 100 and greater than 50,000 IU/L ranges.^{35,42} Although one can be *somewhat* reassured that tubal rupture is less likely at low β hCG levels, rupture can certainly be seen at low levels. In one series, 10% of ectopic pregnancies with β hCG less than 100 IU/L were ruptured, and 7% of ruptures occurred at β hCG less than 100 IU/L.³⁵ In summary, single quantitative β hCG levels are poor predictors of ectopic pregnancy size and tubal rupture risk.³⁵ Additionally, quantitative β hCG poorly predicts utility of sonography. However, quantitative values are useful

serially (β hCG dynamics) and to interpret the results of indeterminate sonography (discriminatory zone).

Sonography

Pelvic ultrasonography has become the key diagnostic test to ascertain pregnancy location in symptomatic first trimester pregnancy.⁴³ Endovaginal ultrasonography by emergency resident and attending physicians was successfully incorporated into protocols for the diagnosis of ectopic pregnancy as early as 1996,^{44,45} and has become part of the core curriculum of emergency medicine residencies.⁴⁶

The goal of imaging is to ascertain whether the pregnancy is intrauterine or not. The presumption is that, if an IUP exists, an ectopic pregnancy is extremely unlikely. Parenthetically, this same assumption is used in evaluating uterine curettage specimens. The incidence of coexisting intrauterine and ectopic pregnancies is traditionally reported as 1 : 30,000 pregnancies.^{47,48} More current estimates of heterotopic pregnancy (simultaneous intrauterine and extrauterine pregnancies) are 1 : 1500 to 1 : 3900,⁹ 1 : 4000,⁴⁷ and 1 : 2600.⁴⁸ In women undergoing ovulation induction, risk is much greater, up to 1 : 35 (2.9%).^{47,48} In these high-risk patients, proof of an IUP may not exclude ectopic pregnancy, but in most women it does with a very high degree of confidence.

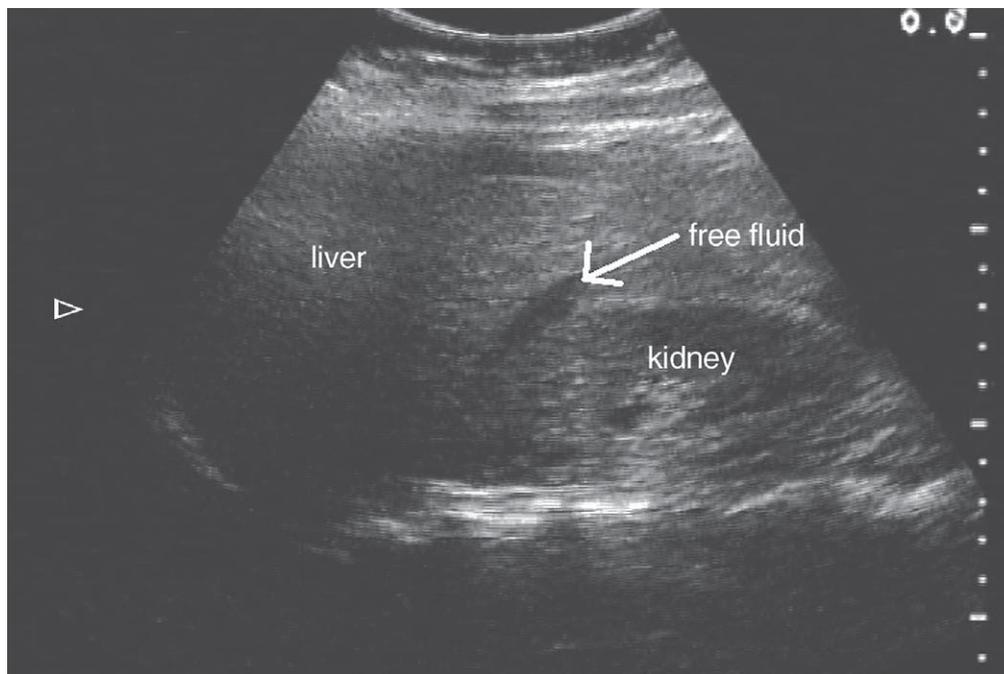

Results of sonography require careful interpretation (Fig. 90-1 and Table 90-3).^{28,40,43,49-75} Pregnancy location is not definitely established until fetal heart activity is localized, but uterine or adnexal signs are suggestive. Definite or probable

diagnosis of intrauterine or ectopic pregnancy can usually be made by vaginal sonography.⁴⁰ The presence of a true gestational sac (intradecidual, double sac sign), yolk sac, and fetal pole infers a greater degree of certainty to the probable diagnosis of IUP. Cystic masses, cul-de-sac fluid (simple, particulate), tubal rings, and complex adnexal masses likewise make the tentative diagnosis of ectopic pregnancy more likely. Doppler may be helpful in further defining adnexal masses.^{76–78} However, not uncommonly the sonogram of a pregnant woman with abdominal pain or vaginal bleeding will be normal and yield none of these signs. Such “nondiagnostic” sonograms could represent early IUP, blighted ovum, threatened or missed abortion, or ectopic pregnancy.⁵² It is here that use of quantitative β hCG levels may be helpful (Table 90–4).^{9,18,28,40,52–57,79–83}

Combination of Sonography with Quantitative β hCG: The Discriminatory Zone

Kadar and colleagues developed the concept of the *discriminatory zone* to help interpret transabdominal sonograms when an IUP was not seen.⁵⁴ The discriminatory zone is the level of β hCG at which almost all viable IUPs should be seen.⁵⁴ As such, it is dependent upon ultrasound resolution, operator skill, and hCG assay used. An empty uterus in combination with a β hCG level above the discriminatory zone is often diagnostic of ectopic pregnancy.⁵⁴ The zone will vary from institution to institution; however, advances in transvaginal sonography have reduced the discriminatory zone to as low as the β hCG range of 1200 to 1500 IU/L.^{58,80}

“Nondiagnostic” ultrasounds (i.e., no IUP) are, in fact, abnormal when β hCG *exceeds* the discriminatory zone. This combination implies abnormal gestation, and is highly specific for ectopic gestation (86% to 100%).^{9,81,83} Further diag-

Table 90–4

Performance of Sonography in Possible Ectopic Pregnancy^{9,18,28,40,52–79–83}

Transvaginal Sonography

Diagnostic in 80–90% of “possible ectopic pregnancy” patients at 5–7 weeks’ gestation
 Intrauterine pregnancy (IUP) visualized in most (76–98%)
 Ectopic pregnancy (EP) visualized in many (20–62%)
 Failure to visualize EP never rules it out: 20% of EP patients have normal sonograms
 Indeterminate sonograms (10–20%)

Use of Quantitative β hCG to Interpret Indeterminate Sonogram

Discriminatory zone of β hCG (DZ): β hCG level above which all viable IUPs should be seen
 If β hCG > DZ: abnormal
 86–100% are EP → pursue diagnosis
 If β hCG < DZ: truly nondiagnostic
 Early IUP, nonviable IUP, EP

Abbreviation: β hCG, β -human chorionic gonadotropin.

nostic efforts are justified (e.g., diagnostic laparoscopy, dilation and curettage [D&C]).⁷⁹ However, a normal sonogram combined with a β hCG level *below* the discriminatory zone is truly nondiagnostic. This scenario could represent early viable IUP, nonviable IUP, or ectopic pregnancy. A thin endometrial stripe, likely correlated with low serum progesterone levels, has been found to be predictive of ectopic pregnancy risk.^{84,85} In the stable patient, observation with serial quantitative β hCG levels is reasonable; repeat sonography when β hCG exceeds the discriminatory zone is suggested.⁷⁹ Regardless of β hCG level, indeterminate sonography will require further diagnostic efforts in coordination with gynecology.

Why is sonography recommended on the basis of a positive qualitative β hCG, that is, before a quantitative β hCG? As sonography has improved, the “window” between positive β hCG pregnancy testing and sonographic evidence of pregnancy has narrowed. Currently β hCG tests become positive at about 3½ weeks from the last menstrual period (LMP)^{81,86,87} and vaginal sonography at about 4½ weeks.^{52,63,88} In a prospective study of 200 potential ectopic pregnancy patients, vaginal sonograms were diagnostic in 91% of patients without quantitative β hCG data.⁵⁵ Quantitative β hCG levels do not assist in the diagnosis in the great majority of cases, but they play a helpful role in the minority with nondiagnostic sonograms.^{40,55}

Sonography may often demonstrate an IUP when β hCG is less than the discriminatory zone, and has made the definitive diagnosis of ectopic pregnancy with quantitative β hCG levels as low as 30 to 60 IU/L.⁶⁴ One study found that 89% of ectopic pregnancy patients with β hCG less than 1000 IU/L had suggestive sonographic signs such as cul-de-sac fluid or adnexal masses. In fact, 25% of all patients diagnosed with ectopic gestations had low β hCG and suggestive ultrasounds.⁸⁹ This suggests that β hCG level cannot predict the utility of sonography and thus sonography should be pursued regardless of quantitative β hCG level.

Improved imaging combined with quantitative β hCG data allows more ectopic pregnancy patients to reach a definite diagnosis at the first visit, often by 35 to 37 days post LMP, and before significant risk of tubal rupture.⁵⁰ The diagnostic accuracy of the combination of sonography with the β hCG discriminatory zone is excellent. The best diagnostic criteria, based on literature evidence, are the absence of an intrauterine sac when β hCG is greater than 1000 IU/L and/or the presence of an adnexal mass.⁵⁵ This criteria set has a sensitivity of 97%, a specificity of 98%, a positive predictive value of 98%, and a negative predictive value of 98%. Similar results have been obtained in other studies.^{80,83} Thus the need for serial β hCG monitoring has diminished and other diagnostic procedures have assumed more of a confirmatory role.

Additional Laboratory Diagnostic Tests

SERIAL β HCG TESTING: β HCG DYNAMICS

Normally β hCG rises from about 100 IU/L at 4 weeks to greater than 100,000 IU/L at the end of the first trimester (Table 90–5).^{27,50,90-104} Early concentrations of β hCG increase exponentially, reflecting trophoblastic proliferation. The early exponential increase in β hCG in healthy IUPs is fairly predictable, with levels doubling approximately every 2 days. Mean doubling time for normal IUPs is 1.9 ± 0.5 days, with an upper 95% confidence level of 2.8 days when initial β hCG is less than 10,000 IU/L.⁹¹ An increase in β hCG of greater than 66% over 48 hours has been found to be the minimum seen at the 85% confidence level for normal IUPs.⁹³

The value of β hCG dynamics is in differentiating normal from abnormal gestations, including ectopic pregnancy.^{105,106} In ectopic pregnancy, inadequate tubal decidual reaction results in stunted trophoblastic tissue growth, and β hCG production lags. Subnormal increases in β hCG are seen in 85% of ectopic pregnancies.⁹³ When β hCG rises less than 66% over 48 hours, the pregnancy is often abnormal.⁹³ Thus an abnormal rise in β hCG *could* be a normal IUP (15%), but one must suspect an abnormal pregnancy, such as ectopic

Table 90–5 β hCG Dynamics^{27,50,90-104}

Normal Intrauterine Pregnancies (IUP)

50–100 IU/L at 4 wk from last menstrual period
Reach maximum of 100,000 IU/L at 12 wk
Doubling times 1.9 ± 0.5 days when β hCG < 10,000 IU/L

Normal Dynamics

$\geq 66\%$ increase in β hCG over 48 hr
Occurs in 85% of normal IUPs
May occur in early, asymptomatic ectopic pregnancy

Abnormal Dynamics

<66% rise in β hCG over 48 hr
May occur in 15% of normal IUPs
Suggests abnormal gestation
75% sensitive, 93% specific
Occurs in 85% of ectopic pregnancy patients (especially if symptomatic)
May be nonviable IUP

Declining β hCG Values

Indicate nonviability
Spontaneous intrauterine abortion
Tubal regression/abortion
May be useful in monitoring success of therapy

Abbreviation: β hCG, β -human chorionic gonadotropin.

pregnancy, impending miscarriage, or blighted ovum. However, ectopic pregnancies may initially have normal β hCG dynamics,^{91,93} especially in asymptomatic patients.^{50,94} Ultimately, 85% of ectopic pregnancy patients do manifest abnormal β hCG dynamics.⁹⁴

Declining β hCG values indicate nonviability of the pregnancy, either intra- or extrauterine. In these patients, D&C may be helpful by documenting the presence of a blighted IUP rather than ectopic pregnancy. Declining β hCG values may represent complete abortion or tubal regression/abortion; thus observation alone may be reasonable in the asymptomatic patient.⁹⁶ However, tubal hematoma rupture remains possible, and clinical symptoms must be heeded.¹⁰⁷ After therapy, lack of decline in β hCG can be helpful in monitoring for treatment failure and persistent ectopic pregnancy.^{108,109}

PROGESTERONE

Progesterone is often low in abnormal pregnancies.^{90,110-113} Low levels of this hormone may reflect decreased production by abnormal trophoblastic tissue, or decreased corpus luteal function.⁹⁰ Normal corpus luteal function early in abnormal pregnancies may account for low sensitivities of these assays.⁹⁰ Most nonviable pregnancies have progesterone less than 10 ng/ml.¹¹⁰ Progesterone values greater than 25 ng/ml imply a 97% chance of normal IUP.¹¹¹⁻¹¹³ However, no single cutoff value can predict ectopic pregnancy.^{39,41,110,114-116} One cannot rely on progesterone levels to diagnose ectopic pregnancy, but low values should heighten suspicion for an abnormal pregnancy. Progesterone probably has more value in settings in which sonography is less available,¹¹⁷ or in selected patients when diagnosis is uncertain after sonography and quantitative β hCG have been performed.^{112,118,119}

Diagnostic Procedures

Dilation and Curettage

D&C is helpful in establishing the presence of an IUP and, thus, virtually excluding ectopic pregnancy. If products of

conception are present, this makes ectopic pregnancy doubtful, given the rarity of heterotopic pregnancy in most populations. D&C should only be undertaken to establish the location of a pregnancy when nonviability is assured, unless the patient desires termination of the pregnancy. Nonviability may be established by stable or decreasing serial β hCG levels or suggested by very low progesterone values (<5.0 ng/ml).¹²⁰

Laparoscopy

This technique provides the opportunity for the definitive diagnosis and treatment of ectopic pregnancy.^{79,121} Due to advances in noninvasive diagnostic (transvaginal sonography) and pharmacologic methods for treating ectopic pregnancy, the role of laparoscopy has diminished somewhat.^{51,80} However, diagnostic laparoscopy remains the procedure of choice in the patient with uncertain diagnosis despite thorough evaluation.⁷⁹

With ectopic pregnancy, laparoscopy usually reveals a characteristic bluish swelling of the tube, but can be falsely negative early¹²² in about 3% to 4% of cases.¹⁵ False positives reportedly occur in 5% of cases.¹⁵

Important Clinical Features and Considerations

Common pitfalls in making the diagnosis of ectopic pregnancy generally arise from failure to consider the diagnosis or misinterpretation of diagnostic tests²² (Table 90–6).

Management

Emergency physician therapy of ectopic pregnancy consists of stabilization. Resuscitation of the unstable patient follows the usual guidelines: securing airway, breathing, and circulation; establishing intravenous lines (large bore); providing fluid resuscitation with crystalloid and red blood cell transfusions; and initiating prompt definitive therapy (gynecologic consultation for surgical management). Rh immuno-

prophylaxis (50 μ g anti-D immune globulin intramuscularly) is generally recommended in the Rh-negative woman with ectopic pregnancy or spontaneous abortion, although use of Rh₀(D) immune globulin is currently without clear-cut justification in threatened miscarriages of less than 7 weeks.^{48,109,124,125}

Stable patients allow for a more sequential evaluation. Therapeutic options are more varied, and decisions may be influenced by the methods necessary for diagnosis as well as the preferences of the gynecologist.¹²⁶⁻¹⁵⁰ Many gynecologists still prefer surgery, although laparoscopy now supplants laparotomy in most centers.¹⁵¹⁻¹⁵⁴ With improved anesthesia and laparoscopy skills, this has become an option even in unstable patients.¹⁵⁵⁻¹⁵⁷ Surgeons may prefer laparotomy in patients with tubal rupture and larger volumes of intraperitoneal blood.¹⁵⁷

Medical therapy of early ectopic pregnancy with the folate antagonist methotrexate has expanded greatly given its efficacy and cost effectiveness.^{152,153,158-160} In a randomized trial of methotrexate versus laparoscopy, no significant differences were seen in primary treatment success, tubal preservation, or patency.¹⁶¹ Although methotrexate involved more side effects¹⁶¹ and outpatient follow-up,¹⁵⁸ significant savings in terms of hospitalization and overall cost can be achieved.^{152,158,159} Contraindications to medical management are unstable vital signs or active bleeding, tubal rupture, or contraindications to methotrexate (liver, renal, or hematologic disease). Various relative exclusions, including larger tubal size, higher β hCG level, and fetal heart activity, have been applied since failure rates are higher with these signs of more advanced disease.^{109,126,162} Methotrexate achieves successful resolution in 92% of cases (range 78% to 96%).¹⁶² Tubal patency is preserved in 78% of cases, with subsequent pregnancy rates (65%) and ectopic rates (13%) similar to those in laparoscopically treated groups.¹⁶² Although regimens involving oral, intravenous, multiple dose, and local injection are possible, methotrexate is most commonly given by single-dose intramuscular injection (50 mg/m²), with repeat doses as needed based upon close observation of β hCG patterns. About 8% to 20% of patients will need repeat methotrexate, often when β hCG levels at posttreatment day 7 fail to fall below day 4 levels.^{126,163} The emergency physician must be aware of the potential for methotrexate failure, continued growth of the ectopic pregnancy or hematoma, and tubal rupture; thus close follow-up with the treating physician is imperative. β hCG levels often need to be followed for weeks until resolution, with reliability an issue to consider in adolescents.

Outcome is measured in terms of morbidity/mortality, success in eradicating ectopic pregnancy (i.e., persistent ectopic pregnancy rate), complications (bleeding), rapidity of convalescence, and future fertility (IUP rate, recurrent ectopic pregnancy rate). In general, conservative laparoscopic surgery (linear salpingostomy) is the current standard, although medical management (methotrexate) is being utilized with increasing frequency.

Summary

Ectopic pregnancy is an increasingly common and potentially catastrophic condition that often presents to the ED with abdominal pain or vaginal bleeding. Recent

Table 90–6 Clinical Pitfalls

Failure to Consider the Diagnosis

Ignorance of the clinical spectrum of presentation (minimal or atypical symptoms)
Failure to consider diagnosis when risk factors are present, or if pain or bleeding exists

Misinterpretation of Diagnostic Tests

Failure to understand the limitations of various tests
Failure to pursue additional diagnostic testing
Dismissing low β hCG level
Does not preclude EP or rupture: symptomatic patients with low β hCG are at increased risk of EP¹²³
Does not predict utility of sonography: many scans show IUP or signs of EP even with low β hCG values
Sonography
Pseudosacs, nonspecific intrauterine fluid collections: occur in up to 20% of EPs
Should not exclude EP until more definitive signs of IUP are present (double decidual sac sign, yolk sac, fetal pole)

Abbreviation: β hCG, β -human chorionic gonadotropin; EP, ectopic pregnancy; IUP, intrauterine pregnancy.

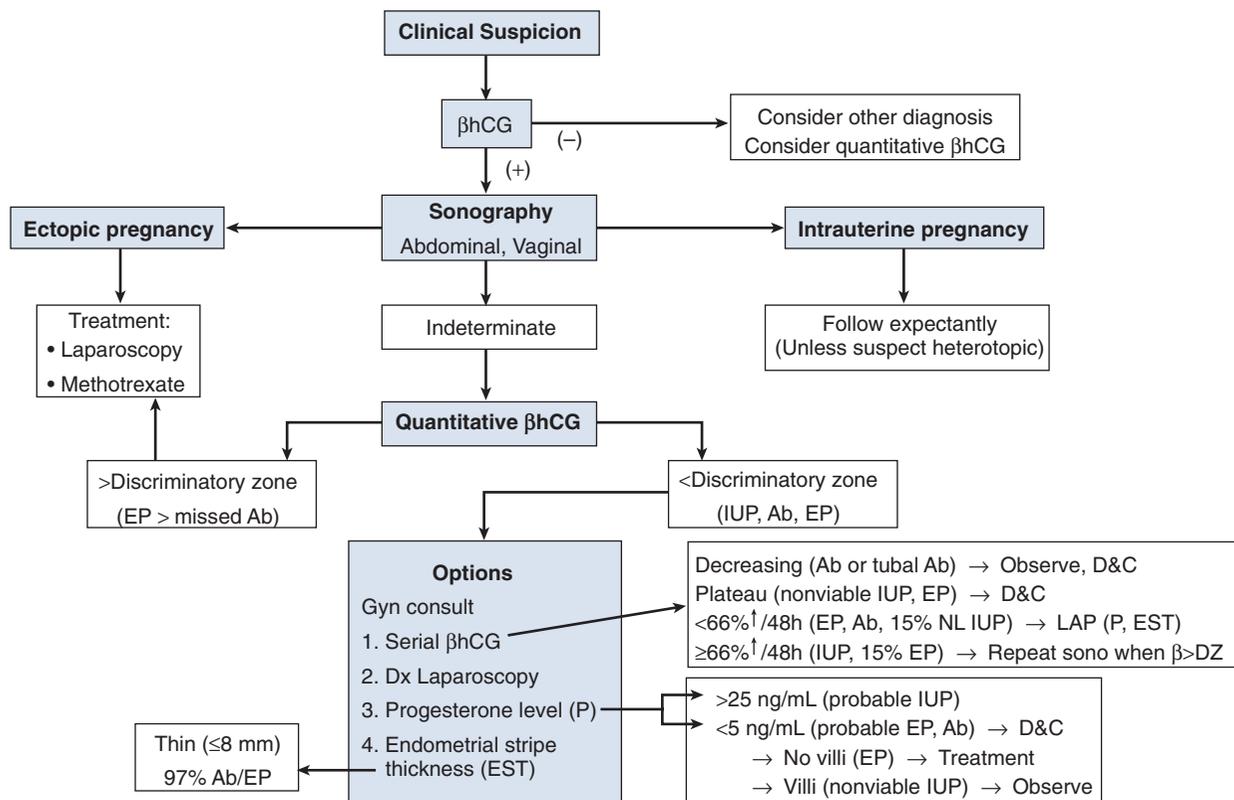

FIGURE 90–2. Diagnostic algorithm for ectopic pregnancy. NOTE: If the patient is unstable, resuscitation and immediate gynecology consultation for laparoscopy are recommended. Abbreviations: Ab, abortion; β hCG/ β , β -human chorionic gonadotropin; D&C, dilation and curettage; Dx, diagnostic; DZ, discriminatory zone; EP, ectopic pregnancy; LAP, laparoscopy; IUP, intrauterine pregnancy; NL, normal; SONO, sonography.

developments in the laboratory (sensitive β hCG and progesterone assays), in ultrasonography (transvaginal probes, Doppler ultrasound), and in the combination of modalities (discriminatory zone of hCG for ultrasonographic evidence of IUP) have allowed the earlier diagnosis of ectopic pregnancy. Conservative laparoscopic surgery and medical treatment options have evolved, making maternal mortality rare ($<0.04\%$)² and future fertility more viable.

Understanding the strengths and limitations of the variety of diagnostic modalities available will allow the clinician to formulate a rational strategy for the early diagnosis of ectopic pregnancy. Numerous algorithms have been developed.^{9,28,48,51,52,79,80,111,122,164} All begin with high clinical suspicion in women of reproductive age with abdominal/pelvic pain or vaginal bleeding. Pregnancy testing with a sensitive β hCG qualitative test is next. In stable patients found to be pregnant, sonography follows, first transabdominally and then transvaginally. Unstable patients require immediate resuscitation and gynecology consultation; invasive diagnostic methods may supplant laboratory tests and sonography. Unclear cases may require the use of quantitative β hCG (discriminatory zone), other pregnancy hormones (progesterone), invasive procedures (laparoscopy, culdocentesis, D&C), or observation (serial β hCG levels). A suggested algorithm incorporating these elements is presented in Figure 90–2.

Collaboration of emergency physicians and obstetrician-gynecologists is essential for patients with possible ectopic pregnancy. In the unstable patient, the transition of care from the ED resuscitation and stabilization phase to the gynecologist for subsequent evaluation and therapy best

serves the patient when well planned and coordinated. Local resources such as bedside sonography will make the details site specific. More commonly, stable patients are being evaluated for possible ectopic pregnancy, which increasingly can be diagnosed within the initial ED visit. In children's facilities without gynecology services, transfer agreements will facilitate the coordination of care for both groups. Finally, many patients will remain with ectopic pregnancy as a diagnostic consideration after indeterminate ED sonography and low quantitative β hCG level. This last group, if stable, are candidates for further evaluation as outpatients. Often this entails arranging follow-up in 48 hours for serial β hCG determination and gynecologic examination. Patients should also receive threatened abortion and ectopic pregnancy precautions, with instructions to return to the ED for increased pain or signs of increased bleeding.

Chapter 91

Pregnancy-Related Complications

Angela M. Mills, MD and Elizabeth M. Datner, MD

Key Points

All adolescent females should be tested for pregnancy; social support and appropriate referrals should be provided to all pregnant teenagers.

Vaginal bleeding in the first trimester should be evaluated with the focus to rule out ectopic pregnancy and stabilize the patient hemodynamically.

Seizures in the setting of pregnancy should be considered as possible eclampsia.

Futile resuscitation of a gravid patient with a potentially viable fetus should prompt consideration of emergency cesarean section.

All pregnant patients should be screened for domestic violence and offered referral resources and safe housing.

Introduction and Background

Teenage pregnancy is an important public health concern, accounting for over 10% of all births in the United States in 2003.¹ Even with recent declines in adolescent birth rates, approximately 800,000 to 900,000 adolescents become pregnant yearly.² This population has unique issues and requires a distinct understanding of both their medical and psychosocial circumstances. In comparison to pregnancies in adult women, teenage pregnancies have been associated with an increased risk of adverse outcomes, including preterm deliveries, low birth weight, and higher neonatal mortality.³⁻⁵ Younger adolescents may be at even higher risk. One study demonstrated that teenage mothers under 15 years of age are less likely than older adolescents to have adequate prenatal care.⁶ In addition to inadequate utilization of prenatal care, pregnant adolescents are also more likely to have poor health habits and engage in health risk behaviors such as smoking, which is one of the strongest risk factors for adverse perinatal outcomes.⁷ The psychosocial concerns of pregnant teenagers are myriad and are equally important as the medical issues,

if not more so. They may include but are certainly not limited to an unstable home life, lost educational opportunities, poor employability, and welfare dependence.⁵

Because of the high-risk nature of teen pregnancy, all female adolescents who seek care in emergency departments should be tested for pregnancy in order to identify patients who may need referral for early prenatal care. In addition, those who present with abdominal pain, vaginal bleeding, syncope, altered mental status, or hypotension and are pregnant will require further detailed evaluation specifically addressing potential pregnancy-related complications. The clinician must maintain a high suspicion for pregnancy, and especially ectopic pregnancy, when treating adolescents (see Chapter 90, Ectopic Pregnancy). This chapter focuses on other pregnancy-related complications in the adolescent patient.

Selected Diagnoses

- First trimester bleeding
- Complications of induced abortion
- Amniotic fluid embolus
- Molar pregnancy
- Nausea and vomiting of pregnancy and hyperemesis gravidarum
- Pregnancy-induced hypertension
- Vaginal bleeding in the second half of pregnancy
- Trauma in pregnancy
- Rh immunization
- Medication use in pregnancy

Discussion of Individual Diagnoses

First Trimester Bleeding

First trimester vaginal bleeding is common, occurring in up to 25% of all pregnancies, with spontaneous abortion (SAb) resulting in over half of cases prior to sonographic evaluation.^{8,9} Spontaneous abortion (also termed *miscarriage*) occurs in several stages, with *threatened abortion* defined as vaginal bleeding during the first half of pregnancy with a closed cervical os. If cervical dilation is present, the term *inevitable abortion* is used. *Incomplete abortion* occurs with partial passage of the gestational products. When all fetal tissue is passed and the cervical os is closed, a *complete abortion* has occurred. This may be difficult to distinguish

Table 91–1 Definitions of Terms for Vaginal Bleeding at Less Than 20 Weeks of Pregnancy

Cervix Examination	Products of Conception	Abortion Term
Closed	Present	Threatened
Closed	Absent	Complete
Open	Present	Inevitable
Open	Partially passed	Incomplete

from an incomplete abortion and may require diagnosis with pathologic confirmation of the products of conception. A SAb is defined as any unintentional fetal loss prior to 20 weeks' gestation (Table 91–1). A *missed abortion* is the term for a fetal death at less than 20 weeks' gestation when the products of conception have not been passed for more than 4 weeks.

Patients with the diagnosis of threatened abortion at any time in the first trimester are at increased risk for spontaneous loss prior to 24 weeks' gestation. The risk of pregnancy loss is directly proportional to the amount of vaginal bleeding experienced by the patient.⁸ The risk rises with increasing maternal age, multiparity, and history of prior vaginal bleeding. Although SAb is more common in older women, approximately 12% occur in women less than 20 years of age. Women with heavy vaginal bleeding in the first trimester are also at increased risk for preterm delivery, intrauterine growth retardation, placental abruption, premature rupture of the membranes, and cesarean delivery. If a viable fetus is diagnosed by ultrasound when first trimester bleeding has occurred, greater than 95% of these pregnancies will continue to the second half of pregnancy.⁸

The history of patients with bleeding in the first trimester should include the date of the last menstrual period, quantity of bleeding, and passage of clots or tissue. Pelvic examination is necessary to determine the status of the cervical os, the amount of bleeding, and whether fetal tissue is evident. Products of conception at the os should be gently removed using a ring forceps to decrease bleeding and discomfort. However, if any resistance to removal is encountered, the tissue should be left in place until obstetric evaluation is possible. Ancillary testing should include a quantitative serum β -human chorionic gonadotropin (β hCG) level, blood type with Rh factor, and pelvic ultrasound (US). Rh-negative women require immune globulin as discussed later.

β -hCG is a hormone secreted by the placenta that doubles approximately every 48 hours in early pregnancy. This hormone may be correlated with US by use of the discriminatory zone, which is the β -hCG level above which an intrauterine pregnancy (IUP) may be visualized using US with near-100% sensitivity. This level varies by institution and is approximately 1200 to 1500 mIU/ml when using transvaginal US and between 4000 and 6500 mIU/ml with transabdominal US. If the level is above the discriminatory zone and an IUP is not visualized, ectopic or abnormal pregnancy must be considered.^{10–12} In one study, the group of patients with a β -hCG level below the discriminatory zone with an indeterminate US was found to have a fourfold higher relative risk of ectopic pregnancy than patients with higher β -hCG levels.¹³ Other studies have found lower rates of ectopic preg-

nancies in this subgroup.¹¹ The differential diagnosis in this group of patients includes ectopic pregnancy, early viable IUP, and nonviable IUP. An accepted protocol in the stable patient who is not bleeding excessively is following serial β -hCG levels with repeat US on an outpatient basis. Gynecologic consultation for follow-up is necessary in patients with indeterminate US (see Chapter 90, Ectopic Pregnancy).

Patients who are bleeding heavily or have an open cervical os require gynecologic consultation, as dilation and evacuation may be necessary. Stable patients with the diagnosis of threatened abortion may be discharged with close follow-up. Precautions should be given for prompt return if there is heavy bleeding (soaking more than one pad per hour), symptomatic anemia, fever, or significant pain.

Complications of Induced Abortion

Approximately 2% of all women of reproductive age in the United States elect to have an induced abortion each year, and in 2001, teenagers accounted for 18% of all abortions. Adolescents under 15 years had the highest abortion ratio at 744 per 1000 live births.¹⁴ Induced abortion may be performed either medically or surgically. Legal abortion is one of the safest surgical procedures with a relatively low complication rate. In a large case series of over 170,000 first trimester abortions, complications requiring hospitalization comprised 0.7 per 1000 abortions and included suspected perforation, sepsis, ectopic pregnancy, hemorrhage, and incomplete abortion. Less serious complications, defined as those not requiring referral to a hospital, included mild infection, retained tissue or clots requiring resuctioning, cervical tear, and underestimation of gestational age. These accounted for 8.46 per 1000 abortions, with an overall complication rate of 9.05 per 1000 abortions.¹⁵

Adolescents are more likely than older women to have abortions later in pregnancy. Approximately 15% of abortions in patients less than 15 years old, and 10% of those in patients between 15 and 19 years of age, occur later than 15 weeks' gestation, higher than any other age group.¹⁶ Therefore, teens are less often candidates for medical abortion and may require surgical abortion instead. One study showed greater than a third of mortality risk in teenagers was due to having an induced abortion at a later gestational age when compared to women over 30 years of age.¹⁷ The risk factor that continues to be most strongly related to mortality from legal abortion is gestational age at the time of abortion.

The most common complications of induced abortion include hemorrhage, retained products of conception, hematometra, and infection. Hemorrhage is commonly due to uterine atony, retained tissue, and, less often, traumatic injury. Patients with retained tissue usually present with vaginal bleeding and abdominal cramping within the first few days after surgical abortion. Ultrasound may aid in diagnosis. Hematometra, or the accumulation of blood clots in the uterus, may occur after surgical abortion. Symptoms include pelvic or rectal pressure with a tense and tender uterus on examination. Acutely, vaginal bleeding is often minimal while dark clots may be passed with delayed hematometra. Sonography may demonstrate heterogeneous echoes within the uterus.

Perforation is a less common complication of induced abortion and may range from a simple puncture of the uterine wall to injury to the blood vessels or intra-abdominal

contents. Practitioners must be concerned about perforation when patients present with atypical or refractory abdominal pain or persistent bleeding after an induced abortion. Infection after abortion is often characterized by endometritis with uterine tenderness with or without fever. Less common infectious complications include salpingitis, peritonitis, pelvic abscess, and sepsis.¹⁸ Prophylactic antibiotics have been shown to decrease infection and are routinely prescribed after elective abortions.¹⁹ Complications of induced abortion necessitate gynecologic consultation. Care of the adolescent in the emergency department may also provide an opportune time to offer contraceptive and sexually transmitted infection counseling.

Amniotic Fluid Embolus

Amniotic fluid embolus is a rare and rapidly progressive complication of pregnancy with high maternal morbidity and mortality. Historically mortality rates were over 60%, although more recent studies suggest mortality rates of less than 30%.²⁰ Patients often present with sudden cardiovascular collapse, disseminated intravascular coagulation, and death. Amniotic fluid embolus is most common during labor but may also occur during induced and spontaneous abortions. It is thought that this disease process is consistent with an allergic or anaphylactic reaction rather than a true embolism, and the term *anaphylactoid syndrome of pregnancy* has been proposed.²¹ Diagnosis is based on the clinical setting with a high index of suspicion. Treatment involves prompt resuscitation with airway and hemodynamic support. Emergent cesarean section may be required.

Molar Pregnancy

Gestational trophoblastic disease (GTD) consists of a spectrum of conditions originating from the placenta and is characterized by disordered proliferation of chorionic villi. The spectrum includes complete hydatidiform mole, where there is an absence of fetal tissue; incomplete mole, when fetal tissue is present; and invasive moles, gestational choriocarcinomas, and placental site trophoblastic tumors. Molar pregnancies occur in approximately 1 in 1500 pregnancies in the United States. Risk factors include extremes of maternal age (<15 years and >45 years), prior GTD, and Asian race.²²⁻²⁴ Metastatic disease may occur, requiring chemotherapy and oncologic management.

Patients may present with vaginal bleeding or hyperemesis gravidarum (HG), and are found to have uterine enlargement greater than expected for dates, absent fetal heart tones, and an abnormally high level of β hCG for gestational age.²⁵ Patients with GTD may also develop pregnancy-induced hypertension (PIH) or preeclampsia. Diagnosis of molar pregnancy may be established using US. As some molar pregnancies are not detected by sonography, histologic examination of abortion specimens should occur. Patients with suspected GTD should have immediate gynecologic consultation.

Nausea and Vomiting of Pregnancy and Hyperemesis Gravidarum

Nausea and vomiting are very common in early pregnancy, occurring in up to 80% of all pregnant women, with 10% to 20% requiring medications.²⁶ Nausea and vomiting of pregnancy (NVP) may begin shortly after the first missed menses and usually resolves by the 16th to 20th week of gestation.

Symptoms are often worse in the morning but may continue throughout the day. Vomiting has been shown to be more common in younger women, primigravidas, obese women, and nonsmokers.²⁶ NVP may be quite disruptive and may greatly affect utilization of health care resources, lost time from work, and quality of life.²⁷ HG is a more severe form of NVP, occurring in approximately 1% to 2% of pregnancies, and is often defined as nausea and vomiting leading to dehydration, weight loss, ketosis, and electrolyte abnormalities.²⁷ Up to 1.5% of all pregnancies may require hospitalization due to HG.²⁸

The cause of NVP is unclear, but various etiologies have been suggested, including increasing estrogen and human chorionic gonadotropin levels, other maternal hormone levels, thyroid hormones, genetic factors, and lifestyle factors, including tobacco and caffeine use.²⁹ One study found a significantly increased female:male infant sex ratio in those patients requiring hospitalization for HG, which may in part be due to increased estrogen levels.²⁸ Nausea and vomiting accompanied by abdominal pain, or severe vomiting occurring after the first trimester, may be due to other underlying diseases and requires further evaluation.

Initial management of NVP includes rehydration with intravenous fluids and antiemetics (Table 91-2). Intravenous isotonic fluids containing 5% glucose may be used for volume repletion and to reverse ketonuria. A number of medications and nondrug therapies have been used with various success rates and side effects, including pyridoxine (vitamin B₆), acupuncture or acupressure, ginger, antihistamines, phenothiazines, and corticosteroids.³⁰ Most standard antiemetics are classified as category C in the Food and Drug Administration (FDA) classification of teratogenic risk of medications but have been used successfully for the treatment of NVP. In severe cases, enteral nutrition may be necessary.²⁷ For discharge, patients should demonstrate ability to tolerate oral hydration and may require outpatient antiemetic therapy.

Pregnancy-Induced Hypertension

Hypertension is the most common medical condition affecting pregnancy, occurring in approximately 10% to 20% of pregnancies worldwide.³¹ Several syndromes with hypertension as the key element should be considered in the hypertensive pregnant patient. PIH, or gestational hypertension, is defined as a systolic blood pressure (BP) of greater than 140 mm Hg and/or a diastolic BP of greater than 90 mm Hg diagnosed after the 20th week of gestation, which resolves postpartum.^{32,33} It can also occur before the 20th week of gestation in women with a molar pregnancy. This is distinct from a pregnant patient with preexisting chronic hypertension; however, these patients may also develop the associated hypertension related complications. Preeclampsia is defined as PIH with proteinuria (>300 mg/24-hour period or >30 mg/dl on dipstick on two occasions at least 6 hours apart) and is the second leading cause of maternal death in the United States.³² Preeclampsia may occur in up to 7% of healthy primigravid women. In addition to nulliparity, other risk factors for preeclampsia include prior history of preeclampsia, extremes of maternal age, twin or molar pregnancies, obesity or high body mass index, and family history of preeclampsia.^{34,35} Severe PIH and preeclampsia are defined as a systolic BP of greater than 170 mm Hg and/or a diastolic BP greater than 110 mm Hg. Symptoms of PIH may include

Table 91–2 Medications Commonly Used for Complications of Pregnancy

	Medication	Dosage/Administration	FDA Category*
Vaginal bleeding in Rh-negative mother	Anti-D immune globulin (RhoGAM)	50 mcg IM <12 wk 300 mcg IM >12 wk	C
	Promethazine (Phenergan)	25–50 mg IV/IM push or over 2 hr 25 mg PO q4h 25 mg PR q4h	C
Nausea and vomiting/hyperemesis gravidarum	Prochlorperazine (Compazine)	5–10 mg IV over 10 min (max 40 mg/day) 25 mg PR q12h 10 mg PO q6–8h	C
	Chlorpromazine (Thorazine)	25 mg in 500 ml 0.9% NS at 250 ml/hr IV 10–25 mg PO q4–6h 100 mg PR q6–8h	C
	Metoclopramide (Reglan) Ondansetron (Zofran)	10 mg IV over 1–2 min or 10 mg PO qid 4–8 mg IV over 15 min q12h 8 mg PO q12h	B B
Eclampsia or severe preeclampsia Hypertension	Magnesium sulfate	2–6 g IV over 15 min, followed by 2 g/hr	A
	Labetalol	20 mg slow IV, then 40–80 mg IV q10min (max 300 mg)	C
	Hydralazine	Initial dose 5 mg IV, then maintenance dose of 5–10 mg IV q20min	C

*Food and Drug Administration categories for medications used in pregnancy are as follows:

A: Adequate, well-controlled studies in pregnant women have not shown an increased risk of fetal abnormalities.

B: Animal studies have revealed no evidence of harm to the fetus, however, there are no adequate and well-controlled studies in pregnant women OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus.

C: Animal studies have shown an adverse effect and there are no adequate and well-controlled studies in pregnant women OR no animal studies have been conducted and there are no adequate and well-controlled studies in pregnant women.

D: Studies, adequate well-controlled or observational, in pregnant women have demonstrated a risk to the fetus. However, the benefits of therapy may outweigh the potential risk.

X: Studies, adequate well-controlled or observational, in animals or pregnant women have demonstrated positive evidence of fetal abnormalities. The use of the product is contraindicated in women who are or may become pregnant.

Abbreviations: IM, intramuscularly; IV, intravenously; NS, normal saline; PO, orally; PR, rectally.

nausea, vomiting, midepigastric abdominal pain, and headache. The HELLP syndrome (*hemolysis, elevated liver enzymes, and low platelets*) is a particularly severe form of PIH complicating up to 10% of patients with preeclampsia. The presence of HELLP syndrome is associated with an increased risk of both maternal and fetal morbidity and mortality. Diagnosis, management, and outcome remain controversial for this syndrome.^{36,37}

The cause of preeclampsia remains unknown, with multiple etiologies proposed. Some potential causes include immunologic intolerance of fetoplacental tissue, genetic factors, dietary deficiencies, uterine blood vessel invasion by abnormal trophoblasts, and maladaptation to the changes of pregnancy.³⁴ Currently there are no screening tests to predict preeclampsia or methods to prevent the disease. There have been various conflicting trials examining calcium for the prevention of preeclampsia. A large randomized, prospective trial of almost 4600 healthy nulliparous women showed no reduction in the rate of preeclampsia with calcium supplementation.³⁸ Low-dose aspirin has also been studied for preeclampsia prevention. A large multicenter trial with over 2500 high-risk women with chronic hypertension, multifetal gestations, history of preeclampsia, or pregestational diabetes showed no benefit from low-dose aspirin.³⁹ Eight other large trials including a total of over 30,000 patients showed minimal to no benefit in preventing preeclampsia with low-dose aspirin.^{34,40,41}

Eclampsia is the new onset of seizures, not attributable to other causes, in a woman with preeclampsia. Eclampsia

occurs in approximately 1 in 2000 births in developed countries, and the incidence may be higher in developing countries.^{42,43} Patients with severe preeclampsia have the highest risk, but less than 1% of preeclampsia patients develop eclampsia.⁴⁴ Seizures attributable to eclampsia may occur in patients without warning signs of preeclampsia; in one study, seizures were the first sign of preeclampsia 60% of the time.⁴⁵ Caution when evaluating patients with pre-eclampsia as digital examination may precipitate eclampsia. Eclampsia may lead to maternal death, stillbirth, or neonatal demise.

Definitive treatment for eclampsia and severe preeclampsia is delivery of the fetus, with the ultimate goal of maternal and fetal safety by preventing seizures and minimizing end-organ damage. Intravenous magnesium sulfate is the drug of choice for the treatment of seizures in eclampsia and the prevention of seizures in preeclampsia.^{42,43} The dosage of magnesium is 2 to 6 g intravenously over 15 minutes followed by a maintenance drip of 2 g/hr. A large randomized, placebo-controlled trial showed magnesium to halve the risk of eclampsia and to reduce maternal mortality.⁴³ Magnesium toxicity is characterized by slurred speech, areflexia, and neuromuscular depression leading to respiratory and cardiac depression and arrest. Deep tendon reflexes, respiratory rate, and urine output should be monitored in those patients receiving magnesium infusions. Loss of deep tendon reflexes precedes respiratory arrest. Serum levels between 4 and 7 mEq/L are desired for therapeutic effect; toxic side effects are typically seen at levels greater than 8 mEq/L. Magnesium excretion is impaired by renal insufficiency. If toxicity is

present, the infusion should be stopped, and 1 g of calcium gluconate (10 ml of a 10% solution administered intravenously over 2 minutes) may be used as an antidote. For continued seizures despite magnesium, consider alternate diagnoses and seizure management (see Chapter 40, Seizures). BP control may be achieved using labetalol or hydralazine. Antihypertensives are indicated for diastolic BP \geq 105 mmHg with the goal of decreasing to 90–95 mmHg or lower if baseline is $<$ 75 mmHg. Some studies have shown a benefit to using labetalol in preference to hydralazine. Labetalol may be given as a dose of 10 to 20 mg intravenously followed by repeat doses if needed to a maximum of 80 mg. Hydralazine may be dosed initially as 5 mg intravenously followed by 5 to 10 mg every 20 minutes as needed to keep diastolic blood pressure below 110 mm Hg.^{31,46,47} Fetal heart rate should also be monitored, and obstetric consultation should be obtained immediately. Steroids are recommended to reduce neonatal complications in pregnancies less than 34 weeks' gestation with severe preeclampsia.⁴⁸

Vaginal Bleeding in the Second Half of Pregnancy

Vaginal bleeding in the second half of pregnancy is relatively uncommon, yet it is responsible for a significant amount of maternal and fetal morbidity and mortality. The differential diagnosis includes abruptio placentae, placenta previa, preterm labor, and bleeding lesions from the lower genital tract. In the emergency department, patients should be stabilized with two large-bore intravenous catheters, fluid resuscitation with crystalloid and packed red blood cells if needed, and fetal monitoring. Obstetric consultation and transfer to a facility with obstetric and pediatric capabilities should be initiated early.

Abruptio placentae (or placental abruption), a premature separation of the placenta from the uterine wall, accounts for about 30% of bleeding during the latter half of pregnancy. Approximately 1 in 120 births is complicated by abruption, which is responsible for approximately 20% of perinatal mortality.^{49,50} Hemorrhage may be concealed as the blood can be contained between the uterus and the detached placenta, or it may dissect along the uterine wall and through the cervix and present as vaginal bleeding.⁵⁰ Placental abruption should be suspected in women who present with unexplained vaginal bleeding after the 20th week of gestation, spontaneous preterm labor, premature rupture of membranes, abdominal pain, uterine tenderness, excessive contractions, or fetal distress.⁵¹ Absence of any of these signs or symptoms does not rule out the diagnosis as vaginal bleeding occurs in approximately 80% and uterine pain or tenderness in 66% of patients with abruption.⁵⁰

Risk factors for abruption include maternal hypertension, multiparity, cigarette smoking, drug abuse (specifically cocaine), advanced maternal age, unmarried status, and previous SAB.^{51–53} One study that examined the increasing trends in abruption showed the greatest increase among women under the age of 25, unmarried mothers, and those women on Medicaid.⁵⁴ Another study showed no association between placental abruption and eclampsia, proteinuria, or blood pressure, but abruption was associated with platelet count less than 60,000/mm³ and bleeding.⁴⁹ Although various risk factors may lead to abruption, approximately 70% of cases occur in low-risk pregnancies as a sudden, unpredictable

emergency.⁵² Abruption may also occur secondary to trauma. Placental abruption is responsible for significant complications, including preterm delivery, low birth weight, intrauterine growth retardation, stillbirth, and perinatal death.^{51,52} Unlike placenta previa, abruption is not easily identified with US, which diagnoses only half of all cases. Patients with placental abruptions require continuous fetal monitoring and hospitalization and may need early delivery. Treatment varies with gestational age and maternal and fetal condition.⁵⁰ Maternal hemodynamic instability and coagulopathies can result in cases of severe placental abruptions.

Placenta previa, or implantation of the placenta over the cervical os, accounts for approximately 20% of bleeding in the latter half of pregnancy and results in significant maternal and fetal morbidity and mortality. Risk factors include multiparity, advanced maternal age, history of prior cesarean section, and increasing number of previous abortions.^{55–57} The most common presenting symptom is sudden, painless, bright red vaginal bleeding. Pregnancies complicated by placenta previa are at risk for preterm delivery and hemorrhage that may require transfusion and even hysterectomy.⁵⁷

Digital examination may precipitate severe hemorrhage with placenta previa and is therefore contraindicated. Ultrasound localization of the placenta is thus necessary and has a diagnostic accuracy of 90% to 95%.⁵⁸ Transvaginal sonography is a safe and accurate method of diagnosing placenta previa and is superior to the transabdominal approach.^{59,60} If ultrasound is inconclusive, vaginal examination (if necessary) should be performed in an operating room in case of hemorrhage. Expectant management is the treatment of choice in those preterm patients who are not actively hemorrhaging, while cesarean section is indicated for severe bleeding.⁵⁰

Trauma in Pregnancy

Trauma affects approximately 7% of all pregnancies and is the leading cause of nonobstetric maternal mortality. Severe or nonsevere, trauma has been associated with an increased risk of spontaneous abortion, preterm labor, placental abruption, uterine rupture, stillbirth, and maternal death. Even minor traumas can lead to significant adverse outcomes in pregnancy. Motor vehicle crashes, falls, and assaults, including domestic violence, account for the majority of trauma.^{61,62} While domestic violence is known to be common during pregnancy, it is even more prevalent in the pregnant adolescent population. One study noted that as many as 21% of pregnant adolescents were abused and thus at greater risk for vaginal bleeding, poor weight gain, smoking, and alcohol or drug abuse.⁶³ Various studies have shown an increased risk of injury and adverse outcomes in pregnant adolescents when compared with older pregnant women who have been abused.^{61,64} Screening for domestic violence in all pregnant patients is necessary as domestic abuse is a significant risk factor for repeated injury during pregnancy, with resultant morbidity and mortality.⁶²

Maternal stabilization is the most important aspect in the management of the pregnant patient sustaining trauma. Thus all initial resuscitation efforts should be directed at maternal evaluation and hemodynamic support. The normal physiologic changes of pregnancy—increased blood volume, relative hypotension, tachycardia, tachypnea, respiratory alkalosis, and decreased hematocrit—may make the diagno-

sis of shock more difficult. These changes may allow for a greater loss of blood volume before the clinical signs of hypovolemia are evident. Oxygen and blood volume reconstitution should be provided to patients with even minor trauma. The enlarging uterus of pregnancy compresses the retroperitoneal vasculature when the patient is supine, decreasing venous return. As a result of this recumbent position, cardiac output may be decreased by 25% in the latter portion of pregnancy.⁶⁵ While resuscitating the critically ill patient beyond approximately 20 weeks' gestation, left lateral displacement of the uterus or a 30-degree left lateral tilt should be performed to limit aortocaval compression and optimize venous return. When maternal resuscitation is futile and a viable fetus is present, emergent cesarean section should be considered and performed.

As transplacental hemorrhage (also called fetomaternal hemorrhage) may occur with trauma, the Kleihauer-Betke test is recommended for hemorrhage quantification in patients with abdominal trauma. Some authors suggest the Kleihauer-Betke test is not indicated in the Rh-positive patient.^{62,66} This test has traditionally been used to detect subclinical volumes of hemorrhage to determine the need for prophylaxis against Rh sensitization. The Kleihauer-Betke test has also been studied as an independent predictor of preterm labor in 71 pregnant trauma patients.⁶⁷ Forty-four of 46 women with a positive test also had contractions while none of the 25 patients without contractions had a positive test.⁶⁷ We recommend use of the Kleihauer-Betke test in all cases of suspected transplacental hemorrhage in pregnant trauma patients.

Disposition after maternal trauma varies with the severity of injury and the resulting signs and symptoms. It is recommended that patients beyond 20 weeks' gestation with blunt abdominal trauma be closely monitored with continuous cardiotocography for 4 to 6 hours in the absence of and for 24 hours in the presence of uterine tenderness, preterm labor, abnormal fetal heart rate tracings, vaginal bleeding, and/or significant injury to the mother.^{62,66,68} Development of fetal distress in these situations may necessitate emergency cesarean section.

Rh Immunization

Rh immunization occurs when an Rh-negative mother is exposed to Rh-positive fetal blood during pregnancy or delivery secondary to fetomaternal hemorrhage. When the mother and fetus are ABO compatible, the risk of Rh immunization is 16%, whereas it is only 2% if they are ABO incompatible. This risk of sensitization also occurs with spontaneous and therapeutic abortion, and therefore anti-D immune globulin (RhoGAM) is indicated in all Rh-negative mothers with bleeding during pregnancy. A dose of 50 mcg intramuscularly prior to 12 weeks' gestation, and 300 mcg after 12 weeks' gestation, is indicated.⁶⁹

Medications in Pregnancy

The FDA classifies the teratogenic risk of medications used during pregnancy. Acetaminophen, standard asthma treatments, penicillins, and cardiopulmonary resuscitation drugs are considered safe in pregnancy. For a complete listing, consult a Physician's Desk Reference or the Internet site maintained by the Food and Drug Administration (<http://www.fda.gov>) and the Center for the Evaluation of Risks to

Human Reproduction (<http://cerhr.niehs.nih.gov>). Medications that are commonly used for the complications of pregnancy discussed in this chapter, and their FDA classifications, are listed in Table 91–2.

Summary

Teenage pregnancy presents a unique set of circumstances to the emergency department physician and is often associated with unfavorable pregnancy and birth outcomes. Pregnancy in adolescents is common in all social, economic, and racial groups, although adolescent mothers are more likely to be psychosocially disadvantaged and biologically immature. Both the medical complications and psychosocial concerns should be attended to and addressed, with appropriate social support and referrals provided.

Menstrual Disorders

Sandra H. Schwab, MD and Jill C. Posner, MD, MSCE

Key Points

Pregnancy should be considered first and foremost in any adolescent presenting with a menstrual disorder.

The need for a pelvic examination should be tailored to each individual patient; in many instances, the speculum examination may be omitted.

Dysfunctional uterine bleeding secondary to anovulatory cycles is the most common cause of menorrhagia in adolescents, but it is a diagnosis of exclusion.

Half of all patients with newly diagnosed coagulation disorders present at menarche with heavy vaginal bleeding.

Introduction and Background

In order to understand and diagnose menstrual disorders, a basic understanding of normal pubertal development and the menstrual cycle is essential. The classic method of describing pubertal development is by Sexual Maturity Rating (SMR) or Tanner staging¹ (Table 92–1). There is wide variation in timing of individual development through the stages, but the physiologic changes and physical signs of puberty are predictable at the various stages. Females generally attain menarche at SMR 3 to 4, with 90% menstruating by SMR 4. The average age of menarche in the United States is 12 to 13 years. The normal menstrual cycle lasts 21 to 35 days and with adolescents may be as long as 45 days, with the first day of menstruation marking the beginning of each cycle. Bleeding occurs for 3 to 7 days on average. A normal cycle has between 20 and 40 ml of blood loss, and greater than 80 ml is considered abnormal. In general, changing three to six pads per day without soiling from oversaturation suggests normal flow.² Menstrual disorders and irregular cycles are common in adolescents, especially in the first few years after menarche. The later a female experiences menarche, the longer it takes to achieve normal ovulatory cycles. Menstrual irregularities

constitute a large proportion of female health concerns, beginning in adolescence.³

In addition to the medical aspects of the encounter, the physician should be sensitive to the various emotional and psychosocial stresses that the patient may be facing. This may be the first encounter with a medical professional dealing with the physical and sexual changes that adolescence brings. The clinician must also keep an open mind and allow the patient to express any concerns in a confidential manner. Some adolescents may use menstrual complaints as a way to approach subjects of sexual activity and preference, pregnancy, contraception, fear of sexually transmitted infections (STIs), assault, and various other sensitive topics.

Recognition and Approach

Any patient presenting with menstrual complaints requires a complete menstrual and sexual history. This is best accomplished in private so the patient will feel at ease to disclose any pertinent information (Table 92–2). Most parents will leave the examination room willingly when this is requested by the clinician. In addition, pregnancy testing should be routine for all adolescents with menstrual complaints, even if sexual activity is denied.

Once a history is obtained, the physician can tailor the physical examination to each patient and chief complaint. In addition to the general examination, an examination of the genital area is essential for patients with a menstrual complaint. This may or may not include a speculum examination depending on the individual needs of each patient. A pelvic examination consists of three components: the external genital examination, the bimanual examination, and the speculum examination. Every patient with a menstrual complaint should have an external genital examination. This allows for SMR staging, recognition of external genital abnormalities, and evaluation of the genital tract as the source of the bleeding. The bimanual examination is tolerated by most pubertal females and should be done in the majority of cases. A bimanual examination is indicated in patients with abdominal pain, abdominal mass, vaginal discharge, menorrhagia, suspected foreign body, or known sexual activity. The speculum examination is the most anxiety-provoking portion of the examination for young females. The speculum examination is indicated when it is essential to visualize the cervical os, for example, in patients with an unclear source of bleeding or suspected pregnancy.

Table 92-1 Classification by Sexual Maturity Rating (SMR)

	Breasts	Pubic Hair
SMR 1	No development	Vellous hair
SMR 2	Small buds	Sparse, straight, downy hair
SMR 3	Areolas and breasts enlarged, no separation	Sparse, dark, coarse hair
SMR 4	Elevation of areolas, secondary mounds	Dark, coarse, adult-type hair but decreased
SMR 5	Mature female breasts	Inverse triangle, spread to medial thighs

Table 92-2 Adolescent Menstrual and Sexual History

History of Present Illness
Last menstrual period
Irregular bleeding
Amount of bleeding

Hirsutism
Abbreviations: IUD, intrauterine device; OCPs, oral contraceptive pills.

It is also indicated if cervical cultures are needed to rule out STIs. Recent advances in the ability to detect chlamydia and gonorrhea in the urine via nucleic acid testing negate the need for the speculum examination in a majority of patients with abnormal vaginal bleeding. Therefore, a clinician may opt to defer this examination if no additional information will be gained from direct visualization of the vaginal walls or cervix. It is imperative that a speculum examination be performed for pregnant adolescents and children with vaginal bleeding, but the clinician should consider obtaining an ultrasound prior to a speculum examination, especially in patients suspected of being beyond the first trimester of pregnancy.

Table 92-3 Differential Diagnosis of Amenorrhea

Genetic Abnormalities
Turner syndrome

Selected Diagnoses

Primary amenorrhea
 Secondary amenorrhea
 Oligomenorrhea
 Dysmenorrhea
 Metorrhagia
 Menorrhagia
 Premenstrual syndrome

Discussion of Individual Diagnoses

Primary Amenorrhea

Primary amenorrhea is defined as failure to reach menarche by age 16 when development of secondary sexual characteristics is evident, or by age 14 when no secondary sexual characteristics are present. There are three broad categories to describe causes of amenorrhea: genetic etiologies, structural and developmental abnormalities, and alteration of growth and sexual hormonal axes (Table 92-3). It is estimated that genetic and developmental disorders account for 60% of primary amenorrhea cases, while the remaining 40% are due to endocrine and hormonal causes.⁴

After exclusion of pregnancy and pregnancy-related disorders, a detailed history and physical will guide additional

diagnostic and therapeutic interventions. Constitutional delay is hereditary, and a family history with otherwise negative findings is suggestive. Long-standing problems with growth and development suggest a genetic abnormality such as Turner's syndrome or hypothalamic or pituitary pathology. A history of cyclic abdominal pain would suggest a vaginal outlet obstruction such as imperforate hymen or vaginal septum, especially if there is a discrepancy between the patient's advanced pubertal development (i.e., SMR staging) and the apparent absence of menarche. The general physical examination provides information about body habitus and growth. Eating disorders affect as many as 1% of young women in developing countries, and often present with menstrual irregularity or amenorrhea in adolescence.⁵ Hirsutism, severe acne, and signs of systemic disease such as acanthosis nigricans or thyroid enlargement should be noted. A thorough neurologic examination might reveal central nervous system (CNS) pathology. Development of secondary sexual characteristics and/or signs of virilization should be noted on the external genital examination.

The emergency physician should ensure that serious or life-threatening causes or complications of an underlying disorder are not present. Laboratory tests such as blood glucose, serum chemistries, complete blood count, and thyroid studies should be considered. An electrocardiogram should be performed for patients with suspected anorexia nervosa because of the potential for arrhythmias related to electrolyte disturbances. Imaging such as a computed tomography (CT) scan of the head or magnetic resonance imaging (MRI) should be done if a CNS tumor is suspected. A pelvic ultrasound or MRI will aid in diagnosis and treatment of underlying structural or developmental abnormalities. Physicians should consider hospital admission for further workup in patients with abnormal screening tests.

Many of the causes of primary amenorrhea require a comprehensive diagnostic evaluation that may involve subspecialists and a multidisciplinary team approach. This is best coordinated by a primary care physician, and can be done in the outpatient setting. Appropriate follow-up should be arranged prior to discharge from the emergency department.

Secondary Amenorrhea

Secondary amenorrhea is strictly defined as absence of menstruation for greater than 6 months after menarche. Some practitioners use absence of menstruation for three cycle lengths in the setting of oligomenorrhea, 6 months after establishing regular menses, or by 18 months after menarche as a working clinical definition.⁶ Excluding the genetic and developmental etiologies, many of the causes of primary amenorrhea can also present as secondary amenorrhea. Again, pregnancy should be excluded at the onset of evaluation. Unlike adults, in whom the most common cause of secondary amenorrhea is pregnancy, immaturity or disruption of the normal hypothalamic-pituitary-ovarian axis is the most common cause in adolescents. Many adolescent girls have anovulatory cycles due to this physiologic immaturity of the hypothalamic-pituitary-ovarian axis. Most girls with anovulatory cycles experience an absence of regular monthly bleeding or irregular periods, though some will develop menorrhagia (see section on menorrhagia for details). Polycystic ovarian syndrome is another common cause of

secondary amenorrhea and may account for up to a third of menstrual irregularities in young females.⁷ The clinical manifestations, such as obesity, hirsutism, acne, and irregular menstrual cycles, are a result of the hyperandrogenic state and ovarian dysfunction that are hallmarks of the disease. Specific questions addressing eating habits, current medications, and contraception can narrow the differential diagnosis in females with previously normal cycles.

The physical examination and diagnostic workup can be tailored to each individual case. As with primary amenorrhea, the emergency physician should ensure that any serious or life-threatening causes or complications are identified. The remainder of the workup, such as a progesterone challenge and measurement of the various sex hormone levels, should be done on an outpatient basis with the primary physician coordinating care with any necessary subspecialists.

Oligomenorrhea

Oligomenorrhea is defined as menstrual cycle length of greater than 35 days. The various causes of secondary amenorrhea may first present as oligomenorrhea. Like secondary amenorrhea, a common cause of oligomenorrhea in adolescents is a hyperandrogenic state secondary to polycystic ovarian disease.⁸ The approach to the patient with oligomenorrhea is the same as with secondary amenorrhea. After ruling out pregnancy and other serious and life-threatening causes and complications, the emergency physician should ensure proper follow-up. The majority of the diagnostic workup and treatment are best done in the outpatient setting with a primary physician coordinating care.

Dysmenorrhea

Dysmenorrhea is defined as cyclic abdominal pain and uterine cramping associated with ovulatory menstrual cycles. It is the most common gynecologic complaint and the leading cause of school and work absenteeism among young women.^{9,10} In the absence of underlying organic pathology, it is considered primary dysmenorrhea. If pelvic pathology such as endometriosis is present, secondary dysmenorrhea is diagnosed. Nausea, vomiting, back pain, headaches, and leg pain are common associated symptoms. The vast majority of adolescents with dysmenorrhea have primary dysmenorrhea, with prevalence rates greater than 90% in some studies.^{11,12}

Primary dysmenorrhea varies widely among females and ranges from mild, without any disruption of daily living, to severe, causing absence from school or work. Symptoms begin just prior to or at the onset of menstruation and typically last 1 to 2 days. The pain is bilateral and colicky in nature, and resolves with the end of menstruation. If the patient's presentation is consistent with primary dysmenorrhea, little additional workup needs to be done. The complete pelvic examination may be deferred, and no laboratory studies are required. If the presentation is atypical, the physician should consider other causes of abdominal pain and vaginal bleeding, especially potentially life-threatening disorders related to pregnancy, such as ectopic pregnancy, spontaneous abortion, or placenta previa/abruption. Other possibilities to consider include ovarian cysts, endometriosis, pelvic neoplasms, and gastrointestinal disease.^{13,14} Sexual

assault and its lasting physical and emotional consequences should also be considered, as gynecologic complaints such as dysmenorrhea are more common among victims with such a history.¹⁵

Nonpharmacologic alternative and traditional medical therapies are commonly used by patients. Adolescents report using a wide range of nonpharmacologic treatments such as rest, heat, exercise, and even alcohol or illegal drugs for relief of symptoms.¹² Other reported treatments include acupuncture, spinal manipulation, electromagnetic therapy, vitamin and herbal supplements, and dietary changes. Many of these treatments are based on anecdotal accounts and have not been shown to consistently relieve dysmenorrhea in randomized clinical trials.¹⁶

The first line of medical therapy for treatment of dysmenorrhea is the use of analgesic and anti-inflammatory medications such as nonsteroidal anti-inflammatory drugs (NSAIDs). Multiple studies have shown the effectiveness and safety of this group as a whole, even with over-the-counter dosing. Naproxen may provide faster, more effective relief of symptoms than ibuprofen or acetaminophen.¹⁷ For patients with more severe symptoms, oral contraceptives, taken for at least 3 months, have shown significant reduction in incidence and severity of symptoms.¹⁸ Topical glyceryl trinitrate ointment has shown some promising results, but continues to be under investigation.¹⁹

Metrorrhagia

Metrorrhagia is abnormal bleeding between regular menstrual periods. Few data exist on the prevalence of metrorrhagia in adolescents. Common causes of metrorrhagia include pregnancy, use of certain contraceptives (especially Depo-Provera) and intrauterine devices, and STIs. Other causes include coagulation disorders, genital trauma, neoplasms, and infections such as tuberculosis. The history should include questions focusing on these etiologies, specifically addressing accompanying symptoms such as abdominal pain and vaginal discharge. A complete pelvic examination, including a speculum examination, should be considered when other symptoms are present.

Diagnostic testing and treatment depend on the etiology of the metrorrhagia. As with any other menstrual complaint, pregnancy should be ruled out at the onset of evaluation. Breakthrough bleeding with initiation of Depo-Provera is common, and reassurance is sufficient in the absence of other symptoms. The clinician should consider screening tests for STIs even if sexual activity is denied due to the potential for serious lifelong complications if untreated. Other tests, such as coagulation studies, pelvic ultrasound, or abdominal/pelvic CT scan, should be considered on an individual basis.

Menorrhagia

Menorrhagia is defined as excessive bleeding (>80 ml) or prolonged bleeding (>7 days) during the menstrual cycle. Menorrhagia is more common among adolescents than adults and is frequently diagnosed in the first few years after menarche. The most common causes of menorrhagia in adolescents are anovulatory cycles and cervicitis due to STIs. Other causes of menorrhagia include pregnancy-related disorders, hematologic disorders, trauma, systemic disease, and, rarely, neoplasms²⁰ (Table 92–4). Dysfunctional uterine

Table 92–4 Causes of Abnormal Vaginal Bleeding

Anovulation

- Hypothalamic dysfunction
- Polycystic ovarian syndrome
- Breakthrough bleeding secondary to hormonal contraception
- Physiologic immaturity of the hypothalamic-pituitary-ovarian axis

Infectious Causes

- Pelvic inflammatory disease
- Vaginitis
- Cervicitis

Pregnancy-Related Conditions

- Ectopic pregnancy
- Threatened or spontaneous abortion
- Complications of termination procedures

Coagulation Disorders

- Thrombocytopenia (idiopathic thrombocytopenic purpura, leukemia)
- Platelet function disorders (von Willebrand's disease)
- Clotting factor abnormalities
- Anticoagulation medications

Trauma

- Accidental injury
- Coital trauma
- Sexual abuse
- Foreign body

Neoplasms

- Vaginal tumor
- Cervical carcinoma
- Uterine myoma
- Ovarian tumor
- Uterine carcinoma
- Polyyps

Systemic Diseases

- Hepatic dysfunction
- Renal dysfunction
- Diabetes mellitus

Endocrine Causes

- Thyroid disease
- Prolactinoma
- Adrenal disease

bleeding (DUB) is a specific type of menorrhagia defined as excessive bleeding in the absence of organic pathology or systemic disease. DUB is a diagnosis of exclusion, and the clinician should use this term only if other causes have been ruled out.

Anovulatory cycles are most common in the first years after menarche and are due to immaturity of the hypothalamic-pituitary-ovarian hormonal axis. In anovulatory cycles, the second half of the normal menstrual cycle (i.e., the luteal phase) does not occur. As a result, the follicular phase continues and the uterine lining is subjected to unopposed estrogen stimulation. When unopposed by luteal-phase progesterone, estrogen overstimulation causes the uterine lining to proliferate beyond the supporting capabilities of the stroma. Eventually, erratic sloughing of the lining occurs and, in some areas, the basal arterioles are exposed, resulting in heavy bleeding.

Coagulation disorders account for 3% to 33% of hospitalized adolescents with abnormal vaginal bleeding.^{21–23} In one

series, 50% of patients with newly diagnosed coagulation disorders presented at menarche.²¹ A case-control study in one center revealed that 5 of 38 patients (13%) given an initial diagnosis of DUB were later diagnosed with von Willebrand's disease.²⁴

Although exact amounts of blood loss are difficult to assess, patients may give a history of soaking through multiple pads, clothing, and bedding. In addition to excessive bleeding, patients may present with symptoms and signs of anemia such as fatigue, shortness of breath, and pallor. In extreme cases, patients may present in hypovolemic shock with hypotension and severe anemia secondary to blood loss.

The physical examination, laboratory evaluation, and treatment depend on the etiology and severity of the bleeding. For unstable, actively bleeding patients, resuscitation should begin immediately with securing the airway, breathing, and circulation; establishing vascular access; and providing volume resuscitation as well as transfusion of blood products if necessary. Packing the vagina with sterile gauze may be necessary to stop acute hemorrhage. A pregnancy test is again essential. Serum specimens for a complete blood count, coagulation studies, and type and crossmatch should be sent. After stabilization, a complete pelvic examination, including speculum examination, to evaluate the origin of the bleeding is necessary. Further evaluation, such as ultrasound, STI testing and hematologic workup, may be necessary. Immediate consultation with a gynecologist, preferably one with experience treating adolescent patients, is recommended. Other consultants who may be required for definitive care, depending on the situation, are endocrinologists, adolescent medicine specialists, and pediatric surgeons. If these resources are unavailable, the patient should be transported to a facility that can provide such services after stabilization. For hemodynamically stable patients, a tailored physical examination, pregnancy test, complete blood count, and STI screening should be included in the initial evaluation.

Treatment should be directed at the underlying cause of vaginal bleeding. If no cause is identified, a diagnosis of DUB is made. Treatment of DUB depends on the severity of bleeding and whether the patient is symptomatic. For asymptomatic patients with mild DUB and normal hemoglobin (Hb), high-dose NSAIDs and iron supplementation can be initiated. Reassurance and follow-up should be emphasized.

For those patients who are symptomatic or anemic (Hb < 12), or have active hemorrhage, hormonal therapy is indicated. Treatment is directed at restoring a normal uterine lining, including the denuded areas of exposed basal arterioles, and requires both estrogen and progesterone in most cases. Oral and intravenous regimens are effective in stopping acute bleeding.^{25,26} Intravenous conjugated estrogen (20 to 25 mg every 4 to 6 hours, maximum of six doses) can be used as initial therapy for unstable patients requiring inpatient treatment. Low dose oral contraceptive pills (OCPs) with combined norethindrone/ethinyl estradiol (30 mcg/0.3 mg) may be used alternatively, and should be initiated as soon as possible in patients receiving intravenous therapy. A simple regimen to remember is 1 pill every 6 hours until bleeding stops, followed by a taper of 1 pill four times daily for 4 days, then 1 pill three times daily for 3 days, and 1 pill twice daily for weeks. Then, after a 7-day OCP-free period

(placebo pills) and withdrawal bleeding, 1 pill daily on a normal OCP schedule for an additional six cycles is recommended.²⁷ It is important to prescribe antiemetics for patients taking more than one OCP per day due to the high incidence of nausea and vomiting with this regimen. For patients in whom estrogen is contraindicated, cyclic oral medroxyprogesterone (10 mg daily for 10 days, repeated monthly for three to six cycles starting on day 14 of the cycle) can be used. Admission should be considered for symptomatic patients, those with active heavy bleeding, and those with moderate to severe anemia (Hb < 9). Re-evaluation with a primary care provider is necessary to determine if additional therapy is needed.

Premenstrual Syndrome

Premenstrual syndrome (PMS) is a collection of physical and emotional changes that occur in the luteal phase (second half) of the menstrual cycle. Eighty percent of women have some premenstrual symptoms, although most do not have alterations in their daily living. There is now recognition of a wide clinical spectrum of these premenstrual symptoms, with the most severe symptoms being classified as premenstrual dysphoric disorder (PMDD). PMDD is considered a "Depressive Disorder Not Otherwise Specified" in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV). Severe PMS and PMDD affect 3% to 8% of menstruating women.²⁸⁻³⁰

Symptoms begin after ovulation, around day 14 of an average cycle, and continue until menstruation. There is a symptom-free period during the follicular phase of the cycle. PMS includes physical changes such as breast tenderness, bloating, headaches, and extremity edema. In addition, most affected females report significant emotional changes such as irritability, mood swings, anxiety, social withdrawal, and, in most severe cases, major depression.

In order to diagnose PMS or PMDD, it is recommended that a prospective symptom diary be completed by the patient.³¹ This will allow the clinician to determine if a symptom-free period exists after menstruation. If there are continued symptoms throughout the entire menstrual cycle, a mood disorder exacerbated by hormonal changes is more likely.

Selective serotonin reuptake inhibitors are the mainstay of treatment for moderate to severe PMS and PMDD. Treatment may be continuous or intermittent depending on tolerance of the medications and severity of symptoms. Patients with PMS and PMDD usually begin to note changes within 3 days of starting medication, unlike patients with mood disorders, in whom 4 to 6 weeks are needed to see effects. These medications are more appropriately instituted by a continuing care physician, with prompt referral made at the time of emergency department disposition.

For minor symptoms, a variety of therapies ranging from herbal and complementary treatments to vitamin supplements and OCPs have been tried. Many of these are based on anecdotal evidence and show conflicting results in scientific trials.^{32,33} Some studies have shown benefits of daily vitamin B₆ (50 to 100 mg) and calcium carbonate (1200 mg) supplementation.³⁰ Some therapies such as exercise, dietary changes, and weight control have not been shown to unequivocally help with PMS symptoms, but are recommended for good general health and are relatively risk free.³²

Ovarian Disorders

Beverly H. Bauman, MD and Robert L. Cloutier, MD

Key Points

The prompt and accurate diagnosis of pediatric ovarian disorders can be challenging because symptoms are often nonspecific, physical examination is difficult, and the differential diagnosis includes many common gastrointestinal and genitourinary emergencies.

The possibility of a pediatric ovarian disorder should be considered when evaluating a female pediatric patient across a wide variety of chief complaints, such as abdominal pain, vomiting, and lower abdominal mass.

Color flow Doppler ultrasound is the most useful diagnostic study in the evaluation of pediatric ovarian disorders.

Ovarian torsion is a surgical emergency that requires rapid consultation with a surgeon or gynecologist to relieve pain and attempt salvage of the ovary.

Selected Diagnoses

- Ovarian cysts
- Mittelschmerz
- Ovarian neoplasm
- Ovarian and adnexal torsion
- Polycystic ovarian syndrome

Discussion of Individual Diagnoses

Ovarian Cysts

Ovarian cysts may occur in all age groups and are very frequently seen in adolescents after the onset of menarche. Most neonates also have small cysts, which develop in response to maternal hormones.^{1,2} The majority of ovarian cysts are painless and are incidental findings when patients undergo an ultrasound of the abdomen or pelvis for the evaluation of another condition. However, large functional ovarian cysts may also be the source of pain or hemorrhage that can prompt

a child or adolescent to present to the emergency department for evaluation and treatment. Ovarian cysts also predispose to ovarian torsion, an important surgical emergency.^{3,4}

There are two types of physiologic or functional ovarian cysts: follicular and corpus luteum cysts. Follicular cysts are the result of a functioning hypothalamic-pituitary-ovarian axis. During the menstrual cycle, when primordial follicles are stimulated by follicle-stimulating hormone, one primordial follicle develops into a dominant follicle prior to ovulation. This dominant follicle is normally a small simple fluid-filled follicular cyst. Once ovulation occurs, the dominant follicle becomes a corpus luteum cyst. Occasionally the follicular cyst will grow excessively large in response to hormonal stimulation and will fail to quickly involute after ovulation. This large follicular cyst can produce symptoms of unilateral pelvic pain or heaviness. The corpus luteum cyst may likewise become symptomatic if it becomes a larger mass and hemorrhages into the cyst.

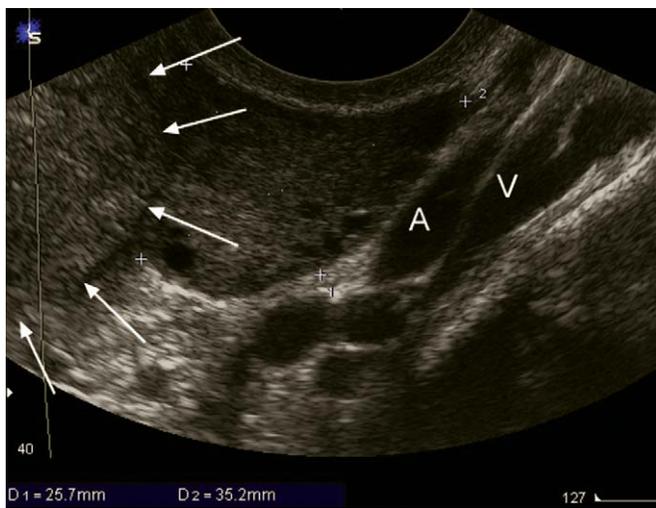

In the emergency department, ovarian cysts are frequently diagnosed by ultrasound imaging (Fig. 93–1). When a large follicular cyst is diagnosed, it should be followed over several weeks to ensure that it resolves and does not enlarge further.⁵ The majority of these cysts will resolve without sequelae. Oral contraceptives may be prescribed to prevent ovulation and the formation of further new cysts while the cyst in question is being monitored. Oral contraceptives will not cause resorption or resolution of the current cyst.

When a large follicular or corpus luteum cyst ruptures acutely into the peritoneal cavity, it may cause considerable pain from transient irritation and peritonitis. Free fluid will be seen on ultrasound of the pelvis. Rarely the rupture of a cyst may cause considerable intraperitoneal bleeding if the rupturing cyst crosses a large vessel. If the hemorrhage is significant, serial hemotocrits and monitoring for hemodynamic instability may be necessary. Rarely, severe hemorrhage from a ruptured cyst necessitates surgical intervention.

Ovarian cysts predisposing to torsion in younger children do occur and require vigilance on the part of practitioners due to the wide variability of clinical presentations; this is discussed later.

Mittelschmerz

During ovulation, the follicular cyst ruptures and can release a small amount of free intraperitoneal fluid. This fluid may be irritating to the peritoneum and cause acute unilateral

A

B

FIGURE 93-1. Endovaginal images of a normal ovary (**A**) and one with several abnormally large cysts (**B**) (calipers in both cases). **A**, The ovarian parenchyma is typically slightly less echodense (darker) than the adjacent uterus (outlined by arrows). The ovary is often found between the uterus and the internal iliac vessels (A and V). Normal ovarian follicles are usually defined as being less than 10 mm in diameter; when larger than this, they are referred to as “cysts.” Many larger cysts are part of the normal ovulatory cycle. More than 14, and up to more than 30, follicles in an ovary have been advocated as the criterion for polycystic ovarian syndrome. The follicles are often arrayed around the periphery of the ovary with the appearance of a “string of pearls” (not shown). **B**, An ovary with multiple large cysts, including one with internal hemorrhage as suggested by a fluid-fluid level (arrows), is shown. The reticular heterogeneity of the clot suggests that it has been present for long enough to be partially organized. Cysts can cause acute pain from internal hemorrhage, external hemorrhage, or torsion.

lower abdominal or pelvic pain, which is called *mittelschmerz*. This condition is benign, and treatment is directed at control of symptoms. However, emergency providers will need to consider other more serious causes of acute pelvic pain prior to making the diagnosis of *mittelschmerz*. *Mittelschmerz* pain is a postmenarchal phenomenon and presents in a fashion similar to that in adult females.

Ovarian Neoplasms

Benign or malignant ovarian neoplasms are uncommon in the pediatric age range, yet an ovarian tumor may occasionally explain signs and symptoms for which a patient presents to the emergency department.⁵ Complaints may be acute or chronic abdominal pain, abdominal distention, anorexia, weight change, back pain, or bowel or bladder dysfunction. Because ovarian tumors may be large, the physical appearance of an adolescent with an ovarian tumor may resemble pregnancy. Some hormonally active ovarian tumors can cause signs of precocious puberty in a child.^{5,6} If the neoplasm is complicated by ovarian torsion, the pain may be acute and severe.³

The ovary consists of three types of cells: oocytes, follicular cells, and the supporting stromal cells. Benign or malignant ovarian tumors may arise from any of these three cell types. While there are numerous classification schemes for ovarian tumors, fundamentally there exist three general types: (1) epithelial cell tumors, (2) germ cell tumors, and (3) metastatic tumors. The vast majority of pediatric ovarian masses are germ cell tumors, which include dermoid tumors (which fall under the subclassification of teratomas), yolk sac tumors, and choriocarcinoma. Dermoid tumors tend to be benign and are characterized by multiple tissue types within the tumor, and frequently include calcified tissues that show up on abdominal plain films.⁶

Ultrasound findings that indicate the possibility of an ovarian tumor include a solid mass, a complex mass, or a large cyst that does not resolve under surveillance over 6 to 10 weeks. If the emergency physician identifies an ovarian mass, prompt consultation with a gynecologist or pediatric surgeon is indicated for further workup and treatment of a suspected ovarian neoplasm.

Ovarian and Adnexal Torsion

Ovarian and adnexal torsion is the twisting of the ovary on its pedicle. Ovarian enlargement with cysts or benign or malignant masses, predisposes to ovarian torsion, yet torsion has also been described in normal-appearing ovaries.⁷ With torsion, the ovarian blood supply is compromised by the twisted vascular pedicle, and this results in acute pain from ovarian ischemia. This constitutes a surgical emergency to promptly relieve the pain and attempt to preserve ovarian perfusion and prevent ovarian necrosis.⁸ Therefore, immediate consultation with gynecologic or surgical colleagues is essential when the diagnosis is made or highly suspected.

Although ovarian torsion is rare in infants and children, it may occur in females of all ages and has even been described in female fetuses antenatally.⁷ However, torsion is much more common after menarche because large ovarian cysts produced during the menstrual cycle can predispose to torsion. Diagnosis can be challenging because the presenting signs and symptoms mimic other more common causes of abdominal pain.⁹⁻¹¹ The classic presentation is the sudden onset of severe, focal, constant, unilateral lower abdominal and pelvic pain, which may be associated with nausea, vomiting, or urinary tract symptoms. However, the pain may also be described as a dull ache and radiate to the flank or leg. The pain may have intermittent exacerbations if the ovary torses and then detorses spontaneously.⁸ Physical examination may reveal a palpable painful pelvic or abdominal mass if the

torsion is associated with a large ovarian mass. In prepubertal females, the ovarian mass associated with torsion is frequently located within the abdominal cavity, but in pubertal females, the ovarian mass is typically within the pelvis. The white blood cell count is commonly elevated in pediatric patients with ovarian torsion, and this can confuse the clinician when considering other causes of abdominal and pelvic pain related to infections, such as appendicitis, tubo-ovarian abscess, or pelvic inflammatory disease.^{8,9,12}

Color flow Doppler ultrasound is a very useful test to evaluate for an ovarian mass and to visualize blood flow to the ovary and adnexa. If blood flow is abnormal within the vascular pedicle, then perfusion to the ovary is decreased, yet even this test can produce false-negative results.¹³⁻¹⁵ If the clinician continues to suspect ovarian torsion after color flow Doppler ultrasound, surgical consultation for laparoscopic visualization may still be needed to diagnose torsion. With laparoscopy, surgeons may attempt to salvage the ovary through detorsion or perform salpingoophorectomy if necrosis has already occurred.¹⁶ Recent data suggest that salvage rates may be as high as 27% and that ovaries may be salvageable up to 24 hours after onset of symptoms.¹⁷

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome is a common chronic endocrine disorder that causes menstrual irregularities in adolescents. Increased ovarian androgen production results in hirsutism. Most of these adolescents are obese and have oligomenorrhea. Ultrasound reveals multiple small follicles on the ovarian periphery, which is often described as the appearance of a “string of pearls.” While patients are not likely to present to the emergency department with acute symptoms related to polycystic ovarian syndrome, emergency providers should be aware of this common condition that may be discovered during the evaluation of other conditions.

Chapter 94

Vaginal and Urethral Disorders

Beverly H. Bauman, MD, and Robert L. Cloutier, MD

Key Points

In the neonatal period and 6 to 12 months before menarche, girls will have a normal white mucoid discharge (physiologic leukorrhea) that does not require evaluation or treatment.

Labial agglutination is a common perineal finding in infants and toddlers. It is not urgent or even necessary to separate the labial skin unless there is obstruction to urinary flow.

Congenital obstruction to vaginal flow may not be detected in the newborn nursery and may present during adolescence with primary amenorrhea and abdominal pain.

Urethral prolapse is an uncommon cause of perineal bleeding in prepubertal girls and is frequently misdiagnosed on initial presentation.

maternal estrogen transplacentally prior to birth, and for several weeks after delivery her hymen and vagina will show the effects of estrogen. The hymen appears pale, thickened, and redundant and the vagina secretes a normal mucoid discharge. The endometrium in the uterus of a neonate also responds to maternal estrogen, and after birth a small amount of vaginal bleeding can sometimes be seen from estrogen withdrawal. Six to 12 months prior to the onset of menarche, physiologic leukorrhea will again appear in response to the young adolescent's increased levels of estrogen. No treatment except reassurance is needed for physiologic leukorrhea and neonatal withdrawal bleeding.

Pathologic vaginal discharge and inflammation (vaginitis) is much more common in postmenarchal adolescents and adults than in the pediatric age range (see Chapter 70, Sexually Transmitted Infections). If the inflammation includes the vulva, it is termed *vulvovaginitis*. Pediatric patients may complain of pruritis, perineal pain, and dysuria.^{1,2} Reduced levels of estrogen and the more alkaline pH of the vagina in premenarchal girls are two important reasons why the prevalence, etiology, and presentation of vaginitis is different in premenarcheal girls than postmenarchal adolescents and adults. After puberty, the vagina changes in response to estrogen and the normal flora has a greater amount of *Lactobacillus* species.

In premenarchal girls, the etiology of vaginitis and vulvovaginitis may be local irritation, poor hygiene, and a variety of bacterial, viral, helminthic, or protozoal infections. The majority of cases of premenarchal vulvovaginitis are not caused by an infection, yet when the patient has a visible vaginal discharge, there is a higher likelihood of a specific infectious cause.^{1,2} Workup includes a careful history and physical examination with consideration for the risk of a sexually transmitted infection (from sexual abuse). If a discharge is present, workup includes culture, wet mount, and potassium hydroxide preparation. These studies will help guide specific therapy when it is indicated and help avoid unnecessary antibiotics for nonspecific vaginitis. Nonspecific vaginitis and vulvovaginitis may be precipitated by poor local hygiene or spread of enteric organisms from the rectum to the vulvar and vaginal areas. Irritation from bubble baths or soaps, vaginal foreign bodies, and viruses and bacteria from upper respiratory tract infections can also cause nonspecific vaginitis. Based on the findings from history and physical examination, treatment for nonspecific vaginitis may include removal of a vaginal foreign body, improved

Selected Diagnoses

- Vaginal discharge and vaginitis
- Vaginal foreign body
- Labial adhesion (labial agglutination)
- Vaginal outflow obstruction
- Bartholin's duct cyst and abscess
- Urethral prolapse
- Urethritis

Discussion of Individual Diagnoses

Vaginal Discharge and Vaginitis

Staining discovered on the undergarments or diapers of infants and children presumed to be from vaginal discharge or bleeding may prompt an emergency department evaluation. However, in neonates and premenarchal young adolescents, not all types of vaginal discharge are pathologic. Estrogen effects on the vagina cause physiologic leukorrhea, a white or clear mucoid discharge. A newborn acquires

perineal hygiene, teaching a child to wipe her perineum from the front to the back after using the toilet, avoidance of irritating bubble bath products and soaps, and avoidance of tight-fitting pants.

Candidal vaginitis is common in adolescents and adults, yet uncommon in children. Diagnosis is by microscopy of the discharge with potassium hydroxide preparation. If candidal vaginitis is seen in a child, it may be related to recent broad-spectrum antibiotic use, immunosuppression, or diabetes. Treatment is with topical or oral antifungal agents.³ Common causes of bacterial vaginitis in children include several types of streptococcus and *Staphylococcus aureus* and coagulase-negative staphylococci. Gram-negative organisms have also been cultured from children with vaginitis.^{1,2,4} Pinworms (*Enterobius vermicularis*) can migrate from the rectum to the vagina, also resulting in vaginitis. These parasites lay their ova at night on the perirectal skin, which can be detected using the “tape test” (cellophane tape pressed to the perineum) to collect the ova for diagnosis by microscopy. One study found a significant number of unsuspected cases of *Neisseria gonorrhoeae* in children with a vaginal discharge and concluded that cultures for gonococcus should be included in routine bacterial cultures for children with a discharge² (see Chapter 70, Sexually Transmitted Infections; and Chapter 118, Sexual Abuse).

After the first few weeks of life, when a neonate may have estrogen withdrawal bleeding, vaginal bleeding in prepubertal children mandates a thorough evaluation to rule out potentially serious causes such as a malignant tumor or trauma. Less worrisome causes of bleeding from the genital area that may present as vaginal bleeding include precocious puberty, vulvovaginitis, hemangioma, vaginal foreign body, urethral prolapse, hematuria, and lichen sclerosus, which is an uncommon chronic pruritic inflammatory skin disease of the perineum and perianal area.⁵ The examination to determine the source of the vaginal bleeding may require monitored sedation or general anesthesia because the hymen of a prepubertal child is very sensitive.

Vaginal Foreign Body

A vaginal foreign body should be considered in the differential diagnosis of a child presenting with persistent vaginal drainage or bleeding, although it is an uncommon finding.^{1,6} A wad of toilet paper is one of the most common vaginal foreign bodies in children,⁶ while a retained tampon is a common vaginal foreign body in adolescents. Visualization of the vaginal foreign body may be easiest with the child in the knee-chest position. If the foreign body is large, it might be palpable with a rectal examination. Techniques to remove the foreign body include gentle irrigation with saline using a small catheter and gentle extraction with forceps. Monitored sedation or general anesthesia may be needed in prepubertal girls when attempting vaginal foreign body removal.⁶

Labial Adhesions (Labial Agglutination)

Fusion of the labia minora is a common condition in infants and toddlers that may be found incidentally on examination or during attempts to perform urinary catheterization.⁷ The delicate skin of the labia minora can be easily irritated and inflamed from mild local trauma, harsh soaps, or soiled diaper contents. Upon healing, the labial surfaces may become fused to one another, resulting in labial agglutina-

tion. Usually the adhesions start in the area of the posterior forchette and slowly advance towards the clitoris. This fusion may prevent visualization of the hymen and urethral opening (Fig. 94–1).

Most young children are asymptomatic with labial adhesions, and therefore treatment is not routinely necessary. The adhesions may spontaneously resolve or resolve later around puberty with endogenous estrogen. However, if the patient has dysuria or if the parents have a preference to treat the condition, it can be managed with a several-week course of once- or twice-daily application of topical 0.1% conjugated estrogen cream (Premarin cream). Potential side effects from systemic absorption of topical estrogen cream include breast tenderness. Therefore, parents should be cautioned to avoid excessive use of the topical estrogen cream and discontinue its use after the adhesions have resolved. Following successful labial separation, the application of petrolatum jelly to the labial area at night for several weeks can help prevent recurrence of adhesions. Routine rapid forceful separation of the adhesions is discouraged because it is painful and will likely result in bleeding. If the labial adhesions cause urinary obstruction, topical lidocaine may be used to decrease the pain of manual separation in the emergency department, yet the procedure is still likely to be painful, so systemic analgesics are advised.^{7,8}

Vaginal Outflow Obstruction

Several congenital anomalies may cause obstruction to vaginal outflow. The most common causes of vaginal outflow

FIGURE 94–1. Labial adhesions. (From Rink R, Kaefer M: Surgical management of intersexuality, cloacal malformation, and other abnormalities of the genitalia in girls. In Wein A (ed): Campbell-Walsh Urology, 9th ed. Philadelphia: WB Saunders, 2007.)

obstruction are imperforate hymen and a transverse vaginal septum. Although these conditions are present at birth, the diagnosis may be easily missed during the newborn examination because of the small size of the newborn perineum and the thick and redundant state of the newborn hymen under the effect of maternal estrogen. A female infant may present to the emergency department with mucocolpos (the distention of the vagina from the collection of vaginal secretions) or hematocolpos (the distention of the vagina from endometrial blood) related to withdrawal from maternal estrogen. If the diagnosis of vaginal obstruction is not made in the newborn period, the fluid will be reabsorbed and the patient usually remains asymptomatic until puberty, when menstrual blood accumulates proximal to the obstruction. Family history may be helpful in arriving at the diagnosis of imperforate hymen because some families demonstrate an inheritance pattern consistent with either a dominant or recessive mode of genetic transmission.⁹

Signs and symptoms related to vaginal outflow obstruction in postmenarchal girls include primary amenorrhea, pelvic or abdominal pain that may or may not be cyclical, and difficulties with urination or defecation related to distention of the vagina. Physical examination may reveal a lower abdominal or pelvic mass (hydrometrocolpos). The hymen may be bulging and have a bluish discoloration if the etiology of obstruction is an imperforate hymen (Fig. 94–2). If the cause of the vaginal outflow obstruction is located higher in the vagina, such as from a high transverse vaginal septum, the hymen may have a normal appearance.

In the emergency department, urinary retention caused by the distended vagina can be temporarily treated with a

FIGURE 94–2. Imperforate hymen. (From Rink R, Kaefer M: Surgical management of intersexuality, cloacal malformation, and other abnormalities of the genitalia in girls. In Wein A (ed): Campbell-Walsh Urology, 9th ed. Philadelphia: WB Saunders, 2007.)

urinary catheter. Definitive treatment of the vaginal outflow obstruction will require surgical repair by a consulting gynecologist or pediatric surgeon. Transabdominal ultrasound provides useful anatomic information to aid in specific diagnosis and assist the surgeon or gynecologist in preoperative evaluation.¹⁰

Bartholin's Duct Cyst and Abscess

Disorders related to Bartholin's duct and glands may present at puberty when the gland starts secreting fluid into the vaginal vestibule. The two Bartholin's glands are located at approximately the 4 o'clock and 8 o'clock positions of the labia minora when a female is examined in the dorsal lithotomy position. These pea-sized glands drain through ducts into the vaginal vestibule, near the hymenal ring. Cysts and abscesses of the duct and glands may develop if secretions or infection occlude the duct. Small cysts (1 to 3 cm) that are not infected are typically asymptomatic and do not require drainage. Larger cysts and abscesses cause pain with sitting, walking, or sexual intercourse and will require incision and drainage for treatment. This simple procedure can be performed in the emergency department under local anesthesia with an incision through the mucosa using a number 11 scalpel blade. After incision and drainage, an inflatable Word catheter is placed to allow ongoing drainage and the formation of an epithelialized tract. The Word catheter is left in place for 2 to 4 weeks or as needed prior to removal. Alternatively, the abscess cavity may be packed with sterile gauze. Recurrent Bartholin's cysts may require marsupialization of the cyst cavity or excision of the gland by a gynecologist. Bartholin's duct abscesses are typically polymicrobial and should be treated with empirical broad-spectrum antibiotics directed against *N. gonorrhoeae* and *Chlamydia trachomatis* in sexually active patients, as well as against skin flora.¹¹

Urethritis

Urethritis is an inflammation of the urethra, which has many possible etiologies: chemical irritation, trauma, foreign body, systemic inflammatory disease, allergic reaction, or infection. In comparison to adults, pediatric patients with urethritis are much less likely to have an infection as the source of the inflammation. The history of the presenting illness may include contact with irritants such as soaps or bubble bath, trauma from catheter placement or other foreign body, systemic illness and rash, or concern of sexual assault in small children or history of sexual activity in adolescents. Catheters made of latex are more likely to cause an allergic reaction in the urethra than are silicon catheters.¹²

Presenting signs and symptoms may include discomfort with urination, urinary frequency and urgency, itching and pain in the genital area, and hematuria or blood seen on the underpants. The urethral inflammation may be also associated with vaginitis or vulvovaginitis. Kawasaki disease, a pediatric multisystem vasculitis, is also associated with sterile pyuria and urethritis.¹³

A urine specimen should be obtained to look for white blood cells and red blood cells on microscopy and a culture sent to evaluate for infection. If sexually transmitted infections are suspected by history, studies to detect *C. trachomatis* and *N. gonorrhoeae* should be specifically obtained since

FIGURE 94–3. Urethral prolapse. (From Elder JS: Urologic disorders in infants and children: abnormalities of the penis and urethra. In Behrman RE, Kliegman RM, Jenson HB (eds): Nelson Textbook of Pediatrics, 17th ed. Philadelphia: WB Saunders, 2004.)

routine bacterial urine cultures will not detect those infections.

Urethral Prolapse

Urethral prolapse is an uncommon pediatric condition. It is the protrusion of distal urethral mucosa through the urethral meatus. Although it is usually asymptomatic and found incidentally on examination, it may also present as blood-stained diapers or undergarmets, dysuria, urinary frequency, or urinary obstruction. Urethral prolapse typically appears as a red circular mass around the end of the urethra (Fig. 94–3). The exact etiology of this condition is not known, but it is most commonly seen in African American infants, tod-

dlers, and young girls. Conservative treatment is a trial of topical estrogen cream and gentle hygiene to prevent infection. Children should have follow-up for this condition as conservative measures frequently fail, and it may require surgical resection by a urologist for definitive repair.^{5,14}

Musculoskeletal Disorders in Systemic Disease

Blake Spirko, MD and Allison V. Brewer, MD

Key Points

Kawasaki disease should be considered in the differential diagnosis of all children with a prolonged fever.

Since the earlier manifestations of Lyme disease are easier to treat than the later stages, early diagnosis and treatment are particularly important.

Acute rheumatic fever is characterized by nonsuppurative manifestations weeks after a preceding group A streptococcus pharyngeal infection.

The diagnosis of juvenile rheumatoid arthritis encompasses a heterogeneous group of chronic arthritic conditions and is made by exclusion.

Selected Diagnoses

- Kawasaki disease
- Lyme disease
- Acute rheumatic fever
- Juvenile rheumatoid arthritis

Discussion of Individual Diagnoses

Kawasaki Disease

Kawasaki disease is the most frequent pediatric vasculitis, and, more importantly, it is the most common cause of acquired heart disease in children.¹ Kawasaki disease is a systemic vasculitis with significant complications from coronary vessel involvement. Development of coronary artery ectasia and aneurysms can lead to myocardial ischemia, infarction, and sudden death. Although the etiology of this condition is uncertain, early treatment decreases the incidence of coronary artery aneurysms and thrombosis. Early treatment of Kawasaki disease (within the first 10 days of fever) decreases the appearance of coronary artery aneu-

rysms and ectasia from 20% to less than 5%.² The vascular inflammation is slowly replaced by fibrinous tissue, and, although usually not clinically significant, there is evidence of abnormal endothelial function years after disease onset.³ Eighty-five percent of cases develop in children less than 5 years old, with the average age being approximately 2 years.⁴

Clinical Presentation

Kawasaki disease requires a clinical diagnosis, as there is no definitive diagnostic test. The original diagnostic criteria include fever for 5 days plus four out of five principal clinical criteria: (1) nonexudative conjunctival injection, (2) oropharyngeal mucosa abnormalities, (3) changes in the peripheral extremities, (4) polymorphous rash, (5) cervical lymphadenopathy greater than 1.5 cm⁵ (Table 95–1). Conjunctival injection typically is painless and spares the limbus (Fig. 95–1). Uveitis may occur in a large number of cases. The pharynx and lips typically become red within 1 to 3 days of the onset of disease. The lips are often dry, crusted, and fissured and may become secondarily infected (see Fig. 95–1). Hypertrophy of tongue papillae gives rise to a strawberry appearance. The hands and feet become edematous while the palms and soles become red within 3 days of onset (Fig. 95–2). Edema is nonpitting and lasts approximately 1 week. Peeling of the hands and feet begins at the nail margins and occurs 10 to 14 days after onset. The rash is most commonly a diffuse, deep red, maculopapular eruption. The rash may resemble erythema multiforme, scarlet fever, or erythema marginatum. Dermatitis in the diaper area is also common. With time, macules and papules become confluent. Desquamation occurs within 1 week, with onset of perineal desquamation 2 to 6 days before desquamation of the fingertips and toes. Lymphadenopathy is usually nontender and nonsuppurative and is often limited to a single lymph node.

While 5 days of fever is typically required to make the diagnosis, the American Heart Association recommends making the diagnosis with only 4 days of fever if four or more principal criteria are present.² The diagnosis can also be made with less than four principal criteria if echocardiography demonstrates coronary artery features consistent with Kawasaki disease. Infants are less likely to meet the original diagnostic criteria compared to older children.⁶ Some experts

FIGURE 95-1. Nonpurulent conjunctival injection and “cherry-red” lips with fissuring and crusting are early signs of Kawasaki disease. (From Habif TP: *Clinical Dermatology: A Color Guide to Diagnosis and Therapy*, 4th ed. St. Louis: Mosby, 2004, p 475.)

Table 95-1 Principal Criteria of Kawasaki Disease

Fever persisting at least 5 days PLUS	
Presence of at least 4 of 5 principal features:	
1.	Bilateral nonexudative bulbar conjunctival injection Typically appears shortly after fever onset
2.	Mucosal changes Red, fissured, perhaps bleeding lips Strawberry tongue (identical to that of streptococcal scarlet fever) Oral/pharyngeal mucosal injection
3.	Altered appearance of extremities Erythema of palm and soles Edema of hands and feet
4.	Polymorphous rash Most commonly diffuse maculopapular eruption May be scarlatiniform or erythema multiforme-like Usually extensive
5.	Cervical lymphadenopathy > 1.5 cm Least common of principal features Usually unilateral and within the anterior triangle

Adapted from Newburger J, Takahashi M, Gerber M, et al: Diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Circulation* 110:2747-2771, 2004.

recommend that infants less than 6 months old with fever for 7 days and an undetermined etiology should have laboratory testing (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]) looking for a systemic inflammatory process. If laboratory tests indicate an inflammatory process, echocardiography should be performed even if there are no other signs of Kawasaki disease.²

Although not part of the original diagnostic criteria, other clinical and diagnostic features can aid in the diagnosis. Irritability is characteristically seen in young children. Aseptic meningitis develops in approximately 50% of patients.⁷ Periungual desquamation typically occurs in the second and third week of illness, thus limiting its usefulness as a diagnostic clue in the emergency department. A vesicular rash is rare. Cervical lymphadenopathy is the least common principal feature and usually is not diffuse in nature. Children also may develop hydrops of the gallbladder. Laboratory values that aid but do not confirm the diagnosis include increased ESR and CRP values, pyuria from urethritis, anemia, and slightly increased transaminase values.⁸ Obtaining both an ESR and a CRP level will increase the sensitivity for diagnosing this disorder.⁹ A reactive thrombosis tends to develop after the first week of illness. The majority of electrocardiograms are normal; however, approximately 35% show some abnormalities consistent with myocarditis, such as T-wave flattening and ST-segment changes. Children with Kawasaki disease and a brain natriuretic peptide level greater than 50 pg/ml usually have acute myocarditis.¹⁰

An incomplete form of the disease occurs and can make the diagnosis even more challenging. Patients with incomplete Kawasaki disease have a fever for 5 days but have less than four diagnostic criteria. The clinical features that develop are still typical. Unfortunately, patients with incomplete Kawasaki disease also have a propensity for coronary artery aneurysms.¹¹ The American Heart Association has provided guidelines for the evaluation of suspected incomplete Kawasaki disease. Patients with two or three principal criteria and fever for 5 or more days should be assessed clinically for Kawasaki disease. CRP and ESR levels are recommended if an alternate diagnosis is not suspected. If the CRP

FIGURE 95–2. Hand and foot edema typically occurs within the first 3 days of illness in Kawasaki disease. (From Habib TP: *Clinical Dermatology: A Color Guide to Diagnosis and Therapy*, 4th ed. St. Louis: Mosby, 2004, p 475.)

is 3.0 mg/dl or greater or the ESR is 40 mm/hr or greater, treatment should be instituted in patients with three clinical criteria. Patients with only two criteria who meet these laboratory cutoff values require an echocardiogram. If the echocardiogram shows evidence of Kawasaki disease, these patients should also be treated. Echocardiographic evaluation focuses on measurement of coronary artery diameter for evidence of ectasia and aneurysm formation. Other possible echocardiographic signs include perivascular echogenicity, depressed ventricular contractility, aortic root dilation, pericardial effusion, and valvular regurgitation.² Small studies indicate that multidetector computed tomography may be as accurate as echocardiography at detecting coronary aneurysms and may detect the stenoses and occlusions in most adolescents.¹² If verified in larger studies, this technique may augment echocardiography in the future.

The differential diagnosis varies with the clinical presentation but includes adenovirus and other viral infections. Other considerations include drug reactions, scarlet fever, staphylococcal scalded skin syndrome, and bacterial cervical lymphadenitis (see Chapter 120, Skin and Soft Tissue Infec-

tions; Chapter 123, Classic Viral Exanthems; and Chapter 126, Other Important Rashes). Clinical subjectivity of the principal diagnostic criteria often makes the diagnosis challenging. Depending upon the institution, pediatric cardiologists, rheumatologists, and infectious disease physicians often have expertise in diagnosing and treating Kawasaki disease and may be a helpful resource.

Management

The emergency physician's main role is to formulate a timely diagnosis and admit patients with Kawasaki disease to the hospital for intravenous gamma globulin (IVIG) and high-dose salicylate treatment. IVIG is administered by a slow infusion at a dose of 2 g/kg.¹³ IVIG treatment has better efficacy if given before day 10 of illness, and ideally should be administered before the seventh day.² Treatment prior to the fifth day is effective but is also associated with an increased need for IVIG retreatment.¹⁴ High-dose aspirin therapy (80 to 100 mg/kg per day) is instituted during the acute phase of illness. Typically, a few days after defervescence, aspirin therapy is converted to a lower dose (3 to 5 mg/kg per day). Low-dose salicylate treatment is continued during a prolonged follow-up period that includes repeat echocardiograms. Debate exists as to the utility of steroids in Kawasaki disease. One meta-analysis concluded that adding corticosteroids to standard aspirin and IVIG regimens significantly reduces the incidence of coronary aneurysms.¹⁵ A more recent randomized, double-blinded, placebo-controlled trial did not support the use of single pulse dose steroids.^{15a}

Although coronary artery aneurysms develop later in the disease course, baseline coronary artery evaluation by echocardiography is recommended early in the management of the disease. Occasionally, children may present with myocardial ischemia or infarction secondary to coronary artery thrombus formation, which differs from atherosclerotic plaque rupture as seen in adults. In general, modified adult acute coronary syndrome protocols are used in the treatment of children presenting with a myocardial infarction, including such therapies as aspirin, heparin, and thrombolytic therapy. As there are no randomized controlled trials for pediatric patients, the American Heart Association extrapolated adult data and recommends using either thrombolytic or mechanical reperfusion therapy for acute ischemia depending upon available expertise and time constraints.²

Summary

Kawasaki disease should be considered in the differential diagnosis of all children with persistent fever. The diagnosis of this systemic inflammatory condition must be made clinically, with incomplete presentations making the diagnosis more challenging. Specialists with expertise in Kawasaki disease, such as pediatric infectious disease clinicians or pediatric cardiologists, may help confirm the diagnosis. Patients with Kawasaki disease require admission for treatment with both IVIG and high-dose salicylates in addition to cardiac evaluation. Early treatment significantly reduces coronary artery aneurysm and ectasia formation and possible subsequent thrombosis.

Lyme Disease

The spirochete *Borrelia burgdorferi* causes Lyme disease. Since the earlier manifestations of Lyme disease are easier to

treat than the later stages, early diagnosis and treatment are particularly important. The spirochete is transmitted by *Ixodes* tick bites, most commonly in the Northeast and Midwest, although most states have reported the disease. In 2002, 95% of Lyme cases came from the following 12 states: Connecticut, Delaware, Rhode Island, Maine, Maryland, Massachusetts, Minnesota, New Jersey, New Hampshire, New York, Pennsylvania, and Wisconsin.¹⁶ Among children, the incidence is highest among those between 5 and 14 years.¹⁷ The incidence within different regions of a state is also highly variable. Patients who spend time outdoors in these endemic regions are the most susceptible. The *Ixodes* ticks transmit Lyme disease mostly during the late spring and summer while in their smaller nymph stage, although the larger adult tick can transmit the disease. Nymph ticks are 1 to 2 mm in size, and most patients do not recall a tick bite. Spirochete transmission generally requires tick attachment for a minimum of 24 hours; however, periods greater than 48 to 72 hours of tick attachment may be required.^{18,19} Even in endemic regions only about 1.4% of patients bitten by *Ixodes* ticks develop Lyme disease, because most of the ticks are not infected with the spirochete and there is a need for a prolonged tick attachment period.²⁰

Clinical Presentation

Lyme disease is classified into three stages. The first stage is the erythema migrans or early localized stage. Erythema migrans occurs in approximately 80% of cases²¹ and usually develops 7 to 10 days after the tick bite, although the range is 1 to 36 days.²² The erythematous macular or papular rash generally expands over a period of days to an average diameter of 16 cm²³ (Fig. 95–3). Erythema migrans can take various shapes, and often does not have a classic central clearing. Associated flulike symptoms may accompany this first stage, including mild myalgias, fever, chills, fatigue, lymphadenopathy, and stiff neck.²² Patients with erythema migrans present most often during the summer months.

The early disseminated stage or second stage of Lyme disease develops weeks to months after the tick bite. This stage has a vast array of presentations as the disease may involve most organ systems, including cutaneous, neuro-

logic, cardiac, ophthalmologic, and musculoskeletal. Skin lesions called secondary erythema migrans may develop. These lesions are similar in appearance to erythema migrans but tend to be smaller and develop in multiple locations. Cardiac involvement may include pericarditis, myocarditis, and various degrees of atrioventricular blocks²⁴ (see Chapter 47, Peripheral Neuromuscular Disorders; and Chapter 64, Pericarditis, Myocarditis, and Endocarditis). Neurologic involvement may include lymphocytic meningitis and facial nerve palsies. Approximately 50% of facial nerve palsies in children living in endemic areas are due to Lyme disease.²⁵ Bilateral seventh nerve palsy occurs approximately one third of the time.²⁶ Arthritis can also develop during the second or third stage of the disease. Lyme arthritis tends to be monoarticular or oligoarticular and has a propensity for larger joints, especially the knee.²⁷ Arthritis tends to be transient, brief, and minimally painful, although large effusions may develop. Late Lyme disease includes chronic recurrent or persistent arthritis as well as chronic neurologic syndromes. Neurologic syndromes include such entities as neuropathies, subtle encephalopathies, and fatigue syndromes.

The diagnosis of erythema migrans or stage one Lyme disease should be made clinically as two thirds of erythema migrans patients have false-negative results by serologic testing. Furthermore, serologic testing at the time of a tick bite is not recommended.²⁸ The likelihood of spirochete exposure by means of outdoor activities in endemic regions should be considered when making the diagnosis. The peak incidence of erythema migrans is from May through August. Unlike stage one, patients thought to have early disseminated Lyme disease should have serologic testing. Testing should include an enzyme-linked immunosorbent assay, with positive results confirmed by a Western blot as recommended by the Centers for Disease Control and Prevention.²⁹ Clinic judgment is important when ordering serologic testing as false-negative and false-positive results are common. Other laboratory tests have limited roles in making the diagnosis of Lyme disease, although they may aid in making other diagnoses. The complete blood count and ESR are generally normal in Lyme disease.³⁰ Cerebrospinal fluid (CSF) and synovial joint fluid analyses are more helpful in their ability

FIGURE 95–3. Erythema migrans: enlarging macular rash with central clearing and target appearance. (From Cohen J, Powderly WG (eds): Infectious Diseases, 2nd ed. St. Louis: Mosby, 2004, p 594.)

to exclude bacterial causes rather than confirm Lyme disease. Lyme CSF typically has a lymphocytic pleocytosis with less than a few hundred cells. Synovial fluid from Lyme arthritis typically has between a few hundred and 50,000 white blood cells with a predominance of polymorphonuclear cells.³¹

The differential diagnosis varies depending upon the stage of disease and the predominant organ systems involved. Spider bites and cellulitis can present similarly to erythema migrans but are generally more tender (see Chapter 120, Skin and Soft Tissue Infections; and Chapter 141, Snake and Spider Envenomations). Target lesions of erythema multiforme and viral exanthems can be confused with secondary erythema migrans (see Chapter 121, Erythema Multiforme Major and Minor; and Chapter 123, Classic Viral Exanthems). The neurologic manifestations of Lyme disease can also be consistent with the diagnoses of idiopathic Bell's palsy or aseptic meningitis. Juvenile rheumatoid arthritis (JRA) and septic arthritis are considered in the differential with Lyme arthritis, yet Lyme arthritis tends to cause less discomfort than a septic joint.

Management

All stages of Lyme disease are treated with antibiotics. Erythema migrans is treated orally with doxycycline 1 to 2 mg/kg twice a day (maximum, 100 mg/dose) for 14 to 21 days in children 8 years old or greater. As doxycycline is relatively contraindicated in children less than 8 years old, amoxicillin 50 mg/kg per day (maximum of 500 mg/dose three times a day) or cefuroxime 30 mg/kg per day (maximum of 500 mg/dose twice a day) for 14 to 21 days is used at this age. Patients with mild early disseminated Lyme disease, including mild cardiac involvement and isolated facial nerve palsy, can be treated with the same regimen as used for erythema migrans. Lyme arthritis can be treated with either oral or intravenous antibiotics. Doxycycline and amoxicillin can be administered in the doses mentioned previously, but the duration should be for 28 days. Severe cardiac involvement, meningitis, and severe arthritis are treated with ceftriaxone 75 to 100 mg/kg per day (maximum, 2 g) by intravenous administration for 14 to 28 days.³² Because the CSF analysis is usually abnormal, some experts urge CSF analysis in all children with a seventh cranial nerve palsy in endemic areas.³³ Clinical outcomes, however, are typically good with either oral or intravenous treatment.³⁴

Prophylactic antibiotics for *Ixodes* tick bites can be considered in highly endemic areas. In one study, a single 200-mg dose of doxycycline decreased the risk of Lyme disease from 3.2% to 0.4%.³⁵ The study showing this benefit occurred where the prevalence of infected *Ixodes* ticks is high, ticks were determined to be *Ixodes scapularis* by entomologists, and patients less than 12 years old were not included.^{35,36} Although pediatric antimicrobial prophylaxis for *Ixodes* tick bites is not routinely recommended,²⁰ it can be supported in highly endemic areas for patients 12 years old or greater who are bitten by partially engorged nymphal deer ticks.

In general, the emergency management of Lyme disease consists of making a proper diagnosis and initiating antimicrobial therapy. Serologic testing is indicated for cases of suspected early disseminated and late Lyme disease. Although most patients with Lyme disease are treated with oral antibiotics as an outpatient, patients with complicated disease

manifestations will require hospital admission and antibiotics administered intravenously.

Acute Rheumatic Fever

Acute rheumatic fever (ARF) is characterized by nonsuppurative manifestations (arthritis, carditis, subcutaneous nodules, chorea, erythema marginatum) that occur between 2 and 3 weeks after a group A streptococcus (GAS) pharyngeal infection.³⁷ While the exact pathophysiology of ARF is still unknown, there is strong evidence that a preceding streptococcal pharyngeal infection is required for manifestation of the disease. Pharyngitis is the only streptococcal infection known to be associated with ARF in industrially developed regions of the world. The severity and mortality of the disease have declined since the initiation of antibiotics in developed countries, but still remain a serious problem in undeveloped countries where the majority of the world population resides.³⁷

Clinical Presentation

ARF presents as an acute febrile illness associated with any combination of the following symptoms: migratory polyarthritis primarily involving the large joints, erythema marginatum, chorea, carditis, and/or subcutaneous nodules. The disease usually first presents in patients between 5 and 15 years of age, with approximately 5% of cases presenting before the age of 5.^{38,39} While the majority of the clinical manifestations resolve without sequelae, patients with cardiac involvement can have progressive deterioration, including death, secondary to congestive heart failure and dysrhythmias.³⁷

Arthritis occurs in three fourths of patients with ARF and is usually the first manifestation of disease. Inflammation is migratory, and several large joints are usually involved (e.g., knee, ankle, elbow, wrist). Joint fluid analysis usually reveals 2000 to 50,000 white blood cells per milliliter with a predominance of neutrophils. Rheumatic heart disease due to carditis is the most serious manifestation of rheumatic fever and occurs in 50% to 60% of cases. Inflammation can affect the myocardium, pericardium, and endocardium (valves). Signs and symptoms of myocarditis or pericarditis may occur (see Chapter 64, Pericarditis, Myocarditis, and Endocarditis). Acute valvular involvement manifests as a murmur and occasionally congestive heart failure due to aortic or mitral regurgitation. Over time, progressive valvular deterioration can occur necessitating replacement. Sydenham's chorea is uncommon in rheumatic fever, occurring in only 10% to 15% of cases. Clinical features include involuntary spontaneous movements, lack of coordination of voluntary movements, and muscular weakness. Involvement may be unilateral.⁴⁰ The face, tongue, and upper extremities are most commonly involved. Emotional lability, dysarthria, restlessness, and facial grimacing occur. Neurologic manifestations increase with stress and disappear with sleeping. Clinical maneuvers that elicit chorea include asking the patient to squeeze the examiner's fingers, which causes irregular contractions of the muscles of the hands (milkmaid's grip); arm extension, which leads to spooning and pronation of the hands; tongue protrusion with uncontrolled darting movements; and drawing and writing, which reveal loss of fine motor skills. Neurologic abnormalities usually resolve within 2 to 3 months.⁴¹ Erythema marginatum occurs in a small

Table 95–2 Diagnostic Requirements for Acute Rheumatic Fever

Diagnosis requires evidence of group A streptococcal (GAS) infection PLUS fulfillment of the Revised Jones Criteria*

Evidence of GAS Infection (confirmed by one of these criteria)[†]

Positive throat culture for GAS
Increased streptolysin O or other streptococcal antibodies
Positive rapid direct GAS carbohydrate antigen test
Recent scarlet fever

Jones Criteria (Revised)

Diagnosis requires that 2 major, or 1 major and 2 minor, criteria are met

Major Criteria	Minor Criteria
Carditis	Fever
Polyarthritides	Arthralgia
Chorea	Previous rheumatic fever or heart disease
Subcutaneous nodules	Elevated acute-phase reactant levels
Erythema marginatum	Leukocytosis
	Prolonged PR interval

*Patients with latent manifestations of chorea or carditis are the exceptions to this rule and do not have to have evidence of GAS infection to be diagnosed with ARF.

[†]Antibodies are the test of choice, as throat cultures are often negative by the time of onset of ARF, and do not distinguish between active infection and carrier state.

Adapted from Gibofsky A: Rheumatic fever: the relationships between host, microbe, and genetics. *Rheum Dis Clin North Am* 24:237–259, 1998.

number of patients with rheumatic fever. The rash is nonpruritic, red, seriginous, and macular with a pale center in the macules. It occurs on the trunk and extremities, spares the face, and is accentuated by warming the skin. Subcutaneous nodules are the least common major manifestation of rheumatic fever. They are firm nodules that are located along the extensor surfaces of tendons near bony protuberances.⁴⁰

The diagnosis of ARF is often difficult to make. A diagnosis of ARF requires both evidence of recent streptococcal infection and appropriate application of the revised Jones criteria.^{37,42,43} Evidence of GAS infection can be confirmed by one of the following: positive throat culture for GAS, increased antistreptolysin O or other streptococcal antibodies, positive rapid direct GAS carbohydrate antigen test, or recent scarlet fever.^{37,42} Serum antibodies are the test of choice, as throat cultures are often negative by the time of onset of ARF, and do not distinguish between active infection and carrier state.³⁷ Patients with latent manifestations of chorea or carditis are the exceptions to this rule, and are not required to have evidence of GAS infection to be diagnosed with ARF. The revised Jones Criteria are used to help with the diagnosis of ARF, and require that two major or one major and two minor criteria are met (Table 95–2).^{37,42,43}

Acute-phase reactants (ESR, CRP), while nonspecific, are usually elevated with acute disease unless chorea is the only presenting symptom. In addition to supporting the diagnosis of ARF, acute-phase reactants also serve as markers for resolution as well as recurrence of the disease.³⁷ While chest radiographs and an electrocardiogram should be obtained as basic screening tests, a complete echocardiogram should also be performed for more specific evaluation and assessment of

cardiac function and valvular lesions that may not be clinically apparent.⁴²

Management

The management of ARF is directed at accomplishing three major goals: symptomatic and supportive treatment of acute disease processes, antibiotics to ensure eradication of GAS, and prophylaxis for prevention of future disease. Emergency department management of patient care is directed at recognition of the disease, as well as initial treatment with antibiotics, salicylates, and supportive treatment depending on the severity of symptom manifestation. All patients should be admitted to the hospital for complete evaluation and treatment. Transfer to an appropriate intensive care facility should be arranged for patients with acute life-threatening carditis.

All patients with ARF are treated with antibiotics to eliminate streptococcal organisms and bacterial antigens. Penicillin is the drug of choice and is recommended orally for a 10-day course or as a one-time intramuscular dose of benzathine penicillin G (600,000 units for children <27 kg, or 1.2 million units for those >27 kg) to ensure compliance. If patients are penicillin allergic, narrow-spectrum cephalosporins, clindamycin, azithromycin, or clarithromycin are also acceptable choices. Family members should be cultured, and treated if they are GAS positive. Antibiotics do not alter the course, frequency, or severity of cardiac involvement of ARF.³⁷

High-dose salicylates (80 to 100 mg/kg per day in children, up to 4 to 8 g/day) are most commonly used for symptomatic relief of arthritis and fever, often producing dramatic results soon after initiation of therapy. If no contraindications exist, treatment is continued until symptom resolution and normalization of acute-phase reactants.³⁷ All other clinical manifestations of ARF are treated individually depending on symptom severity.

Cardiac manifestations of ARF are the most severe sequelae, and must be recognized and treated promptly. Valvular and muscular damage result in a variety of clinical signs, including murmurs, cardiomegaly, atrioventricular blocks, pericarditis, and congestive heart failure.³⁷ While corticosteroids and intravenous immunoglobulins have frequently been implemented in the treatment of carditis, current evidence has shown that there is no risk reduction or alteration of the natural history or course of heart disease with either of these agents.^{44,45} Unfortunately, no known current therapy that has been shown to alter the course of heart disease in ARF.⁴⁵ Patients with carditis and severe heart failure should be treated supportively and conventionally with digoxin, vasodilators, and diuretics as appropriate, and with prompt involvement of a cardiology specialist. It is currently believed that severe connective tissue destruction rather than myocyte damage leads to the valvular incompetence that causes the heart failure associated with ARF.⁴⁶ Surgery, including valve replacement or balloon mitral commissurotomy, may be necessary if heart failure is refractory to medical treatment. Rheumatic heart disease (RHD), the most devastating sequela of ARF, is still the most commonly acquired heart disease in the world. RHD most often presents 10 to 20 years after the initial attack of ARF, secondary to severe mitral valve stenosis from valvular calcification.³⁷

Chorea often responds to haloperidol and sedation to achieve complete physical and mental rest. Arthritic pain is

best treated with aspirin as well as bed rest until symptoms resolve to prevent joint damage. Both the rash and subcutaneous nodules often resolve spontaneously during the course of the disease and do not need specific treatment.

Prevention of further infection and attacks is accomplished by long-term antimicrobial prophylaxis, which should be started immediately after the resolution of an acute exacerbation of ARF. Most commonly, recurrences of ARF occur within the first 2 to 5 years after the initial attack, but they can present at any time. Therefore, prophylaxis is recommended for 10 years after the last episode of ARF, or until patients are well into adulthood. However, patients with documented RHD, or those at risk for frequent exposure, may benefit from continuous, indefinite prophylaxis. This can be accomplished by the use of either oral penicillin, sulfadiazine, or penicillin G intramuscularly every 4 weeks.⁴⁷

The prognosis of ARF is highly variable. Ninety percent of patients have resolution of the episode within 3 months with adequate treatment and rest. All patients require period follow-up as outpatients to ensure complete resolution of symptoms and to ensure compliance with prophylactic treatment. Extended antibiotic courses are usually due to unremitting carditis or prolonged chorea. Although patients with underlying heart disease are at higher risk for a more severe course of carditis, 65% to 70% of all patients will not have sequelae. Those that have recurrence are at high risk of severe cardiac failure, which may lead to death.³⁷ Future advancements in the prevention and treatment of ARF lie in vaccine development aimed at the eradication of GAS,^{37,48} as well as in advancements of echocardiography.⁴²

Juvenile Rheumatoid Arthritis

JRA is defined as an arthritic process lasting a minimum of 6 weeks, affecting at least one joint, and presenting in a child less than 16 years of age. It is a diagnosis of exclusion.^{49,50} The prevalence of JRA, also known as juvenile idiopathic arthritis, ranges between 0.16 : 1000 and 1.1 : 1000.⁵¹ The incidence varies among different ethnic and geographic regions of the world.⁴⁹ JRA is further classified into one of three main categories: pauciarticular, polyarticular, and systemic.

Clinical Presentation

Pauciarticular JRA is not associated with systemic symptoms and affects fewer than five joints.⁵⁰ A monoarticular presentation is seen in 50% of cases. Asymptomatic uveitis is the only associated extra-articular presenting sign.^{49,51} Pauciarticular JRA can be further subdivided into type 1 and type 2, both of which are rheumatoid factor negative. Type 1 predominately affects girls ages 2 to 5, most commonly involving knee and ankle joints, followed by elbows and wrists, and rarely involving the hips. Affected joints are typically warm yet without erythema, and parents often bring the child to medical attention with complaints of a limp.⁵¹ Type 2 typically occurs in children 8 years and older and tends to involve the lower extremities (tarsal, ankle, knee, and hip joints), often causing an enthesitis of the Achilles, plantar, and patellar tendons. Most laboratory values are normal with the exception of a positive antinuclear antibody (ANA), which is present 85% of the time.⁵⁰ The prognosis of pauciarticular JRA is relatively good, with spontaneous resolution often seen within 6 months. Recurrences of

pauciarticular JRA occur in 20% of those affected, most commonly within the first year after initial onset. Patients who develop extended pauciarticular JRA often have destructive disease that lasts well into adulthood, and require aggressive treatment, similar to those with polyarticular JRA. The most severe and common sequela of pauciarticular JRA is uveitis, and routine ophthalmologic screening must be performed every 4 to 6 months in any child with the diagnosis of JRA for prevention of ocular complications.^{52,53}

Polyarticular JRA involves five or more joints but often begins insidiously, leading to multiple joint involvement over a period of 6 months. It is subdivided into rheumatoid factor negative and positive subgroups. Rheumatoid factor–negative patients are typically girls less than 6 years old, while the rheumatoid factor–positive patients are generally early adolescents. Extra-articular manifestations such as vasculitis, lung disease, and rheumatoid nodules can develop in rheumatoid factor–positive patients. Laboratory values often show a positive ANA, anemia, and elevated acute-phase reactant levels.⁴⁹⁻⁵¹ Polyarticular JRA has a guarded prognosis, with 50% of cases leading to disabilities.⁵⁴

Systemic JRA is associated with high intermittent fevers, rash, lymphadenopathy, hepatosplenomegaly, anemia, leukocytosis, pericarditis, peritonitis, pleuritis, and arthritis affecting any number of joints at a time. Children often present acutely and are ill appearing, making this subset of JRA the most difficult to both treat and diagnose. Systemic JRA has no gender preference, may occur at any age under 16, and is the only subset of JRA that involves the hips.⁴⁹⁻⁵¹ The diagnosis of systemic JRA is one of exclusion and requires the combination of arthritis and daily fevers greater than 38.5° C that are present for at least 6 weeks.⁵⁵ Many of the following laboratory abnormalities are suggestive of the disease and can help with diagnosis: profound leukocytosis, thrombocytosis, anemia, and elevated ESR and CRP. Rheumatoid factor and a positive ANA are not present. Systemic JRA has a highly variable course and prognosis. Nearly three quarters of patients will have remission of their articular erosions at 5 years after disease onset. Approximately one third will have a prolonged course and commonly have significant morbidity due to destructive arthritis, persistent systemic manifestations, medication side effects, and growth retardation.⁵⁶

Management

Nonsteroidal anti-inflammatory agents (NSAIDs) are the initial treatment of choice for all subtypes of JRA. Children with refractory disease or failure to respond to NSAID use alone require prompt consultation with a pediatric rheumatologist for the initiation of appropriate second-line immunosuppressive agents with the intention of preventing permanent joint destruction. Risk:benefit ratios should always be considered when initiating any new therapeutic modalities.^{49-51,56} JRA is a diagnosis of exclusion, with a complex differential including connective tissue diseases, malignancy, malaria, infective or reactive arthritis, postinfectious arthritis, systemic lupus erythematosus, systemic inflammatory conditions, orthopedic disorders, pain syndromes, immunodeficiencies, and other rheumatic diseases. Patients presenting with acutely inflamed joints, systemic signs of illness, or hip involvement are more likely to have an alternate diagnosis.

Emergency physicians may encounter patients with various complications due to JRA. Pericarditis occurs in 10% to 36% of JRA patients, while myocarditis develops much less frequently.⁵⁷ JRA patients may present with respiratory distress due to rare causes such as cardiac tamponade, pleural effusions,⁵⁷ and cricoarytenoiditis.^{58,59} Emergency treatment of these complications requires steroids as well as potentially requiring specific cardiopulmonary resuscitation measures such as pericardiocentesis for cardiac tamponade⁵⁷ and endotracheal intubation for cricoarytenoiditis.⁵⁸ JRA may cause joint disease of the upper cervical spine in which atlantoaxial instability may develop.⁶⁰ Understanding this potential instability is particularly important for patients requiring endotracheal intubation and those presenting secondary to trauma. In summary, emergency physicians are more likely to treat complications of JRA than to make the initial diagnosis. Understanding of the varied presentations of this disease and its associated complications will serve to improve the outcome for these children.

Bone, Joint, and Spine Infections

Charles G. Macias, MD, MPH and Coburn Allen, MD

Key Points

A history of trauma or upper respiratory infection occurs in a significant number of children with septic arthritis and may lead to misdiagnosis of this disorder.

Acute-phase reactants (erythrocyte sedimentation rate and C-reactive protein) are more likely to be elevated than a white blood cell count in septic arthritis and osteomyelitis.

Bone scans are helpful in detecting subtle evidence of osteomyelitis or multiple bone involvement. Magnetic resonance imaging is helpful in detecting subtle changes in osteomyelitis and is the preferred imaging modality for identifying infections of the spine.

Antimicrobial treatment strategies for bone and joint infections should consider community resistance patterns, which vary between geographic regions.

Clinical Presentation

CA-MRSA osteomyelitis, the most common cause of bone infections in children, is characterized by increasing extremity pain often associated with systemic signs and symptoms of infection. Infection of the bone usually occurs following bacterial seeding from bacteremia related to a distant source. Infection often begins where sludging of blood flow occurs within the distal metaphysis. Other, less common variants of osteomyelitis include posttraumatic or postsurgical (via direct inoculation of bone) osteomyelitis, and chronic wound—or chronic ulcer—associated osteomyelitis.

Other diseases that may present similarly to acute hematogenous osteomyelitis include septic arthritis; toxic synovitis; skin and soft tissue infections; fractures and sprains; bone pain or infarct secondary to hemoglobinopathies; osteosarcoma and Ewing's sarcoma; and autoimmune processes such as juvenile rheumatoid arthritis, lupus, mixed connective tissue disease, and rheumatic fever. Often the diagnosis of acute hematogenous osteomyelitis cannot be made by clinical findings alone and requires ancillary studies (e.g., blood and tissue cultures), imaging, and pathology studies.

Multiple clinical, laboratory, and radiographic predictors of acute hematogenous osteomyelitis in children exist (Table 96–1).^{1–5} Classically, this disease is associated with fever and point tenderness in the metaphyseal regions of long bones (most commonly the femur, tibia, or humerus, although any bone can become infected).^{1,2} A history of recent trauma to the involved bone is obtained in more than a third of patients and may be explained by increased blood flow to the damaged area boosting the likelihood of bacterial seeding.^{1,2} The majority of cases in children occur in those less than 10 years of age, with almost half of the cases in children less than 5. Males have twice the risk of developing osteomyelitis compared to females, perhaps secondary to increased trauma and associated skin scrapes and insect bites acting as portals of entry.^{1–3} These factors may also explain why more episodes occur during warmer times of the year than during cooler seasons.

Specific underlying diseases entities increase the risk of an atypical pathogen-related osteomyelitis. Most notable is the association between hemoglobinopathies and *Salmonella* species. Additional relationships exist between recent varicella infection and *Streptococcus pyogenes* (group A streptococci); intravenous drug abuse and *Pseudomonas aeruginosa*; vertebral/sacral involvement and *Brucella* species; and

Selected Diagnoses

- Acute hematogenous osteomyelitis
- Other forms of osteomyelitis
- Septic arthritis
- Spine infections

Discussion of Individual Diagnoses

Acute Hematogenous Osteomyelitis

Osteomyelitis, or bone infection, is a rare condition in children. However, it is a disorder that must be recognized early and treated adequately in order to prevent chronic sequelae. In recent years, the emergence of community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) has added another level of complexity to managing pediatric osteomyelitis. The most common form of osteomyelitis in children is acute hematogenous osteomyelitis, which occurs when bone (usually the metaphysis) is seeded with pathogens from the bloodstream.

Table 96–1 Features of Acute Hematogenous Osteomyelitis¹⁻⁵

Findings	% Present
History of fever	40–92
History of extremity pain	84
History of recent trauma	35
Point tenderness	84
Adjacent arthritis	16–35
Chills	9
Malaise	12
ESR > 15–20 mm/hr	86–100 (mean 47–70 mm/hr)
CRP > 1 mg/dl	90–97
WBC > 15,000/mm ³	32–33
Initial radiographic bony changes	19–21
Bone scan abnormal	94

Abbreviations: CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; WBC, white blood cell count.

chronic granulomatous disease and *Mycobacterium tuberculosis*, *Aspergillus*, and *Serratia*.⁶

Most children with acute hematogenous osteomyelitis have a normal white blood cell count; however, the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are almost always elevated.^{1-3,7} Blood cultures are positive in approximately a third of patients, while bone aspirate or open bone cultures are diagnostic in most cases.^{1,3} Children with culture-negative acute hematogenous osteomyelitis tend to have delayed presentations, are older, and are less likely to report prior trauma or localizing soft tissue changes.² Pathologic examination of bone obtained by biopsy (needle aspiration or open) is particularly useful in confirming the diagnosis of osteomyelitis and providing information about the chronicity of the condition.

Plain films are usually normal in children with acute hematogenous osteomyelitis at the time they present for medical evaluation. Radiographic changes begin to appear 1 week after symptom onset since up to 50% demineralization of the affected bone must occur before changes are visualized.⁸ Soft tissue swelling and periosteal elevation at the metaphyseal region of the affected extremity is usually the first radiographic finding on plain films (Fig. 96–1).^{1,3} Magnetic resonance imaging (MRI) may detect bone marrow changes consistent with osteomyelitis early in the course of the illness, and has a high sensitivity and specificity as a diagnostic tool (Fig. 96–2). A bone scan is less sensitive and specific than MRI; however, it can prove helpful in cases in which the location of the infection is uncertain (i.e., toddler with a limp and fever), or if multiple bones appear to be involved (e.g., neonates).⁸

Management

A small percentage of children presenting with osteomyelitis will require rapid stabilization, generally secondary to associated bacteremia and sepsis. Specifically, antibiotics and fluid resuscitation should not be delayed in order to further evaluate the presence of a bone infection. In children who are not systemically ill, empirical antibiotics may be withheld for a minimal period of time while microbiologic and pathologic studies are obtained to maximize the chance of a specific etiologic diagnosis.

FIGURE 96–1. Osteomyelitis of the distal fibula in a 15-year-old male. Note the periosteal elevation (*arrowheads*), an early finding in osteomyelitis. (From Perron AD: Orthopedic pitfalls in the ED. *Am J Emerg Med* 21:61–67, 2003.)

The management of acute hematogenous osteomyelitis optimally involves medical and surgical therapy. Generally, empirical parenteral antimicrobial therapy should cover the most likely organisms involved. *Staphylococcus aureus* accounts for 70% to 90% of recovered organisms. Other less common pathogens include group A streptococci, coagulase-negative staphylococci, and gram-negative organisms such as *P. aeruginosa*, *Escherichia coli*, and *Salmonella* species, especially if specific risk factors exist. In younger children, *S. aureus* is less commonly recovered, although in all age groups it remains the most common pathogen.^{1-3,6,7,9-11}

With the advent of CA-MRSA, it is important to know the local prevalence of this pathogen. In areas where CA-MRSA

FIGURE 96-2. MRI of fifteen-year-old male with knee pain and acute osteomyelitis. Coronal T1 weighted image of the knee demonstrates low signal in the proximal epiphysis extending through the growth plate into the metaphysis of the tibia. (From Santiago Restrepo C, Gimenez CR, McCarthy K: Imaging of osteomyelitis and musculoskeletal soft tissue infections: current concepts. *Rheum Dis Clin North Am* 29:89-109, 2003.)

is common, empirical therapy for acute hematogenous osteomyelitis should include clindamycin, vancomycin, or linezolid.^{12,13} If CA-MRSA is unlikely, clindamycin, nafcillin, or oxacillin has traditionally afforded excellent results for methicillin-susceptible *S. aureus* (MSSA). In septic-appearing children with suspected staphylococcal disease, published recommendations from the American Academy of Pediatrics include the use of empirical vancomycin plus nafcillin (or oxacillin) plus gentamicin.¹⁴ Children with historical predictors associated with atypical organisms should receive broadened empirical therapy (i.e., additional gram-negative coverage) until antimicrobial sensitivities become available.

The need for surgical therapy for routine cases of acute hematogenous osteomyelitis is controversial. Most cases do not require an open drainage procedure.⁴ However, the decision to operate is left to consulting orthopedic surgeons. From a diagnostic standpoint, an orthopedic procedure doubles the chance of recovering an organism either by simple needle aspiration of subperiosteal pus, or by open biopsy and cultures of tissue.¹ Findings more likely to require surgical intervention include involvement of the adjacent joint, a subacute (≥ 2 weeks) to chronic presentation, atypical organisms, and the presence of an abscess within the bone marrow (Brodie's abscess).¹⁵

Occasionally, acute hematogenous osteomyelitis will occur in nontubular bones such as the calcaneus, pelvis, or vertebrae. In one series, the calcaneus was the third most common bone involved (13% of cases) and was not associated with puncture wounds in any patient, as had been reported in prior studies.³ A recent review of pelvic osteomyelitis in 146

children reported that these children, compared to children with tubular bone involvement, were younger (2 to 5 vs. 8.1 years), had less prior trauma (17% vs. 35%), more commonly were males than females but to a lesser degree (1.5 : 1 vs. 2 : 1 male:female ratio), and had a more subacute or atypical presentation. This led to a delayed diagnosis in most cases (12 days vs. 5 to 7 days). This delay is likely due to the fact that these children are younger and have fewer "classic" signs and symptoms. Often, the pain of pelvic osteomyelitis will refer to the hip or thigh, leading to an incorrect initial diagnosis in up to 66% of cases. Of interest, the right side of the pelvis was twice as likely to be involved as the left, and the most common area involved was the ilium in nearly half of the cases. *Staphylococcus aureus* was recovered in 92% of cases with an etiology identified.¹⁶ In a series of 14 children with vertebral osteomyelitis, unique features included prolonged symptoms prior to diagnosis (average 33 days), refusal to walk in young children, and localized back pain in older children. Although *S. aureus* was the most common etiologic agent, atypical organisms such as *Bartonella henselae* (cat-scratch disease), *Salmonella*, and *Propionibacterium* species were recovered more often than expected (4 of 10 cases with known etiology). MRI was found to be helpful in making the diagnosis, as only half of the cases had abnormal radiographs on presentation.¹⁷

The initial management of acute hematogenous osteomyelitis requires hospital admission with administration of parenteral antibiotics. Most patients require at least a week of antibiotics in the hospital while clinical and laboratory improvement is documented. Children are discharged once fever resolves, extremity pain improves, pus is drained, and inflammatory markers (ESR and CRP) approach normal. Children can be switched to suitable oral antibiotics once such improvement occurs, and complete a prolonged (typically 3 to 6 weeks) course at home with stringent follow-up to detect recurrence of infection or complications of disease or therapy.^{4,5}

Complications or sequelae of acute hematogenous osteomyelitis (e.g., growth delay, arthritis, recurrence of infection) occur in fewer than 10% of affected children. While the goal of aggressive therapy is to prevent all of these problems, complications still occur with appropriate therapy.^{1-3,16,18,19}

Other Forms of Osteomyelitis in Children

The two most common traumatic mechanisms associated with osteomyelitis in children are plantar puncture wounds and open fractures, especially of the tibia. A disproportionately high percentage of plantar puncture wound osteomyelitis is due to *P. aeruginosa* (especially if puncture occurs through a rubber-soled shoe), while staphylococcal, streptococcal, and mixed infections are not unusual.²⁰⁻²² Plain films of the foot are abnormal in more than half of cases, but when no changes are noted, MRI can prove diagnostic accuracy.^{22,23} Surgical débridement is usually required, and empirical antibiotics should cover the wide range of possible pathogens (i.e., vancomycin or clindamycin plus ceftazidime or cefipime or ticarcillin or piperacillin).²⁴ Children with open fractures of the lower leg develop osteomyelitis in up to 3% of cases.²⁵⁻²⁷ It may take a week to several months postinjury for these patients to present for care. The likelihood of polymicrobial infection (including skin flora, soil organisms, and anaerobes) in these contaminated wounds is high, and they require

extensive débridement and broad-spectrum empirical antibiotics.^{28,29}

Children rarely develop diabetes-related ulcers, but may develop pressure sores that predispose them to this form of osteomyelitis. Children with cerebral palsy, spina bifida, and neurodegenerative disorders are especially vulnerable. Pressure sores tend to be superficial to the greater trochanter, sacrum, ischium, and calcaneus. Lack of improvement with local therapy is associated with a prolonged duration of healing, deep sores (especially if bone is exposed), and abnormal plain radiography. Bacteria colonizing or infecting soft tissue may not be responsible for the underlying bone infection. Most cases of confirmed osteomyelitis due to soft tissue infection grow more than one species of bacteria from bone biopsy cultures. Typically, cultures grow gram-negative (including *P. aeruginosa*) and gram-positive aerobes combined with anaerobes. Bone scans, although sensitive, are nonspecific in this population, as many patients have false-positive scans due to pathologic bone. The best method for confirming the diagnosis is bone biopsy for culture (anaerobic and aerobic) and pathology. Empirical antibiotic selection should be broad, and can be withheld in non-toxic-appearing patients until deep cultures and débridement have been obtained.³⁰

Septic Arthritis

The terms *septic arthritis*, *infectious arthritis*, and *pyogenic arthritis* are often used interchangeably. They refer to microbial invasion and subsequent inflammation of the joint space. Early recognition is essential as a delay in diagnosis can lead to cartilaginous destruction. Septic arthritis is a medical and surgical emergency requiring prompt action.

Septic arthritis is primarily a disease of children^{31,32} and occurs most frequently in children less than 2 years old.³³⁻³⁵ It appears to be more common in males.³⁵⁻³⁸ Several mechanisms have been proposed to explain how organisms enter into the joint. The most common mechanism is hematogenous spread.³⁹ Other mechanisms include local spread from a contiguous osteomyelitis or cellulitis rupturing into the joint; direct inoculation from trauma, such as from a penetrating wound; and infection acquired as a complication of a surgical procedure, such as an intra-articular steroid infection.^{36,38,39} Over 90% of cases are monoarticular.^{33,37,38} Most involve the lower extremity, with the knee and hip being the most common sites.^{31-34,37}

Clinical Presentation

Pain is the most common and earliest symptom of septic arthritis.^{31,33,35,40} In contrast to adults, children may not be able to verbalize or localize their pain. They may present with nonspecific clues of discomfort such as limp, inability to ambulate, or simply not using the affected extremity. Children often have referred pain. For example, children with a septic hip may present with thigh or knee pain. Infants with pain due to a septic arthritis may present with even more nonspecific findings such as poor feeding, irritability, or pseudoparalysis of the affected extremity.

Most patients with septic arthritis have systemic symptoms such as fever, malaise, or poor appetite within the first few days of infection. Children with septic arthritis are more likely to demonstrate a history of fever ($>38.5^{\circ}\text{C}$)⁴¹ during the week before the initial evaluation than those

with transient synovitis. Children with septic arthritis have significantly higher temperatures (mean 37.7°C to 38.7°C) than children with transient synovitis (mean 36.6°C to 37.4°C).⁴²⁻⁴⁴ However, one third of the children have peak temperatures less than 38.3°C .^{33,38} Thus fever may not always be present. This is especially true in neonates with septic arthritis, in whom fever may be absent in most cases.^{45,46}

There is some evidence that a recent upper respiratory infection^{33,37} or traumatic injury³⁷ may predispose a child to septic arthritis. A history of immune deficiency or systemic disease may also predispose children to developing septic arthritis. Recent antibiotic use may make the diagnosis of septic arthritis a more difficult task. In one series, approximately one third of the patients had received an antibiotic in the week prior to admission.³³

The infected joint is usually swollen, warm, and tender to palpation. Both active and passive motion of the joint are extremely painful and therefore limited.³¹ An effusion may be present. Joint dislocation may be observed.³⁶ The affected joint is usually held in a position that allows for maximum joint distention. If the hip is involved, the leg may be abducted and externally rotated, while knee involvement leads to slight flexion, and ankle involvement manifests with plantar flexion. There is a wide range of possible presentations, from the child with septic arthritis who presents moribund in septic shock, to the well-appearing child with a limp who is afebrile.

As there is no single diagnostic test that can diagnose septic arthritis, clinical evaluation in combination with test results can help guide management. The peripheral leukocyte count may be elevated in septic arthritis (mean $13,200/\text{mm}^3$ vs. mean $11,200/\text{mm}^3$ in transient synovitis),^{37,43} thereby providing a means to differentiate septic arthritis from transient synovitis of the hip.⁴²⁻⁴⁴ Other studies have described a white blood cell count of greater than $11,000/\text{mm}^3$ to $12,000/\text{mm}^3$ to be an independent predictor of acute septic arthritis.^{43,44} However, the peripheral leukocyte counts are not reliable indicators. In one series,⁴⁶ only 23% of patients had a leukocyte count greater than $15,000/\text{mm}^3$. Similarly, another described only one third of the septic arthritis cohort with leukocytosis.⁷

The ESR is a nonspecific marker of inflammation or infection that has been used to aid in the diagnosis of septic arthritis and in monitoring response to treatment. The ESR is elevated ($>20\text{ mm/hr}$) in 85% to 90% of children with septic arthritis at the time of admission.^{33,38,47} It has also been recommended as a tool in combination with other factors to differentiate septic arthritis of the hip from toxic synovitis,⁴²⁻⁴⁴ and is a more sensitive indicator of septic arthritis of the hip than temperature or leukocyte count.⁴⁶ It does not appear to correlate with the duration, severity, or final outcome of the disease. Furthermore, the ESR does not rise until 24 to 48 hours after the onset of symptoms or signs of infection and stays elevated 3 to 4 weeks after resolution of the infection.^{48,49}

CRP, another acute-phase reactant, has gained favor because it is a rapid indicator of inflammation, rising within 6 hours of the triggering stimulus.^{40,50} Therefore, it has been recommended as a more accurate independent predictor of septic arthritis than the ESR.⁵¹ In one study, only 13% of children with suspected joint infection and a CRP of less than 1.0 mg/dl had septic arthritis.⁵¹ It has also been recommended as an adjunct screening test with the ESR in septic

arthritis because it increases and decreases much more quickly than the ESR.⁵² It may also be useful in detecting potential complications sooner than other laboratory indices (e.g., ESR).⁵² In this regard, it has been shown to be useful in the identification of concurrent septic arthritis in children who have acute osteomyelitis.⁴⁹ Lastly, it may be of greater value than the ESR in determining resolution of inflammation.^{40,49,50}

Although many studies have attempted to incorporate several of these combined variables into predication models that distinguish septic arthritis of the hip from transient or toxic synovitis,^{41-44,51,53} (Table 96-2) most clinical prediction models have failed to demonstrate sufficient validity outside of the originating institution.⁵³

Septic arthritis must be differentiated from other causes of limb pain in children, including fractures, sprain, strains, neoplasms (metastatic disease, Ewing's and osteogenic sarcoma), ischemia or infarction from hemoglobinopathies, slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, transient synovitis, cellulitis, myositis, bursitis, and osteomyelitis. In general, these disorders do not cause the same degree of joint pain, joint swelling, and limited joint range of motion compared to septic arthritis. It also must be distinguished from other causes of arthritis, including reactive arthritis, rheumatic fever, juvenile rheumatoid arthritis, Lyme disease, serum sickness, lupus erythematosus, Henoch-Schönlein purpura, parvovirus, mumps, rubella, hepatitis B, and fungal causes. The presence of specific diagnostic features and arthrocentesis are required to differentiate these disorders from septic arthritis.

Blood cultures should be obtained on all patients with possible septic arthritis. They are positive in 30% to 40% of

patients.^{33,34,38,54} Although the yield may be relatively low, the ease of obtaining the culture can be instrumental in isolating an etiologic organism and enabling the most effective treatment. Furthermore, in as many as 20% of cases of septic arthritis, there is a positive blood culture in the presence of a negative synovial fluid culture.³³⁻³⁵

The most important diagnostic test is direct aspiration of the joint and subsequent fluid analysis. Others have provided extensive detail regarding the techniques for aspiration of specific joints for diagnostic purposes (Table 96-3).^{54a} Gram stain should always be performed and will yield a presumptive diagnosis in about one third of patients.³⁴ A joint fluid leukocyte count greater than 80,000 to 100,000/ml with greater than 70% to 75% polymorphonuclear neutrophils is consistent with a septic joint. However, one study of 126 cases with a known bacterial etiology³⁴ demonstrated that 55% had joint cell counts $\leq 50,000$ cells/mm³ and 34% had counts $\leq 25,000$ cells/mm³. A low glucose (less than one third of serum value) is also consistent with a septic joint, yet in that same study of 126 children with proven bacterial septic arthritis, glucose levels were above 40 mg/dl in 44 specimens and reduced in only 41 specimens.³⁴ The confirmatory study is a positive synovial fluid culture, present in 50% to 70% of patients.^{33-36,54} A significant number of children with septic arthritis have persistently negative cultures even without receiving antibiotics prior to diagnosis. Culture-negative cases have been shown to have clinical and synovial similarities to those with positive cultures. Therefore, the same aggressive therapy is recommended in those cases with or without identification of a causative organism.⁵⁵

In septic arthritis, plain radiography may show joint space widening, disruption of the normal fat planes (which may

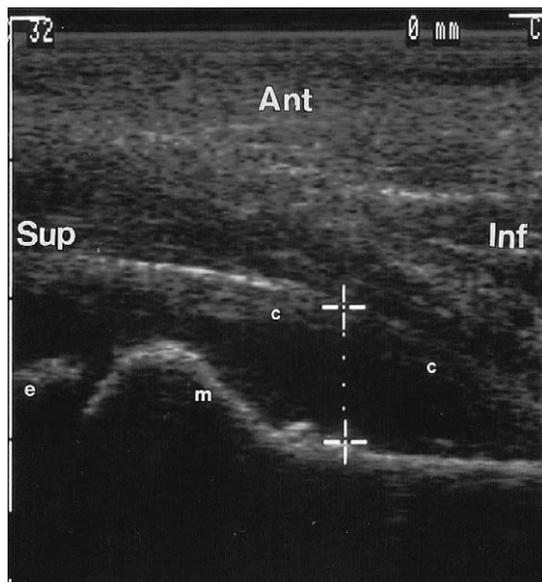

FIGURE 96–3. An effusion is diagnosed on ultrasound (US) when the joint capsule bows anteriorly or distends 3 mm or more with fluid, or when the distention of the capsule is 2 mm more than the contralateral asymptomatic side. This US shows joint effusion within the hip of an infant found to have septic arthritis. (From Bellah R: Ultrasound in pediatric musculoskeletal disease: techniques and applications. *Radiol Clin North Am* 39:597–618, 2001.)

require contralateral films for comparison), or soft tissue swelling. Neonates with septic arthritis of the hip have a higher incidence of subluxation with hip infection, and therefore should have plain films obtained as part of their diagnostic workup.⁵⁶ Another role for plain films in the pediatric population is to rule out other causes of pain such as fractures, slipped capital femoral epiphyses, or avascular necrosis of the femoral head.

Ultrasound may be useful in detecting early fluid collections and can provide guidance for aspiration of an effusion (Fig. 96–3). However, ultrasound cannot differentiate infectious from noninfectious effusions and cannot reliably detect osteomyelitis.⁵⁷ Bone scans and computed tomography (CT) scans are less sensitive for identifying joint effusions but may demonstrate areas of adjacent osteomyelitis.⁵⁸ MRI is highly

sensitive in detecting even a small joint effusion⁵⁸ and is superior to CT for delineating soft tissue structures that can aid in diagnosing adjacent osteomyelitis. No radiographic study should delay definitive care of a patient with septic arthritis. Only those studies that are absolutely necessary to establish a diagnosis and can be obtained expeditiously should be performed. Antibiotics should never be withheld because of delays in obtaining imaging studies.

Management

The management of infants and children with septic arthritis begins with establishing the diagnosis as quickly as possible. Aspiration of synovial fluid should be performed promptly once a septic joint is suspected. This is especially important in the hip, where the blood supply to the epiphyseal plate and femoral head may be compromised.³⁴ Depending on the level of suspicion, intravenous antibiotics should be administered. Gram stain may guide the antibiotic choice; otherwise, empirical antibiotic choice should be based on the pathogens common to the patient's age group and the known antibiotic resistance patterns in the demographic area. Since the introduction of *Haemophilus influenzae* type B immunization, *S. aureus* has become the predominant isolate in young children with septic arthritis.⁵⁹ *Kingella kingae* has also become especially common in children below the age of 4 years.⁶⁰ A reasonable empirical approach would include a third-generation cephalosporin and coverage for *S. aureus* (e.g., vancomycin). Patients with acute septic arthritis should be admitted to the hospital.

Established indications for surgical drainage in children with septic arthritis include (1) involvement of the hip joint; (2) presence of large amounts of pus, fibrin, or loculation within the joint space; and (3) lack of clinical improvement noted within 3 days of appropriate therapy.³⁶

Delay in diagnosis and treatment is the single most important factor affecting prognosis of septic arthritis in children.⁴⁷

Spine Infections

Diskitis

Although children have a fairly high incidence of back pain, they seldom seek medical attention for minor symptoms. Thus the incidence of organic causes in children who seek

medical attention is high.⁶¹ Several mechanisms are postulated to cause diskitis and other spinal infections: direct inoculation after accidental trauma or surgical procedures, contiguous spread from an adjacent infection, or hematogenous spread of pathogens (presumed to be the most common cause). The relative avascularity of the intervertebral disks facilitate the growth of bacteria.

CLINICAL PRESENTATION

The clinical presentation of diskitis is variable, owing to the child's developmental level and ability to localize symptoms, and the variable nature of growth of the child and the spine.^{62,63} A concurrent or recent illness, or a history of trauma that may be unrelated to the anatomic location of the disease, may be described.⁶³ Symptom duration may be from days to weeks, but a median duration of 14 days has been described.⁶⁴ The chief complaint is influenced by the child's level of development: one study described 67% of children 3 years and older as presenting with back pain, whereas 78% of children less than 3 years old had gait-related presenting symptoms (difficulty walking/refusal to walk or bear weight, limp, or unsteady gait).⁶³

Acute toxicity is rarely described in children with diskitis.^{60,61} Fewer than 26% to 28% of children may present with a temperature of greater than 100.3° F.^{63,65} Any loss of normal and fluid spinal motion with walking or playing, or a history of abnormal gait, should alert the examining physician to conduct a more thorough spinal examination.^{60,63} Approximately 78% to 83% of children with diskitis have involvement of the lumbar or lumbosacral area.^{63,65} Infants and children may have generalized back, buttock, or leg pain from nerve root irritation.⁶² Neurologic findings (e.g., decreased muscle tone, muscle weakness, decreased tendon reflexes) are dependent on the degree of inflammation and infection that extends from the intervertebral disk. Consequently, neurologic impairment should not exclude a diagnosis of diskitis, but should alert the clinician to the need for imaging studies to exclude intraspinal involvement.⁶⁴

The mean white blood cell count at admission in one of the larger cohorts of children was 10,900/mm³ with a range of 7500 to 25,400.⁶³ In one study, only 10% of children with diskitis had an elevated white blood cell count and only 5% had a mild left shift.⁶⁴ In this same study, 94% had an ele-

vated ESR.⁶³ Unfortunately, these indicators are nonspecific. CRP has been suggested to test for early infection, but its predictive value for diskitis in children has not been described.

Blood cultures seldom yield pathogens⁶³ and may confound the picture if contaminants are responsible for positive blood cultures, but continue to be recommended by many authors. *Kingella kingae* is one organism that has been increasingly isolated on blood culture.⁶⁴ In most studies, disk aspiration seldom yields positive cultures, but when positive, *S. aureus* and *K. kingae* are most commonly isolated.⁶⁶⁻⁶⁸ Biopsy should be reserved for intravenous antibiotic treatment failures and not for routine diagnosis.⁶²

Radiographs may be abnormal in 76% to 82% of children with diskitis.^{62,69} Four phases of radiologic findings have been described for diskitis⁷⁰:

1. Normal radiograph shortly after onset of symptoms (latent phase)
2. Narrowed isolated intervertebral disk space, decreased vertebral height, and demineralized adjacent vertebral margins 2 to 4 weeks later in the acute phase (Fig. 96-4)
3. Distinct vertebral margins from remineralization 2 to 3 months after onset in the healing phase
4. Flat vertebral bodies with narrow involved disk space and marginal irregularities (with variable reconstitution of the disk) in the late phase and long-term follow-up.

In general, the most commonly described plain radiographic finding among children with diskitis is decreased height of the disk space and erosion of adjacent vertebral end plates⁶³ (see Fig. 96-4). Technetium-99m-labeled bone scan can confirm a diagnosis where clinical suspicion persists despite negative plain radiograph. Technetium scanning abnormalities usually precede changes on plain radiographs, with abnormalities occurring as early as 3 to 5 days after the onset of symptoms^{62,63} (see Fig. 96-4). However, bone scans may be more useful in the patient with poorly localized findings (i.e., younger patients). In contrast, MRI is more sensitive than nuclear studies or CT scan and can help differentiate diskitis from vertebral osteomyelitis or paraspinal or epidural abscesses.⁶² MRI can define vertebral osseous involvement and inflammatory lesions in adjacent structures, making it

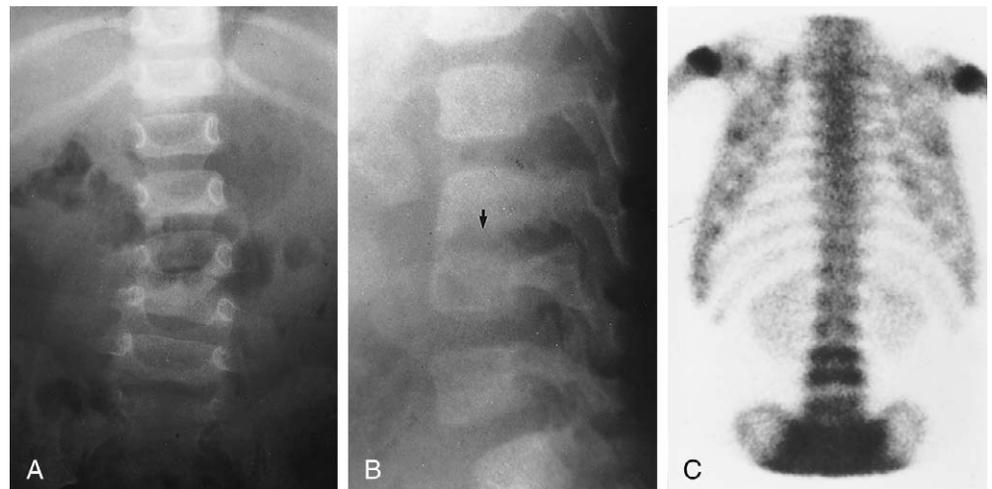

FIGURE 96-4. Diskitis in a 9-month-old girl with a history of refusing to sit up and bear weight, mild fever, and increased sedimentation rate for 2 weeks. Frontal (A) and lateral (B) radiographs of the lumbar spine show narrowing of the L3-4 intervertebral disk space with irregularity of the adjacent vertebral end plate (arrow). C, Radioisotope bone scan shows increased activity at L3 and L4 levels. (From Mahboubi S, Morris MC: Imaging of spinal infections in children. *Radiol Clin North Am* 39:215-222, 2001.)

the study of choice for diskitis among children with negative plain radiographs.⁷¹

MANAGEMENT

Management goals are directed at the presumption that the disease is infectious despite the lack of comprehensive controlled trials to guide therapy. Prior retrospective studies have concluded that treatment with antibiotic therapy is more likely to result in symptom relief without recurrence of disease, regardless of the use of immobilization.⁶⁵ Empirical therapy should be directed against *S. aureus* (the most commonly described causative agent), with a recommended duration of intravenous antibiotics of 1 to 8 weeks, while oral antibiotics may be continued for as long as 3 to 6 months.^{62,66,72,73} The duration of therapy is uncertain; therefore, some experts base treatment duration on changes of CRP and ESR levels. Relative rest and immobilization with an orthotic device may help reduce pain.⁶²

Inpatient observation is indicated to initiate intravenous antimicrobial therapy and to help coordinate care. Transfer to a tertiary pediatric center from institutions with limited access to pediatric subspecialty services is warranted for non-emergent consultation with pediatric infectious disease and pediatric orthopedics. Surgical intervention is rarely necessary, but should be considered if clinical improvement does not occur in a patient with a documented abscess who is systemically ill or has neurologic deficits.^{62,66,74}

Spinal Epidural Abscess

A spinal epidural abscess (SEA) is a collection of pus in the epidural space; it may arise secondary to pyogenic infection of the spine (described as a secondary epidural abscess), or as an entity independent of spondylodiskitis (described as a primary epidural abscess).⁷⁵ The incidence has been described as less than 0.2 to 1.2 per 10,000 hospital admissions.⁷⁶ SEA occurs more frequently in adults than in children; one review of spinal epidural abscesses in children described fewer than 90 cases reported in the literature from 1945 to 1994.⁷⁷

CLINICAL PRESENTATION

The history may reveal a distant focus of infection in 25% of cases, including skin infections, urinary tract infections, pneumonia, or pharyngitis.^{77,78} A history of back trauma may precede SEA in 17% of patients. SEA is speculated to occur from a small hematoma that may have developed from trauma in the epidural space and created a focus for bacteria.⁷⁷

The clinical presentation has been described in four phases: (1) back pain and fever result from a growing spinal epidural abscess; (2) neurologic symptoms that may include root pain that mimics sciatic/hip pain, extremity pain or acute abdomen, and changes in reflexes that can precede motor weakness; (3) increasing muscle weakness and bowel/bladder symptoms; and (4) total paralysis.^{77,79-82} These phases may vary and develop in as little as a few hours.^{77,81} In the presence of epidural abscess or epidural granulation tissue, neurologic deficits may manifest in 37% of adults (primarily paralysis), although 18% recovered with surgery.⁷⁵ The concern for neurologic morbidity comes from direct pressure on the cord and ischemia from blood supply compromise by inflammation and edema.^{77,83} Up to 80% of children have some neuro-

logic compromise prior to surgical intervention.⁷⁷ In the adult population, the most common site for secondary epidural abscess is the lumbar spine (39%); however, the rate of epidural abscess complicating spondylodiskitis is increased when more cephalad regions of the spine are involved (e.g., 90% of cervical spine epidural abscesses have a preceding spondylodiskitis).⁷⁵

Laboratory evaluation is most significant for elevated white blood cell count and ESR (sensitivity of 90% and 100%, respectively).⁷⁵ *Staphylococcus aureus* (with methicillin resistance becoming increasingly important) has been described as the most common pathogen (79% to 86%). Other pathogens include *Streptococcus viridans*, *Streptococcus pneumoniae*, *Salmonella enteritidis*, *Pseudomonas*, and *E. coli*.^{76,77,84} Patients may have normal lumbar punctures (10%) or may manifest purulent cerebrospinal fluid (52%), mild leukocytosis or low glucose levels (26%), and increased protein (12% to 53%).^{76,85} If frank pus is aspirated during lumbar puncture, the abscess is usually dorsal to the cord.⁷⁷

Plain radiographs are usually negative (unless osteomyelitis is present). Thus, MRI is the imaging modality of choice.^{77,82} MRI of the entire spine should be obtained when there is suspicion of a SEA, as multiple abscesses may be present.^{77,80,86}

MANAGEMENT

Disease lasting for more than 2 weeks may be self-contained and result in epidural granulation tissue rather than frank purulent abscess.^{77,87} The mortality rate in children has been reported at 12%, and 41% of children will manifest neurologic deficits at follow-up.⁷⁷ Although treatment with antibiotic therapy alone is often successful in adults, evidence of success with this approach in children is lacking. Given the absence of evidence for a definitive approach, most authors recommend surgical drainage (typically by laminectomy) and antibiotic therapy, while cases without neurologic deficits may be considered for management with antibiotics alone.^{76,77,82,85}

Immediate stabilization efforts are directed to the patient's individual presentation. An extensive physical examination looking for an infectious source with a thorough neurologic evaluation should be performed. While laboratory tests are often suggestive (e.g., elevated ESR and CRP), MRI is performed to confirm the diagnosis. If MRI is unavailable, contrast CT can reveal adjacent bone destruction and fluid collections. Inpatient management for antibiotic therapy and surgical consultation and intervention is required. Transfer to a tertiary care facility should be considered if pediatric orthopedic, pediatric neurology, and pediatric neurosurgery consultants are unavailable.

Summary

Young children with bone and joint infections often present with irritability, pain, and fever. Tenderness to palpation of the extremity in the absence of a skin lesion may suggest osteomyelitis, whereas refusal to use the extremity or complaint of joint pain may suggest a septic arthritis. Back pain (especially lumbosacral pain) with refusal to walk, with or without localized back tenderness, may indicate diskitis, vertebral osteomyelitis, or spinal epidural abscess. Radiographs may aid in the diagnosis of most bone and joint infections

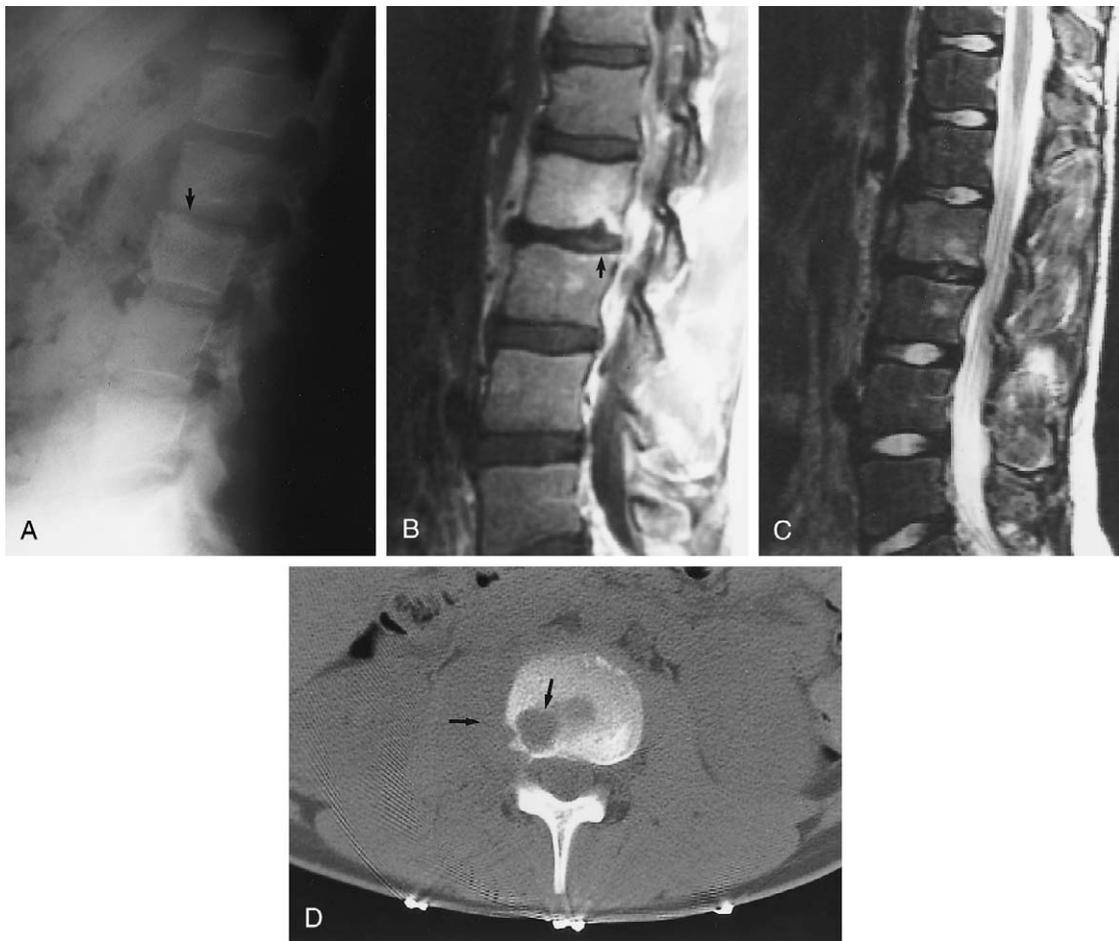

FIGURE 96-5. Spinal staphylococcus osteomyelitis in a 15-year-old boy. **A**, The lateral radiograph of the spine shows loss of a distinct cortical margin of the adjacent L2 and L3 end plates (arrow). **B**, Sagittal T1-weighted image (TR 566, TE 16) after intravenous administration of gadolinium diethylene-triamine pentaacetic acid (DTPA) shows enhancement of the affected vertebrae at L2-3 with loss of disk height (arrow). **C**, Sagittal T2-weighted image (TR 4000, TE 102) shows focal area of increased signal in the inferior part of the body of L2 and decreased signal within the intervertebral disk at L2-3. **D**, Prone axial CT scan before biopsy of L2 shows lytic lesion with destruction of the overlying cortex in the vertebral body and right paraspinal soft tissue mass (arrows). (From Mahboubi S, Morris MC: Imaging of spinal infections in children. *Radiol Clin North Am* 39:215–222, 2001.)

and help to rule out fractures. Bone scans may be helpful to detect early osteomyelitis and spinal infections (in young children without localizing signs). MRI is the test of choice for subtle osteomyelitis or spinal infections (to describe the extent of involvement) (Fig. 96–5). *Staphylococcus aureus* (including methicillin-resistant forms) has emerged as one of the most common pathogens in bone and joint infections in children.

Chapter 97

Muscle and Connective Tissue Disorders

Vivian Hwang, MD

Key Points

Connective tissue disorders and inflammatory myopathies are uncommon in children.

Most of these disorders have prominent clinical manifestations that the emergency physician should be familiar with. It is important to note, however, that some of the classic findings associated with these diseases may be age dependent.

Patients may present with life-threatening complications related to their underlying disease, and young patients without a known diagnosis who present to the emergency department with an atypical illness can be truly challenging both diagnostically and therapeutically.

Selected Diagnoses

- Marfan syndrome
- Ehlers-Danlos syndrome
- Scleroderma
- Juvenile dermatomyositis

Discussion of Individual Diagnoses

Marfan Syndrome

Marfan syndrome is a variable, autosomal dominant connective tissue disorder that primarily involves the skeletal, ocular, and cardiovascular systems (Table 97–1). Diagnosis is based on clinical manifestations, some of which are age dependent. Progressive dilation of the aortic root and ascending aorta is the major life-threatening complication of this disorder, and patients may present to the emergency department (ED) with aortic valve incompetence or aortic dissection.

Marfan syndrome occurs in approximately 1 in 10,000 births.¹ All ethnic groups are affected. It is an autosomal dominant disorder that results from a mutation involving the fibrillin 1 gene on chromosome 15. Fibrillin is a glycoprotein

that is the main component of the microfibril found in tissues such as the aorta, ciliary zonules in the eye, bone periosteum, and tendon.¹ Within the aorta, the abnormal fibrillin results in elastic fiber fragmentation and disarray, paucity of smooth muscle cells, and deposition of collagen and mucopolysaccharide between the cells of the media, also described as “cystic medial degeneration.”² This leads to reduced distensibility in response to the pulse pressure wave and gradual dilation of the aorta.

Clinical Presentation

It is important to be able to recognize patients with clinical manifestations of Marfan syndrome as patients may present to the ED without a known diagnosis. The Ghent nosology is a recently revised set of diagnostic criteria that require a patient to have at least one major criterion in two organ systems and involvement of a third³ (Table 97–2). Echocardiography is indicated to evaluate for aortic root dilation and other cardiac abnormalities in these patients. Slit-lamp examination should be performed to evaluate for ocular abnormalities such as lens dislocation.

Marfan syndrome may be more difficult to recognize in younger patients because many features are age dependent in their occurrence. For example, the development of scoliosis and protrusio acetabuli occurs following periods of rapid growth. In one series of children less than 16 years old with established Marfan syndrome, tall stature with a height greater than the 97th percentile was the most common presenting feature.⁴

Neonatal Marfan syndrome is typically a more severe disease and may present with hypotonia and clinical findings suggestive of failure to thrive. Physical examination may reveal arachnodactyly, joint laxity and dislocations, flexion contractures, heart murmurs, and ocular abnormalities. Young patients who either have a family history of Marfan syndrome or have a marfanoid appearance without a family history and do not completely fulfill the diagnostic criteria often will require repeat evaluations to assess for age-dependent features.

The skeletal features of patients with Marfan syndrome are unique and include an elongated facies; a tall, slender body habitus; disproportionately long extremities (dolichostenomelia); and arachnodactyly (Fig. 97–1). Objectively, adult

Table 97–1 Manifestations of Select Collagen Vascular and Muscular Disorders

Disorder	Etiology	Female : Male Ratio	Prominent Clinical Features	Important Complications
Marfan syndrome	Defect in gene that encodes glycoprotein fibrillin, a major building block for structural components of the suspensory ligament of the lens and substrate for connective tissues	1 : 1	<ul style="list-style-type: none"> • Height >97th percentile for age • Long thin face, narrow maxilla • Ectopic lentis, myopia, blue sclera • Pectus excavatum or carinatum • Long, thin fingers that are hyperextensible • Steinberg thumb sign (see Fig. 97–2) • Walker-Murdoch wrist sign • Skin hyperelasticity • Fragile skin (scarring and poor healing) • Fragile blood vessels (easily bruised) • Joint hypermobility • Muscle weakness, hypotonia • Short stature • Abnormal facies • Skin hyperpigmentation • Skin thickening/tightness • Myalgias, fatigue, weight loss • Raynaud's phenomenon • Pulmonary fibrosis • Cardiomyopathy, pericardial effusion • Reflux, esophagitis, malabsorption • Proximal > distal muscle weakness with high CPK, LDH and abnormal electromyogram • Stiff and sore muscles • Arthralgias, dysphagia, dysphonia • Nonpitting edema • Heliotrope (violaceous erythematous) rash—especially eyelids • Scaly, red, atrophic skin over extensor surface of joints • Subcutaneous calcinosis 	<ul style="list-style-type: none"> • Aorta and aortic root dilation with aortic valve disorder and aortic dissection • Lens dislocation • Spontaneous pneumothorax • Pulmonary blebs • Scoliosis • Recurrent temporomandibular joint dislocations • Dental caries • Arterial aneurysms • Mitral valve prolapse • Spontaneous pneumothorax • Joint dislocations • Visceral perforations • Spontaneous vessel ruptures (abdominal and splenic) • Accelerated hypertension • Renal failure • Pulmonary hypertension and respiratory failure
Ehlers-Danlos syndrome	Quantitative defect in collagen and connective tissue synthesis and structure (>10 different variants exist)	1 : 1	<ul style="list-style-type: none"> • Skin hyperelasticity • Fragile skin (scarring and poor healing) • Fragile blood vessels (easily bruised) • Joint hypermobility • Muscle weakness, hypotonia • Short stature • Abnormal facies • Skin hyperpigmentation • Skin thickening/tightness • Myalgias, fatigue, weight loss • Raynaud's phenomenon • Pulmonary fibrosis • Cardiomyopathy, pericardial effusion • Reflux, esophagitis, malabsorption • Proximal > distal muscle weakness with high CPK, LDH and abnormal electromyogram • Stiff and sore muscles • Arthralgias, dysphagia, dysphonia • Nonpitting edema • Heliotrope (violaceous erythematous) rash—especially eyelids • Scaly, red, atrophic skin over extensor surface of joints • Subcutaneous calcinosis 	<ul style="list-style-type: none"> • Accelerated hypertension • Renal failure • Pulmonary hypertension and respiratory failure • Gastrointestinal bleeding or perforation • Respiratory infection/failure • Extremity contractures
Scleroderma	Unknown cause that may be related to endothelial cell injury, fibroblast activation, or immunologic derangement	5 : 1	<ul style="list-style-type: none"> • Skin hyperpigmentation • Skin thickening/tightness • Myalgias, fatigue, weight loss • Raynaud's phenomenon • Pulmonary fibrosis • Cardiomyopathy, pericardial effusion • Reflux, esophagitis, malabsorption • Proximal > distal muscle weakness with high CPK, LDH and abnormal electromyogram • Stiff and sore muscles • Arthralgias, dysphagia, dysphonia • Nonpitting edema • Heliotrope (violaceous erythematous) rash—especially eyelids • Scaly, red, atrophic skin over extensor surface of joints • Subcutaneous calcinosis 	<ul style="list-style-type: none"> • Accelerated hypertension • Renal failure • Pulmonary hypertension and respiratory failure • Gastrointestinal bleeding or perforation • Respiratory infection/failure • Extremity contractures
Juvenile dermatomyositis	Unknown cause with nonsuppurative inflammation of skeletal muscle and skin lesions	2 : 1	<ul style="list-style-type: none"> • Skin hyperpigmentation • Skin thickening/tightness • Myalgias, fatigue, weight loss • Raynaud's phenomenon • Pulmonary fibrosis • Cardiomyopathy, pericardial effusion • Reflux, esophagitis, malabsorption • Proximal > distal muscle weakness with high CPK, LDH and abnormal electromyogram • Stiff and sore muscles • Arthralgias, dysphagia, dysphonia • Nonpitting edema • Heliotrope (violaceous erythematous) rash—especially eyelids • Scaly, red, atrophic skin over extensor surface of joints • Subcutaneous calcinosis 	<ul style="list-style-type: none"> • Accelerated hypertension • Renal failure • Pulmonary hypertension and respiratory failure • Gastrointestinal bleeding or perforation • Respiratory infection/failure • Extremity contractures

Abbreviations: CPK, creatine phosphokinase; LDH, lactate dehydrogenase.

patients have an upper segment-to-lower segment ratio of less than 0.86 (with the lower segment measured from the symphysis pubis to the floor) or an armspan-to-height ratio of greater than 1.05.² Archnodactyly can be identified by the Steinberg thumb sign, in which the entire thumbnail projects beyond the ulnar border of the hand, and the Walker-Murdoch wrist sign, in which the thumb and fifth finger overlap around the wrist.² Other skeletal abnormalities that may be evident on physical examination include pectus excavatum or pectus carinatum and scoliosis. Diagnostic imaging may be required to evaluate for protrusio acetabuli and dural ectasia.

The major ocular abnormality that occurs in patients with Marfan syndrome is lens dislocation. This can occur as early

as infancy, and clinical findings of megalocornea or iridodonesis may be helpful clues. Slit-lamp examination aids in the diagnosis. Other complications include retinal detachment and acute glaucoma.

The cardiovascular manifestations that occur contribute to both morbidity and mortality. Progressive mitral valve prolapse can cause substantial morbidity with the development of arrhythmias, heart failure, thromboemboli, or endocarditis. Mitral regurgitation is common, with approximately 50% of patients younger than 20 years of age affected. Dilation of the aortic valve and ascending aorta leading to aortic valve incompetence typically occurs as the patient ages, with 90% of patients having some aortic root dilation by age 20 years. Aortic dissection is a life-threatening complication of

Table 97-2 Ghent Criteria for Diagnosis of Marfan Syndrome**Skeletal System**

A major skeletal criterion is assigned when at least four of the following are present:

- Pectus carinatum
- Pectus excavatum requiring surgery
- Upper segment-to-lower segment ratio < 0.86 or armspan-to-height ratio >1.05
- Wrist and thumb signs: both signs should be present to diagnose arachnodactyly according to the Ghent criteria
- Scoliosis > 20 degrees or spondylolisthesis
- Reduced elbow extension (<170 degrees)
- Pes planus
- Protrusio acetabuli

Involvement of the skeletal system is diagnosed when two of the major features above, or one major feature and two of the following, are present:

- Pectus excavatum of mild severity
- Joint hypermobility
- High palate with dental crowding
- Characteristic facies (dolicocephaly, malar hypoplasia, enophthalmos, retrognathia, down-slanting palpebral fissures)

Cardiovascular System**Major:**

- Aortic root dilation
- Dissection of the ascending aorta

Involvement:

- Mitral valve prolapse
- Dilation of the pulmonary artery
- Calcified mitral annulus in individuals < 40 years of age
- Other dilation or dissection of the aorta

Ocular System

Major: Lens dislocation (ectopia lentis)

Involvement:

- Flat cornea
- Increased axial length of globe (causing myopia)
- Hypoplastic iris or ciliary muscle (causing decreased miosis)

Skin/Integument System

Major: None

Involvement:

- Striae atrophicae
- Recurrent or incisional hernia

Pulmonary System

Major: none

Minor:

- Spontaneous pneumothorax
- Apical blebs

Nervous System

Major: lumbosacral dural ectasia

Minor: none

Genetic Criteria**Major:**

- Parent, child, or sibling meets the criteria independently
- *FBN1* mutations known to cause Marfan syndrome
- Inheritance of DNA marker haplotype linked to Marfan syndrome in the family

Minor: none

Marfan syndrome, with pain being the most common presenting complaint. It is usually described as an acute onset of sharp, excruciating pain either in the chest, neck and jaw, interscapular area, or lumbar area depending on the site of the dissection. Physical examination may reveal hypertension or hypotension, aortic regurgitation, findings suggestive of cardiac tamponade, pulse deficits, and blood pressure dis-

crepancies between limbs. Diagnostic imaging is necessary to make a definitive diagnosis of aortic dissection. Chest radiography is often abnormal in patients with aortic dissection; however, the findings are typically nonspecific. Noninvasive imaging modalities that are highly sensitive for detection of aortic dissection include computed tomography (CT), magnetic resonance imaging, and transesophageal echocardiography.⁵

Management

Once aortic dissection is suspected, medical therapy must be initiated immediately with the goal of stabilizing the dissection and preventing rupture. Blood pressure and heart rate control can be achieved with labetalol, an α - and β -adrenergic antagonist, or a combination of a β -blocker such as esmolol or propranolol and a vasodilating agent such as sodium nitroprusside. It is important to start the β -blocker before the vasodilating agent to prevent tachycardia.⁶ With Marfan syndrome, dilation is usually confined to the proximal ascending aorta, and patients will ultimately require surgery for definitive repair.

Patients are at risk for recurrent spontaneous pneumothoraces as a result of increased distensibility of the lung parenchyma. Management includes chest tube thoracostomy.

The cardiovascular complications that occur with Marfan syndrome primarily determine life expectancy in these patients. Recent studies, including a randomized clinical trial involving adult and adolescent patients with Marfan syndrome, have shown that β -blocker treatment reduces the rate of aortic dilation and aortic complications.⁷ Although the exact mechanism is not fully understood, it is believed that long-term treatment with β -adrenergic blockade reduces the impulse of left ventricular ejection (dp/dt) and the heart rate, consequently reducing repeated strain on the aortic root.⁷

The long-term survival for patients with Marfan syndrome has certainly increased because of effective medical therapy with the use of β -adrenergic blockade and prophylactic aortic root surgery. Unfortunately, there are patients without a known diagnosis who present with a catastrophic cardiovascular event, and it is important for the emergency physician to be able to recognize patients who may have this condition.

Patients with a known diagnosis of Marfan syndrome may present to the ED with a complication related to their condition. If an ocular abnormality is suspected, appropriate consultation and close follow-up with an ophthalmologist are warranted. Patients who present with a cardiovascular complication and require blood pressure control with intravenous titratable agents must be admitted to an intensive care unit, and will likely require a multidisciplinary approach by a team of specialists for appropriate treatment. Patients without a known diagnosis of Marfan syndrome who present to the ED for other reasons and are found to have features suggestive of Marfan should be queried about a family history of the disease and be referred to their primary care physician for additional testing.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) is a heterogeneous, hereditary soft connective tissue disease characterized by excessive skin elasticity, joint hypermobility, and easy bruising. There are many different types, as well as variations within each type, of EDS. The basic underlying defect is an abnormality

FIGURE 97-1. A young child with Marfan syndrome. Skeletal features include an elongated facies, long extremities (dolichostenomelia), and mild scoliosis. (From Robinson L: Marfan syndrome. *In* Behrman R, Kliegman R, Jenson H [eds]: *Nelson Textbook of Pediatrics*, 17th ed. Philadelphia: WB Saunders, 2004, p 2339.)

of collagen synthesis and metabolism. Life-threatening complications, including vascular catastrophes, occur with EDS type IV. EDS is a rare disorder with a reported incidence of one in 150,000.⁸ It is now recognized that patients with EDS can have variable clinical manifestations with symptoms so mild that they often go unrecognized. Thus the incidence is probably much greater than previously reported.

Over eight different kinds of collagen have been identified in connective tissues. Abnormalities of type I or III collagen are associated with the different forms of EDS.⁹ Currently, there are 10 recognized types of EDS of which most are autosomal dominant. Each type depends on the type of collagen affected, the structural integrity, and quantity produced. There is considerable variability within each type as well as overlap of different types, with approximately half of patients not meeting the criteria for any one specific type.¹⁰ Type IV, ecchymotic (arterial) type, involves a defect in type III procollagen, which is found in arteries, skin, peritoneum, and intestines. Among the different types, it occurs in approximately 4% of all EDS cases.¹⁰ However, it is most commonly associated with life-threatening complications, including rupture of large vessels and hollow organs.

Clinical Presentation

Children with EDS often appear normal at birth. Some types of EDS, including type IV, are associated with premature birth and low birth weight. These infants often exhibit hypotonia. Short stature may be recognized as these patients age. Other characteristics include a unique facies with midface flattening, floppy ears, thin lips, broad or thin nose, and

widely spaced eyes. Not all patients with type IV EDS exhibit these abnormal features. A biochemical diagnosis is the preferred way of establishing EDS and relies on the use of molecular probes on protein extracts or RNA obtained from cultured skin fibroblast or other tissues rich in type III collagen.

It is common for patients with EDS to have benign clinical manifestations, including mild skin elasticity and hypermobile joints, that are unrecognized. Unfortunately, there are case reports of young patients with the more severe type IV EDS who are diagnosed at autopsy after presenting with a vascular catastrophe.¹⁰ It is often found in retrospect that these patients have had a history of joint hypermobility and easy bruisability. Thus the emergency physician should keep in mind the possibility of a life-threatening problem when encountering a young patient with an atypical chief complaint and a history causing concern for EDS.

Joint hypermobility is one of the hallmark characteristics found with EDS. Objective scoring methods using maneuvers shown in Figure 97-2 are used to define joint hypermobility in these patients.¹¹ Other musculoskeletal findings include joint dislocation, scoliosis, broad clavicles, occipital horns, carpal bone fusion, and arthritis.¹⁰

EDS is characterized by skin elasticity and skin fragility. Gorlin's sign, in which a patient is able to touch the tip of the tongue to the nose, may be demonstrated. Patients tend to bruise easily, and skin lesions often heal slowly after injury or surgery. Patients are prone to the development of "cigarette paper" scars in which the skin on the forehead, chin, and lower extremities appears thin, atrophic, and hyperpigmented.¹¹ The connective tissue defects with EDS may also lead to the development of ocular fragility, periodontitis, hernias, and striae distensae.

Patients with type IV EDS typically die before the fifth decade of life.¹⁰ The most important complication is spontaneous rupture of the great vessels, although aneurysms have also been reported in other large vessels. Resuscitative procedures and surgical repair are often met with difficulty because of the fragility of these tissues. Other serious complications include colon perforation, pneumothorax, and splenic and uterine rupture. Pregnancy is not recommended in patients with EDS type IV; the reported maternal death rate is 25%.⁸

Management

Currently, there is no cure for EDS. The goals are to recognize patients with this disease and its complications as well as to prevent further injury. Because EDS is uncommon, a young, otherwise healthy patient presenting to the ED with an atypical illness can truly be a diagnostic challenge. Patients in whom a vascular or visceral complication is suspected require an approach similar to that for other patients who require emergent resuscitation. Two large-bore peripheral intravenous lines are preferred over central venous access because of the tissue friability that occurs with EDS. Potential complications include hematoma formation, persistent bleeding, and thrombosis. If central venous access becomes necessary, a compressible site is preferred.

Noninvasive diagnostic modalities such as CT, magnetic resonance imaging, ultrasound, and transesophageal echocardiography are preferred for the detection of aneurysms and/or dissection because of the possibility of complications

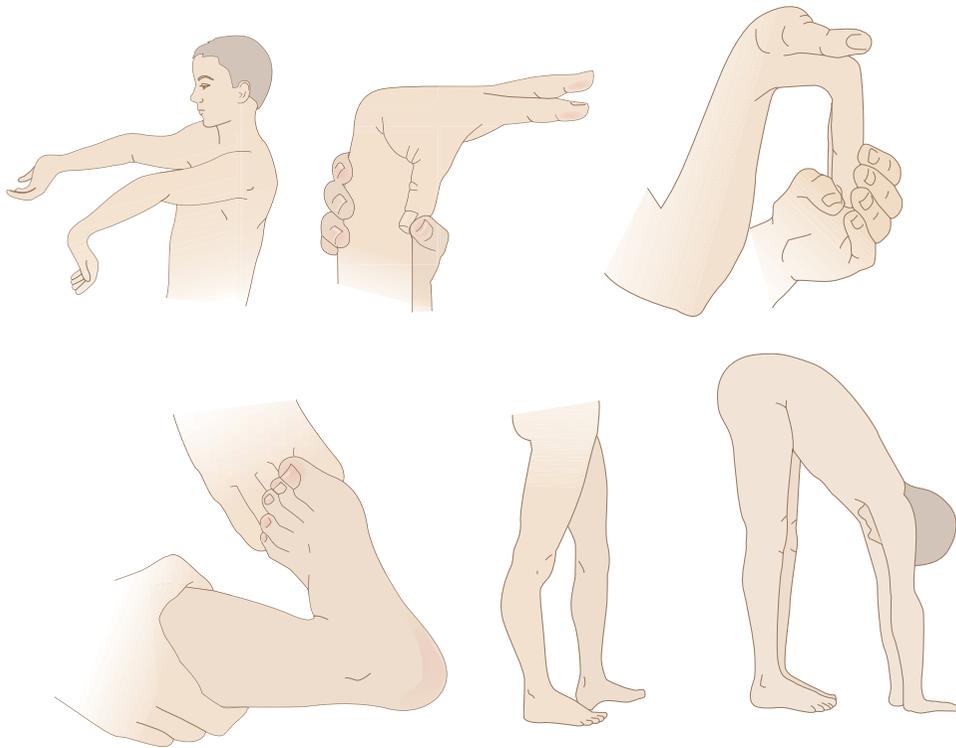

FIGURE 97-2. Maneuvers demonstrating joint laxity in Ehlers-Danlos syndrome. (From Shapiro J, Rowe D, Sponseller P: Heritable disorders of structural proteins. In Harris E, Budd R, Firestein G, et al [eds]: *Kelley's Textbook of Rheumatology*, 7th ed. Philadelphia: Elsevier Saunders, 2005, p 1561.)

associated with invasive procedures such as arteriography. In fact, arteriography has a 67% complication rate in these patients.¹²

Early surgical consultation and evaluation is extremely important if vascular or intra-abdominal pathology is suspected in these patients. It is imperative to communicate to the surgeon that a patient has known or suspected EDS as it may impact the choice of surgery, instruments, and materials used.¹³ Patients requiring emergent surgery for either vascular or intra-abdominal pathology require admission to an intensive care unit. Patients who come to the ED for concerns unrelated to EDS but have features causing concern for EDS should be referred to their primary care physician for further evaluation.

Scleroderma

Scleroderma, or systemic sclerosis (SSc), is an autoimmune connective tissue disease that has variable effects on several organ systems, including the skin, gastrointestinal (GI) tract, lungs, kidney, and heart. It is characterized by fibrosis and vascular obliteration of these organs with debilitating and life-threatening complications.

Scleroderma is rare, with an annual incidence of 0.6 to 19.1 in 1 million per year.¹⁴ The incidence is higher in African Americans with females more commonly affected.¹⁴ Children make up fewer than 10% of all cases. It is common for patients with scleroderma to have first-degree relatives with another autoimmune disorder such as systemic lupus or rheumatoid arthritis.¹⁴

The cause of scleroderma is largely unknown, but it seems to have an immunologic basis involving both cellular and humoral immunity.¹⁵ Other implicated factors include genetic, toxic, and infectious factors.¹⁴ Fibrosis occurs pri-

marily in small arteries, microvessels, and the diffuse connective tissue. Histologically, there are increased amounts of the usual components of connective tissue in both the interstitium and the intima of small arteries.¹⁶ This leads to significant vascular and microvascular lesions.¹⁶

Clinical Presentation

Scleroderma is classified as either localized or generalized. Localized disease does not involve visceral organs. Generalized scleroderma is subdivided into diffuse (dSSc) or limited scleroderma (lSSc) depending on the extent of skin involvement.¹⁶ Localized scleroderma occurs in three forms depending on the involved area: morphea, linear scleroderma, and generalized morphea. Although limited to skin, this disease can have cosmetic and debilitating manifestations including contractures and growth failure.¹⁷ Patients with lSSc, previously referred to as CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias), represent the majority of patients with generalized scleroderma. It is a more stable disease in which complications tend to develop later in life. Patients with dSSc tend to be young or middle-aged females with more rapidly progressive disease resulting in early and significant organ failure.¹⁶ Both localized and generalized scleroderma occur in children, with the localized form being more common. There may be a delay in diagnosis of dSSc due to the subtle early manifestations of the disease.¹⁸ Children have clinical findings similar to those in adults.

Patients with SSc require routine evaluation for the development of cardiac, pulmonary, and esophageal complications. Testing may include echocardiography, pulmonary function testing, radiography, CT scan, and esophageal motility studies.

FIGURE 97-3. Typical facies of scleroderma, characterized by tightening of the skin, loss of subcutaneous tissue in the face, and small mouth. (From Uziel Y, Miller M, Laxer R: Scleroderma in children. *Pediatr Clin North Am* 42:1777, 1995.)

Skin changes are characteristic of scleroderma, with edema occurring in the early stages of the disease followed by tightening and atrophy of the skin as a result of fibrosis. The skin often has a shiny, waxy appearance (Fig. 97-3). Skin ulceration and calcinosis may develop over pressure points (e.g., elbows). Sclerodactyly develops as skin tightens over the fingers, giving them a tapered appearance. Telangiectasias are also characteristic.

Raynaud's phenomenon is one of the hallmark features of the disease and is often the earliest manifestation, preceding other involvement by months to years. It is characterized by episodic digital ischemia provoked by cold and emotion. It is important to recall that it can occur in isolation or with conditions other than SSc.

Complications of SSc are related to progressive organ failure. Lungs are affected as fibrosis causes interstitial lung disease and eventually pulmonary hypertension. Myocardial fibrosis can develop and lead to a cardiomyopathy. Pericarditis as a primary disease has also been reported.¹⁹ Other complications include esophageal dysmotility manifesting as dysphagia, renal hypertensive crisis and oliguric renal failure, and biliary cirrhosis.

Management

ED management consists of recognition and treatment of disease complications (e.g., acute hypertension, renal failure, cardiac or respiratory compromise) and medication side effects (e.g., infection, nephrotoxicity). Long-term therapy of SSc includes vasodilators (e.g., calcium channel blockers, angiotensin II receptor blockers, and prostaglandins); antiplatelet aggregation drugs; immunosuppressants (e.g., methotrexate, cyclosporine); and antifibrotic agents (D-penicillamine, colchicines, interferon-gamma, and relaxin).¹⁵ Corticosteroids are not useful in improving or preventing the progression of skin involvement.¹⁵

Scleroderma can have a variable course depending on the extent of organ involvement. Ten-year survival rates are roughly 60% to 70% for patients with lSSc and 20% for patients with dSSc. The prognosis for children with dSSc is especially poor.¹⁸ Patients with the generalized form of sclero-

derma are often managed by a multidisciplinary team of specialists including a rheumatologist, pulmonologist, and gastroenterologist. Patients with dSSc will inevitably develop complications related to progressive organ failure necessitating inpatient care.

Juvenile Dermatomyositis

Dermatomyositis is an autoimmune, multisystemic disorder most commonly involving the skin and muscles. It is characterized by an inflammatory myopathy as well as cutaneous manifestations. Juvenile dermatomyositis is considered to be a subset of the idiopathic inflammatory myopathies, which include dermatomyositis, polymyositis, myositis with cancer, and myositis overlapping with another collagen vascular disorder. The childhood form is frequently complicated by calcinosis, which can be both painful and debilitating.

Juvenile dermatomyositis (JDM) is a rare disorder in which the etiology is largely unknown. It accounts for approximately 6% of children with a major connective tissue disease in pediatric rheumatology clinics.¹⁸ Onset typically occurs between 4 and 10 years of age and occurs more frequently in girls.¹⁸ JDM has been demonstrated to have an immunologic basis and has been shown to be associated with particular human leukocyte antigen class I and II antigens as well as specific autoantibodies.²⁰ Infectious agents such as group A streptococcus have also been implicated as potential precipitants.²¹

Clinical Presentation

The inflammatory myopathy is caused by a complement-mediated microangiopathy that leads to loss of capillaries, muscle ischemia, muscle fiber necrosis, and perifascicular atrophy.²² Clinically, this results in muscle weakness that occurs primarily in the proximal muscles. This disease is usually suspected based on the clinical manifestations. Diagnostic criteria for dermatomyositis include symmetric proximal muscle weakness, elevated muscle enzyme levels, abnormal findings on electromyogram, abnormal findings from muscle biopsy, and typical cutaneous findings. Dermatomyositis is considered *definite* with the presence of three of four criteria, *probable* with two, and *possible* with one; all cases are associated with the characteristic skin rash.²³

The onset of JDM is usually indolent, but a fulminant course is possible. Children often present with a dermatitis, proximal muscle weakness, and constitutional symptoms including low-grade fever, fatigue, weight loss, and anorexia. There is a greater potential for calcinosis in children, with a reported rate of up to 40%.²⁴

This disease is usually suspected based on the clinical manifestations; however, muscle involvement can be identified with the use of enzymatic testing. Characteristically, there is an increase in concentrations of creatine kinase, lactate dehydrogenase, aldolase, or alanine aminotransferase.¹⁸ Patients have characteristic electromyogram abnormalities and muscle biopsy findings.

The heliotrope rash (Fig. 97-4) and Gottron's papules are pathognomonic cutaneous manifestations of dermatomyositis. The heliotrope rash is a violaceous to dusky erythematous rash, with or without edema, that involves the periorbital tissues in a symmetric distribution. Gottron's papules are slightly raised violaceous papules and plaques found

FIGURE 97-4. Heliotrope rash on upper eyelids and facial erythema demonstrated in a child with juvenile dermatomyositis. (From Pachman L: Juvenile dermatomyositis. In Behrman R, Kliegman, Jenson H [eds]: Nelson Textbook of Pediatrics, 17th ed. Philadelphia: WB Saunders, 2004, p 814.)

most commonly on bony prominences, particularly on the hands.²⁴

Calcinosis, which develops more often in children, is associated with increased morbidity and mortality.²¹ Calcium deposits are found mainly in the subcutaneous tissue and fascia and around joints. They may not only be painful and debilitating, but can serve as a nidus for infection, leading to sepsis and death. Hypercalcemia can occur as calcinosis resolves.²⁵ Other cutaneous manifestations include cuticular changes with hypertrophy of the cuticle, malar erythema, poikiloderma, and scaly alopecia. Both localized and generalized edema can occur, with anasarca usually associated with severe disease activity.²⁶

The myopathy that occurs with JDM primarily affects the proximal muscles in a symmetric distribution. Symptoms occur over a period of weeks to months and include myalgias, fatigue, and weakness. Patients may complain of difficulty walking up stairs or raising their arms to brush their hair. Gowers' sign, in which patients attempting to stand from the ground begin with both hands and feet on the floor and then work up the legs with the hands, may be demonstrated. Esophageal involvement may manifest as dysphagia or dysphonia. It is associated with a poor prognosis as patients are at risk for sudden aspiration.¹⁸

JDM is a multisystem disorder that can involve other organ systems, leading to complications involving the lungs, heart, and GI tract. Although the association of dermatomyositis with malignancy at disease onset has clearly been established in adults, this does not appear to be the case for children.²⁷

All patients with respiratory symptoms require evaluation for pneumonia due to aspiration or opportunistic infections. All patients with pneumonia should be admitted as respiratory failure can occur due to weakened respiratory muscles. Gastrointestinal complications can also be life threatening. Since most patients are on some type of immunosuppressant, presenting features may be masked. Moreover, 17% to 21% of patients with GI perforation may have normal plain film findings, and CT may be required to make the diagnosis. Suspicion of carditis requires electrocardiography, chest

radiography, cardiac enzyme tests, echocardiography, and inpatient management.

Management

The mainstay of chronic treatment for JDM is systemic corticosteroids. However, there are patients who are resistant to steroids or are dependent on high doses, making this disease often difficult to treat. For refractory cases, immunosuppression with azathioprine and cyclosporine has been used with success.²⁴ In addition, recent trials in adults have shown high-dose intravenous immune globulin to be a safe and effective treatment for refractory dermatomyositis.²² Plasmapheresis has also been used but may not offer increased benefit.²⁸ Hydroxychloroquine is used for patients with only mild cutaneous findings and appears to be steroid sparing.^{18,21}

Calcinosis may not respond to steroids and immunosuppressant therapy used to treat the myositis. The use of diltiazem, a calcium channel blocker, has anecdotally been shown to cause regression of calcinosis.²⁹ Other treatments for calcinosis, including low-dose warfarin, aluminum hydroxide, and probenecid, have met with mixed success.¹⁸ Spontaneous remission can occur.

In contrast to adults, children with dermatomyositis have a fairly good prognosis, with an overall mortality rate of about 1%. The course can be variable, but patients typically have myositis and dermatitis for 1 to 2 years followed by functional recovery with residual muscle atrophy and contractures with or without calcinosis.¹⁸ Children with JDM are typically followed closely by a pediatric rheumatologist. Patients may come to the ED with complications such as aspiration pneumonia and sepsis, necessitating aggressive inpatient care.

Chapter 98

Overuse Syndromes and Inflammatory Conditions

Charles G. Macias, MD, MPH and Victoria S. Gregg, MD

Key Points

Either an increased frequency of a defined activity or a new type of activity can place young athletes at risk for overuse syndrome.

Children in organized sports are at higher risk for overuse injuries than children who are engaged in day-to-day play.

Most overuse injuries can be treated conservatively with nonsteroidal anti-inflammatory medications and ice, but the most critical therapy is an adequate period of rest.

Ligament and tendon injuries are rare in children until growth plates fuse.

Selected Diagnoses

- Specific overuse syndromes of the upper extremity
 - Rotator cuff tendonitis
 - Little League shoulder (proximal humeral epiphysitis)
 - Little League elbow (proximal epicondylar apophysitis)
- Specific overuse syndromes of the lower extremity
 - Osteochondral injuries
 - Osgood-Schlatter disease (tibial tubercle apophysitis)
 - Sinding-Larsen-Johansson disease and jumper's knee
 - Iliotibial band syndrome
 - Sever's disease (calcaneal apophysitis)
 - Plantar fasciitis
 - Medial tibial stress syndrome (periostitis)
 - Köhler's disease
- Spine injuries
 - Spondylolysis
 - Juvenile kyphosis (Scheuermann's disease)

Discussion of Individual Diagnoses

Specific Overuse Syndromes of the Upper Extremity

Athletes who play sports such as baseball, softball, tennis, and swimming are at risk for developing overuse injuries of the shoulder and arm due to the repetitive overhead motions required by these activities (Table 98–1). In one report of patients evaluated for sports injury, 20% were less than 16 years of age, and 15% of these injuries involved the upper extremity (with shoulder injuries comprising 45% of upper extremity injuries).¹

Rotator Cuff Tendonitis

Tendonitis refers to injury of the tendon or tendon sheath almost always due to overuse. It is uncommon in children because the structures adjacent to tendons are weaker and more likely to fail. However, chronic injury (typically from overuse) can lead to tissue injury and repair that ultimately results in a weakened tensile strength as compared to that of healthy tendon. The rotator cuff includes four muscles and their conjoined tendons (supraspinatus, infraspinatus, teres minor, and subscapularis muscles). They control internal and external rotation of the shoulder and keep the humeral head in place during upward elevation of the arm. Shoulder laxity and muscle imbalance places younger athletes at greater risk for rotator cuff tendonitis than older athletes, who are more prone to impingement of the tendons along the coracoacromial arch.

Patients with rotator cuff tendonitis typically complain of dull localized pain or pain referred to the lateral arm with overhead activity. The diagnosis is based on shoulder examination by demonstrating weakness of the rotator cuff muscles. In the drop arm test, the examiner passively abducts the patient's shoulders to 90 degrees with the thumbs pointed downward. If the patient is unable to hold this position, a complete tear of the rotator cuff should be suspected.² Radiographs may be helpful in young children to rule out an avulsion fracture at the site of tendon attachment. Acute treatment involves ice, nonsteroidal analgesics, and rest from the offending activity for 2 to 6 weeks. Additionally, physical therapy should be considered to strengthen shoulder and

Table 98–1 Common Sporting Activity Associated with Overuse Injuries

Location	Overuse Injury	Associated sport
Shoulder	Rotator cuff tendonitis Little League shoulder	Swimming, softball, tennis, racquetball Baseball
Elbow	Little League elbow, Panner's disease	Baseball, softball, tennis, golf
Back	Spondylolysis Juvenile kyphosis	Gymnastics Football, weightlifting, skating, dancing
Patella	Sinding-Larsen-Johansson syndrome, jumper's knee	Volleyball, basketball

Heel	Sever's disease, plantar fasciitis, Köhler's disease	Soccer, track and field

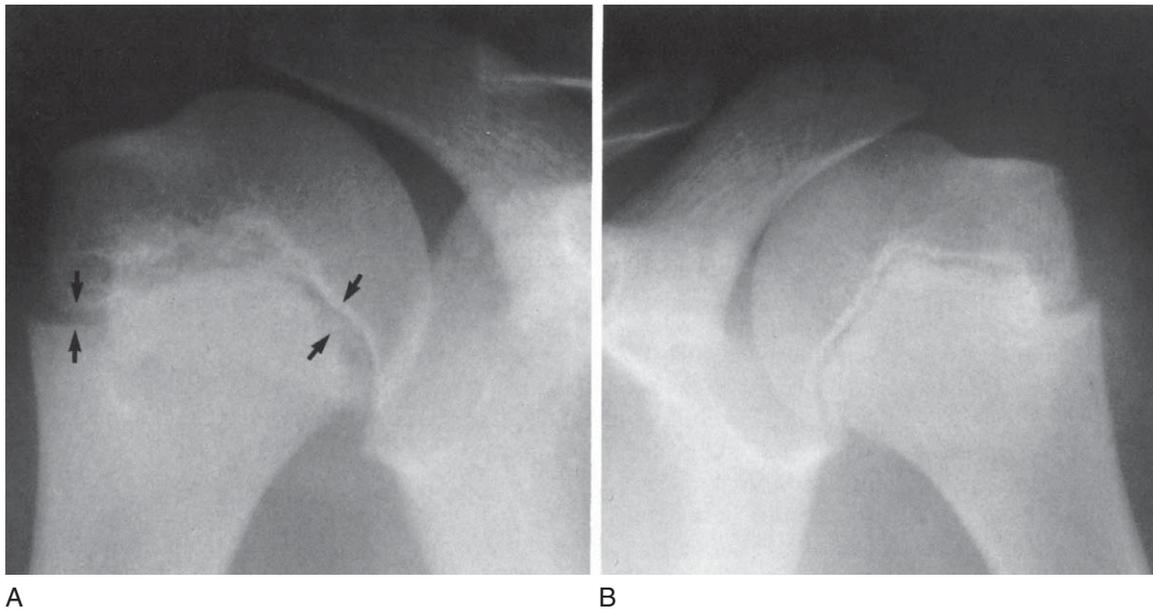

FIGURE 98–1. **Left,** A normal shoulder without widening of the physis. **Right,** “Little League shoulder” with widening of proximal humeral physis consistent with a stress fracture. (From DeLee J, Drez D [eds]: *DeLee & Drez’s Orthopaedic Sports Medicine*, 2nd ed. Philadelphia: WB Saunders, 2003, p 1136.)

rotator cuff muscles.³ Surgical intervention is typically reserved for complete tears.⁴

Little League Shoulder (Proximal Humeral Epiphysitis)

The demand of large rotational forces necessary to throw a ball causes repetitive microtrauma to the skeletally immature athlete. However, it is unclear whether “Little League shoulder” is due to inflammation or a Salter I fracture of the proximal humeral physis.^{4,5} Children ages 11 to 16 years are typically more at risk for Little League shoulder than more skeletally mature adolescents.⁶ Children who throw repetitively for longer durations (i.e., a pitcher or a catcher) are prone to overuse throwing injuries. The chief complaint is pain in the lateral aspect of the proximal humerus while throwing. The onset of symptoms is gradual, as is the case in most overuse injuries. Athletes may notice a loss of speed and/or control of pitches.

The physical examination may be unremarkable. In one series, 87% of patients had tenderness to palpation over the proximal humerus and 70% had tenderness over the lateral aspect of the proximal humerus.⁶ Decreased active and passive range of motion at the shoulder joint also may be present. Cervical spine pathology should be excluded by

evaluating for referred pain from the neck. Radiographs can help confirm the diagnosis by demonstrating a widening of the proximal humeral physis (Fig. 98–1). Associated lateral fragmentation or calcification, sclerosis, demineralization, or cystic changes also may be present.⁶ As physeal widening may be subtle, comparison views may be helpful. Magnetic resonance imaging (MRI) and computed tomography are usually not necessary.

Acute treatment involves anti-inflammatory medications. Treatment should also include rest (for at least 3 months) and physical therapy programs to enhance strength and flexibility of the rotator cuff.^{3,6} Little League shoulder is usually a self-limited injury, with a return of full strength and full range of motion and no apprehension or discomfort while throwing. Although concerns for complications such as avascular necrosis, growth plate injuries, and permanent loss of speed and accuracy while throwing have been described, there appear to be no significant growth disturbances in long-term follow-up among patients with appropriate treatment.⁶

Little League Elbow (Medial Epicondylar Apophysitis)

Apophyses are attachment sites of muscles and tendons to bone that develop as accessory ossification centers. In younger

children, apophyseal inflammation and microtrauma are more common than tendon injuries. Sports involving jumping motions, such as basketball, volleyball, or track and field events such as the long jump or hurdles, may predispose a young athlete to traction injuries to the apophysis.⁴ “Little League elbow” is a common apophyseal injury. The term describes a spectrum of etiologies that include hypertrophy of the ulna, osteochondritis dissecans of the capitellum, fragmentation of the medial epicondyle, and medial epicondylitis.⁷ The medial epicondyle of the humerus is the weakest structure in the skeletally immature elbow and can easily be damaged by the forces generated with throwing and racket sports. It is most commonly seen in 8- to 15-year-old athletes.⁵

The chief complaint is typically pain in the medial elbow and proximal forearm while throwing, or prolonged pain for 24 hours after throwing. The physical examination may be normal, but may also reveal pain over the medial epicondyle. Pain may also be elicited with resisted wrist flexion and pronation, and with valgus stress to a 20- to 30-degree flexed elbow.⁴ Signs and symptoms of advanced pathology include pain when performing any task that requires rotational movement. Sensory abnormalities following the ulnar nerve distribution suggest more extensive involvement.⁴ Apophysitis may often be accompanied by avulsion fractures; thus radiographs may be important in the initial evaluation of this injury.

Osteochondrosis of the capitellum, or Panner’s disease, occurs in children 6 to 12 years old, almost exclusively in baseball pitchers.⁸ *Osteochondrosis* refers to the degeneration, then reossification, of one of the ossification centers in children. Panner’s disease is a benign process that causes pain over the lateral elbow and resolves with rest. In contrast, osteochondritis dissecans of the capitellum also presents with pain over the lateral elbow, but this disease can be debilitating with resultant vascular insufficiency and avascular necrosis.⁹

Although radiographs are usually normal in Little League elbow, widening of the medial epicondylar physis and sclerosis and fragmentation of the lateral epicondyle apophysis may be seen. A comparison view of the other elbow may be helpful.

Acute treatment includes ice, anti-inflammatory medications, and rest. Physical therapy to include wrist flexor strengthening is also warranted. Return to play is advised when the patient experiences full range of motion without pain.

Specific Overuse Syndromes of the Lower Extremities

Osteochondral Injuries

Osteochondral injuries are characterized by injury to cartilage and bone at the joint surfaces with resultant fragmentation and sclerosis. Osteochondritis dissecans is one type of osteochondral injury in which a segment of subchondral bone and articular cartilage separates from the underlying bone. In the lower extremity, the usual areas of involvement are the medial or lateral epicondyle of the knee or the patella, while the capitellum, radial head, trochlea, and olecranon are the most commonly affected sites in the upper extremity (Fig. 98–2).

Although marginal vascularity and coagulopathies may predispose athletes to this type of injury, the etiology of

FIGURE 98–2. Osteochondritis dissecans in a 12-year-old male with recurrent knee pain while training for football. Note the well-circumscribed crescent-shaped area of radiolucency above an area of subchondral bone, separated from the femoral condyle.

osteochondritis dissecans is thought to involve repetitive microtrauma.¹⁰ The lesions are most commonly seen during adolescence at the end of growth and in early adulthood. Symptoms may include pain and a mild effusion. Classification schemas describe stages of disease in which a progression to instability and finally separation of the lesion ensue, with the development of a loose body of bone. Osteochondritis dissecans lesions can often be appreciated on plain radiographs, but MRI may be needed to help determine the classification of injury and appropriate management (i.e., conservative vs. operative). Dynamic bone scans in younger patients can help assess activity and healing potential.

Acute therapy involves symptomatic treatment, but bracing and physical therapy may also be necessary. Activity restriction is also warranted because this injury often has a poor outcome with the potential to cause permanent disability. Athletes should not return to play until they have pain-free range of motion. In multicenter studies of osteochondritis dissecans of the knee, preadolescent children tended to have a more favorable prognosis than older children.¹¹ Smaller lesions, earlier onset, and a more favorable location (classic

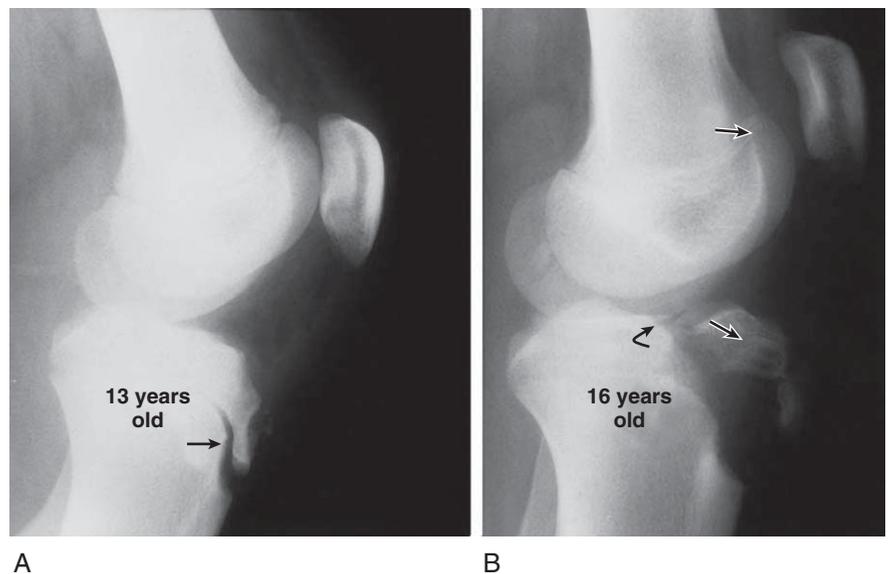

FIGURE 98-3. **A,** Osgood-Schlatter changes (arrow) in a 13-year-old male. **B,** Acute tibial tubercle avulsion fracture 3 years later in the same patient, predisposed to fracture due to Osgood-Schlatter history. Top arrow shows patella alta; curved arrows show fragment displacement and patellar tendon avulsion fragment. (From DeLee J, Drez D [eds]: *DeLee & Drez's Orthopaedic Sports Medicine*, 2nd ed. Philadelphia: WB Saunders, 2003, p 1768.)

medial epicondyle) also dictate a better prognosis as opposed to large lesions (>2 cm) in load-bearing areas of joints.

Osgood-Schlatter Disease (Tibial Tubercle Apophysitis)

Osgood-Schlatter disease or tibial tubercle apophysitis is one of the most frequently diagnosed overuse injuries in children. Repeated contraction of the quadriceps muscle results in injury of the tibial tubercle.⁷ It occurs in children 10 to 15 years old, with onset in girls preceding that of boys by approximately 2 years.^{4,12} Signs and symptoms include pain, tenderness, and swelling over the tibial tubercle. Pain may worsen with jumping sports, climbing stairs, or rising from a seated position.⁷ Radiographs are not needed but may show soft tissue swelling or fragmentation of the tibial tubercle (Fig. 98-3).

Treatment includes local pressure, anti-inflammatory medications, ice, and rest. Severe pain may require a 1- to 2-week period of knee immobilization. Resolution may be slow, often taking 12 to 18 months.¹² Once the growth plate is closed, persistent pain may indicate a residual ossicle. Surgical excision of the tubercle may relieve pain.¹³ Although the disease is generally self-limited, patients with the disease may go on to experience some level of disability with sports activity later in life.¹⁴

Sinding-Larsen-Johansson Disease and Jumper's Knee

Sinding-Larsen-Johansson (SLJ) disease is an apophysitis that typically occurs in children 10 to 13 years old. Its cause is repetitive tensile stress at the junction of the patella and patellar tendon with subsequent calcification and ossification of the inferior aspect of the patella. Patients may describe a subtle onset of pain and demonstrate palpable pain isolated to the inferior pole of the patella (allowing it to be easily distinguished from Osgood-Schlatter disease). Pain occurs during jumping, climbing, or kneeling or with direct trauma to the area. Radiographs may show fragmentation of the distal pole of the patella, but imaging is not needed for diagnosis. Treatment includes rest, anti-inflammatory medica-

tions, and quadriceps flexibility exercises.¹⁵ Resolution typically occurs in 6 to 12 months.¹²

Although commonly combined in the category of SLJ, patellar tendonitis or “jumper’s knee” is thought to occur from partial thickness tears of the patella tendon.⁴ It is characterized by proximal patellar tendon pain and tenderness on palpation. This entity may result in long-lasting symptoms.¹⁶ A progressive exercise plan for drop squats and quadricep extension and hamstring exercises has been reported to successfully reduce pain at 12 weeks.¹⁷ Occasionally, surgical repair may be necessary to relieve symptoms.¹⁸

Illiotal Band Syndrome

The illiotibial band extends from the tensor fascia lata and inserts on the lateral aspect of the proximal tibia. This band changes position during knee extension, snapping forward over the lateral condyle from its posterior location behind the lateral epicondyle when the knee is flexed. The movement is only detectable when there is inflammation. Running with a high step (e.g., up and down stairs) elicits pain. A positive Noble test is diagnostic: the physician places a thumb over the lateral femoral epicondyle and actively flexes and extends the knee with the patient supine. Pain over the epicondyle is reproduced when the knee is in 20 to 30 degrees of flexion.² Radiographs are generally not necessary. Treatment includes rest, anti-inflammatory medications, and reduction of all activities that involve heavy weight bearing. Local corticosteroid injection has been described in adults with recent onset of symptoms, but is not well described in children.¹⁹

Sever's Disease (Calcaneal Apophysitis)

This overuse injury occurs at the insertion of the Achilles tendon into the secondary ossification center of the calcaneus from repetitive traction, subsequent inflammation, and fragmentation. Whether the injury represents a true metaphyseal trabecular stress fracture or an apophysitis is controversial.²⁰ The patient typically complains of heel pain that worsens during activity. Physical examination is remarkable for pain that is elicited by lateral and medial pressure on the calcaneus. Radiographs often show fragmentation and sclerosis

FIGURE 98-4. Sever's disease in an 11-year-old male with fragmentation of the calcaneal apophysis. (From Green NE, Swiontkowski MF [eds]: *Skeletal Trauma in Children*, 3rd ed. Philadelphia: WB Saunders, 2003, p 540.)

of the secondary ossification center (Fig. 98-4). A return to sports can be expected in approximately 2 months if patients adhere to a treatment regimen that includes rest, anti-inflammatory medications, Achilles tendon stretching exercises, and orthotics.²¹

Plantar Fasciitis

Pain at the insertion of the plantar fascia into the calcaneus is suggestive of plantar fasciitis. Patients often complain of heel pain after a period of inactivity that gradually subsides with increased activity (e.g., inactivity at bedtime with pain on awakening). However, the pain will become continuous when untreated. If the pain becomes acutely severe, a partial or complete disruption of the plantar fascia or nerve entrapment may have occurred.⁷ With the ankle stabilized, pain with dorsiflexion of the first metatarsophalangeal joint is a highly specific but low-sensitivity test for plantar fasciitis.²² Radiographs are usually normal. Treatment primarily involves ice, anti-inflammatory medications, rest, and gradual re-introduction of activity. Non-weight-bearing stretching exercise specific to the plantar fascia has been shown to improve symptoms in patients with chronic pain within 8 weeks.²³

Medial Tibial Stress Syndrome (Periostitis)

Medial tibial stress syndrome (MTSS) is a common cause of shin pain. It results from repetitive forceful pronation and plantar flexion of the foot leading to periosteal inflammation along the tibia at the insertion of the soleus muscle. Patients

with MTSS complain of diffuse pain along the middle and distal third of the posteromedial aspect of the tibia. Initially the pain resolves with exercise and returns with rest, but, as the problem persists, the pain will increase with activity. Pain can be elicited with ankle plantar flexion against resistance, by having the patient stand on the toes, or by asking the patient to jump in place. The pain of MTSS is diffuse in contrast to that of stress fractures, which is localized with point tenderness over the bone. The location of pain in addition to the adjunct of normal radiographs and a normal neurovascular examination assure the diagnosis. Treatment includes ice and rest (generally for a 3- to 4-week period).²⁴ MTSS can progress to a stress fracture, so athletes should not be allowed to “work through the pain.” Many variables contribute to the development of MTSS; therefore, preventative measures, including proper shoes, evaluation of running surfaces, and stretching and strengthening exercises, are useful in preventing further injury.⁷

Köhler's Disease

Also known as tarsal navicular osteochondritis, this disease affects younger children (<9 years old). Pain occurs in the midfoot, and physical examination is remarkable for point tenderness overlying the navicular bone. Radiographic changes, depending on the stage of the disease, may show initial collapse of bone, patchy deossification, or a reconstituted navicular bone.¹² The disease is self-limited and responds to rest, ice, and anti-inflammatory medications. Application of a cast that allows weight bearing for a brief period may be required for patients with severe symptoms.²⁵

Spine Injuries

Pediatric athletes presenting with back pain are more likely than adult patients to have a pathologic cause for their symptoms.²⁶ Athletes who participate in sports with axial stresses are susceptible to injuries of the spine and may commonly experience back pain.

FIGURE 98-5. Scheuermann's disease in a 12-year-old female gymnast with chronic back pain. Note anterior wedging of three adjacent vertebrae (T12, L1, and L2). (From Green NE, Swiontkowski MF [eds]: *Skeletal Trauma in Children*, 3rd ed. Philadelphia: WB Saunders, 2003, p 51.)

Spondylolysis

Spondylolysis results from repetitive loading of the lumbar spine with a resultant stress reaction and defects of the pars interarticularis. The stress fracture of the pars interarticularis is usually at the level of L5. Although many hereditary risk factors may contribute to the development of the lesion, it is believed that repetitive hyperextension and lateral flexion of the spine during strenuous exercises and torsion against resistance contribute to this injury.²⁷ During a period of rapid adolescent growth, patients complain of dull back pain. Physical examination reveals pain overlying the lumbar paraspinal region. Rest alleviates pain except in progressive disease. The pars fracture may be seen on oblique radiographs, but a bone scan offers a definitive diagnosis.

Longitudinal studies demonstrate that early diagnosis is essential to the complete resolution of symptoms as conservative measures alone allow young athletes to regain full function in 4 to 6 weeks.^{28,29} If under-arm bracing and limitation of movement do not improve symptoms, or if the disease is identified too late in its progression, surgical intervention may be needed.^{30,31} Abdominal and hamstring strengthening exercises provide spinal support and can sometimes prevent progression of disease.

Juvenile Kyphosis (Scheuermann's Disease)

Repetitive axial loading (e.g., weight lifting) produces trauma that injures the apophyses of the involved vertebrae, causing an increase in the normal thoracic kyphosis or a decrease in the normal lumbar lordosis of the spine. Most patients are asymptomatic or have mild pain, but a progressive deformity of the spine causes them to seek medical attention. The diagnosis is confirmed by classic radiographic findings that include anterior wedging of three or more adjacent vertebrae (Fig. 98–5). Treatment regimens for the patient who is experiencing pain should include flexibility and strengthening exercises, and bracing for severe kyphosis (>50 degrees).³² Operative spinal correction is only necessary with progressive thoracic kyphosis.

Summary

Musculoskeletal pain in the young athlete should never be overlooked. The diagnosis of most overuse injuries is suggested by the history of the offending activity and the risk factors associated with various sports activities. Conservative management with rest, ice, and nonsteroidal analgesia is adequate acute treatment for most overuse injuries in children. A plan for initial rest with gradual return of activity, and educating families on developmentally appropriate training programs, equipment, and facilities, should be addressed with all overuse injuries. The earlier most overuse injuries are diagnosed and treated, the better the prognosis.

Chapter 99

Rhabdomyolysis

Nicole S. Sroufe, MD, MPH and Rachel M. Stanley, MD, MHSA

Key Points

The classic triad of rhabdomyolysis includes myalgias, muscle weakness, and dark urine (myoglobinuria).

Elevations in creatine kinase are diagnostic of rhabdomyolysis, but are not prognostic.

A urinalysis positive for blood with the absence of red blood cells occurs in rhabdomyolysis.

The mainstay of therapy for rhabdomyolysis is aggressive hydration, alkalinization of the urine, and adequate diuresis to prevent the development of acute renal failure.

Introduction and Background

Rhabdomyolysis is a potentially lethal syndrome that occurs after skeletal muscle injury with release of intracellular myocyte contents into extracellular fluid, resulting in elevations of serum myoglobin, creatine kinase (CK), lactate dehydrogenase (LDH), aldolase, aspartate aminotransferase, and alanine aminotransferase.¹⁻⁷ Rhabdomyolysis was defined by Gabow as any condition resulting in a fivefold or greater rise in serum CK (in the absence of brain or heart disease).^{1,8} However, others have defined rhabdomyolysis by elevations of CK from at least 3- to more than 100-fold, the upper limit of normal.⁸

As a result of skeletal muscle injury with loss of integrity of the myocyte, several physiologic alterations occur, including hyperkalemia, hyperphosphatemia, hyperuricemia, hypocalcemia, metabolic acidosis, hypoalbuminemia, and myoglobinuria.^{1,2,8,9} These electrolyte derangements contribute to the multiple complications that occur in patients with rhabdomyolysis. Many complications may arise in patients with rhabdomyolysis, including acute renal tubular necrosis, myoglobinuric renal failure, severe muscle necrosis, cardiac arrhythmias resulting in arrest, disseminated intravascular coagulation (DIC), lactic acidosis, and compartment syndrome.^{2,5,9-13}

Recognition and Approach

Epidemiologic information regarding rhabdomyolysis in the pediatric population is limited given that no large case series have been reported. The list of disorders causing rhabdomyolysis is extensive (Table 99-1).

Rhabdomyolysis may occur in isolation, or in combination with other features diagnostic of specific syndromes. Heat stroke is defined by altered mental status in patients with core temperatures of 39.5° C or more, leading to multisystem organ failure, including circulatory collapse, liver failure, neurologic dysfunction, DIC, renal failure, and rhabdomyolysis.¹⁴ In malignant hyperthermia, an autosomal dominant disorder of skeletal muscle, susceptible patients develop a potentially fatal hypermetabolic reaction with hyperthermia, muscle rigidity, tachycardia, metabolic acidosis, and rhabdomyolysis when exposed to depolarizing muscle relaxants and inhalation anesthetics, as well as extreme stress in the form of heat or exercise.¹⁵⁻¹⁷ When neuroleptic malignant syndrome develops as an adverse effect of antipsychotic medication, patients experience muscle rigidity, hyperthermia, altered mental status, autonomic dysfunction, and rhabdomyolysis.¹⁸ Rhabdomyolysis may also develop in patients with propofol infusion syndrome, characterized by the sudden onset of refractory bradycardia progressing to asystole, lipemia, fatty infiltration of the liver with hepatomegaly, and severe metabolic acidosis.^{19,20}

Rhabdomyolysis may develop acutely in otherwise healthy children, or intermittently in children affected by myopathies, muscular dystrophies, and metabolic derangements.¹⁰ Many acquired illnesses, including infections secondary to viral or bacterial agents, have resulted in the development of rhabdomyolysis.^{3,4,11,12,21-25} Medications, exposure to toxins, and the use of drugs of abuse have also resulted in the development of rhabdomyolysis.^{7,9,15-20,26-38} Traumatic injury with insult to muscle tissue secondary to nonaccidental trauma, immobilization, crush injury, electrical injury, burns, and ischemic injury may also result in rhabdomyolysis^{10,13,39-42} (see Chapter 26, Burns; Chapter 119, Physical Abuse and Child Neglect; and Chapter 142, Electrical Injury). Conditions resulting in hyperthermia predispose patients to the development of rhabdomyolysis, as does exertion in the untrained/unconditioned athlete or in individuals with sickle cell trait.^{2,14-18,43,44} Metabolic derangements, including diabetic ketoacidosis, nonketotic hyperosmolar coma, hypothyroidism/

hyperthyroidism, and electrolyte imbalances, may also precipitate rhabdomyolysis^{10,41,42,45,46} (see Chapter 105, Diabetic Ketoacidosis; Chapter 109, Thyrotoxicosis; Chapter 110, Dehydration and Disorders of Sodium Balance; Chapter 111, Metabolic Acidosis; and Chapter 114, Hyperkalemia). Children with disorders of metabolism and myopathies often present with intermittent rhabdomyolysis and myoglobinuria.^{1,5,11,15,35,41,45,47}

A 3-year retrospective study of neurology consultations at the University of California, San Diego, demonstrated an

incidence of childhood rhabdomyolysis of 0.26% of hospital admissions.¹¹ A retrospective review of children admitted to the Medical College of Virginia during an 8-year period identified 19 cases of rhabdomyolysis (excluding intermittent/relapsing rhabdomyolysis) with causes ranging from trauma (5 cases), nonketotic hyperosmolar coma (2 cases), viral myositis (2 cases), dystonia (2 cases) and malignant hyperthermia-related conditions (2 cases), and additional cases resulting from hypernatremia, polymyositis, hypothermia, and muscle exertion.¹⁰

Clinical Presentation

Rhabdomyolysis is characterized by the classic triad of myalgias, muscle weakness, and darkened urine, although a broad spectrum of symptoms and disease severity can occur.^{5,7,43} Myoglobin released from myocytes after cell injury is partially excreted by the kidneys, resulting in the dark brown pigmentation of the urine.^{7,8} Patients may report localized or diffuse muscle tenderness, weakness, and stiffness, and may develop muscle edema, skin changes consistent with pressure necrosis, or compartment syndrome.^{2,5,10,12,19,43} Systemic symptoms including fever, malaise, nausea, and vomiting may be present, dependent on the underlying cause of muscle injury.^{10,19}

Early in the disease course, patients may present only with myalgias and weakness without darkened urine, given that 100 g of muscle tissue must be injured before serum proteins become saturated and patients develop myoglobinuria.^{7,8} As additional muscle is injured, serum myoglobin increases and myoglobinuria develops. Therefore, patients may be misdiagnosed as having merely a viral syndrome with myalgias. Conversely, patients presenting late in the disease course may present in acute, fulminant renal failure.⁷ Patients presenting with lethargy or coma or as victims of severe trauma may be diagnosed with rhabdomyolysis much further into their disease course.^{7,10}

Serum CK is the most sensitive biochemical indicator of myocyte injury, and should be measured to assess for rhabdomyolysis.^{1,5,43,48} The MM fraction of CK reflects skeletal muscle injury; CK begins to rise within 2 hours of myocyte injury, peaks within 12 to 36 hours, and decreases by 40% each day after the insult to muscle tissue ceases.^{1,5,7,43} Rhabdomyolysis may be present with elevations of CK from as little as 3- to more than 100-fold the upper limit of normal.⁸ Although CK is highly sensitive for identifying myocyte injury, elevations of CK are not predictive of disease severity, or of progression to myoglobinuric renal failure.^{1,10,48}

Additional laboratory studies provide support for the diagnosis of rhabdomyolysis, but are not diagnostic. Careful evaluation of the dipstick urinalysis can provide valuable clues indicative of myocyte injury. A positive urine dipstick for blood with no, or very few, red blood cells visualized with microscopy is suggestive of myoglobinuria, and should prompt an investigation for the presence of rhabdomyolysis.^{7,10,12,43} Myoglobinuria can be confirmed with direct measurement of myoglobin in the urine. Myoglobin may also be quantitated in serum, increasing quickly after myocyte injury, and normalizing within 1 to 6 hours of the cessation of cellular injury.¹⁰ Given the short half-life of myoglobin, it is not reliable in confirming the diagnosis of rhabdomyolysis. In fact, nearly 50% of patients with rhabdomyolysis do not have myoglobinuria on presentation.^{5,7} Myoglobinuria may be the only feature that cues the clinician to consider the diagnosis of rhabdomyolysis. However, myoglobinuria is not predictive of the development of renal failure.¹

Serum electrolytes, LDH, aminotransferases, and creatinine should be assessed in the evaluation of rhabdomyolysis, as myocyte injury results in the release of potassium, phosphorus, purines, and LDH from muscle tissue.^{7,8,12,19,43} Serum aldolase is also elevated.^{7,8,12} Additionally, renal function should be evaluated, given that myoglobinuria results in acute tubular necrosis with potential for renal failure.^{3,5,9-11,43}

Additional disorders of muscle tissue may present with myalgias and weakness, including autoimmune disorders, genetic defects of metabolism, and dermatomyositis, requiring further investigation based on clinical suspicion⁵ (see Chapter 95, Musculoskeletal Disorders in Systemic Disease; and Chapter 97, Muscle and Connective Tissue Disorders). Additionally, inflammatory conditions in localized muscle tissue may present with muscle pain. Myositis, inflammation of muscle secondary to infection of deep fascial and muscle planes, and pyomyositis, a bacterial infection of skeletal muscle resulting in abscess formation, should be differentiated from rhabdomyolysis, which is a noninflammatory condition.^{3,49}

Important Clinical Features and Considerations

Early recognition of rhabdomyolysis is paramount to prevent potentially fatal complications. The most common and potentially devastating complication of rhabdomyolysis is acute renal failure. The incidence of acute renal failure in children ranges from 5–42%.^{1,10,50} A recent retrospective review of 191 children with rhabdomyolysis reported that the risk of acute renal failure in this series was much less than the risk reported for adults.⁵⁰ Renal failure develops as a result of myoglobin casts obstructing renal tubules, decreased glomerular filtration rate, and the direct nephrotoxic effects of myoglobin by-products.^{3,5,7,9-11,43} In an acidic milieu, with a pH less than 5.6, myoglobin dissociates into ferriheme and globin.⁵ Ferriheme is directly nephrotoxic, impairs renal tubular transport, and produces additional renal injury secondary to the production of free hydroxyl radicals.^{7,43} Patients with urinary pH less than 5.6, hypovolemia, and metabolic acidosis are at greater risk for the development of renal failure.

The release of intracellular potassium from myocytes results in hyperkalemia. Hypocalcemia develops due to the deposition of calcium in injured tissues and is exaggerated by the formation of calcium-phosphorus precipitants resulting from hyperphosphatemia.^{2,5,7,11,43} These electrolyte imbalances place patients at risk for cardiac arrhythmias and arrest.^{2,5,7,10,43,50} Interestingly, patients with rhabdomyolysis secondary to heatstroke are less likely to develop hyperkalemia given the presence of a respiratory alkalosis, increased sweating, and overproduction of aldosterone.¹⁴ These patients commonly present with normal serum potassium levels or hypokalemia.¹⁴

DIC may develop in patients with rhabdomyolysis, further complicating their course and management.^{2,5,7} Compartment syndrome also may develop as a result of fluid accumulation in muscle tissue secondary to intracellular fluid shifts.⁷

Management

Standard protocols for the management of rhabdomyolysis do not exist, and no randomized controlled trials have been carried out to evaluate the efficacy of current recommended therapies. Attention should be focused on primary resuscitation efforts, ensuring adequate ventilation and circulation.^{5,7,43} All patients require continuous cardiac monitoring, frequent assessment of vital signs, and monitoring of

urine output. An appropriate evaluation to determine the cause of muscle injury must be completed to identify and treat potential causes of myocyte destruction (hyperthermia/hypothermia, electrolyte abnormalities, metabolic derangements, toxins, hypovolemia)^{5,7,43} (see Chapter 111, Metabolic Acidosis; Chapter 114, Hyperkalemia; and Chapter 139, Hyperthermia).

The mainstay of therapy for rhabdomyolysis is aggressive hydration with isotonic saline to restore intravascular volume, induce diuresis, and prevent renal failure.^{5,9,11,43} Urine output must be closely monitored and adequate urine output maintained (>2 to 3 ml/kg per hour) to reduce the risk of acute tubular necrosis. Sodium bicarbonate administration is recommended to alkalinize the urine to a pH greater than 6.0 to prevent the breakdown of myoglobin into ferriheme, preventing ferriheme precipitation in the renal tubules.^{7-9,14,43,50} To further induce diuresis and prevent oliguric renal failure, osmotic agents are recommended.^{9,11,14,43} Mannitol (0.5 to 1 g/kg intravenously [IV] initially, followed by 0.25 to 0.5 g/kg IV every 4 to 6 hours) and furosemide (1 mg/kg IV every 6 hours) have been used successfully to induce diuresis in patients with rhabdomyolysis.^{9,11,14,43}

In addition to ensuring adequate hydration and renal perfusion, electrolyte disturbances that occur secondary to muscle injury must be aggressively treated. Treatment of hyperkalemia must be a priority, and appropriate therapy should be instituted promptly (see Chapter 114, Hyperkalemia).^{5,11,43} If oliguric renal failure or persistent electrolyte disturbances develop, dialysis may be required.⁴³ However, dialysis does not prevent acute renal failure as myoglobin is not a dialyzable substance.¹¹ Early consultation with a pediatric nephrologist is encouraged when managing rhabdomyolysis in patients with renal insufficiency and failure.

Additional therapy may be required, specific to the complications that develop from rhabdomyolysis. DIC must be treated aggressively with platelets, coagulation factors, and other blood products to prevent further complications,⁵ and the development of compartment syndrome will require appropriate surgical consultation with the potential need for fasciotomy.⁷ If malignant hyperthermia (autosomal dominant patients with muscle rigidity after succinylcholine or anesthetic) or neuroleptic malignant syndrome are considerations, dantrolene (2 to 3 mg/kg IV) should be administered (see Chapter 139, Hyperthermia).

Summary

Rhabdomyolysis results from various insults to skeletal muscle via direct or indirect means. Given the potentially fatal complications, patients with rhabdomyolysis require aggressive treatment in an inpatient setting. The primary treatment goal is to prevent further skeletal muscle breakdown and the development of acute renal failure.¹¹ Additional data are needed in the pediatric population to better define the most appropriate approach to the management and care of children with rhabdomyolysis.

Given the limited data available in pediatric populations, the mortality secondary to rhabdomyolysis is not well defined. However, patients with myoglobinuric renal failure tend to have a better prognosis if hypotension is minimized and cortical necrosis avoided.⁵ Some authors report a return of full muscle mass and function within 1 to 6 weeks of the

initial insult, with variable degrees of residual weakness observed.¹¹

Diseases of the Hip

Ronald I. Paul, MD

Key Points

Hip disease should be considered in any child with thigh, groin, or knee pain.

Although specific hip disorders are more common in specific age ranges, there is a considerable amount of overlap.

The absence of hip ossification centers makes the diagnosis of developmental dysplasia of the hip difficult in young infants.

Selected Diagnoses

- Developmental dysplasia of the hip
- Legg-Calvé-Perthes disease
- Slipped capital femoral epiphysis
- Transient synovitis of the hip

Discussion of Individual Diagnoses

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) describes a spectrum of diseases that result from abnormal formation of the hip joint during fetal development and the first few months of life. The term replaces the older and more traditional designation, “congenital dislocation of the hip,” which was too narrow in its description. Many cases are not dislocated at the time of diagnosis, and not all cases are congenital. Although most cases are detected during routine newborn and early infancy examinations by a primary care physician, some cases either are not discovered early or have a delayed presentation.

Clinical Presentation

DDH is variable in its presentation, depending on the severity and age at diagnosis. Some newborn hip joints are simply loose or slide in the acetabulum and are referred to as being subluxatable. Other hip joints lie within the acetabulum, but are dislocatable as they can be manually displaced with an audible “click” or palpable “clunk.” The least common but

more severe form of DDH includes hips that are dislocated while at rest. They may or may not be able to be reduced with simple measures.

The incidence of hip dysplasia in neonates is thought to be 1%, with 0.1% dislocated.¹ However, routine ultrasonography of babies in England has shown up to a 6% incidence of abnormal hips, although 90% of these return to normal by 9 weeks of age.² DDH is found more often in white and less often in African American infants.¹ Female gender and family history of DDH are risk factors, and up to 25% of DDH infants are born breech.^{2,3}

Because of the variability in presentation of DDH, clinical findings and appropriate diagnostic tests depend on the severity of dysplasia and patient age. Initially, parents may report difficulty in diapering an infant whose hips resist abduction. If not detected prior to walking, parents may notice gait asymmetry due to leg length differences. Eventually, pain in the hips and increasing limp will be noticed by the parent, patient, or physician.

The Ortolani and Barlow maneuvers have been the standard examination techniques used by physicians⁴ (Fig. 100–1). Both techniques should be performed on calm infants as a crying infant’s muscle tone may inhibit the subtle changes in DDH. In the Barlow maneuver, each hip should be flexed to 90 degrees while one hand stabilizes the other hip or pelvis. The thumb is placed on the medial thigh and the index and middle fingers are placed on the greater trochanter. The thigh is adducted and then pressure is applied longitudinally in a posterior direction in an attempt to dislocate the hip. A palpable clunk or audible click may occur with dislocation. The Ortolani maneuver is used to detect a hip that is dislocated by trying to reduce the dislocation. The thigh is flexed and abducted and the femoral head is lifted anteriorly into the acetabulum. If reduction is possible, the relocation will be felt as a clunk, not heard as a click. Loose hips may be detected by increased laxity in the hip joint.

Ortolani or Barlow maneuvers become more difficult to detect as the infant ages beyond 4 to 6 months because soft tissue contractures develop as the hip becomes more fixed in place. After this time, the infant may have a hip dislocation with severe limitations of abduction along with other signs, including leg-length discrepancy and asymmetric thigh skinfolds.

Although most cases are diagnosed clinically, radiographs and ultrasonography (US) have been helpful in confirming the diagnosis.⁵ Some centers recommend routine US of all

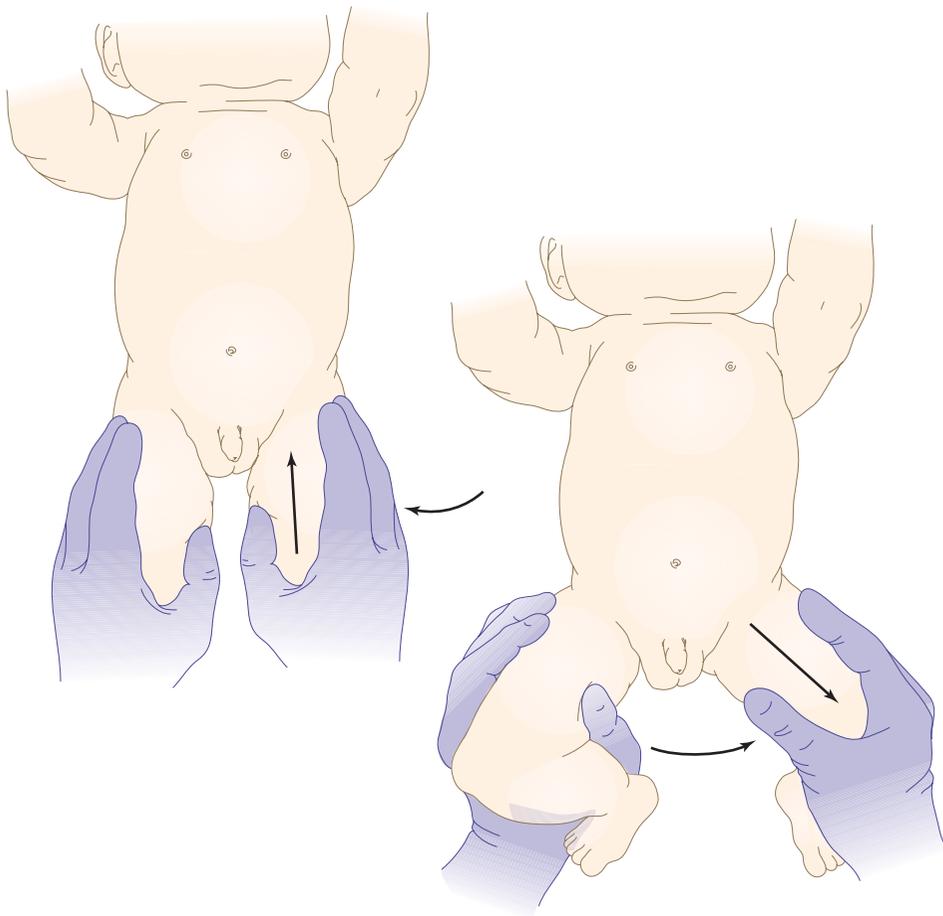

FIGURE 100-1. Ortolani (right) and Barlow (left) tests for detecting development dysplasia of the hip.

FIGURE 100-2. Radiograph of a 17-month-old infant with congenital dislocation of the right hip. There is delayed ossification of the femoral epiphysis and an abnormal position of the femoral metaphysis.

infants for DDH. However, US is not routinely performed in the United States since it may be too sensitive for mild hip dysplasia, and many cases will resolve spontaneously.^{1,2,5} Therefore, clinical examination is the primary method of diagnosis until 4 to 6 weeks of age. Ultrasound may be helpful at that time if clinical examination results warrant it. Plain radiographs of the pelvis are helpful, but only after the femoral head starts to ossify at about 4 months of age.⁵ Prior to 4 months of age, plain radiographs may be difficult to interpret and falsely reassuring. Abnormal position or delayed

ossification of the femoral head may be seen in older patients with DDH (Fig. 100-2).

The differential diagnosis of DDH is broad. Consideration should be given to causes of abnormal hip movement or abnormal resting position of hips. The list includes trauma, septic joints, and contractures caused by cerebral palsy (see Chapter 20, Lower Extremity Trauma; Chapter 21, Pelvic and Genitourinary Trauma; Chapter 46, Disorders of Movement; and Chapter 47, Peripheral Neuromuscular Disorders). An older child who presents with unrecognized DDH and a limp

should be investigated for metatarsus adduction, internal tibial torsion, Legg-Calvé-Perthes (LCP) disease, slipped capital femoral epiphysis, and transient synovitis of the hip. The workup will depend on patient age and other associated symptoms and physical findings.

Management

Once the diagnosis is made, management is directed by orthopedic consultants. Treatment is more successful when DDH is recognized earlier in its course. Mild laxity that is recognized in the first few days of life may not need therapy if the follow-up examination becomes normal. If symptoms persist, the main therapy is a Pavlik harness, which splints the leg in flexion and abduction. The splint prevents hip extension and limits adduction. If unsuccessful, a hip spica cast may be necessary. Infants older than 6 months may need closed reduction of a dislocated hip under general anesthesia. If unsuccessful, open reduction or femoral osteotomies may be needed. Prognosis is excellent if diagnosed early in the newborn period. Untreated patients are at risk for osteoarthritis, gait disturbances, leg-length discrepancies, and chronic pain.

Legg-Calvé-Perthes Disease

LCP disease, named after the three physicians who first described this disorder in the early 1900s, is a sequence of events that includes ischemic hip degeneration and subsequent regeneration that takes place in young children over several years. Although the disease is self-limited and usually has a benign outcome during childhood and adolescence, many patients develop significant osteoarthritis later in life. The etiology of LCP disease is unclear, and the disease may have a hormonal or an abnormal blood viscosity or clotting origin.^{6,7} The end result is an ischemic insult to the developing femoral head resulting in necrosis.

The disease occurs in a young age group, with 80% of patients between 4 and 9 years of age, and an outer range of 2 to 13 years of age.⁸ The disease is more common in males than females and there is an increased incidence in siblings.⁷ Birth weight below 2.5 kg, short stature, and delayed skeletal maturation have also been shown to be risk factors. About 10% of patients will develop bilateral disease.

Clinical Presentation

Children with this disease generally present with pain or a limp. Pain may be localized to the hip, groin, thigh, or knee. Parents may relate the pain or limp to minor trauma. Pain onset is usually not abrupt, but develops over days to months. Physical examination may show a limp (antalgic gait) secondary to either pain or a leg-length discrepancy. The length of both legs should be measured and compared in the supine position by measuring from the anterior superior iliac spine to the medial malleolus. The patient may also have pain with external hip rotation, and limited internal rotation and abduction.

Radiographs are the most common method for confirming a diagnosis. The diseased hip joint will progress through several stages, and radiographs will demonstrate different findings. Initially, anteroposterior and frog-leg lateral pelvic radiographs will demonstrate a smaller femoral head compared to the contralateral normal hip. A widened joint space may also be apparent. Within several months, a crescent-shaped radiolucent line may appear in the femoral head as it becomes more radiopaque. Following this, the epiphysis becomes fragmented (Fig. 100–3). Finally, reossification takes place, which may leave a residual deformity in both the femoral head and corresponding acetabulum. The entire process may take 2 to 4 years. Magnetic resonance imaging (MRI) has been used to evaluate children with LCP disease. With MRI, cartilaginous and metaphyseal abnormalities can be seen. The thickness of the articular cartilage of the femoral head has been shown to be increased in LCP disease and may be associated with loss of containment of the femoral head. Importantly, MRI has been shown to be more sensitive than radiography for the determination of subluxation of the femoral head during the active phase of LCP disease.⁹

The differential diagnosis of patients with LCP disease is large and includes inflammatory disorders, trauma, neoplasias, and congenital abnormalities. DDH also may occur in this age group, especially if it is unrecognized in infancy.

Management

Since the disease is self-limiting and resolves in 2 to 4 years, initial treatment is aimed at reducing pain. This may be

FIGURE 100–3. Radiograph of an 8-year-old boy with left hip pain. There is fragmentation of the left femoral head demonstrating Legg-Calvé-Perthes disease.

accomplished with nonsteroidal anti-inflammatory drugs and reduction of activity. Occasionally, non-weight-bearing, braces, casting, and osteotomies are utilized to decrease pain and improve femoral head reossification in a normal spherical shape.¹⁰ Orthopedic outpatient referral is appropriate for most cases.

Long-term outcome studies show that most patients are active and pain free for 20 to 40 years postdiagnosis. However, beyond 40 to 50 years, over 50% of patients develop degenerative joint disease and osteoarthritis.^{6,10} The largest prognostic risk factors for long-term morbidity are age at diagnosis and the extent of residual femoral head deformity.⁶ Patients who are diagnosed at an earlier age (under 6 years of age) do better than older children. Patients with more residual deformity in the femoral head are at risk for earlier onset of degenerative joint disease.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) is defined as displacement of the femoral epiphysis (femoral head) on the femoral metaphysis (femoral neck). The slippage initially occurs in a posterior and medial direction, and occurs most frequently during adolescent growth spurts. Due to the potential for damage to the tenuous vascular supply of the femoral head, the process is an important one to diagnose as delays in implementing treatment can lead to further slippage and increased morbidity.

Most practitioners now classify SCFE into two categories, stable and unstable.^{11,12} Clinically, a stable SCFE is one in which the patient can bear weight with or without crutches and an unstable SCFE is when the child cannot walk, even with crutches. An older classification based on duration of symptoms (chronic vs. acute) is no longer recommended as it has less prognostic capabilities. The vast majority of patients present with a stable SCFE, which carries a better prognosis if recognized early.

Although SCFE is usually associated with overweight children, it can also occur in nonobese patients. It is thought that obesity causes increased shear forces across an already weak and vertically oriented physis, resulting in slippage.¹² It occurs more often in African Americans compared to whites, and 60% of patients are male.¹³ SCFE usually occurs in adolescents during prepubescent growth. Therefore, it occurs earlier in females (average 12 years) than males (average 13.5 years) and rarely occurs after menarche in females.^{12,14} Between 25% and 40% of children with SCFE have bilateral involvement, with 50% of these presenting with simultaneous involvement and the others develop symptoms on the contralateral side within 18 months of initial diagnosis.¹²

Clinical Presentation

Children present with a variety of symptoms, including a limp and pain. Symptoms are usually present for several weeks before diagnosis and may be initially attributed to minor injuries or “growing pains.” Patients may have pain in the hip, thigh, groin, or knee. The absence of hip pain and the presence of thigh pain have been associated with a missed diagnosis.¹⁵ Errant diagnoses by physicians have included Osgood-Schlatter disease, bursitis, growing pains, chondromalacia, thigh contusions, muscle strains, stress fractures, and tendonitis. Because delayed diagnosis can result in further slippage, it is important for practitioners to include

SCFE in their differential diagnosis whenever evaluating patients with thigh, groin, or knee pain. In addition to pain, children may have an antalgic gait or loss of internal rotation of the hip. As slippage increases, there will be a worsening gait abnormality and decreased internal rotation of the hip. Unstable SCFE presents with extreme pain and can be thought of as an acute Salter-Harris type I fracture.¹⁶ Minor trauma, as in slipping off a curb edge or simply twisting in bed, may immediately precede an unstable SCFE. In addition to severe pain, patients with an unstable SCFE will resist any motion at the hip. The hip is usually held in flexion and external rotation. Gentle passive hip flexion usually leads to external rotation of the hip. No attempts at reduction should be made in the emergency department as this can cause further damage to the femoral head’s vascular supply.¹⁷

All patients with symptoms compatible with a stable SCFE should have anteroposterior and frog-leg lateral pelvic radiographs. Because early slippage is posterior and inferior, initial radiographic findings may only be seen on the lateral radiographs, revealing minimum posterior step-off at the physeal plate. Klein’s line represents a line drawn along the femoral neck on an anteroposterior film that should bisect the lateral portion of the femoral head. In patients with mild slippage, the line will be flush with or lateral to the lateral edge of the epiphysis (Fig. 100–4). As the slippage continues, there is further inferior and posterior movement of the epiphysis relative to the metaphysis, and radiographs will eventually show the typical picture similar to a scoop of ice cream slipping off a cone.

Patients suspected of having an unstable SCFE should not be forced into a frog-leg lateral position, but should have a lateral hip radiograph taken instead. A lateral view or frog-leg lateral view of the opposing leg should be taken for comparison and to detect mild slippage in bilateral cases.

The differential diagnosis for patients with SCFE includes other processes that can cause pain in the hip and lower leg. LCP disease usually occurs in younger children, but there is overlap in the age distribution. Patients with transient synovitis, septic hip, osteomyelitis, and muscle or ligamentous injuries of the thigh or hip may also present with similar symptoms (see Chapter 20, Lower Extremity Trauma; Chapter 21, Pelvic and Genitourinary Trauma; Chapter 95, Musculoskeletal Disorders in Systemic Disease; and Chapter 96, Bone, Joint, and Spine Infections). Because hip pathology often presents with knee pain, acute or chronic injuries of the knee, including Osgood-Schlatter disease and chondromalacia, should be considered. However, the knee examination is usually normal in patients with SCFE.

Management

All patients with SCFE need orthopedic referral as surgery is needed in all cases. Patients with unstable SCFE will need immediate orthopedic referral. Children with stable SCFE can be made non-weight bearing with crutches and seen promptly as outpatients. The most common surgical procedure for stable SCFE is a single central screw to maintain the femoral head in its current location until the physis is closed.¹² No attempts are made to reduce the slippage. Once physeal closure occurs, the patient is able to return to running and contact sports. Surgical treatment for unstable SCFE is controversial and may involve closed reduction, single or multiple screws, or osteotomies, and will depend on the degree of slippage and the preference of the orthopedic surgeon.¹⁸

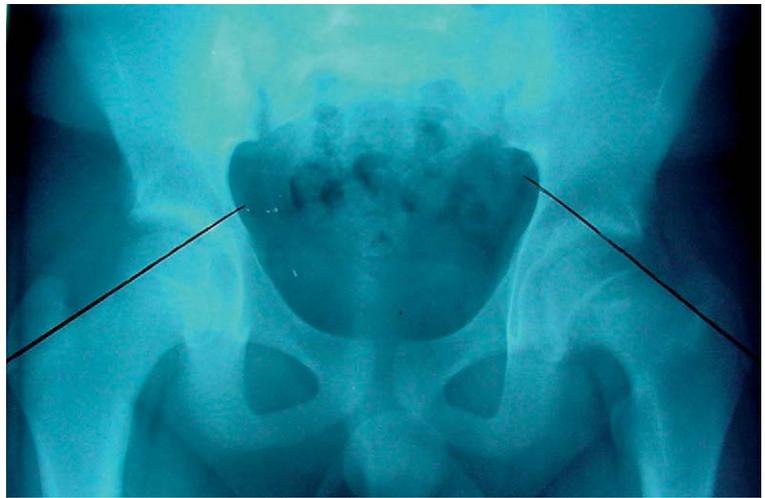

FIGURE 100–4. Radiograph of a 12-year-old with left hip pain. There is mild slippage of the left femoral epiphysis. Klein's line, drawn along the femoral neck, does not bisect the left femoral epiphysis as it does on the normal right hip.

Patients with stable SCFE usually do very well with minimal complications or morbidity, especially when diagnosed early. Complications of unstable SCFE include avascular necrosis of the femoral head, occurring in up to 35% of cases, and chondrolysis or loss of cartilage in the femoral head and acetabulum.^{10,15,17} Chondrolysis also develops more often as the degree of slippage increases and underscores the need to avoid missed or delayed diagnoses.

Transient Synovitis of the Hip

The most common cause of painful hips in children is transient synovitis of the hip (TSH). While the etiology of TSH is unknown, there is usually no long-term morbidity from this disorder. Importantly, clinicians must be able to differentiate this disorder from serious disorders causing a painful hip, including septic hip, osteomyelitis, LCP disease, SCFE, and neoplasias.

Although cases have been described in infants as young as 9 months and children as old as 18 years, the average age of children with TSH is 6 years, with a typical range of 3 to 10 years.^{19,20} This range overlaps with other causes of hip disease, including LCP disease and SCFE. The disorder is found more often in males, with a male:female ratio of between 1.5 : 1 and 2.6 : 1.^{19,21,22} Over 95% of children present with unilateral involvement, with an even distribution between right and left hips.²⁰

Clinical Presentation

Many patients have pain or limp for less than 24 hours, and two thirds have symptoms for less than 1 week.²⁰ Most others have symptoms for less than 1 month. A preceding or concurrent respiratory infection is found in 50% of patients with TSH, leading some to believe there is an infectious or postinfectious etiology. Most patients will either be afebrile or have a low temperature elevation,^{20,22} although temperatures as high as 40° C have been reported.²⁰ Patients may report pain of the hip, thigh, or knee, and have a mild limp or refuse to bear weight. Infants and children are not ill appearing and have a varying degree of restriction of hip movement and pain elicited at extremes of rotation.

The evaluation of patients suspected of having TSH should include a white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) level,

and a blood culture to differentiate this disorder from septic arthritis.^{21–25} The WBC count is usually normal to mildly elevated, with a mean count between 8600/mm³ and 11,200/mm³.^{20,21} However, some patients may have a WBC count greater than 20,000/mm³. The mean ESR is less than 20 mm/hr but may be greater than 20 mm/hr in as many as 25% of cases.²² CRP is usually less than 1 mg/dl but may be greater than 2 mg/dl in up to 14% of cases.²²

Radiographs may be normal or may show signs consistent with a joint effusion, with widening of the joint space or displacement or obliteration of periarticular fat planes. All patients with TSH will have an abnormal US showing mild or moderate effusion, with a small percentage showing severe effusion^{22,26,27} (Fig. 100–5). Joint aspiration is performed by orthopedic consultants and is reserved for patients in whom septic arthritis is still considered as a possible diagnosis after review of the clinical examination findings and other less invasive laboratory studies. Joint fluid should be sterile in TSH, with no bacteria seen on Gram stain and negative synovial fluid culture.

Although many etiologies have to be considered in the differential diagnosis of a child with a painful hip, radiographs can usually reveal abnormalities associated with LCP disease, SCFE, and trauma. Clinicians must be able to differentiate TSH from a septic hip. Several studies have found that the historical features and diagnostic adjuncts differ statistically between the two diseases: mean WBC count, ESR, CRP, temperature, joint space differences, history of fever, and an inability to bear weight.^{21–25} A combination of several factors, including temperature greater than 37° C to 38° C, WBC count greater than 11,000/mm³, ESR greater than 20 mm/hr, CRP greater than 1 mg/dl, joint space difference of greater than 2 mm on radiographs, and a history of fever or non-weight bearing, is more predictive of patients at increased risk of septic hip and therefore in need of a hip aspiration. If none of these features is present, the probability of septic arthritis is less than 1%^{22–25} (see Chapter 96, Bone, Joint, and Spine Infections). The more abnormal factors present, the greater likelihood the patient has a septic hip and not TSH.^{22–25} Limited studies have found MRI to be helpful in differentiating between the two entities, although there should be no delay in confirming the diagnosis of septic hip.²⁸ If septic arthritis is suspected after initial imaging and

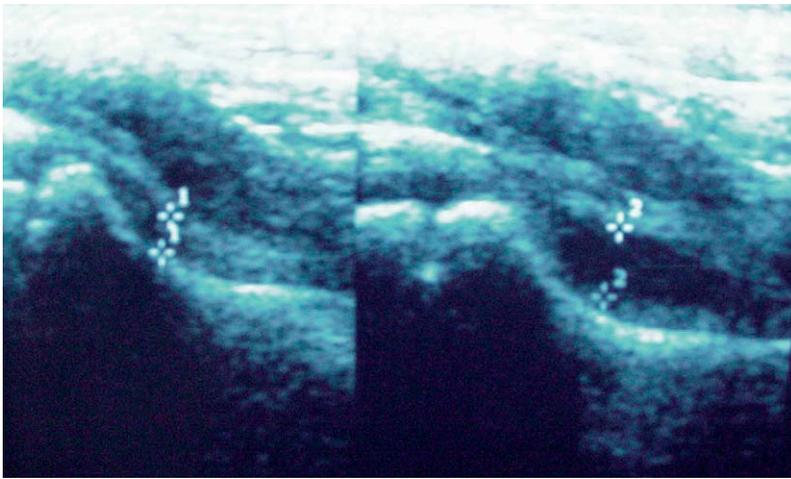

FIGURE 100-5. Ultrasound of a 5-year-old with right hip pain. Hip effusion is demonstrated with widening of the intracapsular space, especially when compared with normal left hip.

laboratory evaluation, orthopedic specialists should be consulted for hip joint aspiration.

Management

Most patients with TSH have rapid resolution of symptoms with bed rest. While most patients can be treated at home, some with more severe symptoms are treated in the hospital with traction for pain management. Recurrence of symptoms after initial resolution is unusual but may occur in 4% of cases.¹⁹ Follow-up US examinations or radiographs in 6 months may reveal a small number of patients who develop LCP disease,^{19,20,22} although it is unclear if TSH increases the risk for LCP disease, or the LCP cases were simply not recognized during the initial presentation. Because of the reported association with LCP disease, patients with TSH should be considered for repeat US examinations or radiographs if recurrent symptoms develop several months later. Unlike septic arthritis and SCFE, no long-term complications or morbidity is associated with TSH.

Serum Sickness

Lee S. Benjamin, MD

Key Points

Serum sickness is now rare in the United States due to the substitution of newer medications for those historically made from animal serum.

A condition with a clinical presentation similar to serum sickness, known as “serum sickness–like reaction,” is sometimes referred to as “serum sickness.” This intermingling of terms likely leads to some confusion.

The signs and symptoms of serum sickness are fever, arthralgia, skin eruptions, lymphadenopathy, nephritis, edema, and neuritis. The signs and symptoms of serum sickness–like reactions, in contrast, may include fever and lymphadenopathy, but are otherwise confined to the skin and joints.

Antibiotics are the most common medications to cause serum sickness–like reactions.

A latent period of 2 to 17 days is expected between antigen exposure and the onset of serum sickness–like reactions.

Introduction and Background

Serum sickness is an uncommon clinical syndrome associated with exposure to animal serum. The typical symptoms include fever, arthralgias, skin eruptions that can include palpable purpura or urticaria, lymphadenopathy, nephritis, edema, and neuritis.^{1,2} Historically, antisera derived from horse serum were the most common causes of serum sickness. These antisera were used to treat snake bites, botulism, and pneumococcal, meningococcal, and streptococcal infections, and to immunize patients against diphtheria, tetanus, and rabies.^{3–7} Refinements and advances in treatments for these conditions have substantially mitigated the risk of serum sickness for patients in recent years.

Serum sickness–like reactions are more common than cases of serum sickness. Serum sickness–like reactions have

some clinical signs and symptoms in common with serum sickness. These include rash and joint pains.^{8–11} The rash may include urticaria or erythema multiforme, or be morbilliform. The child may exhibit arthralgias or clinically appreciable arthritis. The presence of fever or lymphadenopathy is variable. Unlike serum sickness, serum sickness–like reactions are not associated with circulating immune complexes. Therefore, palpable purpura, nephritis, edema, and neuritis are not expected in cases of serum sickness–like reactions. Oral antibiotics are currently the most common cause of serum sickness–like reactions.⁹ Even though they share some clinical features, it is unknown if serum sickness–like reactions and serum sickness are different points along a single continuum. Unfortunately, the term *serum sickness* is sometimes applied to cases of serum sickness–like reactions.¹² This intermingling of terms likely leads to confusion.

Recognition and Approach

There are no recent epidemiologic studies reporting the incidence, but clinical experience suggests serum sickness presenting to the emergency department is rare. Serum sickness is a type III hypersensitivity reaction to foreign proteins that leads to the development of circulating immune complexes that deposit in small vessels, activation of complement, and recruitment of granulocytes.^{1,3,13–15} The deposition of the circulating immune complexes is thought to be the dominant pathophysiologic derangement.

Children with serum sickness–like reactions are rare, but relatively more common than those with serum sickness. Population-based epidemiologic data are not available. The pathophysiology of serum sickness–like reactions remains elusive.^{8,10,16} Circulating immune complexes are inconsistently identified. The vast majority of cases of serum sickness–like reactions occur in children younger than 5 years.^{10–12} A history of taking a new antibiotic or other medication is nearly universal¹² (Table 101–1). In particular, the use of oral cefaclor has been implicated in cases of serum sickness–like reactions.^{8,9,12} Prior sensitization to medication is not a prerequisite.^{8,10}

Clinical Presentation

Children may present to the emergency department for evaluation of possible serum sickness or a serum sickness–like reaction. A history of exposure to horse serum makes the

Table 101–1 Medications Associated with Serum Sickness–like Reactions

 Phenytoin
 Propranolol
 Rifampin
 Streptomycin
 Sulfa medications
 Tetracyclines
 Thiouracil

Abbreviation: NSAIDs, nonsteroidal anti-inflammatory drugs.

diagnosis of serum sickness quite likely. However, the history is seldom so straightforward. It is more likely to include some vague symptoms arising after treatment with a new medication has begun. The temporal relationship between starting the new medication and symptom onset is sometimes helpful. For both serum sickness and serum sickness–like reactions, the onset of symptoms is usually delayed several days from the exposure to the inciting antigen. The exact time span is not known. Rough estimates based on limited data suggest the symptoms of serum sickness arise 1 to 2 weeks after antigenic exposure and the symptoms of serum sickness–like reactions arise 2 to 17 days after drug exposure.^{10,13,14} The most common symptoms include rash and arthralgia.^{8,9,11,12,17} A history of neurologic symptoms or dark urine is most consistent with a diagnosis of serum sickness. A history of recently beginning a course of oral cefaclor suggests a serum sickness–like reaction.^{8,9,12,18,19}

Physical examination findings in cases of serum sickness and serum sickness–like reactions are often nonspecific. In both conditions, a rash is expected. In both conditions, the rash may be urticarial or morbilliform.^{8,9,11} In cases of serum sickness, but not serum sickness–like reactions, the rash may include petechiae and palpable purpura. In both conditions, the physical examination may reveal swollen, tender joints consistent with an acute arthritis. Fever and lymphadenopathy are characteristic of serum sickness, but variably seen in cases of serum sickness–like reactions.^{8,9,12–14} Facial edema and an abnormal neurologic examination may be seen in cases of serum sickness, but not cases of serum sickness–like reactions.²⁰ A child with acute nephritis associated with serum sickness may be hypertensive.

Laboratory tests have modest utility in the evaluation of a child with possible serum sickness or a serum sickness–like reaction. For cases suggestive of serum sickness–like reactions, no routine laboratory tests are indicated. The history of initiating a new medication, particularly an antibiotic, 2 to 17 days prior to presentation and the presence of a non-petechial rash and joint pains with or without fever are likely diagnostic. For cases in which serum sickness is likely, testing is generally directed at the overall differential diagnosis. For example, for children with a petechial rash or purpura, a

measurement of platelets (usually obtained as part of a complete blood count) and a prothrombin time are probably indicated. A microscopic urinalysis is helpful for identifying acute nephritis. A measurement of blood urea nitrogen and creatinine is also indicated if serum sickness is suspected. Other laboratory tests are indicated on a case-by-case basis, guided by signs and symptoms. The child's primary care physician may request other tests to guide him or her in the outpatient management of serum sickness.

Important Clinical Features and Considerations

The differential diagnosis of the signs and symptoms associated with children suspected of having serum sickness or serum sickness–like reactions is broad. The differential diagnosis includes conditions such as bacterial, viral, and parasitic infections, as well as vasculitis, connective tissue disease, syphilis, atopic disease, inflammatory bowel disease, sarcoidosis, cystic fibrosis, Behçet's syndrome, pemphigus, bullous pemphigoid, and allergic vasculitis.²¹

Management

Discontinuation of the offending agent is the mainstay of treatment and is usually curative.¹⁷ There is no evidence on which to base management decisions. Although systemic steroids have been recommended, their utility is uncertain, particularly given that the vast majority of children will have spontaneous resolution of their symptoms with the removal of the offending agent as the sole intervention.^{11,17} Other treatments are supportive and symptomatic. These include acetaminophen for fever and analgesia, antihistamines for allergic-type symptoms such as urticaria, and nonsteroidal anti-inflammatory medications such as ibuprofen for joint inflammation and pain. In general, children with serum sickness or serum sickness–like reactions can be managed as outpatients. Uncertainty in the diagnosis may warrant hospital admission or transfer to a tertiary pediatric center to work through the differential diagnosis. The most common reason for admission to the hospital in cases of serum sickness–like reactions is for uncontrollable joint pains.¹¹

In general, the emergency physician should recommend that the family avoid giving the offending agent to the child in the future. One pair of authors recommends avoiding the entire class of medications to which the offending agent belongs.²² There is no evidence to support this recommendation. Others have noted no significant cross reactivity within the same class of medications.^{11,23}

Summary

A history of antigen exposure is very helpful in evaluating a child suspected of possibly harboring serum sickness or a serum sickness–like reaction to a new medication. The presence of palpable purpura, nephritis, edema, and neuritis helps differentiate serum sickness from a serum sickness–like reaction. Removing the offending agent is the mainstay of treatment. Most children do well with symptomatic treatment and recover uneventfully. Avoidance of the offending agent in the future is prudent.

Chapter 102

Vaccination-Related Complaints and Side Effects

Franz E. Babl, MD, MPH and Stuart Lewena, MBBS

Key Points

Most vaccination-related complaints are mild and self-limited.

The probability that a given problem is related to a recent vaccination can be predicted by knowing which vaccines were given and the timing of the administration of the vaccines in relation to the emergency department visit.

Knowledge of the immunization schedule is useful for determining which vaccines a child is likely to have received. This is particularly helpful when the parents cannot reliably identify which vaccines were given during a recent office visit.

Due to the low incidence of some events and the high rate of vaccination in the developed world, it is difficult or impossible to determine if some very rare adverse events are causally related to immunizations or merely temporally associated with them.

Selected Diagnoses

- Allergic reactions and anaphylaxis
- Rash
- Fever
- Encephalitis and encephalopathy
- Generalized weakness
- Seizures
- Syncope
- Hypotonic-hyporesponsive episodes (shocklike state)
- Protracted, inconsolable crying
- Arthralgias and arthritis
- Extensive limb swelling
- Thrombocytopenia

Discussion of Individual Diagnoses

Allergic Reactions and Anaphylaxis

Vaccine-related allergic reactions, particularly serious reactions such as anaphylaxis, are rare.¹ The measles vaccine, diphtheria and tetanus toxoids and pertussis vaccine (DTP) and hepatitis B vaccine (HepB) are the most commonly identified vaccine-related causes of anaphylaxis.² The rates of anaphylaxis are 1.8 per 1 million doses for measles vaccine (0.00018%) and 1.6 per 1 million doses for HepB (0.00016%).^{1,3} Serious allergic reactions due to other vaccines are even rarer.⁴

Vaccines contain various additives and other components that may cause allergic reactions in children sensitive to these agents. The measles and mumps vaccines (most commonly combined in the measles-mumps-rubella vaccine [MMR]) are derived from chick embryo fibroblast tissue and contain very small amounts of egg protein. Children with an egg allergy are at increased risk of having an allergic reaction to these immunizations, but the risk is exceedingly small. In contrast, the influenza vaccine contains a greater amount of egg protein and places children at such a great risk for allergic reactions that it is recommended that this vaccine be withheld from children with egg allergies.⁵ Inactivated poliovirus vaccine (IPV) contains trace quantities of neomycin, streptomycin, and polymyxin B. Children with allergies to any of these antimicrobials are at risk for allergic reactions to IPV. The MMR and varicella vaccines contain trace amounts of neomycin and gelatin. Children allergic to neomycin or gelatin can develop allergic reactions, including delayed-type local reactions manifesting as erythematous, pruritic papules 48 to 96 hours after vaccination.^{3,6,7} Yeast protein is present in HepB, and children with yeast allergies can have reactions to this vaccine.⁶

The timing of allergic reactions, including anaphylaxis, in relation to vaccine administration is an important factor in determining whether or not the vaccine could be the cause. Parents may not be able to list the vaccines given during a recent office visit or may provide inaccurate information.⁸ Because of this, it is helpful for emergency physicians to have some familiarity with the recommended schedule of immunizations to allow for a reasoned guess as to what vaccinations were likely given based on the child's age (Table 102-1).

Table 102–1 Simplified Pediatric Immunization Schedule

Age	Vaccines											
	HepB	DTaP	Tdap	Hib	IPV	PCV	Influenza*	MMR	Varicella	Rota	MCV4	HPV [†]
Birth	✓											
2 mo	✓			✓	✓	✓				✓

6 mo	✓	✓		✓	✓	✓	✓			✓		
12 mo				✓		✓		✓	✓			
15 mo		✓										
4–6 yr		✓			✓			✓	✓			
11–12 yr			✓								✓	✓

*Influenza vaccine is given yearly thereafter up to age 5 years.

[†]HPV is administered as a series of 3 immunizations given over 6 months.

Abbreviations: DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine; HepB, hepatitis B vaccine; Hib, *Haemophilus influenzae* type b conjugate vaccine; HPV, human papillomavirus vaccine; IPV, inactivated poliovirus vaccine; MCV4, meningococcal conjugate vaccine; MMR, measles-mumps-rubella vaccine; PCV, pneumococcal conjugate vaccine; Rota, rotavirus vaccine; Tdap, tetanus and diphtheria toxoids and acellular pertussis vaccine.

Adapted from American Academy of Pediatrics Committee on Infectious Diseases. Recommended immunization schedules for children and adolescents—United States, 2007. *Pediatrics* 119:207–208, 3 p following 208, 2007.

In general, anaphylaxis, if it develops, does so shortly after immunization. In a review of 366 patients with adverse reactions to DTaP, 34 patients developed anaphylaxis and 76 developed urticaria.⁷ Most cases of anaphylaxis manifested within 15 minutes of vaccine administration, and none occurred after 60 minutes. In contrast, urticaria developed up to 24 hours after immunization. In another study of adverse events after 3 million MMR vaccinations, 30 (0.001%) anaphylaxis-like reactions appeared, 29 within 20 minutes of immunization.⁹ None of these cases was fatal. The management of vaccine-related allergic reactions and anaphylaxis does not differ from that for cases due to other causes (see Chapter 14, Anaphylaxis/Allergic Reactions).

Rash

The vaccines most commonly associated with rashes are the varicella and MMR vaccines. A localized injection site rash develops in 4% of children receiving the varicella vaccine.¹⁰ Most varicella vaccine-related rashes become apparent 9 to 16 days after immunization. Most of these cases involve mild, localized, papular lesions. Some children manifest what appears to be a mild case of varicella with a handful of the characteristic vesicular lesions and crusting in approximately the same time frame as the papular rashes. Based on the virology, at least some of these cases are due to varicella infection and not the varicella vaccination. In a polymerase chain reaction analysis of 70 post-varicella vaccine rashes, 61% of cases had the wild-type varicella virus strain and 31% showed the Oka-type vaccine strain.¹¹ Disseminated varicella due to the vaccine strain may occur in previously undiagnosed immune-compromised patients.¹² MMR is associated with transient rashes in 5% of those vaccinated. This rash is fairly nonspecific in appearance and typically occurs 7 to 10 days after immunization.^{4,13} This MMR-associated rash is associated with transient lymphadenopathy in some cases.

Fever

Many childhood vaccines have been associated with causing fever after vaccination.⁶ Febrile episodes occur at low rates, and within the first 1 to 2 days postvaccination, after admin-

istration of HepB, influenza virus vaccine, *Haemophilus influenzae* type b conjugate vaccine, and pneumococcal conjugate vaccine (PCV). Fever due to MMR, however, usually occurs 7 to 12 days after immunization. Approximately 5% of children develop a fever of $\geq 39.4^{\circ}\text{C}$ (103°F) after MMR vaccination.^{13,14} In some ways, fever is so common in children that most are expected to develop fever *at some point* after an immunization. Attributing fever to an immunization is fraught with problems if the time course is drawn out. For example, the incidence of fever within 42 days after the first dose of varicella vaccine is 15%, which is similar to the incidence seen in children who received placebo.^{10,15} Very high fevers may be seen within 48 hours of the administration of DTP.⁶ Temperatures $\geq 40.5^{\circ}\text{C}$ (104.8°F) are seen in 0.3% of children receiving DTP.⁶ Following the introduction of the acellular pertussis vaccine into DTP (designated as DTaP), the incidence of fever has been much lower.⁶ It is prudent to consider alternative diagnoses in children who manifest fever that is temporally associated with vaccines. In one study, 80% of children who experienced fever after receiving the varicella vaccine harbored another illness¹⁰ (see Chapter 32, Fever in the Well-Appearing Young Infant).

Encephalitis and Encephalopathy

Encephalopathy refers to any acute or chronic acquired abnormality of the function of the brain. *Encephalitis* refers to an encephalopathy caused by an inflammatory response in the brain usually manifested by pleocytosis (i.e., white blood cells in the cerebrospinal fluid).² Encephalitis with resultant residual permanent encephalopathy develops in approximately 1 in 1000 people (0.1%) infected with the measles virus.¹³ There is not enough evidence to accept or reject a causal relationship between immunization with live measles vaccine virus and encephalitis or encephalopathy.² In the United States, 166 cases of encephalopathy occurring 6 to 15 days after measles vaccine were identified over 30 years through a number of passive surveillance systems.^{13,16} In other words, the incidence of encephalopathy possibly due to measles vaccines is approximately 1 in 2 million (0.00005%). This incidence is so low and the percentage of the population who receives vaccinations is so high, it is essentially

impossible to perform a study to determine if encephalitis can be caused by the measles component of MMR. So, although measles (the disease) can cause encephalitis, it is not clear if the measles vaccine can cause encephalitis. A 10-year follow-up of a study from the United Kingdom on vaccination-related encephalopathy showed no evidence of a risk of long-term neurological damage associated with measles vaccine.¹⁷ Some strains of the mumps component of MMR can cause aseptic meningitis. However, the strain used in the United States does not.^{2,13} DTP might cause acute encephalopathy, but with an incidence of 0 to 10 cases per million vaccinations (0 to 0.001%).^{1,18} There is no difference in the management of children presenting with acute encephalopathy or acute encephalitis temporally associated with vaccines and that of other children with a similar presentation (see Chapter 11, Altered Mental Status/Coma).

Generalized Weakness

The two main types of weakness associated with vaccines are paralytic poliomyelitis and the Guillain-Barré syndrome. The oral poliovirus vaccine (OPV) has been causally linked with paralytic poliomyelitis.² The case definition of vaccine-associated poliomyelitis is acute flaccid paralysis in a vaccine recipient 7 to 30 days after receiving OPV, with no sensory or cognitive loss, and with paralysis still present 60 days after the onset of symptoms. The risk is low at 1 case per 2.4 million doses (0.00004%).¹⁹ In the United States, the routine childhood immunization schedule has replaced OPV with IPV which is not associated with paralytic poliomyelitis. However, outside the United States, OPV is still widely used. The Guillain-Barré syndrome has been associated with a number of vaccines, but there are inadequate data to determine if a causal relationship exists.^{2,4,19} This is another example of a very rare event occurring in the context of a very high incidence of vaccination.

Seizures

The two vaccines associated with high fevers, MMR and DTP, are also associated with febrile seizures. The available data are difficult to reconcile. For example, the risk of febrile seizures following MMR vaccination has been reported to range from 1 in 100,000 (0.001%) up to 1 in 3000 (0.03%).^{9,20} Case definitions likely cause these differences. The timing of the febrile seizures correlates with the timing of peak post-vaccination temperatures.²¹ There is no evidence that MMR is associated with an increased risk of epilepsy.² The change from DTP (with the whole-cell pertussis adsorbed component, also referred to as DTwP) to DTaP (with an acellular pertussis component) vaccine has dramatically decreased the risk of fever and also febrile seizures. The incidence of febrile seizures associated with DTaP is 0.5 events per 100,000 vaccinations (0.0005%).²² The treatment of febrile seizures associated with vaccinations is no different than that of children with febrile seizures thought to be due to other causes (see Chapter 40, Seizures).

Syncope

Syncope can occur after any of the routine childhood vaccinations.²³ Syncope can be preceded by symptoms such as light-headedness, dizziness, diaphoresis, and visual changes. Syncope associated with vaccinations is typically brief. Adolescent girls are the most common population to experience

syncope following vaccination.^{23,24} In a review of 697 cases of syncope after vaccination, 57% occurred within 5 minutes of administration, 80% occurred within 15 minutes, and 88% within 30 minutes. Like other causes of syncope, 24% of the children experiencing syncope manifested some brief seizure-like movements.²³ In most cases, postvaccination syncope is neurocardiogenic. The approach to children who experience syncope following vaccination is the same as that of other children who experience syncope (see Chapter 61, Syncope).

Hypotonic-Hyporesponsive Episodes (Shocklike State)

Hypotonic-hyporesponsive episodes have been associated with DTP vaccines. Although the highest rates occur after immunization with the older DTwP, episodes may occur after DTaP administration.²⁵ These events occur with an incidence of 0 to 140 cases per 100,000 doses (0 to 0.14%).^{4,18,26} Hypotonic-hyporesponsive episodes have been defined as limpness or hypotonia, reduced responsiveness, and pallor or cyanosis occurring within 48 hours of immunization and lasting from 1 minute to 48 hours in children younger than 10 years of age.²⁷ The etiology and pathophysiology of these events is unknown. By the time patients present for medical attention, symptoms have often resolved. In a series of 215 cases of hypotonic-hyporesponsive episodes, the median age was 4 months (range, 1 month to 8.9 years) and the median interval from the time of vaccination to onset of symptoms was 3.5 hours (range, 1 minute to 2 days).²⁸ None of the events was fatal, and 99% of children returned to their pre-vaccination state with a median time to return of 6 hours (range, 1 minute to 4 months). The three children reported as not returning to baseline were diagnosed with conditions not known to be causally associated with immunizations.

Assessment of a child with a possible hypotonic-hyporesponsive episode should exclude other known causes of sudden onset of hypotonia, hyporesponsiveness, or pallor. Evidence of preceding seizure activity or a postictal state, or evidence of urticaria, wheezing, or other signs and symptoms of anaphylaxis should be assessed. Other considerations in the setting of immunizations that are painful are syncope and breath-holding spells. There are no known residual effects from having a hypotonic-hyporesponsive episode.^{27,28}

Protracted, Inconsolable Crying

Protracted, inconsolable crying has been recognized as an adverse event causally related to DTP.¹⁸ It has been defined as persistent, severe, inconsolable screaming or crying for 3 or more hours observed within 48 hours of DTP vaccination.⁶ The incidence of this syndrome is 1 in 100 (1%) doses administered for DTP vaccines containing the whole-cell pertussis component (DTwP) and significantly less with newer acellular pertussis vaccines (DTaP).^{6,17,29} The significance or cause of protracted inconsolable crying is unknown.⁶ There are no specific management recommendations for children with protracted inconsolable crying following immunization. Serious sequelae have not been described (see Chapter 31, Excessive Crying).

Arthralgias and Arthritis

Joint symptoms such as arthralgias (i.e., joint pains) and arthritis (i.e., joint redness and swelling) are associated with

the rubella component of MMR. Acute arthralgia or arthritis after vaccination with the rubella vaccine strain used in the United States occurs rarely in children. In contrast, 26% of young women develop acute arthralgias and 11% develop acute arthritis after rubella vaccination.³⁰⁻³² Joint symptoms generally begin 1 to 3 weeks after vaccination, persist for 1 day to 3 weeks, and rarely recur. Although many different joints can be involved in the reaction to rubella vaccines, knees and fingers are the most common. The hips are seldom involved. The question of whether rubella vaccine can cause chronic arthritis in adult women is controversial.¹⁸ Recent data from a prospective, randomized, placebo-controlled trial of 546 seronegative women receiving rubella vaccine show a small excess risk of developing chronic joint pain.³³ There is no evidence that vaccine-related joint problems should be managed differently from non-vaccine-related arthralgias or arthritis (see Chapter 95, Musculoskeletal Disorders in Systemic Diseases).

Extensive Limb Swelling

Extensive limb swelling is defined as edema extending at least to the elbow or knee in a vaccinated limb. In a 13-year review of reports to the Vaccine Adverse Events Reporting System (VAERS), 418 cases of extensive limb swelling were identified.³⁴ A broad range of vaccines have been implicated, with those most frequently cited being the PCV, DTaP, and adult tetanus and diphtheria toxoids (Td) vaccines. In most cases the swelling develops within 24 hours after vaccination and is limited to the proximal half of the extremity. Associated erythema, warmth, or pain was reported in more than 70% of cases, and constitutional symptoms such as fever were reported in 20% to 25%. Children younger than 2 years had associated agitation or crying in 32% of cases of extensive limb swelling. Adolescents and adults had influenza-like symptoms in 10% to 18% of cases.³⁴ Extensive limb swelling has been associated with booster doses of DTaP.³⁵ Extensive thigh swelling was reported in 2% of patients after the fourth dose of this vaccine; most cases were associated with erythema and pain. The etiology of extensive limb swelling is unknown.^{34,35} Extensive limb swelling after vaccination appears to be self-limited and resolves without sequelae. There are no specific management recommendations for patients with extensive limb swelling.

Thrombocytopenia

MMR is associated with thrombocytopenia. The risk of thrombocytopenia is estimated to be 1 in 35,000 doses (0.003%).² It is unknown which vaccine component is responsible for the development of thrombocytopenia. The presentation is similar to cases of idiopathic thrombocytopenic purpura (ITP)^{36,37} (see Chapter 122, Petechiae and Purpura). Vaccine-associated thrombocytopenia typically presents within 6 weeks of MMR immunization, with the highest incidence between 15 and 28 days after vaccination.³⁸ Compared to cases of ITP that are not temporally associated with vaccine administration, vaccine-associated cases tend to be milder and have higher platelet counts.³⁷ There is no evidence to suggest that vaccine-associated thrombocytopenia should be evaluated and managed differently from other cases of thrombocytopenia.

Tetanus Prophylaxis

Fredrick M. Abrahamian, DO and David A. Talan, MD

Key Points

Tetanus in children in the United States is rare.

Children at higher risk for developing tetanus in the United States include those who are not completely vaccinated (including those children whose parents choose not to immunize them), adolescent injection-drug users, and immigrants from outside North America or Western Europe.

The decision to initiate postexposure prophylaxis is dependent on the wound characteristics and the child's vaccination history.

Wounds at higher risk for tetanus include contaminated wounds (e.g., with dirt, feces, soil, or saliva), puncture wounds, avulsions, wounds resulting from missiles, crush injuries, burns, frostbite, and those with neurovascular compromise.

The two important factors to determine about a patient's vaccination history are whether or not the patient has had a primary immunization series (i.e., at least three doses of adsorbed tetanus toxoid) and the elapsed time period since the last vaccination dose.

Introduction and Background

Although the global incidence of tetanus is high and continues worldwide to claim thousand of lives annually, it remains a rare disease in the United States and other developed countries.¹ Implementation of large-scale tetanus immunization programs, widespread availability of tetanus toxoid vaccine and immune globulin, and improved wound care management and childbirth practices have all contributed to the dramatic decline in the incidence of tetanus in developed countries. Although no active immunization practice is considered 100% effective, tetanus immunization has shown to be one of the most effective immunization practices ever developed.^{2,3}

Recognition and Approach

In the United States, tetanus occurs primarily in adults, although internationally, neonatal tetanus accounts for the majority of cases.¹ During 1998–2000, a total of 130 cases of tetanus were reported to the Centers for Disease Control and Prevention (CDC).⁴ The majority were males (60%) between the ages of 20 and 59 years (55%). Twelve (9%) of the cases involved children younger than 20 years of age, including one neonate. Of the 130 cases identified, the outcome was known for only 113 patients. Twenty of these patients died. None of the deaths occurred in children or adults younger than 30 years of age.

From a review of tetanus cases reported to the CDC from 1987 to 2000, the majority of the cases had an acute injury identified prior to the onset of illness.^{4–8} Puncture wounds were the most frequent type of acute injury, followed by lacerations and abrasions. A common circumstance for a puncture wound was stepping on a nail. Other puncture wounds included splinters, tattooing, and animal bites. The sites of antecedent injury were, in order of decreasing frequency, a lower extremity, an upper extremity, the head, and the trunk.

Tetanus surveillance reports indicate that the populations relevant to pediatric emergency medicine that are at highest risk for developing tetanus in the United States are children who are not completely vaccinated, adolescent injection-drug users,^{4–9} and immigrants from outside North America or Western Europe.^{10–12}

Parental objections to immunizations are a key risk factor for children who develop tetanus in the United States. Neonates born to parents who object to and do not receive vaccinations, due to either religious or philosophical reasons, are at higher risk of developing tetanus. During 1992–2000, 13 cases of non-neonatal tetanus in children younger than 15 years were reported. Of those, 11 (85%) were not protected due to parental objections to immunizations.¹³ Similarly, the three reported neonatal tetanus cases in the United States during 1989–2000 were associated with absent or incomplete maternal vaccination.^{5,7,13,14}

Evaluation

The decision to initiate postexposure prophylaxis is dependent on the wound characteristics and the patient's vaccination history. Regarding tetanus postexposure prophylaxis,

the Advisory Committee on Immunization Practices (ACIP) of the CDC categorizes wounds as either clean, minor wounds, or “all other wounds.” Examples of “all other wounds” include contaminated wounds (e.g., with dirt, feces, soil, or saliva), puncture wounds, avulsions, wounds resulting from missiles, crush injuries, burns, and frostbite. These wounds are at higher risk for harboring *Clostridium tetani* since they have occurred in an environment in which *C. tetani* spores are prevalent or they are the type of tissue injury that provides low oxygen tension conducive for anaerobic conditions allowing *C. tetani* spore germination and proliferation.^{15,16} Children who have not received at least three doses of adsorbed tetanus toxoid are also at increased risk for tetanus.¹³

In clinical practice, some parents are uncertain if their child has received a complete primary immunization series.¹⁷ Current tetanus prophylaxis guidelines recommend considering a child as not having had any previous tetanus vaccinations if the history of past immunizations is unknown or uncertain.^{15,16} Fortunately, young adults who have served in the military and children who have attended public schools in North America or Western Europe are likely to have completed a primary immunization series. Immigrants from outside North America or Western Europe and adults who do not have an education level beyond grade school are more likely to lack primary immunization.¹⁰

Management

The primary immunization series ensures adequate baseline levels of tetanus antibody and future anamnestic response to booster injections. Since immunity to tetanus with vaccination declines with time, booster doses are required to keep the antitoxin levels in a protective range. Periodic injections of tetanus toxoid result in sequentially higher peak responses, higher residual antitoxin levels, and longer periods during which antibodies are detected.² Primary immunization is

recommended beginning in infancy with intramuscular (IM) injections of diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP)¹⁸⁻²⁰ (Table 103-1). A catch-up tetanus immunization schedule and minimum intervals between doses for children and adolescents who start late or who are more than 1 month behind is also available¹⁸ (Table 103-2). At age 19 and greater, a booster dose of tetanus and diphtheria toxoids vaccine (adult) (Td) administered every 10 years provides adequate protection for clean, minor, uncontaminated wounds. For all high-risk wounds that are also associated with a shorter tetanus incubating period, to make certain there is rapid attainment of adequate antibody levels, a booster dose is recommended if the preceding tetanus toxoid was given greater than 5 years prior^{15,16,21} (Table 103-3). Since the ACIP regularly updates the recommended childhood and adolescent immunization schedules, we recommend reviewing the latest immunization recommendation by contacting local or state health departments, by accessing the CDC's National Immunization Program web site at <http://www.cdc.gov/nip>, or by calling the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Active Immunization

Active immunization is provided by the administration of tetanus toxoid, which is provided in various preparations²² (Table 103-4). DTaP is indicated for primary and booster vaccinations against diphtheria, tetanus, and pertussis for children 6 weeks to 7 years (i.e., prior to the seventh birthday). DTaP is preferred over diphtheria and tetanus toxoids and whole-cell pertussis vaccine adsorbed (DTwP) due to its lower incidence of local and systemic adverse reactions and improved efficacy.²³ DTaP is given as a 0.5-ml IM injection into the anterolateral aspect of the thigh (for infants) or the deltoid muscle of the upper arm (for children). The most frequently encountered adverse events include local reactions such as injection site tenderness, redness, induration, and

Table 103-1 Routine Diphtheria, Tetanus, and Pertussis Vaccination Schedule Summary for Children and Adolescents

Dose	Customary Age	Age/Interval*	Product
Primary 1	2 mo	6 wk old or older	DTaP [†]
Primary 2	4 mo	4–8 wk after first dose	DTaP [†]
Primary 3	6 mo	4–8 wk after second dose	DTaP [†]
First booster	15–18 mo [‡]	6–12 mo after third dose	DTaP [†]
Second booster	4–6 yr old, before entering kindergarten or elementary school (not necessary if fourth dose [first booster] is administered after fourth birthday)		DTaP [†]
Additional boosters	Recommended at age 11–12 yr if at least 5 yr have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Ages 13–18 yr should serve as a catch-up interval for those who were not immunized at ages 11–12 yr. Subsequent routine Td boosters are recommended every 10 yr		Tdap

*Prolonging the interval does not require restarting the series.

[†]Use diphtheria and tetanus toxoids vaccine adsorbed (pediatric) (DT) if encephalopathy has occurred after administration of a previous dose of pertussis-containing vaccine. If the child is ≥ 1 year of age at the time that primary dose three is due, a third dose 6 to 12 months after the second dose completes primary vaccination with DT.

[‡]The fourth dose of DTaP may be administered at age 12 months provided that 6 months have elapsed since the third dose and the child is unlikely to return at age 15 to 18 months. The final dose in the series should be given at age 4–6 years.

Abbreviations: DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed; Tdap, tetanus and diphtheria toxoids and acellular pertussis vaccine adsorbed formulated for use in adolescents and adults ≤ 64 years of age (Boostrix[®] approved for use in persons aged 10–18 years; Adacel[™] approved for use in persons aged 11–64 years); Td, tetanus and diphtheria toxoids vaccine adsorbed (minimum age: 7 years).

This immunization schedule is based on information in references 18, 19, 20, and 34.

Table 103–2 Catch-up Tetanus Immunization Schedule and Minimum Intervals between Doses for Children and Adolescents Who Start Late or Who Are More Than or Equal to 1 Month Behind—United States, 2007

<i>Catch-up Schedule for Children Ages 4 mo–6 yr</i> <i>Minimum Interval between Doses</i>				
Dose 1 (Minimum Age)	Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4	Dose 4 to Dose 5
DTaP (6 wk)	4 wk	4 wk	6 mo	6 mo*

<i>Catch-up Schedule for Children Ages 7–18 yr[†]</i> <i>Minimum Interval between Doses</i>		
Dose 1 to Dose 2	Dose 2 to Dose 3	Dose 3 to Dose 4
4 wk	8 wk: If first dose administered at age < 12 mo. 6 mo: If first dose administered at age ≥ 12 mo.	6 mo: If first dose administered at age < 12 mo.

Note: There is no need to restart a vaccine series regardless of the time that has elapsed between doses.

*The fifth dose is not necessary if the fourth dose was given after the fourth birthday. Minimum age for DTaP administration is 6 weeks and maximum age is 6 years.

[†]Tdap should be substituted for a single dose of Td in the primary catch-up series or as a booster if age appropriate. Td should be used for all other doses. A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose.

Abbreviations: DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccine adsorbed; Tdap, tetanus and diphtheria toxoids and acellular pertussis vaccine adsorbed formulated for use in adolescents and adults ≤ 64 years of age; Td, tetanus and diphtheria toxoids vaccine adsorbed.

Data from Centers for Disease Control and Prevention: Recommended immunization schedules for persons aged 0–18 years—US, 2007. MMWR Morb Mortal Wkly Rep 55(51&52):1–4, 2007.

Table 103–3 Current Summary Guide to Tetanus Prophylaxis in Routine Wound Management

History of Adsorbed Tetanus Toxoid (Doses)	<i>Clean, Minor Wounds</i>		<i>All Other Wounds[*]</i>	
	Td or Tdap [†]	TIG	Td or Tdap [†]	TIG
Unknown or <3	Yes	No	Yes	Yes
3 or more	No [‡]	No	No [§]	No

*Such as, but not limited to, wounds contaminated with dirt, feces, soil, or saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, or frostbite.

[†]Tdap is preferred to Td for adolescents aged 11–18 years and adults aged 19–64 years who have never received Tdap. The preferred tetanus toxoid-containing vaccine for children aged < 7 years is DTaP. Minimum age for DTaP administration is 6 weeks and maximum age is 6 years. Minimum age for Td is 7 years.

[‡]Yes, if ≥10 years have elapsed since the last tetanus toxoid-containing vaccine dose.

[§]Yes, if ≥5 years have elapsed since the last tetanus toxoid-containing vaccine dose.

Abbreviations: Tdap, tetanus-diphtheria-acellular pertussis vaccine adsorbed formulated for use in adolescents and adults ≤64 years of age (Boostrix[®] approved for use in persons aged 10–18 years; Adacel[™] approved for use in persons aged 11–64 years); Td, tetanus and diphtheria toxoids vaccine adsorbed; DTaP, diphtheria and tetanus toxoids and acellular pertussis vaccines; TIG, human tetanus immunoglobulin.

Data from references 15, 16, 35, and 36.

Precautions to further DTP vaccinations include occurrence of fever ≥40.5° C (105° F) within 48 hours (not due to another identifiable cause), collapse or shocklike state (hypotonic-hyporesponsive episode) within 48 hours, convulsions with or without fever within 3 days, and persistent inconsolable crying lasting ≥3 hours within 48 hours.^{20,24} Children with a personal or family history of seizures are at higher risk for developing seizures following DTP immunizations. We recommend giving these children 15 mg/kg of acetaminophen at the time of vaccination and every 4 hours for the ensuing 24 hours to reduce the possibility of postvaccination fever.^{25,26}

Td is indicated for primary and booster vaccination against diphtheria and tetanus for adolescents, adults, and children 7 years of age or older. Tdap (tetanus and diphtheria toxoids and acellular pertussis vaccine adsorbed formulated for use in adolescents and adults ≤64 years of age) should be substituted for a single dose of Td in the primary catch-up series or as a booster if age appropriate. Td should be used for all other doses. A 5-year interval from the last Td dose is encouraged when Tdap is used as a booster dose. The Tdap or Td is given as a 0.5-ml IM injection into the anterolateral aspect of the upper thigh (preferred site for small children) or the deltoid muscle. A history of a neurologic reaction (e.g., encephalopathy) or an immediate anaphylactic reaction is a contraindication to further Td and Tdap vaccinations. Patients who have experienced an Arthus-type hypersensitivity reaction following a prior dose of tetanus toxoid often have high serum tetanus antitoxin levels due to inadequately spaced booster injections. These individuals should not be given further routine or even emergency booster doses of Td or Tdap more frequently than every 10 years.¹⁶

Immunosuppressed children such as those afflicted with the human immunodeficiency virus, patients undergoing radiation therapy, or those receiving antineoplastic or immunosuppressive agents (e.g., long-term corticosteroid use) may

swelling^{16,24} (see Chapter 102, Vaccination-Related Complaints and Side Effects).

Absolute contraindications to further vaccination with DTP include immediate anaphylactic reaction and encephalopathy, in the absence of other identifiable etiologies, occurring within 7 days following previous DTP vaccination.

Table 103–4 Various Forms of Tetanus Toxoid Preparations

Preparation (Abbreviation)	Route (0.5 ml)	Indication
Diphtheria and tetanus toxoids and pertussis vaccine adsorbed (DTP)	IM	Preferred agent for children <7 yr old; the pertussis component of DTP can be either whole cell (DTwP) or acellular (DTaP). The acellular version is the preferred preparation.
Diphtheria and tetanus toxoids vaccine adsorbed (pediatric) (DT)	IM	Use in children <7 yr old if pertussis vaccine is contraindicated.
Tetanus and diphtheria toxoids and acellular pertussis vaccine adsorbed (adolescents and adults ≤64 years of age) (Tdap)	IM	Boostrix [®] approved for use in persons aged 10–18 years; Adacel [™] approved for use in persons aged 11–64 years.
Diphtheria and tetanus toxoids vaccine adsorbed (adult) (Td)	IM	Use in adults and children ≥7 yr old.
Tetanus toxoid adsorbed (TTA)	IM	Use in patients who have a contraindication to combined antigens. It is the preferred single-agent formulation due to its greater antigenic effects.
Tetanus toxoid fluid (TT)	IM or SC	Use in patients who have a contraindication to combined antigens or those who are hypersensitive to the aluminum adjuvant in the adsorbed toxoid.

Abbreviations: IM, intramuscularly; SC, subcutaneously.

Adapted from Abrahamian FM: Tetanus—an update on an ancient disease. *Infect Dis Clin Pract* 9:228–235, 2000.

receive tetanus toxoid. However, due to their disease state, these children may not mount an adequate immunologic response to the vaccination. Although there is no evidence to suggest Td (classified in U.S. Food and Drug Administration Pregnancy Category C) has any teratogenic effects, as a precaution, the ACIP recommends withholding the Td until the second trimester of pregnancy based on the balance between risks and benefits.^{16,24} Due to lack of safety data, currently Tdap is not recommended for administration in pregnant patients.

Passive Immunization

Passive immunization is provided by the administration of human tetanus immune globulin (HTIG). The dosage for postexposure tetanus prophylaxis is 250 international units (IU) IM into the anterolateral muscles of the lateral thigh (for infants) or the deltoid muscle in the upper arm (for older children). Theoretically, the prophylactic dose of HTIG may be calculated by body weight and administered at a dose of 4 IU/kg. However, we recommend administering the entire contents of the vial (250 IU) regardless of the child's size. This recommendation is based on the concept that the amount of toxin produced by the organism is independent of the child's body size. The 250-IU dose will provide adequate antitoxin levels about 2 to 3 days after administration and for a period lasting at least 4 weeks, with a half-life of 23 days.²⁷

The route of administration of HTIG should be IM. HTIG should not be given intravenously due to an increased risk of developing an anaphylactic reaction. Although intrathecal administration of HTIG has been investigated for therapy of active tetanus, this route is not recommended for prophylactic therapy.^{28,29} Otherwise, there are no specific contraindications to HTIG administration. HTIG is categorized as a Pregnancy Category C drug, and when indicated can be given to a pregnant adolescent. No dosage adjustment is necessary in patients with renal impairment.

Although the concurrent administration of HTIG with tetanus toxoid may result in some period of delay in the induction of active immunity, the ACIP tetanus prophylaxis guidelines recommend HTIG and tetanus toxoid be given at

the same time for patients with tetanus-prone wounds who are uncertain about their primary immunization history or have received fewer than three prior tetanus toxoid doses in the past.^{15,16,27,30–32} (see Table 103–3). However, HTIG and tetanus toxoid should not be administered at the same anatomic site or given by the same syringe. Similarly, immunologic response may diminish with simultaneous administration of HTIG with other live virus vaccines (e.g., measles, mumps, rubella, oral polio). To avoid this interaction, live virus vaccination should be delayed for 3 months after HTIG is given. If simultaneous injections are necessary, administration should occur at different sites. Such patients need to be assessed for seroconversion at a later time and may require revaccination.³³

Summary

Tetanus immunization is one of the most effective immunization practices ever developed. In the United States, tetanus occurs primarily in adults, and the majority of the cases had an acute injury identified prior to the onset of illness. Puncture wounds were the most frequent type of acute injury associated with clinical tetanus, followed by lacerations and abrasions.

Children at higher risk of developing tetanus are those who are not completely vaccinated, adolescent injection-drug users, immigrants from outside North America or Western Europe, and young adults uneducated beyond grade school. Neonates born to parents who object to and do not receive vaccinations are also at higher risk of developing tetanus.

The decision to initiate postexposure prophylaxis is dependent on the characteristics of the wound and the patient's vaccination history. Wounds at higher risk for tetanus include contaminated wounds (e.g., with dirt, feces, soil, or saliva), puncture wounds, avulsions, wounds resulting from missiles, crush injuries, burns, frostbite, and neurovascularly compromised wounds. HTIG and tetanus toxoid should be given at the same time for children with tetanus-prone wounds who are uncertain about their primary immunization history or have received fewer than three prior tetanus toxoid doses in the past.

Chapter 104

Rabies Postexposure Prophylaxis

Fredrick M. Abrahamian, DO and David A. Talan, MD

Key Points

In the United States, bites from raccoons, skunks, bats, foxes, bobcats, coyotes, and mongooses are considered high risk for rabies transmission.

Domestic animal bites (from dogs, cats, ferrets, and livestock) are generally considered low risk; however, dogs along the U.S.-Mexico border and cats that roam freely in endemic areas pose a higher risk.

Rabies postexposure prophylaxis is not warranted for bites from smaller mammals (e.g., mice, squirrels, rabbits, chipmunks, rats, hamsters, gerbils, guinea pigs).

The decision to initiate rabies postexposure prophylaxis is dependent on the animal species; a detailed account of the animal contact, including whether the attack was provoked; local rabies epidemiology for the animal species involved (information typically available from local health officials); and the availability of the animal for observation or euthanasia for rabies brain testing.

Rabies postexposure prophylaxis consists of the administration of human rabies immune globulin and rabies vaccine.

Introduction and Background

Rabies exerts a considerable public health impact worldwide, especially in developing countries.¹ Globally, the annual number of rabies-associated deaths is predicted to be between 40,000 and 70,000.^{2,3} However, in the United States and other developed countries, human rabies remains a rare disease. From 1980 to 1996, only 32 laboratory-confirmed cases of human rabies were diagnosed in the United States, and 1 to 5 cases of rabies each year in humans were reported to the Centers for Disease Control and Prevention (CDC) during 2000–2003.^{4–8} The decline is attributed to the control of rabies

in domestic animal populations and effective pre- and post-exposure vaccination programs.

Worldwide, an estimated 10 million people receive rabies postexposure prophylaxis (RPEP) annually, and although human rabies is rare in the United States, approximately 16,000 to 39,000 U.S. patients per year receive RPEP.^{2,9} A multicenter, prospective study of patients presenting to the emergency department with an animal exposure demonstrated that RPEP is at times used inappropriately.¹⁰ Since children who have sustained animal bites commonly present to the emergency department, the emergency department is a common location for RPEP to be initiated. Emergency physicians will best help their patients if they have a clear understanding of the guidelines published by the Advisory Committee on Immunization Practices (ACIP) on rabies prevention that direct the use of RPEP.¹¹

During 2000–2003, approximately 7000 to 8000 cases of animal rabies were reported to the CDC.^{5–8} In the United States, raccoons, mostly reported from the eastern states, continue to be the most frequently encountered rabid wild-life species. In addition to raccoons, other wild animals most often infected with rabies in the United States, in order of decreasing frequency, include skunks, bats, and foxes.^{5–8} Bites from bobcats, coyotes, and mongooses are also considered high risk for rabies transmission.¹²

Recognition and Approach

Rabies is a deadly disease and surviving it is exceedingly rare. A case report published in 2005 of a 15-year-old girl who survived rabies, albeit with substantial neurologic damage, highlights the rarity of this devastating disease in the United States.¹³ When a child has come into contact with an animal and rabies is a consideration, diagnosing rabies is not the key task of emergency physicians. Instead, prevention of the development of rabies through the selection of appropriate patients for the initiation of RPEP is the main concern for emergency physicians.

Evaluation

The transmission of rabies occurs when the virus is introduced from animal saliva into an open wound from a bite, or when the virus comes in contact with an open wound or

mucous membrane. One of the first steps in evaluating a child who has come into contact with an animal is whether or not there is a reasonable likelihood that clinically significant exposure to the virus has occurred.

Exposures versus Nonexposure Contact

Exposures can be categorized as bites and nonbites. Bites are the predominant type of exposure. Regardless of the severity, bites are always considered potential exposures. Bats, due to their small, thin, and sharp teeth, often leave minimal external signs of a bite, and as a result, their bites may go unnoticed. This circumstance is most likely in preverbal toddlers, minimally verbal developmentally delayed children, and intoxicated adolescents. In the United States, the majority of the human rabies cases are caused by bat-associated rabies virus variant and, in most of these cases, no knowledge of a bite existed.^{4,14,15}

Nonbite exposures include contamination of open wounds (e.g., abrasions, scratches) or mucous membranes with the saliva or neuronal tissue of a potentially rabid animal. In comparison to a bite, exposure via this mechanism carries a lower risk for acquiring the disease. Other reported nonbite modes of transmission include exposure to large amounts of aerosolized rabies virus (e.g., inhaling bat guano in a cave) and organ transplantation from infected donors.¹⁶⁻²¹ The risk of disease transmission to a recipient of an organ from an infected donor is high.²² Apart from transplants, there is no evidence of laboratory-confirmed cases of human-to-human transmission of rabies either among household contacts or in the health care setting.^{11,23}

Activities such as petting a rabid animal are not thought to place the patient at risk for contracting rabies. Similarly, contact with blood, urine, or feces of a rabid animal is also not considered a clinically significant exposure.¹¹

Animal Species

Domesticated Animals

The prevalence of rabies among domestic animals (e.g., dog, cat, ferret, and livestock) has declined dramatically over the past century due to effective rabies vaccination practices. Although bites from domestic animals are generally considered low risk, dogs along the U.S.-Mexico border and cats that roam freely through areas in which animal rabies is endemic are considered to pose a higher risk. In developing countries, dogs are the main reservoir for disease transmission and the principle source of human rabies.²⁴ State or local health officials should be consulted when there is a question regarding the prevalence of rabies in a specific species and region.

Bats

Unlike the varied geographic prevalence of rabies in wild terrestrial mammals, rabies in bats has remained widely distributed throughout the United States. RPEP should be initiated for patients in whom there is apparent or reasonable probability of a bat bite, scratch, or mucous membrane exposure. Postexposure prophylaxis is also warranted if a bat is found in the room of an individual who is incapable of attesting to absence of direct contact. Examples of this situation are when a sleeping person awakens to find a bat in the room or a bat is found in a room occupied by an unat-

tended child, a person with mental disability, or an intoxicated individual. The only exceptions when RPEP could be withheld are if the bat is captured and immediate brain testing is available, or if the individual is certain that contact has not occurred.¹¹

Wild Rodents

Although all mammals are susceptible to rabies virus, smaller mammals (e.g., mice, squirrels, rabbits, chipmunks, rats, hamsters, gerbils, guinea pigs) are often not able to survive an attack from another animal with the potential to transmit rabies. Consequently, these smaller mammals are not thought to be likely to be infected with rabies virus. Larger rodents such as woodchucks and beavers are an exception, and have been reported to be rabid in areas where terrestrial rabies is enzootic.^{12,25}

Wild Terrestrial Carnivores and Hybrids

The prevalence of rabies in wild terrestrial carnivores varies geographically. In most instances, a clinically significant exposure is assumed to have occurred with a bite from a wild terrestrial carnivore (e.g., raccoons, skunks, foxes, coyotes, bobcats, mongoose) or a hybrid resulting from breeding of a wild terrestrial carnivore with a domestic animal (e.g., a wolf-dog hybrid). Patients and their families should not be encouraged to capture the suspected animal since this might result in additional risk of exposure.

Birds, Reptiles, and Sea Creatures

Rabies is exclusively seen in mammals. Nonmammalian bites do not pose a risk of rabies transmission.

Attack Provocation

With the exception of bats, an animal's behavior and the circumstances of an attack are also factors to assess the likelihood of rabies virus exposure. Rabid animals tend to act agitated and attack indiscriminately. Normal behavior in an animal makes the possibility of rabies less likely, although an assessment of "normal" behavior in wild terrestrial carnivores is difficult. Typically, most animals avoid humans and bites are commonly provoked. Feeding, handling, taunting, or surprising animals are considered provocative actions. For exposures involving normally behaving domestic animals (e.g., dogs, cats), in areas where rabies is not endemic, attacks are considered provoked and the animal is unlikely to be rabid.

Local Epidemiology

Local health officials are the best sources of information for the local epidemiology of animal reservoirs of rabies. If an emergency physician is unfamiliar with the local epidemiology, contacting a local health official can clarify many concerns of the health care providers, the patients, and their families.

Management

The three main components of managing a child who has come into contact with an animal and for whom concern about rabies exposure has arisen are local wound care, the decision on whether or not to initiate RPEP, and the implementation of RPEP when indicated.

Local Wound Care

Local wound care should include cleansing the wound with a solution of soap and water, which has been shown to potentially reduce the risk of acquiring rabies.²⁶⁻²⁸ Irrigating the wound with a virucidal cleansing solution based in iodine (e.g., diluted povidone-iodine solution) is also advised.^{11,24} Concentrated forms of povidone-iodine solution, detergents, and hydrogen peroxide are toxic to tissues and should not be used to irrigate wounds.^{29,30} Other basic measures of wound care include débridement of necrotic and devitalized tissues, tetanus prophylaxis, assessment for and management of concurrent injuries (e.g., fractures), and initiation of antibiotics, as indicated (see Chapter 160, Wound Management).

Deciding on Initiating Rabies Prophylaxis

The decision to initiate RPEP is dependent on several key factors that include: animal type and its behavior, type of exposure (e.g., bite vs. nonbite), circumstances of the attack (e.g., provoked vs. unprovoked), local rabies epidemiology for the species involved, and availability of the animal for brain testing or observation (Fig. 104-1).

Animal Observation

Observation allows beloved family pets to be spared immediate death for brain testing. Dogs, cats, and ferrets are the only animal species suitable for observation. Wild animal hybrids (e.g., wild animal crossbred to domestic dogs or cats) are not suitable for observation and they should be regarded as wild animals.¹¹ The observation period is 10 days and is best done by animal control authorities. Rabies vaccination should not be given to the animal during this observation period. Any abnormal behavior or illness developing within this observation period necessitates evaluation by a veterinarian. If rabies is suggested, the animal should immediately be euthanized and undergo brain testing. Although a history of prior rabies vaccination of an animal makes the possibility of rabies infection and transmission unlikely, it should not deter entertaining animal observation, or if necessary, euthanasia and brain testing.^{11,12} Diagnostic testing should be completed within 24 to 48 hours in order to avoid further delay in initiating RPEP. If the diagnosis cannot be made within this time frame, it is best to initiate RPEP pending the results of brain testing.

Active and Passive Immunization

RPEP should always include administration of both active and passive immunization, except in individuals who have previously been immunized. Active immunization is commonly achieved by human diploid cell vaccine. Other licensed preparations include rabies vaccine adsorbed (RVA) and purified chick embryo cell vaccine. RVA is not currently available in the United States.¹² All three types of vaccine are equally safe and efficacious when used properly.¹¹ The development of antibodies by active immunization takes about 7 to 10 days and usually persists for ≥ 2 years. For the purpose of postexposure prophylaxis, a regimen of five 1.0-ml doses of any of the vaccines should be given intramuscularly (IM). The first dose is given as soon as possible after exposure (day 0), with the remaining four doses administered on days 3, 7, 14, and 28 after the first vaccination. Patients with a prior history of vaccination should only receive vaccine on days 0 and 3. The

preferred site for IM injection in adolescents and adults is the deltoid area and in children is the anterolateral aspect of the thigh. The gluteal region should be avoided for rabies vaccine injections due to a diminished antibody response.³¹

Passive immunization is achieved by the administration of human rabies immune globulin (RIG). It provides rapid protection with a serum half-life of 21 days.³² Two human RIG products are available in the United States (BayRab and Imogam Rabies-HT) with equal efficacy and safety profiles.^{11,12} The recommended dosage for both immune globulins is 20 IU/kg body weight and it applies to all age groups, including children. Adherence to this dosage is important since higher doses have the potential for suppressing active antibody production.³³ A full dose should be infiltrated into and around the wounds if anatomically possible.³⁴ If not (e.g., finger wound), following infiltration of the wound area, the remaining dose should be administered IM in the deltoid or quadriceps muscle. To avoid antigen-antibody antagonism, RIG and rabies vaccine should not be administered at the same site or by the same syringe. Repeated injections of RIG are not necessary and should not be administered to individuals with a prior history of rabies immunization. If the administration of rabies vaccine and RIG were not on the same day, RIG may be given up to the seventh day after the first dose of vaccine. Beyond this period, RIG is no longer indicated since active immunization has taken effect.^{11,35}

Humans Previously Immunized Against Rabies

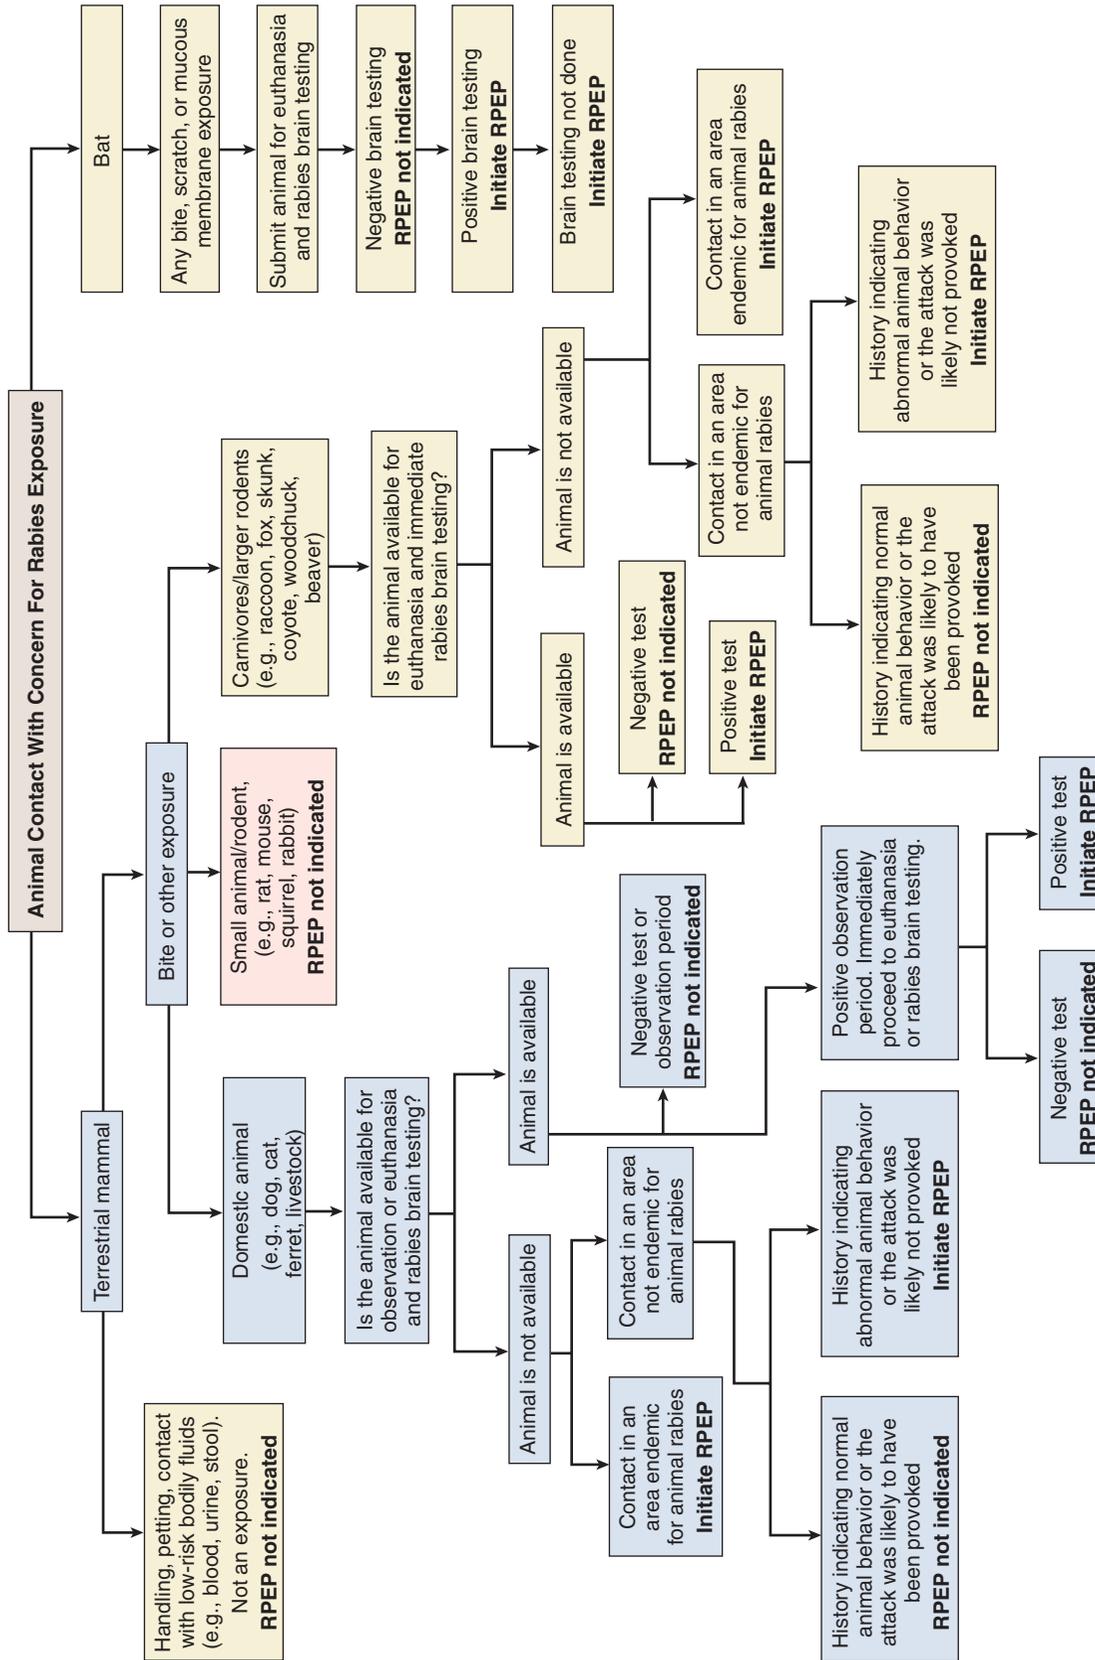

Some animal workers and laboratory assistants who work with the rabies virus routinely get immunized against rabies. These previously immunized individuals should not receive RIG.

Vaccination-Related Complaints

Injection-site reactions (e.g., local tenderness, erythema, swelling) are the most common adverse reactions following vaccination. Systemic reactions are less common and can include headache, myalgias, abdominal pain, and dizziness (see Chapter 102, Vaccination-Related Complaints and Side Effects). There are no contraindications to the administration of rabies biologics during pregnancy.³⁶ Response to active immunization may not be adequate in individuals who are considered immunocompromised or those on immunosuppressive agents (e.g., corticosteroids). In such situations, it is important to assess antibody levels 2 to 4 weeks after postexposure prophylaxis to ensure an acceptable antibody response.¹¹ With the exception of yellow fever and oral Ty21a typhoid vaccines, simultaneous administration of live vaccines (e.g., measles, mumps, rubella, varicella) and human RIG should be avoided for a duration of at least 4 months.^{37,38} If simultaneous administration of measles- or varicella-containing vaccine is necessary, administer the vaccine and human RIG at different sites and revaccinate or test for seroconversion after a period of 4 months. Human RIG and inactivated vaccines or toxoids (e.g., tetanus toxoid) can be administered simultaneously at different sites or at any time between doses.³⁸

Summary

Rabies is rare. Emergency department evaluation of children who have come into contact with an animal is not rare. Familiarity with the overall decision-making strategies for

*RPEP=rabies postexposure prophylaxis

FIGURE 104-1. Algorithm for initiating rabies postexposure prophylaxis (RPEP).

evaluating these children for their risk of exposure to rabies helps emergency physicians and their patients. Since the ACIP regularly updates the recommended childhood and adolescent immunization schedules and practices, readers are advised to review the latest immunization recommendation by contacting their local or state health departments, by accessing the CDC's National Immunization Program web site at <http://www.cdc.gov/nip/>, or by calling the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish) or other professional organizations such as the American Academy of Pediatrics or the American Academy of Family Physicians.

Diabetic Ketoacidosis

Nicole Glaser, MD and Nathan Kuppermann, MD, MPH

Key Points

Classic symptoms of diabetic ketoacidosis (DKA) include polyuria, polydipsia, weight loss, vomiting, abdominal pain, and signs of dehydration

New onset of diabetes or missed insulin injections are the most frequent causes of DKA in children. Infections or other intercurrent illnesses are uncommon in children seen in the emergency department for DKA.

Dehydration, acidosis, and electrolyte depletion are the main physiologic and biochemical abnormalities in children with DKA. These abnormalities can be corrected with insulin, intravenous fluids, and electrolyte replacement.

Bicarbonate should not be routinely administered to children with DKA.

Cerebral edema is the most frequent serious complication of DKA in children.

Introduction and Background

Diabetic ketoacidosis (DKA) is a common presentation of type 1 diabetes mellitus in children. Twenty five percent to 40% of children with a new diagnosis of type 1 diabetes present in DKA.^{1,2} Reports have also documented DKA in children with new diagnoses of type 2 diabetes.^{3,4} In children with established diabetes, DKA episodes occur at a rate of 1% to 8% per year, and most often result from missed insulin injections.^{2,5-7} In contrast to adults, in whom infections or other illnesses are frequently triggers of DKA, intercurrent illness is uncommon in children presenting to the emergency department with DKA.⁸ Although most children with DKA recover uneventfully from the episode, DKA remains the most frequent diabetes-related cause of death in children.^{9,10} The majority of these DKA-related deaths in children result from cerebral edema.

Recognition and Approach

DKA develops in children with diabetes when serum concentrations of insulin are low in relation to those of counter-regulatory hormones (glucagon, cortisol, growth hormone, and catecholamines) (Fig. 105–1). This hormonal imbalance causes hyperglycemia, resulting in osmotic diuresis, as well as hepatic ketone production, resulting in acidosis with an elevated anion gap. Osmotic diuresis leads both to dehydration and to electrolyte depletion with loss of sodium, potassium, calcium, phosphate, and magnesium. Vomiting and increased insensible fluid losses exacerbate this process. Physiologic and biochemical abnormalities in children with DKA thus include hyperglycemia, dehydration, acidosis, and electrolyte depletion.

Classic presenting symptoms of diabetes and DKA include polyuria, polydipsia, and weight loss. Nausea, vomiting, and abdominal pain are also frequently present in DKA. Abdominal pain may be severe and can be mistaken for an acute abdomen. In this regard, the history of persistently increased urine output despite vomiting and signs of dehydration should alert the clinician to the diagnosis of DKA. A fruity breath odor, caused by acetone, may also be present and can be helpful in alerting the clinician to the likelihood of DKA.

Clinical Presentation

Children with DKA typically present with an ill appearance, tachypnea in response to metabolic acidosis, tachycardia, and signs of dehydration. Tachypnea may be extreme and may give the appearance of respiratory distress, initially suggesting a diagnosis of pneumonia or other respiratory disease. A history of polyuria and polydipsia is an important distinguishing factor. Tachycardia is also typically present, along with signs of dehydration such as cool extremities and delayed capillary refill time. Even in the setting of severe acidosis and dehydration, children rarely develop hypotension or cardiovascular instability due to DKA. The presence of hypotension in a child with DKA suggests profound dehydration or the presence of sepsis or another associated illness.

The diagnosis of DKA can be confirmed when laboratory studies demonstrate a serum glucose concentration above 200 mg/dl, a venous pH below 7.30 (or serum bicarbonate concentration below 15 mmol/L), and ketonuria. The severity of DKA is classified according to the severity of acidosis, with mild DKA corresponding to a venous pH less than 7.30

Pathophysiology of Diabetic Ketoacidosis

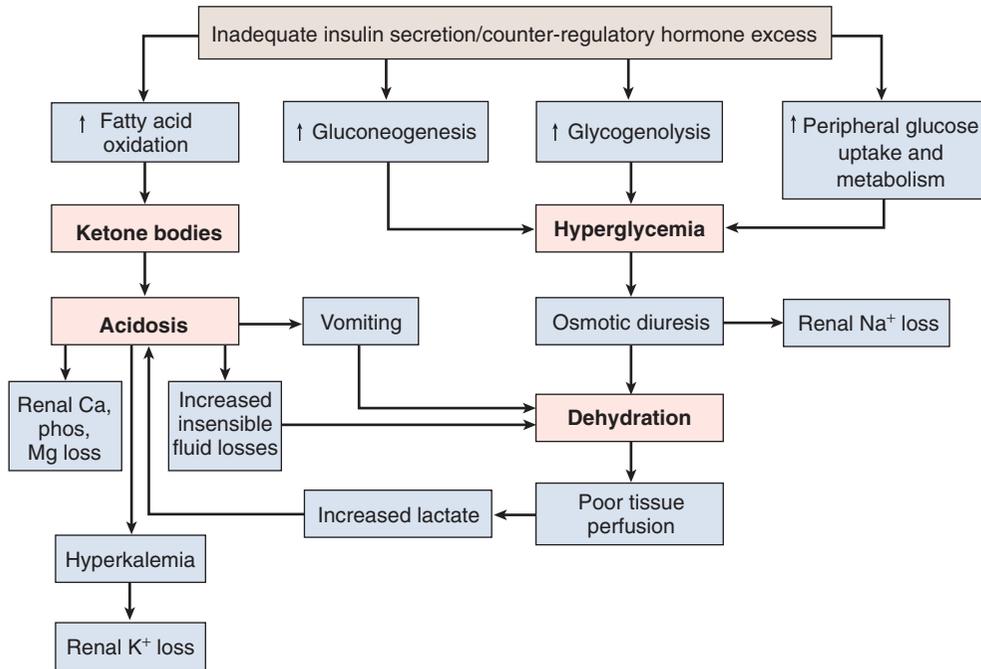

FIGURE 105-1. Pathophysiology of diabetic ketoacidosis. (From Styne DM, Glaser NS: Endocrine disorders. In Behrman R, Kliegman R [eds]: Nelson Essentials of Pediatrics, 4th ed. Philadelphia: WB Saunders, 1997, pp 711–766.)

(or serum bicarbonate concentration <15 mmol/L; moderate DKA to a pH less than 7.2 (or serum bicarbonate <10 mmol/L); and severe DKA to a pH less than 7.1 (or serum bicarbonate <5 mmol/L).^{2,11} Infrequently, DKA can be present in patients with near-normal serum glucose concentrations. “Euglycemic DKA” has been described most frequently in pregnant women,¹² but can also occur in children with known diabetes, typically when additional insulin is administered at home in response to hyperglycemia. In this setting, insulin administration may correct hyperglycemia prior to correction of ketosis and acidosis.

In DKA, an elevated anion gap is present and the partial pressure of CO₂ (Pco₂) is low, reflecting respiratory compensation for metabolic acidosis. Elevated lactic acid concentrations may be present due to poor tissue perfusion and may contribute to acidosis (in addition to the ketosis). Serum sodium concentrations are typically low as a result of the osmotic effect of hyperglycemia. The serum sodium concentration decreases by approximately 1.6 mEq/L for every 100-mg/dl increase in serum glucose concentration above a concentration of 100 mg/dl.¹³ Although serum potassium concentrations are typically normal or elevated at the time of presentation of DKA, total body potassium stores are usually profoundly depleted. Elevated serum potassium concentrations at presentation generally are a reflection of acidosis, and potassium concentrations typically decrease rapidly after the initiation of treatment. This is an important consideration in therapy of DKA.

Dehydration may result in prerenal azotemia with elevated blood urea nitrogen (BUN) and creatinine concentrations. Age-based standards for BUN and creatinine concentrations should be used because the normal ranges for these values increase with age.¹⁴ The serum glucose concentration also may be viewed as an indicator of the adequacy of renal perfusion because serum glucose concentrations generally do not rise above 500 to 600 mg/dl in patients who maintain ade-

quate renal perfusion. Blood glucose concentrations above 600 mg/dl in a child without preexisting renal disease likely reflect diminished renal perfusion resulting in a decreased glomerular filtration rate.

Important Clinical Features and Considerations

In infants and very young children, recognition of DKA may be difficult because polyuria, polydipsia, and abdominal pain are more difficult to detect in preverbal and non-toilet trained children. In young children who present with vomiting and signs of dehydration without diarrhea or other obvious cause, it is therefore advisable to obtain a bedside serum glucose measurement and/or urinalysis to rule out DKA.

While it is important to diagnose DKA and initiate appropriate treatment, clinicians must also attempt to identify the precipitant. New-onset of diabetes and noncompliance are the most common causes of DKA in children.^{1,2,5-7} Insulin pump failure may also result in DKA, if not recognized promptly. Bacterial infections are a cause in only 13% and viral infections in 18% of all cases.⁸ Infection is more likely to be a cause of DKA in children 3 years old and younger compared to older children.⁸ Importantly, the serum white blood cell count is not generally helpful in discriminating between infected and uninfected patients.⁸ In fact, white blood cell count elevations are common in children with DKA and are primarily a reflection of low pH and disease severity, rather than infection.

Management

Initial Management

An initial bolus of isotonic intravenous fluids (10 to 20 ml/kg of 0.9% saline or other isotonic fluid) is often needed to restore adequate perfusion. Additional boluses are necessary

if the patient is severely dehydrated or if hemodynamic instability is present. An initial fluid bolus may not be necessary, however, for patients who are well perfused and hemodynamically stable on presentation. Initial rehydration alone often results in a substantial decrease in the serum glucose concentration through restoration of renal perfusion and a decrease in the levels of counter-regulatory hormones. Rehydration is continued to restore fluid deficits over a 48-hour period. Simultaneous with initiation of intravenous fluids, blood should be obtained for measurement of electrolytes, venous pH, magnesium, calcium, and phosphate. All patients should be placed on a cardiac monitor; an electrocardiogram is also recommended, particularly for children with suspected hyperkalemia.

Treatment with bicarbonate is rarely indicated as children are generally able to tolerate even severe acidosis without hemodynamic instability. Bicarbonate administration does not result in more rapid recovery from DKA, may lead to hypokalemia, and is associated with a fourfold increase in the risk of cerebral edema.¹⁵⁻¹⁹ Therefore, bicarbonate should

not routinely be used in children with DKA. In rare clinical circumstances such as symptomatic hyperkalemia or hemodynamic instability due to extreme acidosis, bicarbonate therapy may be necessary.

Ongoing Management (Table 105-1)

Fluids and Insulin

International consensus guidelines for treatment of DKA have recently been published.^{20,21} Following an initial fluid bolus, an intravenous insulin infusion is initiated at a rate of 0.1 units/kg/hr.²² An initial bolus or loading dosage of insulin is not necessary, provided that a continuous infusion is begun promptly. Intravenous rehydration should be given along with the insulin infusion. The rate of fluid infusion should be calculated to replace the fluid deficit (typically 7% to 10% of body weight²³) evenly over 48 hours. The sodium concentration of the intravenous fluids should be 0.45% saline or greater. Higher concentrations of sodium chloride (up to 0.9% saline) are also acceptable, although the high chloride

Table 105-1 Suggested Approach to DKA Management in Children

Fluid and Sodium Replacement

- Begin fluid replacement immediately.
- Base the volume of initial fluid bolus on the patient's circulatory status. Administer 10 to 20 ml/kg of isotonic fluids (0.9% saline or lactated Ringer's solution) for the fluid bolus(es). Repeat the bolus if necessary to restore perfusion. Some children may not require an initial fluid bolus if they are well perfused at presentation.
- Calculate subsequent fluid replacement rates to replace the fluid deficit (typically ~70 ml/kg), in addition to maintenance fluids, evenly over 48 hours. Use fluids with a tonicity between 0.45% and 0.9% saline.

Insulin

- Administer insulin intravenously at a rate of 0.1 units/kg/hr.
- An initial bolus or loading dose of insulin is not necessary.
- Continue insulin at 0.1 units/kg/hr until ketoacidosis has resolved (pH > 7.30, HCO₃ > 15, normalization of anion gap).
- To prevent hypoglycemia during treatment, add glucose to the intravenous fluids when the plasma glucose concentration falls below ~250 to 300 mg/dl.

Potassium, Phosphate, and Other Electrolyte Replacement

- Potassium replacement is required, and should be based on measurements of serum potassium.
- Begin potassium replacement immediately in patients with hypokalemia, and concurrent with insulin treatment in all others. For patients with hyperkalemia, base potassium replacement on the serum potassium measurement and administer potassium only after adequate urine output has been established.
- The initial potassium concentration in the intravenous fluids should be 30–40 mEq/L, except in rare circumstances in which the patient presents with substantial hyperkalemia. Adjust subsequent potassium administration according to serum potassium concentrations.
- Monitor calcium, magnesium, and phosphate concentrations during therapy. Phosphate concentrations typically decrease during treatment, and replacement of phosphate by using potassium phosphate in combination with potassium chloride can be considered. Replacement of calcium and magnesium is rarely required.

Use of Bicarbonate

- Do not routinely administer bicarbonate.
- Bicarbonate is only indicated in rare circumstances (symptomatic hyperkalemia, cardiovascular instability caused by severe acidosis).

Monitoring

- Assess vital signs hourly. Cardiac monitoring is recommended.
- Record fluid intake and output hourly.
- Measure blood glucose concentrations hourly. Measure electrolytes, serum urea nitrogen, creatinine, venous pH and PCO₂ every 2 to 4 hours. Calcium, magnesium, and phosphate should be monitored approximately every 6 hours. More frequent electrolyte measurements may be necessary in patients with abnormal or rapidly changing electrolyte concentrations.
- Assess mental status hourly. More frequent assessment may be necessary for patients with symptoms or signs of intracranial complications of DKA. The following signs and symptoms should raise concern about the possibility of cerebral edema: headache, inappropriate slowing of heart rate, rising blood pressure, recurrence of vomiting, mental status changes (e.g., irritability, lethargy), and specific neurologic signs (e.g., cranial nerve palsies, diminished pupillary reactivity).

Complications

- Hypokalemia and hypoglycemia occur frequently during DKA treatment, but are usually mild and easily corrected.
- Cerebral edema is the most frequent serious complication of DKA. If cerebral edema is suspected, promptly administer mannitol (0.25 to 1 g/kg).

Data from references 20 and 21.

content of these solutions increases the likelihood of developing hyperchloremic acidosis during therapy.

Typically, hyperglycemia resolves before the resolution of acidosis. For this reason, it is necessary to add dextrose to the intravenous fluids to prevent hypoglycemia during continued insulin infusion. When the serum glucose concentration decreases below approximately 250 to 300 mg/dl, dextrose is added to the intravenous fluids. A “two-bag system” allows more efficient and cost-effective administration of dextrose to children with DKA than traditional methods.²⁴ This system employs two bags of intravenous fluids with different dextrose concentrations (0 and 10%), but identical electrolyte content, administered simultaneously. The relative rates of administration of the two fluids are adjusted to increase or decrease the dextrose concentration while keeping fluid and electrolyte replacement constant. The insulin infusion should not be decreased or discontinued until acidosis has resolved and the serum bicarbonate concentration is above 15 to 18 mmol/L.²⁰

Electrolyte Replacement

Serum potassium concentrations often decrease precipitously after the initiation of insulin therapy; therefore, replacement of potassium is mandatory. With the exception of children who present with significant hyperkalemia, replacement of potassium can be initiated as soon as adequate urine output is verified. Potassium chloride, or a combination of potassium chloride plus potassium phosphate or potassium acetate, is added to the intravenous fluids at a concentration of 30 to 40 mEq/L.

Whether or not phosphate replacement should be given routinely is controversial. Case reports have described rare episodes of severe hypophosphatemia during DKA treatment that resulted in hemolytic anemia and rhabdomyolysis.^{25,26} Phosphate replacement, however, increases the likelihood of hypocalcemia during treatment, particularly if phosphate is infused rapidly. Hypocalcemia is infrequent when phosphate replacement is given in modest dosages.²⁷ Regardless of whether or not phosphate is administered, serum phosphate concentrations, along with calcium and magnesium concentrations, should be monitored during therapy as serum concentrations of these electrolytes tend to decrease during DKA treatment, which may occasionally necessitate replacement.

Monitoring

Monitoring of a child with DKA usually requires a pediatric intensive care unit or a hospital unit with similar capabilities for monitoring and managing such children. Continuous cardiac monitoring should be instituted, and vital signs and neurologic status are assessed hourly, or more frequently if there is concern about possible intracranial complications. Fluid intake and output should be recorded hourly. Glucose concentrations are measured on an hourly basis and electrolyte concentrations every 2 to 4 hours, depending on the degree of initial abnormality and rapidity of change during treatment. Calcium, phosphate, and magnesium concentrations can be measured less frequently, but a minimum of every 6 hours is recommended.

Complications

With appropriate treatment, most children recover uneventfully from DKA. The most frequent complications are hypo-

glycemia and mild hypokalemia, but these are generally easily detected and treated, provided that laboratory studies are measured according to schedule. Hypocalcemia, hypomagnesemia, and hypophosphatemia may occur during treatment but are rarely symptomatic. More serious complications of DKA are rare, but can have devastating consequences. These complications include cerebral edema,¹⁹ pulmonary edema,²⁸⁻³⁰ central nervous system (CNS) hemorrhage or thrombosis,³¹ other large vessel thromboses,³² cardiac arrhythmias,¹⁹ pancreatitis,³³ renal failure,³⁴ intestinal necrosis,³⁵⁻³⁷ and rhinocerebral mucormycosis.³⁸ Several reports have documented a prothrombotic state in both children and adults with DKA.^{32,39} Children who are more severely hyperosmolar at presentation may be at greater risk for thrombotic complications. Femoral venous catheter use is associated with an increased risk for deep venous thrombosis, and should only be used when alternate venous access cannot be obtained.³²

Although most serious complications of DKA are rare, cerebral edema is the most common, occurring in approximately 1% of pediatric DKA episodes.^{19,40,41} The cause of this complication has been the subject of substantial debate. Initial hypotheses attributed cerebral edema to fluid influx into brain cells caused by rapid declines in serum osmolality and rapid fluid infusion. This hypothesis, however, has not been supported by data from clinical investigations. Symptomatic and even fatal cerebral edema can occur before hospital treatment for DKA is initiated. Asymptomatic or subclinical cerebral edema is present frequently, if not uniformly, at presentation.^{10,42-44} In addition, studies that have adjusted for differences in DKA severity among patients have not found statistical associations between fluid or sodium infusion rates, or the rate of change in serum glucose concentration, and risk for cerebral edema.^{19,45} More recent evidence suggests that cerebral edema during DKA may be predominantly vasogenic, and that cerebral ischemia during DKA or other factors may be more important determinants than osmolar changes.^{46,47} Children at greatest risk for cerebral edema are those who present with higher BUN concentrations¹⁹ and more severe hypocapnia.^{19,45} A lesser rise in the measured serum sodium concentration during treatment (as the serum glucose concentration falls) also indicates increased risk for cerebral edema.^{19,48} Finally, bicarbonate therapy, even after adjusting for acid-base status and other markers of severe DKA, has been found to be associated with cerebral edema.¹⁹ Signs and symptoms that should prompt the clinician to consider evaluation for cerebral edema include inappropriate slowing of heart rate, hypertension, headache, recurrent vomiting, and irritability, lethargy, or other mental status changes.

Outcomes of DKA-related cerebral edema are poor, with 21% to 24% mortality and 21% to 26% permanent neurologic deficits.^{19,41} Because DKA-related cerebral edema is relatively rare, few studies have been done to assess the effectiveness of pharmacologic interventions to treat this condition. To date, no pharmacologic agents have been clearly demonstrated to be effective for this condition. Several case reports suggest that treatment with mannitol (0.25 to 1 g/kg) may be beneficial.^{49,50} Therefore, mannitol should be promptly administered if cerebral edema is suspected. Mannitol treatment should not be withheld until cerebral edema is confirmed radiographically, particularly because initial imaging

studies in children with DKA-related cerebral edema may be normal.⁵¹ While intubation may be required due to severe alterations in mental status and impaired airway reflexes, hyperventilation in intubated patients has been associated with poorer outcomes of DKA-related cerebral edema.⁵² Therefore, therapeutic hyperventilation, which attempts to decrease P_{CO_2} below the patient's own compensation for metabolic acidosis in intubated children with DKA, should be avoided except where absolutely necessary to treat impending cerebral herniation. A reasonable approach would be to initially maintain the patient's current P_{CO_2} level and then gradually allow the P_{CO_2} to increase as acidosis corrects. Cranial computed tomography or magnetic resonance imaging is recommended to exclude other etiologies of altered mental status, such as CNS thromboses in children with suspected cerebral edema. Treatment should not be withheld while awaiting imaging results.

Disposition

Most children with DKA require monitoring in a pediatric intensive care unit or other unit with similar capacities because of the requirement for hourly laboratory studies and vital signs and frequent careful assessments of mental status. Transfer to a tertiary care pediatric facility is advisable for children who are very young or who have severe acidosis ($pH < 7.1$), extreme hyperosmolality, risk factors for cerebral edema (e.g., substantially depressed P_{CO_2} or substantially elevated BUN), or altered mental status, severe headache, or other symptoms or signs of complications of DKA.

Summary

DKA occurs frequently in children with new onset of type 1 diabetes. In children with established diabetes, DKA episodes are most often caused by missed insulin injections. A history of polydipsia and persistent polyuria despite signs of dehydration is an important clue to the diagnosis. Once the diagnosis of DKA is established, therapy should be promptly instituted with intravenous rehydration, intravenous insulin infusion, and replacement of electrolytes, particularly potassium. Treatment of acidosis with bicarbonate is rarely indicated and may contribute to the development of cerebral edema. Cerebral edema remains the most frequent serious complication of DKA, and the cause and appropriate treatment of this complication are topics of continued investigation.

Hypoglycemia

Nicole Glaser, MD and Gregory M. Enns, MB, ChB

Key Points

Hypoglycemia should be considered in any child who presents with unexplained lethargy, shock, seizures, or an altered mental status.

Bedside glucose measurements can be used as an initial screening test. If screening shows hypoglycemia, treatment should be initiated without waiting for confirmatory tests.

Hormonal and biochemical studies must be measured *at the time of hypoglycemia, prior to glucose or glucocorticoid administration*, to determine the cause of the episode. Whenever possible, blood should be drawn and saved in a serum-separator tube as well as EDTA, heparin, and sodium fluoride/potassium oxalate tubes on ice.

Hypoglycemia should be treated with rapid intravenous infusion of dextrose (D): 5 ml/kg of D₁₀ in infants under 1 year old, 2 ml/kg of D₂₅ in the 1- to 5-year-old, or 1 ml/kg of D₅₀ in the child greater than 5 years old.

Introduction and Background

The precise blood glucose concentration that should be considered pathologic is a subject of controversy, particularly in neonates. Conservative guidelines suggest that blood glucose concentrations below 40 mg/dl should be considered abnormal at any age, blood glucose concentrations between 40 and 50 mg/dl require further evaluation at any age but may possibly be normal in neonates, and blood glucose concentrations below 60 mg/dl beyond early infancy should be considered borderline, with further evaluation required. Inaccuracies of bedside glucose meters should be taken into account in determining whether to undertake further evaluation and treatment for hypoglycemia. In children with diabetes, hypoglycemic symptoms, including mental status changes, may occur at glucose concentrations above those previously mentioned, particularly in children with chronic poor glycemic control. In this setting, treatment should be

considered even if blood glucose concentrations are in the low-normal range.

Hypoglycemia in Children with Diabetes

Children with type 1 diabetes frequently experience mild episodes of hypoglycemia. These episodes are not associated with significant alterations in mental status and are treated easily with oral glucose. Rarely, children with type 1 diabetes may have episodes of hypoglycemia of sufficient severity to result in mental status changes, loss of consciousness, or seizures. These severe hypoglycemic events occur at a rate of approximately 5 to 19 events per 100 patient-years.¹⁻³ Errors in insulin dosing, inadequate carbohydrate intake, or exercise may cause these severe hypoglycemic episodes, but in almost 40% of episodes, no cause can be determined.³ Severe hypoglycemic events occur more frequently in younger children, those with lower hemoglobin A_{1c} values, underinsured populations, and patients using higher daily insulin dosages.^{1,3}

Hypoglycemia in Children without Diabetes

In children without diabetes mellitus, hypoglycemia may result from a variety of causes, including hormonal excess or deficiency states, sepsis, inborn errors of metabolism, or toxic ingestions. The most frequent causes of hypoglycemia vary according to the patient's age (Table 106-1).

Recognition and Approach

Hypoglycemia in Infants

In infancy, severe hypoglycemia is often the result of hyperinsulinism. Transient hyperinsulinism occurs frequently in neonates born to mothers with poorly controlled diabetes. This disorder, however, is generally recognized at the time of birth and usually resolves before the infant is discharged from the newborn nursery. Persistent hyperinsulinism in infants may be caused by a variety of genetic mutations, most commonly those affecting the sulfonylurea receptor and related proteins.⁴⁻⁸ An additional rare cause of neonatal hypoglycemia is the hyperinsulinism-hyperammonemia syndrome, an autosomal dominant condition caused by hyperactivity of hepatic glutamate dehydrogenase. These disorders vary in severity, and less severe forms may present after the neonatal period. Presentation after the first year of life, however, is rare.

Table 106–1 Causes of Non–Diabetes-Related Hypoglycemia According to Age of Patient

Patient Age	Notable Features
Neonatal–Early Infancy	
Hyperinsulinism	May be large for gestational age High glucose infusion rate required to maintain normal serum glucose
Hypopituitarism/growth hormone deficiency	Microphallus in males, midline craniofacial anomalies Nystagmus/optic nerve hypoplasia
Congenital adrenal hyperplasia	Ambiguous genitalia in females, hyperpigmentation Hyperkalemia, hyponatremia
Galactosemia	Liver disease, renal Fanconi's syndrome, gram-negative sepsis
Hereditary fructose intolerance	Liver disease, poor feeding, vomiting Renal Fanconi's syndrome
Glycogen storage disease type I	Hepatomegaly, enlarged kidneys, lactic acidemia Hypertriglyceridemia, hyperuricemia Hepatomegaly, lactic acidosis
Gluconeogenic disorders (fructose-1,6-bisphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency)	Overwhelming illness Metabolic acidosis, ketosis
Organic acidemias (propionic acidemia, methylmalonic acidemia, isovaleric acidemia)	Feeding difficulty, vomiting, neurologic deterioration; acidosis is uncommon
Maple syrup urine disease	Reye-like syndrome, hypoketosis, cardiomyopathy Lactic acidosis, multiorgan system involvement
Fatty acid oxidation disorders (VLCAD deficiency, MCAD deficiency)	Hyperinsulinism, abnormal fat distribution, strabismus, pericardial effusion
Mitochondrial disorders	Liver disease, protein-losing enteropathy
Congenital disorders of glycosylation	
Late Infancy–Early Childhood	
Ketotic hypoglycemia	Thin child, typically presents in early morning after moderate (10–16-hr) fast
Toxic ingestions	Sulfonylureas, β -blockers, ethanol, salicylates
Hypopituitarism/growth hormone deficiency	(as above)
Hereditary fructose intolerance	(as above)
Glycogen storage disease type I	(as above)
Gluconeogenic disorders (fructose-1,6-bisphosphatase deficiency, phosphoenolpyruvate carboxykinase deficiency)	(as above)
Organic acidemias	(as above)
Maple syrup urine disease	(as above)
Fatty acid oxidation disorders (VLCAD deficiency, MCAD deficiency)	(as above)
Mitochondrial disorders	(as above)
Congenital disorders of glycosylation	(as above)
Late Childhood–Adolescence	
Acquired hypopituitarism or adrenal suppression	Acquired (associated with CNS tumors/CNS trauma) Adrenal suppression due to prior glucocorticoid treatment Hyperpigmentation, weight loss, abdominal pain
Addison's disease	
Ethanol ingestion	
Insulinoma	Hypoglycemia in the absence of significant fasting
Fatty acid oxidation disorders (especially MCAD deficiency)	(as above)

Abbreviations: CNS, central nervous system; VLCAD, very long-chain acyl-coenzyme A dehydrogenase deficiency; MCAD, medium-chain acyl-coenzyme A dehydrogenase deficiency.

Hypoglycemia in infants and toddlers may also be caused by deficiencies in counter-regulatory hormones, mainly growth hormone and cortisol.⁹ Hypoglycemia may occur in infants with isolated growth hormone deficiency or with hypopituitarism (in which both growth hormone and cortisol are deficient). Congenital adrenal hyperplasia also results in cortisol deficiency, and this deficiency may be of sufficient severity to cause hypoglycemia¹⁰ (see Chapter 108, Addisonian Crisis).

Although inborn errors of metabolism may present at any age, these patients usually present during infancy. Gluconeogenic disorders (fructose-1,6-bisphosphatase deficiency and phosphoenolpyruvate carboxykinase deficiency) are often first noted in the neonatal period¹¹ (see Chapter 29, Inborn Errors of Metabolism). Infants with glycogen storage disorders typically present in later infancy, when feedings become

less frequent, but they may present as early as the first week of life.¹² Fatty acid oxidation disorders also typically manifest in later infancy (6 to 24 months).¹³ Hereditary fructose intolerance is first noted after the introduction of fructose and sucrose into the diet, usually between 4 and 8 months. These infants often have associated hepatic dysfunction and a renal Fanconi's syndrome.¹⁴ Hypoglycemia also may occur in organic acidemias (e.g., methylmalonic, propionic, and isovaleric acidemias), but metabolic acidemia and ketosis are more prominent features of these disorders.^{15,16} Hypoglycemia and ketosis may occur in maple syrup urine disease, although ketosis is usually not a prominent early finding. Rare enzymatic defects (succinyl-coenzyme A [CoA]:oxoacid transferase deficiency, glycogen synthetase deficiency [glycogen storage disease type 0], β -ketothiolase deficiency, and short-chain 3-hydroxyacyl-CoA dehydrogenase deficiency)

may present with ketosis and hypoglycemia.^{17,18} Hypoglycemia may also be present in galactosemia and tyrosinemia, but liver disease is usually the primary clinical manifestation.¹⁹ Finally, mitochondrial disorders may first be noted in this age group, although presentation at any age is possible.^{20,21} These disorders typically feature striking neurologic or systemic involvement, but hypoglycemia occasionally may be a feature (see Chapter 29, Inborn Errors of Metabolism).

Hypoglycemia in Toddlers

In toddlers, toxic ingestions are among the more common causes of hypoglycemia (Table 106–2). Important agents that may cause hypoglycemia include sulfonyleureas, β -blockers, ethanol, and salicylates^{22–26} (see Chapter 133, Common Pediatric Overdoses; Chapter 134, Toxic Alcohols; and Chapter 137, Cardiovascular Agents). Plant toxins that contain hypoglycin, such as the Ackee tree found in south Florida and the Caribbean, can cause hypoglycemia.

Table 106–2 Drugs and Toxins That Cause Hypoglycemia

6-Mercaptopurine
Ackee fruit (unripe fruit from Jamaican Ackee tree found in South Florida and Caribbean)
Alcohols (ethanol, methanol, isopropanol, ethylene glycol)
Angiotensin-converting enzyme inhibitors
β -Blockers
Bishydroxycoumarin (rat poison)
Bitter melon gourds
Chlorpromazine
Climbing ivory gourd
Clofibrate
Didanosine
Disodium ethylenediaminetetra-acetic acid
Disopyramide
Fenfluramine
Fenugreek herb
Fluoxetine
Ginseng plant (American, Asian, Siberian)
Haloperidol
Hypoglycemic agents (sulfonyleureas, biguanides, α -glucosidase inhibitors, thiazolidinediones, benzoic acid derivatives)
Insecticides (carbamates and organophosphates)
Insulin (exogenous)
Isoniazid
Lithium
Mamijava plant
Methotrexate
Monoamine oxidase inhibitors
Nonsteroidal anti-inflammatory agents
<i>Para</i> -aminobenzoic acid
Pentamidine
Phenylbutazone
Phenytoin
Pomegranate tree
Probenicid
Quinine
Ritodrine
Salicylates
Sertraline
Steroids (anabolic: stanozolol)
Sulfonamides
Thiazide diuretics
Thioglycolate
Thyroid hormone
Tremetol
Tricyclic antidepressants
Trimethoprim

Ketotic hypoglycemia is also a common cause of hypoglycemic episodes in children over 6 months and under 5 years of age. In one series, ketotic hypoglycemia accounted for 24% of all non–diabetes-related episodes of hypoglycemia presenting to the emergency department in children over 6 months old, and 31% of episodes in children who were previously healthy.²⁷ Most children were less than 5 years old, with a median age of 31 months; two thirds were male, three quarters were white, and 70% weighed below the 25th percentile for their age.²⁷ Most children with this disorder present with symptomatic hypoglycemia during the morning hours after a moderate fast of 10 to 16 hours. Many have a coexisting illness (e.g., gastroenteritis) that contributes to hypoglycemia. Ketotic hypoglycemia is thought to be caused by deficient release of alanine to fuel gluconeogenesis. Symptoms usually disappear by 8 to 9 years of age when a child's muscle mass and glycogen stores increase. Because there is no specific diagnostic test to detect this condition, ketotic hypoglycemia is generally a diagnosis of exclusion that can be made only after ruling out other endocrine and metabolic conditions.

Other metabolic disorders should also be considered in toddlers presenting with hypoglycemia. Many of these conditions require prolonged fasting to provoke hypoglycemia and therefore may not have any manifestations during infancy. Fatty acid oxidation defects, especially medium-chain acyl-CoA dehydrogenase deficiency, are among the most common of these disorders. Fatty acid oxidation defects may present with Reye's syndrome–like features in a child with no past history of illness or other problems. *Hypoketotic* hypoglycemia is characteristic because of the role the fatty acid oxidation cycle plays in generating ketone bodies.¹³

Hypoglycemia in Older Children

In older children and adolescents, hypoglycemia occurs infrequently outside of the setting of diabetes. Disorders that cause hypoglycemia in this age group include acquired hypopituitarism due to central nervous system (CNS) tumors or other brain injury, Addison's disease, and insulinoma (see Chapter 42, Conditions Causing Increased Intracranial Pressure; and Chapter 108, Addisonian Crisis). Ethanol intoxication can also cause hypoglycemia in older children and adolescents. Patients treated for prolonged periods with glucocorticoids (oral or inhaled) may also present with hypoglycemia due to adrenal insufficiency if glucocorticoid preparations are abruptly discontinued or the dosage dramatically decreased^{28,29} (see Chapter 107, The Steroid-Dependent Child). Adolescents with inborn errors of metabolism may also present with hypoglycemia if they are noncompliant with special diets or other measures necessary to control their disorders.³⁰

Unsuspected Hypoglycemia

On occasion, unsuspected hypoglycemia may be encountered in patients who present to the emergency department for evaluation of other disorders. Of children evaluated in the emergency department with an incidental blood glucose concentration below 50 mg/dl, 28% had previously undiagnosed fatty acid oxidation defects and 19% had previously undiagnosed endocrine disorders.³¹ Thus, further evaluation (see later) should always be considered when an incidental blood glucose concentration below 50 mg/dl is detected.

Clinical Presentation

Clinical Manifestations

The manifestations of hypoglycemia in infants differ from those in older children. In infants, symptoms and signs of hypoglycemia are less specific than those in older children and include lethargy or jitteriness, poor feeding, hypotonia, hypothermia, apnea, and seizures.⁴ Such nonspecific findings are often mistaken for sepsis. In older children, manifestations of hypoglycemia are similar to those seen in adults. These manifestations include neuroglycopenic symptoms such as headaches, confusion, lethargy, irritability, and seizures, and adrenergic symptoms such as tremulousness, tachycardia, and sweating.

Diagnostic Clues
